Additional findings in the history or physical examination may provide clues to the cause of the hypoglycemic episode. A history of recent introduction of new foods into the diet of an infant (e.g., fructose, sucrose), weaning, or a history of poor oral intake prior to the hypoglycemic episode suggests the possibility of metabolic disorders. The family history may be significant for similarly affected children or other clues to the presence of an inherited metabolic disorder (e.g., sudden infant death syndrome). Significant hepatomegaly is often encountered in glycogen storage disorders, disorders of gluconeogenesis, and hereditary fructose intolerance. More moderate hepatomegaly can be present during acute decompensation in fatty acid oxidation disorders.¹⁹ Congenital disorders of glycosylation are frequently associated with other systemic manifestations, including dysmorphic features, strabismus, cerebellar hypoplasia, unusual body fat distribution, pericardial effusion, and protein-losing enteropathy.⁸

Hyperpigmentation is a helpful clue to the presence of primary adrenal insufficiency, but is absent in patients with secondary adrenal insufficiency (adrenocorticotropic hormone deficiency) (see Chapter 108, Addisonian Crisis). A history of recent discontinuation of glucocorticoids (including inhaled corticosteroids) suggests the possibility of secondary adrenal insufficiency (see Chapter 107, The Steroid-Dependent Child). Infants with hypopituitarism may have microphallus, optic nerve hypoplasia with nystagmus, or midline craniofacial defects. Ketotic hypoglycemia is most common in boys under 5 years of age who have low body weight.²⁷ Patients with ketotic hypoglycemia typically give a history of hypoglycemic episodes occurring on awakening in the morning after a modest (10- to 16-hour) fast. An anion gap acidosis as well as serum and urine ketones are usually present. Finally, the presence of oral hypoglycemic agents, salicylates, or β -blockers in the home of a toddler suggests the possibility of a toxic ingestion (see Chapter 133, Common Pediatric Overdoses; Chapter 134, Toxic Alcohols; and Chapter 137, Cardiovascular Agents).

Important Clinical Features and Considerations

While the diagnosis of hypoglycemia is straightforward in a child with diabetes who cannot ingest carbohydrates due to vomiting, clinical features in other patients can be subtle or misleading. Rapid bedside glucose testing should be consid-

ered in a wide range of ill infants and children, including those with apnea, sepsis, cyanosis, hypothermia, vomiting, poor feeding, hypotonia, or any neurologic complaint or those who are undergoing resuscitation.³² In fact, any time venous access or venipuncture is undertaken, the clinician should consider whether or not hypoglycemia is a potential cause for a patient's symptoms. If hypoglycemia is a possibility, rapid bedside testing for glucose is mandatory.

Management

Whenever bedside testing reveals hypoglycemia, treatment should be initiated; however, additional evaluation should be performed concurrently. Bedside glucose meters may be inaccurate,³³ and a confirmatory glucose measurement on a venous sample is essential. Venous samples for measurement of glucose should be transported promptly to the laboratory to avoid metabolism of glucose by blood cells, resulting in a falsely low glucose measurement. In addition, at the time of the hypoglycemic episode, a venous sample should be obtained for possible measurement of hormone concentrations and other biochemical measures, including serum insulin, cortisol, growth hormone, ketone, lactate, ammonia, and free fatty acid concentrations³⁴ (Fig. 106–1). A urine sample should also be tested for ketones and reducing substances. Without the diagnostic information gained from these samples, the cause of the hypoglycemic episode generally cannot be determined.

If an inborn error of metabolism is suspected, additional studies should be considered, including plasma quantitative amino acids, carnitine levels, acylcarnitine profile, and urine organic acids. It is essential to obtain metabolic laboratory tests at the time of the hypoglycemic episode, because diagnostic metabolites can disappear or become less apparent after treatment has started.³⁵

Many metabolic disorders are associated with high mortality and may present as apparent life-threatening events or cardiac arrest. Specimens of blood (5 ml in heparinized plasma and 10 ml collected in an ethylenediaminetetra-acetic acid [EDTA] tube) and urine (10 to 20 ml) should be obtained and stored frozen at -20°C for metabolic and genetic testing in all children who die unexpectedly from unknown causes.

If there is a suspicious clinical history, toxicologic screening for ethanol, salicylates, propranolol, and oral hypoglycemic agents should also be considered. In rare cases in which insulin administration to a nondiabetic child is suspected (suicide attempts in adolescents or child abuse), simultaneous measurement of insulin and C-peptide concentrations may be used to distinguish endogenous insulin production from exogenous insulin administration.

Immediate Intervention

Hypoglycemia must be corrected as rapidly as possible with an intravenous infusion of 0.5 g/kg of dextrose. In infants, the typical dosage is 5 ml/kg of 10% dextrose (D_{10}). In toddlers, 2 ml/kg of 25% dextrose (D_{25}) is typically used, and in older children, 1 ml/kg of 50% dextrose (D_{50}). The product of the number of milliliters per kilogram and the dextrose percentage should equal 50. In children with diabetes or known hyperinsulinism of any cause, glucagon (1 mg via intramuscular injection) can be administered if intravenous access cannot be established rapidly. Hypoglycemia caused

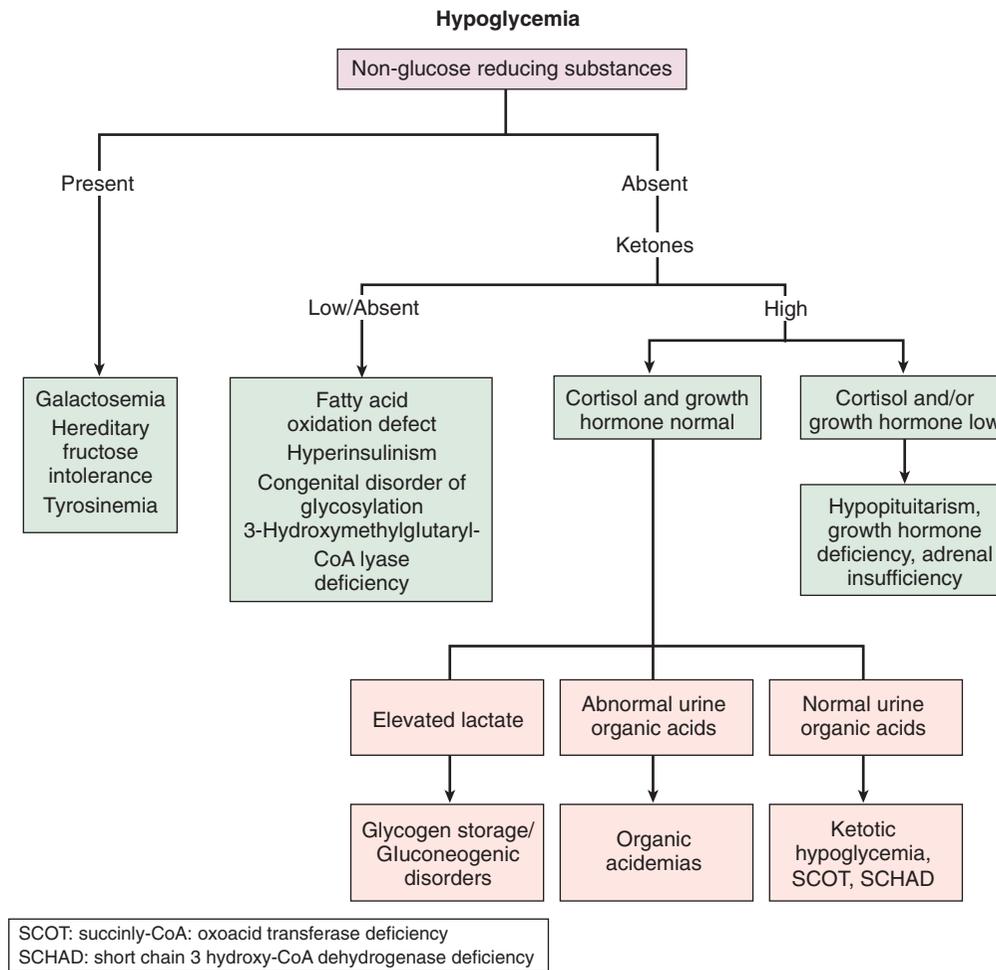

FIGURE 106–1. Algorithm for determining the cause of hypoglycemia. For an episode of hypoglycemia, urine reducing substances and urine ketones along with serum insulin, cortisol, growth hormone, ketone, lactate, ammonia, and free fatty acid concentrations are measured. The algorithm can then be used to determine the most likely cause.

by disorders other than hyperinsulinism, however, generally will not respond to glucagon. If adrenal insufficiency is known or strongly suspected, intravenous hydrocortisone should be administered at a dose of 50 mg for children under 4 years of age and 100 mg for children over 4 years of age.

Definitive Therapy

In children with diabetes, hypoglycemia generally corrects after the initial dextrose infusion, and additional intravenous administration of dextrose is rarely necessary. Despite return of the serum glucose concentration to the normal range, however, alterations in mental status such as irritability, combativeness, lethargy, or disorientation occasionally may persist for prolonged periods. Other neurologic deficits, such as hemiplegia or aphasia, may also occur following such episodes and may likewise persist for many hours.³⁶ Although persistent neurologic abnormalities after severe hypoglycemic events in children with diabetes have been described, additional toxicological studies and CNS imaging should be considered to rule out other possible causes.

In children without diabetes, the initial intravenous bolus of dextrose is followed with a continuous intravenous dextrose infusion sufficient to reverse the catabolic state.

This can generally be accomplished with 10% dextrose in normal saline infused at 1.5 times the maintenance rate. Hypoglycemia caused by an inborn error of metabolism may respond poorly to therapy. These children may require intravenous glucose supplementation at higher than expected levels, and it may be difficult to wean the infusion. Additional treatment may be necessary depending on the cause of the hypoglycemic episode. Details of treatment for toxic ingestions, adrenal insufficiency, and other specific causes of hypoglycemia are beyond the scope of this chapter, but can be found in Chapter 108 (Addisonian Crisis), Chapter 133 (Classic Pediatric Ingestions), and Chapter 134 (Toxic Alcohols).

Disposition

Most children with hypoglycemia in the setting of type 1 diabetes can be safely discharged to home from the emergency department after serum glucose levels have normalized and mental status has returned to normal. Clinicians should ensure that the cause for hypoglycemia is corrected, such as resolution of vomiting, adequate oral intake, or correction of insulin dose. Most children with hypoglycemia of other etiologies, however, require a period of observation in

the hospital. Diagnostic information from blood samples often will not be available for several days, and whether or not the patient can be safely discharged to home will depend on the etiology of the hypoglycemic episode. Consultation with pediatric subspecialists with expertise in endocrinology and metabolism is advisable to assist with making a diagnosis and formulating a treatment plan. Because testing for inborn errors of metabolism is performed only in specialized laboratories, samples for metabolic testing can be obtained and stored for later analysis after consultation has been made with a biochemical geneticist.

Summary

Childhood hypoglycemia occurs most frequently in the setting of diabetes, but also can occur in children with metabolic disorders, deficiencies of counter-regulatory hormones, genetic defects resulting in hyperinsulinism, or toxic ingestions. Infants and young children with hypoglycemia often present with variable symptoms (e.g., jitteriness, poor feeding, hypotonia, hypothermia, apnea), while older children are more likely to develop classic neuroglycopenic or adrenergic symptoms. Rapid bedside glucose testing should be performed for any infant or child who has unexplained lethargy, other mental status abnormalities, or shock or who requires resuscitation in the emergency department. If hypoglycemia is detected, intravenous glucose must be administered as rapidly as possible. At the time of detection of hypoglycemia, critical diagnostic samples of blood and urine should be obtained so that future determination of the cause of the hypoglycemic event is possible.

The Steroid-Dependent Child

Ameer P. Mody, MD, MPH

Key Points

Systemic corticosteroid therapy is used to treat a wide variety of chronic pediatric illnesses, and children undergoing this therapy may present to the emergency department for exacerbations of their illness or unrelated problems.

Steroid-dependent children are susceptible to acute adrenal insufficiency and require the administration of “stress-dose steroids” when ill or injured.

There are many complications from prolonged corticosteroid use, including poor wound healing, infections, hypertension, ulcers, myopathy, osteoporosis, idiopathic intracranial hypertension, medication interactions, and steroid psychosis.

Introduction and Background

The language of “steroids” can be very confusing. The general term *steroid* is defined chemically and therefore includes such disparate substances as progesterone, androgenic and anabolic steroids, cardiac aglycones, bile acids, cholesterol, saponins, toad poisons, carcinogenic hydrocarbons, and corticosteroids.¹ From a medical standpoint, the “steroid-dependent child” is dependent on corticosteroids. Unfortunately, there are multiple synonyms for the word “corticosteroid,” including “adrenocorticoid steroid,” “corticoid steroid,” “adrenal cortical steroid,” “adrenocortical steroid,” “adrenocortical hormone,” and “cortical hormone.”²

Corticosteroids are generally referred to as either glucocorticoids or mineralocorticoids. Glucocorticoids influence carbohydrate, fat, and protein metabolism, and the predominant clinical effect is anti-inflammatory.^{2,3} Mineralocorticoids affect electrolyte and water balance, and the predominant clinical effect is sodium retention.^{2,3} A single corticosteroid may impact both carbohydrate, fat, and protein metabolism and electrolyte and water balance, but be classified only by the term that best fits its predominant action. This leads to the unfortunate situation wherein “glucocorticoids” can have substantial mineralocorticoid effects or none at all. For

example, the glucocorticoid methylprednisolone has five times as much glucocorticoid activity as hydrocortisone, but only half as much mineralocorticoid activity.³ In contrast, another drug also deemed a “corticosteroid,” dexamethasone, has 25 times as much glucocorticoid activity as hydrocortisone, but essentially no mineralocorticoid effects.³ Being aware of the potential confusion that can arise when “steroids” are discussed is useful in understanding the proper care for the “steroid-dependent child.”

Recognition and Approach

Corticosteroids are commonly prescribed to children. Steroids are effective in treating a wide range of diseases mostly because of their anti-inflammatory effects (Table 107–1). There are several commonly employed dosing patterns for corticosteroids. For example, patients who have received solid organ transplants may require continuous low-dose steroid therapy (see Chapter 66, Postsurgical Cardiac Conditions and Transplantation; Chapter 81, Post–Liver Transplantation Complications; and Chapter 88, Renal Disorders). Patients with rheumatologic disease may require relatively frequent, intermittent high-dose steroid therapy. Similarly, patients with leukemia or lymphoma receive pulses of steroids at high doses to initiate tumor lysis and then lower dose steroids as maintenance chemotherapy (see Chapter 128, Cancer and Cancer-Related Complications). There are also children who have had adrenalectomies or have congenital adrenal hyperplasia who receive total steroid replacement therapy for the rest of their lives. Historically, patients with symptoms of moderate or severe asthma have been given systemic steroid therapy for control of symptoms (see Chapter 56, Acute Asthma). The introduction of inhaled corticosteroids has reduced the number of children who require systemic corticosteroid therapy.^{4,5} Inhaled steroids have few systemic effects, and those that occur are mild.⁶ Children taking inhaled corticosteroids are not considered “steroid dependent.”⁶

Long-term and high-dose synthetic corticosteroid therapy can have numerous adverse effects. One well-known effect of exogenous corticosteroids is the suppression of endogenous cortisol release from the adrenal gland via a negative feedback loop on the hypothalamic-pituitary axis. A child on 2 consecutive weeks of systemic corticosteroid therapy may undergo significant suppression of the hypothalamic-pituitary-adrenal axis.^{4,7} Children who have a suppressed

hypothalamic-pituitary-adrenal axis do not make sufficient endogenous corticosteroids and are at risk for adrenal crisis if their long-term steroid therapy is abruptly ended without replacement. In addition, children on chronic corticosteroid therapy do not generate the additional corticosteroids that are normally made during physiologic stressors such as acute illnesses, injuries, or surgical procedures. These children will require additional or increased doses of corticosteroids during acute illnesses or injuries to simulate the normal physiologic response. Without the administration of these "stress-dose steroids," they may have great difficulty recovering from these acute events, or may die.

There are many other documented effects of corticosteroid therapy (Table 107–2). Most of the studies that have evaluated the effects of corticosteroid therapy have included only adults. The incidence of these complications in children is not known. The extent of the hypothalamic-pituitary axis suppression and the incidence of the other side effects correlate with the potency of the corticosteroid drug, dosage, and timing of administration. In many instances, the exact mechanisms by which corticosteroids cause these detrimen-

tal effects are unknown. Pediatric-specific complications, aside from growth retardation, have not been detailed in the literature. However, with the increasing use of steroids in many pediatric conditions, complications are bound to occur, and some of these conditions may cause a patient to present to the emergency department. For example, fractures may arise more commonly due decreased bone mineral density that has been reported in children on long-term glucocorticoids for treatment of nephrotic syndrome, arthritis, Crohn's disease, systemic lupus erythematosus, and cancer.⁸⁻¹²

Multiple drug interactions are associated with steroid therapy.¹³ These interactions may involve the effect of the

steroid or of the other medications. Drug effectiveness or toxicity may be impacted. For example, steroid doses may need to be increased with the coadministration of antacids, barbiturates, phenobarbital, phenytoin, or rifampin. Toxicity associated with cyclosporine or digitalis may occur more often in the steroid-dependent child than in other children. Conversely, chronic steroid therapy may reduce the effectiveness of salicylates.

Clinical Presentation

Steroid-dependent children may present to the emergency department with exacerbations of their underlying illness, complications from their underlying illness, unrelated problems, or complications related to their chronic corticosteroid therapy. Clinical experience suggests it is common for these children to present with some combination of these. The symptoms can range from mild, such as agitation and restlessness, to life-threatening, such as adrenal crisis. It is important to obtain information regarding the length of therapy, dosages, and indication for the patient's treatment. Patients on long-term therapy may manifest the clinical features of Cushing's syndrome: short stature, central obesity, moon facies, hirsutism, and abdominal striae. For patients who are severely ill or injured, steroid dependence may lead to the inability to produce an appropriate stress response, resulting in adrenal crisis with refractory hypotension, hyponatremia, and hyperkalemia.¹⁴

The immunosuppressive and anti-inflammatory effects of corticosteroids contribute to the increased risk of opportunistic infections such as tuberculosis, *Listeria monocytogenes*, *Staphylococcus* species, gram-negative bacteria, varicella virus, herpes simplex virus, cytomegalovirus, *Candida albicans*, *Aspergillus* species, and *Cryptococcus neoformans*.¹⁵ These infections are more common with higher dosages and longer durations of therapy.¹⁵ In addition, many chronic diseases that require corticosteroid treatment further increase the risk of infection. The immunomodulation associated with corticosteroids may diminish the clinical findings associated with acute infection. For example, cellulitis or otitis media may not develop the same degree of inflammation and erythema as normally expected.

The laboratory data necessary to evaluate a steroid-dependent child depend on the presenting clinical situation. Hyperglycemia may be present in any child receiving glucocorticoid therapy. A nonspecific leukocytosis is commonly seen in steroid-dependent children and is not necessarily a marker for infection. Routine cultures of blood and urine may be obtained if there is concern for an infectious process. Serum electrolytes may demonstrate hyponatremia and hyperkalemia with mineralocorticoid deficiency. A serum cortisol level obtained prior to administering corticosteroids to patients suspected of having acute adrenal insufficiency may help with the inpatient management of these children.

Important Clinical Features and Considerations

A variety of conditions are associated with chronic corticosteroid use. Knowledge of the increased likelihood of these conditions may assist the emergency physician in making the

correct diagnosis. Patients on corticosteroid therapy presenting with headache, visual impairment, and nausea may have idiopathic intracranial hypertension (see Chapter 41, Headaches). Proximal, symmetric weakness may be a symptom of steroid-induced myopathy (see Chapter 97, Muscle and Connective Tissue Disorders). Myopathies may occur after any glucocorticoid therapy, but more frequently follow the administration of 9- α -fluorine preparations such as triamcinolone. Additionally, the diagnosis of avascular necrosis of the femoral head should be considered in patients presenting with limp (see Chapter 100, Diseases of the Hip; and Chapter 188, A Quick Look at Limp). Symptoms such as nausea and abdominal pain in a steroid-dependent child may indicate peptic ulcers or pancreatitis (see Chapter 75, Gastrointestinal Bleeding; and Chapter 80, Pancreatitis). Impaired wound healing from inhibited fibroblast function in steroid-dependent children is an important consideration as well (see Chapter 160, Wound Management).

Management

There are four main principles to the emergency department management of the steroid-dependent child. These principles highlight the differences between these children and others who are not steroid dependent. These main principles involve the requirement for stress-dose steroids, the increased risk of common and uncommon infections, the muted signs and symptoms of inflammation, and modifications to wound management.

Stress-Dose Steroids

When a steroid-dependent child is under physiologic stress due to an acute illness or injury, stress-dose steroids should be administered. The dose of hydrocortisone can be calculated based on body surface area, but this is uncommonly done in the emergency department. One suggested approach is to administer 50 mg of hydrocortisone to children younger than 4 years of age and 100 mg of hydrocortisone to children 4 years of age and older.¹⁶ Alternatively, 1 to 2 mg/kg of hydrocortisone may also be a reasonable, as well as simple, dosing regimen (see Table 108–1). The administration of hydrocortisone may be life saving in steroid-dependent children who are in refractory shock.

Increased Risk for Common and Uncommon Infections

Steroid-dependent children are immunocompromised and at increased risk for serious infections. In particular, organisms that rarely, if ever, cause disease in other children may cause steroid-dependent children to become critically ill. Steroid-dependent children are also at increased risk for disseminated infections.¹⁷

Muted Signs and Symptoms of Inflammation

Steroid-dependent children may have muted signs and symptoms of inflammation. This is particularly problematic when diagnosing conditions dependent on pain, erythema, or fever for making the diagnosis. Therefore, common diagnoses such as cellulitis, otitis media, and appendicitis may be missed because the usual features of the disease are muted. This places steroid-dependent children at increased risk for disease progression and resultant complications.

Modified Wound Management

The management of wounds may need to be modified for the steroid-dependent child. The wounds of steroid-dependent children may require a longer time to heal, may occur in skin that has decreased tensile strength, are more likely to become infected and more likely to have relatively subtle signs of infection. Controlling the length of time sutures remain in place to avoid wound dehiscence is an important part of managing wounds in steroid-dependent children. Therefore, it is probably prudent to use nonabsorbable sutures, keep the sutures in place longer than usual, and have frequent rechecks of the wound for these children.

Summary

The broad spectrum of activity of glucocorticoids has made their use common in pediatric medicine. Steroid-dependent children may present to the emergency department with complaints related to the side effects of chronic steroid therapy or with unrelated complaints. Steroid-dependent children are at increased risk for a wide range of complications that may affect nearly every system in the body. Awareness of these risks helps the emergency physician manage these children when they present to the emergency department.

Addisonian Crisis

Ameer P. Mody, MD, MPH

Key Points

Addisonian crisis is caused by the adrenal cortex releasing insufficient cortisol to meet physiologic needs.

Congenital adrenal hyperplasia is a form of primary adrenal insufficiency.

Chronic glucocorticoid use is a common cause of secondary adrenal insufficiency.

The characteristic features of addisonian crisis are altered mental status, hypotension, and hypoglycemia.

The critical, specific intervention in cases of suspected addisonian crisis is the administration of parenteral steroids.

Introduction and Background

Addisonian crisis is named for Thomas Addison, a London doctor who practiced in the mid-19th century.¹ Addison was the first to associate specific clinical features with diseases of the adrenal glands. This original description involved chronic cases of adrenal insufficiency due to tuberculous adrenalitis. In the 20th century, the incidence of tuberculosis fell due to the widespread use of antibiotics, and other causes of adrenal insufficiency and failure were identified.² Even though the importance of the functioning of the adrenal cortex has been recognized for more than 150 years, addisonian crisis remains a life-threatening condition requiring prompt recognition and treatment to avoid death.

Recognition and Approach

A few features of the normal physiology of the adrenal gland are helpful for understanding addisonian crisis. The adrenal gland has two main anatomic divisions, the medulla and the cortex. The adrenal medulla releases catecholamines such as epinephrine and norepinephrine and is not directly involved in addisonian crises. The adrenal cortex releases cortisol, a

key endogenous steroid hormone. The adrenal cortex is under the control of corticotropin, a hormone released from the pituitary gland (Fig. 108–1A). Corticotropin is also known as adrenocorticotropic hormone. Addisonian crisis may arise from failure of the intrinsic function of the adrenal cortex (Fig. 108–1B). This is typically referred to as “primary” addisonian crisis or “primary adrenal insufficiency.” Alternatively, addisonian crisis may arise from a failure in the hypothalamic-pituitary-adrenal axis leading to inappropriately low corticotropin stimulation of the adrenal cortex (Fig. 108–1C and 108–1D). This is typically referred to as “secondary” addisonian crisis or “secondary adrenal insufficiency.” Occasionally, authors will refer to adrenal insufficiency due to malfunction at the level of the hypothalamus as “tertiary adrenal insufficiency.”^{3,4} When acute deterioration occurs, the terms *addisonian crisis* and *acute adrenal failure* are appropriate. When chronic symptoms are present, the terms *Addison’s disease* and *adrenal insufficiency* are appropriate. Adrenal insufficiency and adrenal failure occur along the same clinical continuum.

The causes of primary addisonian crisis and Addison’s disease are few and pathophysiologically varied. One group of conditions frequently implicated in addisonian crises are the congenital adrenal hyperplasias. This is a group of disorders involving autosomal recessive defects in adrenal steroid production.^{5–7} Addisonian crisis associated with congenital adrenal hyperplasia typically occurs in early infancy.^{8,9} Another cause of primary addisonian crises is sepsis, particularly in the setting of meningococcal disease. Since the 1950s, the syndrome of meningitis, fever, coma, cyanosis, petechial hemorrhages of the skin, and adrenal hemorrhages accompanied by adrenal insufficiency has been referred to as the Waterhouse-Friderichsen syndrome.¹⁰ More recent work suggests adrenal insufficiency may arise in the setting of any serious illness.¹¹ It may be the case that the underlying pathophysiologic derangements seen in cases of meningococemia are responsible for the accompanying adrenal insufficiency and are not a feature unique to meningococcal infections.^{12–14} In 2005, methicillin-resistant *Staphylococcus aureus* was implicated in pediatric cases of Waterhouse-Friderichsen syndrome.¹⁵ Tuberculous adrenalitis may still cause primary addisonian crisis, but is unlikely to be seen in children from developed countries. Bilateral traumatic adrenal hemorrhages may cause adrenal insufficiency, and this has been described in adults.¹⁶ Traumatic adrenal hemorrhages are usually unilateral children.^{17–20} Even if present, traumatic

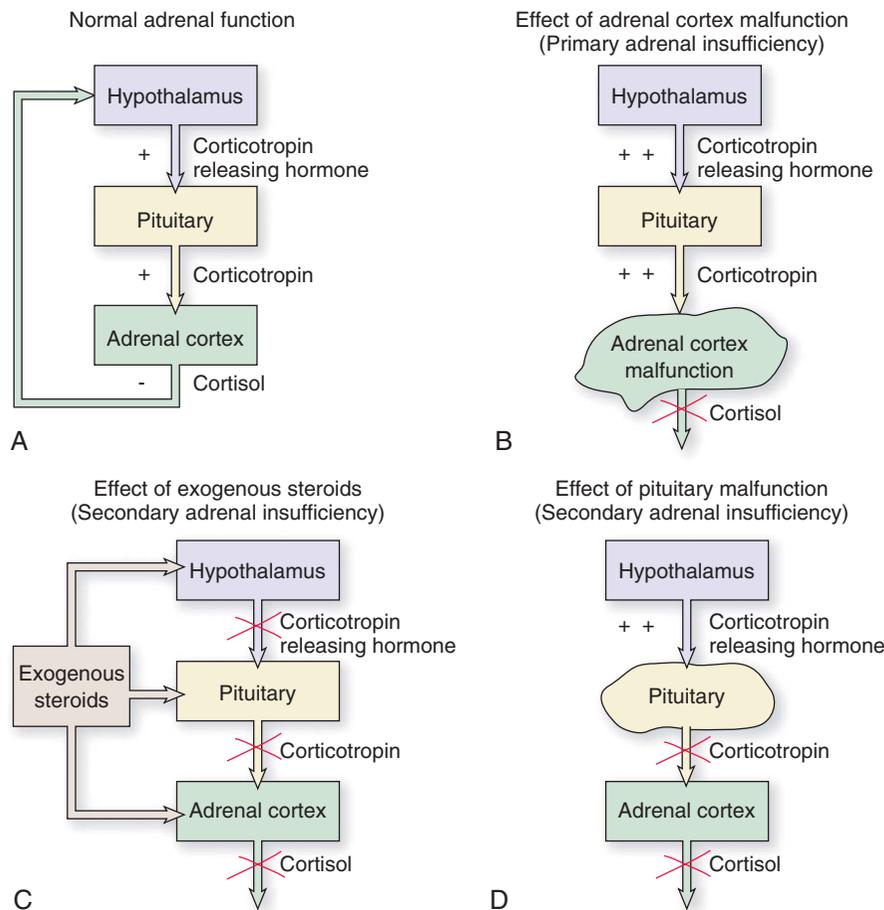

FIGURE 108-1. Simplified schematic representation of the effects of primary and secondary adrenal insufficiency on cortisol production.

bilateral adrenal hemorrhages may not lead to clinically significant adrenal insufficiency in children.¹⁷ Addisonian crisis may occur from an exacerbation of chronic autoimmune adrenal insufficiency.^{8,21} This group of disorders may be the most common cause of adrenal insufficiency in school-age children and adolescents. Another cause of primary adrenal insufficiency are the adrenoleukodystrophies.²² This group of disorders is most prominently characterized by central nervous system dysfunction and adrenal insufficiency.

Secondary Addisonian crisis and Addison's disease is due to disruption of stimulation to the adrenal cortex. Although solid epidemiologic data are not available, it is likely that chronic steroid use is the most common contributing factor to the onset of secondary Addisonian crisis. Glucocorticoids are administered for a wide range of conditions (see Chapter 107, The Steroid-Dependent Child). Systemic steroids (e.g., prednisolone, prednisone, dexamethasone) suppress the hypothalamic-pituitary-adrenal axis^{4,23,24} (see Fig. 108-1C). These exogenous steroids inhibit the usual release of corticotropin from the pituitary. This leads to an inappropriately diminished release of steroids by the adrenal cortex. If a chronically administered steroid is abruptly withdrawn, the hypothalamic-pituitary-adrenal axis cannot recover sufficiently quickly to meet physiologic demands for cortisol. The paradigm for this is the child taking chronic steroids who develops gastroenteritis and repeatedly vomits his or her medications. This leaves the child vulnerable to developing Addisonian crisis.²⁵ Similarly, if a child on chronically administered steroids experiences an acute physiologic stress such

as occurs in an acute infection, during an operation, or because of traumatic injuries, the child's adrenal cortex will not appropriately release cortisol. Addisonian crisis may ensue. In addition, problems with the pituitary gland and hypothalamus may lead to secondary Addisonian crisis. These problems may arise from central nervous system tumors), traumatic brain injury, or pituitary irradiation.

Clinical Presentation

Children experiencing an Addisonian crisis characteristically present in extremis with depressed mentation, hypotension, hypoglycemia, and shock. Patients with chronic adrenal insufficiency will have a slowly progressive, indolent course with a variety of nonspecific constitutional symptoms.

Neonates and Young Infants

Neonates and young infants with primary adrenal insufficiency are likely to have congenital adrenal hyperplasia. In the emergency department, this is most likely to be seen in boys. Girls with congenital adrenal hyperplasia are more likely than boys to be identified in the nursery because of ambiguous genitalia. Male infants may not have genitourinary anomalies, but may exhibit darkly pigmented scrotal skin. The earliest signs and symptoms in infants with primary adrenal insufficiency are nonspecific and include poor feeding, poor weight gain, and lethargy.²⁶ Infants with sepsis and secondary adrenal insufficiency will present in a similar fashion. Many critically ill appearing neonates and young

infants will require a generalized approach due to the non-specific features of addisonian crisis in this age group (see Chapter 7, The Critically Ill Neonate).

Older Infants and Children

Older infants and children with adrenal insufficiency may also present with acute, severe symptoms or with more indolent, chronic symptoms. Primary adrenal insufficiency in this age group is commonly due to an autoimmune or degenerative process with an indolent progression of symptoms. Constitutional symptoms prevail, including developmental delay or poor school performance, weakness, abdominal pain, and failure to thrive.⁸ Skin hyperpigmentation, a result of excessive corticotropin secretion, is not uniformly present, but might be found in areas seldom exposed to the sun and on the oral mucosa.²⁷ Patients with addisonian crisis most commonly present with an altered level of consciousness, hypotension, vomiting, and dehydration.⁸ In this setting, a history of chronic steroid therapy suggests secondary adrenal insufficiency. These children may exhibit cushingoid features such as moon facies, central adiposity, and abdominal striae (see Chapter 107, The Steroid-Dependent Child).

Laboratory Evaluation

The laboratory evaluation of children experiencing addisonian crisis is approached similarly to the evaluation of other seriously ill children (see Chapter 8, Circulatory Emergencies: Shock). Hypoglycemia is common in addisonian crisis and is easily identified with bedside glucose testing (see Chapter 106, Hypoglycemia). Serum electrolytes may reveal hyponatremia and hyperkalemia, particularly in cases of primary addisonian crisis. This finding may be particularly pronounced in young infants with an acute salt-wasting crisis associated with congenital adrenal hyperplasia. A mild metabolic acidosis, evident by a low serum bicarbonate or a low venous pH, is expected in most cases. In cases of suspected, but previously undiagnosed primary addisonian crisis, serum cortisol and corticotropin levels should be obtained prior to the administration of exogenous steroids if this can be done without delaying treatment. This may help with establishing a diagnosis during the inpatient hospital stay.^{28,29}

Important Clinical Features and Considerations

At times, children with known adrenal insufficiency will present to the emergency department with an apparent minor illness or injury. In these cases, in addition to treating the minor illness or injury, the child's steroid dosing will need to be temporarily increased to mimic a normal stress response. Although a rough guide is that the patient's usual steroid dosing will need to be doubled or tripled for a few days,²⁶ coordinating care with the child's pediatric endocrinologist prior to discharge from the emergency department is prudent in these cases.

Management

Initial management of patients suspected of being in addisonian crisis is similar to that for other critical illnesses (see Chapter 8, Circulatory Emergencies: Shock). An evaluation

for a comorbid illness, particularly sepsis is prudent. Initiating empirical therapy for sepsis is also reasonable in most cases (see Chapter 13, Sepsis). Hypoglycemia, substantial dehydration, and a mild metabolic acidosis are common and require prompt treatment. The administration of normal saline to treat dehydration is usually also an effective treatment for hyponatremia if present. Hyperkalemia associated with addisonian crisis seldom requires specific treatment. It is appropriate to treat hyperkalemia if cardiac dysrhythmias are present (see Chapter 114, Hyperkalemia). A reasonable choice for an initial maintenance fluid is 10% dextrose in normal saline (D₁₀NS). Hypotonic fluids and fluids containing potassium should be avoided until serum electrolyte results are available.

For children with a known risk for addisonian crisis, the prompt administration of parenteral steroids may be life saving. For children in refractory shock with hypotension unresponsive to isotonic fluids and vasopressors, the administration of intravenous hydrocortisone may lead to the prompt resolution of shock.¹³ Given the rarity of these conditions, the optimal dosing in children has not been investigated. The recommended dosing for adults is the rapid intravenous administration of 100 mg of hydrocortisone.^{2,3} Unfortunately, recommended dosing for hydrocortisone is sometimes provided as milligrams per square meter of body surface area, units generally unfamiliar to emergency physicians.³⁰ There are accepted calculations for estimating surface area based on body weight³¹ (Table 108–1). There is little downside to administering a slightly larger dose of hydrocortisone than absolutely necessary, but inadequate dosing places the child at great risk. When in doubt, the physician should err on the side of a somewhat higher dose. Both hydrocortisone and methylprednisolone provide some

[†]Hydrocortisone dosing based on 50 mg/m².

mineralocorticoid activity at high doses. Dexamethasone does not provide mineralocorticoid activity, but may be the preferred agent in children with suspected, but undiagnosed secondary adrenal insufficiency because it does not interfere with subsequent diagnostic laboratory testing.²⁸

Summary

Untreated Addisonian crisis is fatal. There is little downside to the empirical administration of a single dose of hydrocortisone to a critically ill child who may harbor adrenal insufficiency. Admission or transfer to a tertiary pediatric facility for intensive care and evaluation by a pediatric endocrinologist is nearly always the best disposition when Addisonian crisis is the likely diagnosis.

Thyrotoxicosis

Ameer P. Mody, MD, MPH

Key Points

Thyrotoxicosis is an uncommon but important endocrine emergency.

The presentation of thyrotoxicosis ranges from mild hypermetabolism to thyroid storm.

Neonatal thyrotoxicosis may mimic sepsis.

β-Blockers and steroids are the mainstays of emergency management for children with thyroid storm.

Introduction and Background

Disorders of the thyroid gland are uncommon in children. However, the systemic effects of thyroid hormone and the occasional insidious onset of disease make these disorders an important part of pediatric emergency care. Thyroid hormone regulates overall metabolic activity. Thyrotoxicosis, the pathologic excess of thyroid hormone, can be due to a variety of etiologies that all result in similar symptoms of hypermetabolism. Thyrotoxicosis can develop in all pediatric age groups. Thyroid storm is a rare but life-threatening complication in patients with thyrotoxicosis and the most extreme form of hyperthyroidism.

Recognition and Approach

The three most common causes of pediatric thyrotoxicosis are Graves' disease and related autoimmune disorders, neonatal thyrotoxicosis, and inappropriate thyroid hormone ingestion.¹⁻¹³ Of these, the most common are Graves' disease and related autoimmune hyperthyroidism.¹⁻⁷ Graves' disease affects girls five times more often than boys.² Graves' disease is an autoimmune disorder in which antibodies are produced against the thyroid-stimulating hormone (TSH) receptor. The result is thyroid gland stimulation. Autoimmune disorders can commonly occur within multiple family members, and up to 50% of children with Graves' disease will have a family history of someone with an autoimmune disease.¹ Graves' disease also occurs more frequently in patients with other comorbid autoimmune disorders.² Neonatal thyrotoxi-

cosis occurs in the setting of maternal Graves' disease.^{10,11} Although TSH and thyroid hormone do not cross the placenta, maternal antibodies are occasionally transmitted, resulting in neonatal thyrotoxicosis. Symptoms are often present at birth, but may be delayed up to 6 weeks due to passage of maternal thyroid receptor–blocking antibodies or treatment of maternal disease. Approximately 20% of neonates with thyrotoxicosis develop high-output cardiac failure.¹⁰ Thyroid replacement medication is used frequently in adult patients. When a child presents with symptoms of thyrotoxicosis, a history of thyroid replacement pills in the home may lead to the diagnosis of exogenous thyroid hormone ingestion.^{12,13}

Other causes of thyrotoxicosis are rare. Patients with Hashimoto's thyroiditis can temporarily experience a hyperthyroid state from thyroid gland inflammation before developing the typical hypothyroidism. McCune-Albright syndrome is an uncommon condition characterized by a triad of polyostotic fibrous dysplasia, skin hyperpigmentation, and precocious puberty that often has accompanying hyperthyroidism.¹⁴ TSH-secreting adenomas and thyroid masses are known causes of hyperthyroidism, but are rare in children.²

Thyroid storm is a rare, hyperacute presentation in patients with thyrotoxicosis. It is a complication that occurs in approximately 1% of patients with hyperthyroidism, often precipitated by infection, surgery, or trauma. Data on thyroid storm in children are limited to case reports,¹⁵⁻¹⁷ but the adult literature suggests a mortality rate of 20%.^{15,18}

Clinical Presentation

The clinical presentation of thyrotoxicosis is variable and somewhat age dependent. Of note, neonatal thyrotoxicosis may not be clinically apparent in the immediate postnatal period. These neonates may be discharged home from the nursery and present to the emergency department with symptoms developing as late as 6 weeks of age. Once apparent, goiter and exophthalmos are typically found in these neonates.^{10,11} The most severely ill neonates may present with tachycardia, poor weight gain in the context of normal or supranormal feeding, congestive heart failure, and jaundice.^{10,11} Neonatal thyrotoxicosis may present with vague symptoms initially indistinguishable from sepsis or other severe neonatal conditions. Children and adolescents with thyrotoxicosis have significant variability in presentation. The most common findings are goiter and exophthalmos.¹

Other common symptoms include weight loss, tremors, polyphagia, and hyperhidrosis. Approximately one third of children and adolescents with thyrotoxicosis will have either psychological problems or a decline in school performance.¹

Patients experiencing thyroid storm present with rapidly progressing, severe symptoms. Thyroid storm generally occurs in patients with previous underlying thyroid pathology exacerbated by surgery, trauma, or infection.¹⁸ When thyroid storm is present, the manifestations of hyperthyroidism are present in an extreme form. Hyperthermia, as high as 41° C (105.8° F), diaphoresis, and tachycardia are characteristic. Mental status may be altered, and patients may experience seizures.¹⁵ Hypertension with widened pulse pressure will also be present in the early phase of thyroid storm. If untreated, the significant hypermetabolic state can eventually lead to hypotension, cardiogenic shock, and death.¹⁸

The diagnostic evaluation of patients with acute thyrotoxicosis involves assessing thyroid function and monitoring for end-organ damage related to the hypermetabolic state. TSH level, thyroxine, free triiodothyronine (T₃), and T₃ resin uptake levels may be obtained to assist with the ongoing inpatient management.² A thyroid assay from the mother of a neonate with thyrotoxicosis may be helpful if the mother does not carry the diagnosis of a thyroid disorder.¹¹ Other studies may be indicated based on consultation with a pediatric endocrinologist. The diagnosis of thyroid storm is a clinical diagnosis, and thyroid levels will not alter the acute management of these patients. If thyroid storm is present, liver function enzymes, creatinine kinase, microscopic urinalysis, and an electrocardiogram are useful for emergency department management.¹⁸ Urine toxicology screening may be helpful if ingestion of a sympathomimetic drug is high in the differential diagnosis.

Important Clinical Features and Considerations

The presentation of hyperthyroid states in children mimics many other conditions. Given the rarity of these conditions, it is often difficult to make these diagnoses in the emergency department. Situations in which thyrotoxicosis is relatively likely include cases in which a known thyroid disease is present in a child or mother of a young infant or exposure to exogenous thyroid hormone is suspected.

Management

The general goal of the emergency management of children presenting with thyrotoxicosis is to counteract the hyperadrenergic effects of thyroid hormone. Patients experiencing thyroid storm or neonatal thyrotoxicosis may present in extremis. For these patients, aggressive measures to restore homeostasis and evaluation for the inciting event are necessary. The initial approach to a child critically ill from thyrotoxicosis is similar to that of other critically ill children (see Chapter 1, Approach to Resuscitation and Advanced Life Support for Infants and Children; Chapter 8, Circulatory Emergencies: Shock; Chapter 11, Altered Mental Status/Coma; and Chapter 13, Sepsis). Patients with milder symptoms of thyrotoxicosis require symptomatic relief and initial diagnostic evaluation if necessary.

β-Blockers are the mainstay of treatment for symptomatic thyrotoxicosis, neonatal disease, and thyroid storm.¹⁸ β-Blockers are effective in treating the majority of symptoms related to thyroid hormone excess. Propranolol given as a 10-mcg/kg infusion over 15 minutes is a reasonable first dose for most children. Additional doses of propranolol are typically indicated to achieve acceptable clinical improvement. A continuous infusion of esmolol is another option.¹⁹

Corticosteroids have also been utilized in the treatment of thyroid storm.²⁰ Studies of adult patients have shown increased survival with their use. Systemic steroids acutely inhibit thyroid hormone release and the conversion from thyroxine to free T₃ in the peripheral tissues.²⁰ Intravenous hydrocortisone given as a 5-mg/kg injection (up to 100 mg) is a reasonable option.

Propylthiouracil and methimazole are the main pharmacologic treatments for chronic hyperthyroidism. They act to prevent synthesis of thyroid hormone and prevent conversion of thyroxine to free T₃. These medications are particularly helpful in treating outpatients with hyperthyroidism.²

Summary

Thyrotoxicosis is an uncommon but important pediatric emergency. The widespread systemic effects of thyroid hormone create symptoms that may mimic other acute illnesses. Appropriate therapy of thyrotoxicosis should resolve symptoms, including behavioral changes, in a short period of time.

Patients with subacute thyrotoxicosis can likely be discharged with close primary and subspecialty care follow-up. Neonatal thyrotoxicosis and thyroid storm patients usually require pediatric intensive care unit admission for stabilization and monitoring.

Dehydration and Disorders of Sodium Balance

Alan L. Nager, MD and Ian K. Maconochie, MBBS

Key Points

The most common cause of dehydration is diarrhea.

The initial estimation of dehydration is based on clinical criteria, not laboratory studies.

Treatments for dehydration include oral, nasogastric, and intravenous rehydration.

Clinically significant sodium disorders are uncommon in previously healthy children.

sodium, or a serum sodium between 130 and 150 mmol/L (130 and 150 mEq/L), can be referred to as “isotonic” dehydration.

Recognition and Approach

In the United States, acute gastroenteritis remains the most significant cause of dehydration. More than 1.5 million outpatient visits occur annually, resulting in 200,000 hospitalizations and 300 deaths per year.⁶ Worldwide, diarrheal disease remains the leading cause of morbidity and mortality, with 1.5 billion episodes and 1.5 to 2.5 million deaths occurring annually for patients younger than 5 years.⁶

The pathophysiology of dehydration and sodium homeostasis is based on the concept of intracellular and extracellular fluid “compartments.” These compartments are idealized intellectual constructs that have some clinical utility. The intracellular compartment contains all of the fluids within cell membranes. These numerous tiny fluid collections are treated as if they are a unified fluid collection. Sodium levels are relatively low in this compartment. The extracellular compartment contains all of the fluids outside cell membranes. Plasma, interstitial fluid, and transcellular fluid are the major components of this compartment. Sodium levels are relatively high in this compartment.

These intracellular and extracellular compartments are useful for understanding the fluid shifts associated with dysnatremias and dehydration. Hyponatremic dehydration is present when the fluid lost contains relatively high levels of sodium. Water then shifts from the intracellular compartment into the extracellular compartment. This shift in water lowers the serum sodium. Hypernatremic dehydration is present with the fluid lost contains relatively low levels of sodium. Water then shifts from the extracellular space into the intracellular space. This shift in water raises the serum sodium. Isotonic dehydration occurs when the fluid lost is isotonic and substantial water shifting does not occur.

Clinical Presentation

For children at risk for dehydration, useful historical features include the environment in which symptoms developed, the presence of associated symptoms, and any prior treatment or

Introduction and Background

Dehydration is the result of a negative fluid balance. This results from decreased fluid intake, increased fluid output, or both. Dehydration occurs along a continuum from a clinically insignificant negative fluid balance to hypovolemic shock and death. The differential diagnosis of dehydration is extensive and heterogeneous (Table 110–1).

When laboratory testing is performed, dehydration is commonly classified according to the serum sodium concentration. A normal serum sodium ranges from 136 to 145 mmol/L (136 to 145 mEq/L).¹ The definition of *hyponatremia* is a “deficiency of sodium in the blood.”² Similarly, the definition of *hypernatremia* is “excessive sodium in the blood.”³ These definitions lack clinical utility and contain no numeric values. It would be technically correct to define hyponatremia as a serum sodium less than 136 mmol/L (136 mEq/L) and hypernatremia as a serum sodium greater than 145 mmol/L (mEq/L). It is likely that clinically significant dysnatremia deviates further from normal than these numeric boundaries. One reasonable approach is to define hyponatremia, or “clinically significant hyponatremia,” as a serum sodium less than 130 mmol/L (130 mEq/L).⁴ Similarly, hypernatremia or “clinically significant hypernatremia” can be defined as a serum sodium greater than 150 mmol/L (150 mEq/L).⁵ Dehydration occurring with a normal serum

home remedies. In addition, assessing the patient's input and output is useful. Attempting to quantify oral intake is helpful. Ascertaining the presence or absence of vomiting is important as vomiting can inhibit adequate oral intake. Output history includes the amount and frequency of urination, the presence of diarrhea and its quantity, and the presence of excessive sweating.⁷ Other useful historical features include changes in the child's level of activity, the presence of fever, changes in mental status, difficulty swallowing, respiratory symptoms, skin changes (including periods of pallor or cyanosis), appetite or thirst changes, medication use (including antibiotics), the potential for a toxic ingestion, the travel history, and a change in weight.⁸

There are specific physical examination findings useful for assessing dehydration. Vital signs may reveal fever, tachycar-

dia, tachypnea, and hypotension. Further evidence suggesting dehydration include listlessness or lethargy, a sunken fontanelle, sunken eyes or absent or diminished tears, dry or sticky mucous membranes, tachypnea, skin that is cool or mottled, delayed capillary refill time, and diminished pulses.

Ideally, the assessment of dehydration would be based on a comparison of the weight on presentation and the pre-illness weight.⁹⁻¹⁴ Unfortunately, an accurate and recent pre-illness weight is seldom, if ever, available. Emergency physicians and others who care for children have come to use clinical criteria to assess dehydration in children¹⁵ (Table 110-2). This type of estimation is useful, but imprecise.

When disorders of sodium are present, signs and symptoms directly related to the serum sodium level may be present. Signs and symptoms of hyponatremia depend on the serum sodium and the speed at which the sodium level falls. Symptoms primarily involve the central nervous or musculoskeletal systems. Neurologic symptoms include nausea, vomiting, headache, mental status changes, altered consciousness, diminished reflexes, hypothermia, pseudobulbar palsy, and seizures. Musculoskeletal symptoms include weakness, muscle cramps, and decreased movement. Signs and symptoms of hypernatremia include mental status changes, muscular weakness, ataxia, tremors, hyperreflexia, seizures, unresponsiveness, and intracerebral hemorrhage.

Routine laboratory testing for dehydration is controversial and has not been shown to be predictive of the degree to which a patient may be dehydrated. In addition, different mechanisms resulting in dehydration reveal varying laboratory abnormalities. Vomiting, for example, can cause a high bicarbonate level due to gastric acid losses or a low bicarbonate level due to volume contractions, lactic acidosis or starvation. Vomiting and diarrhea may lead to a variety of laboratory abnormalities, depending on the severity of vomiting or diarrhea, oral intake, and the duration of illness.¹⁰ Several investigators have attempted to correlate severity of disease with various laboratory abnormalities by looking at bicarbonate, blood urea nitrogen, creatinine, sodium, uric acid, serum and urine anion gap, venous pH, urine specific gravity, and urine ketones.^{7,13,16-19} No single laboratory test has been shown to be an accurate marker for dehydration. If a child is

Table 110-1 Differential Diagnosis of Dehydration

Decreased Intake

Eating disorders
Facial dysmorphism
Gastroesophageal reflux
Inappropriate feedings
Infantile nasal congestion
Lack of access to appropriate fluids
Malaise associated with an acute illness
Mechanical obstruction (e.g., pyloric stenosis)
Oral trauma
Pharyngitis
Stomatitis
Tachypnea interfering with feeding
Uncoordinated swallowing
Vomiting

Increased Output

Cerebral salt-wasting syndrome
Diabetes insipidus
Diabetic ketoacidosis
Diarrhea
Increased metabolism (e.g., fever)
Medication effects (e.g., diuretics)
Renal losses (e.g., nephrotic syndrome)
Tachypnea with respired losses

Table 110-2 Symptoms Associated with Dehydration

Symptom	Minimal or No Dehydration (<3% Loss of Body Weight)	Mild to Moderate Dehydration (3-9% Loss of Body Weight)	Severe Dehydration (>9% Loss of Body Weight)
Mental status	Well, alert	Normal, fatigued or restless, irritable	Apathetic, lethargic, unconscious
Thirst	Normal, might refuse	Thirsty, eager to drink	Drinks poorly; unable to drink
Heart rate	Normal	Normal to increased	Tachycardia, ± bradycardia
Quality of pulses	Normal	Normal to decreased	Weak; thready, or impalpable
Breathing	Normal	Normal; fast	Deep
Eyes	Normal	Slightly sunken	Deeply sunken
Tears	Present	Decreased	Absent
Mouth and tongue	Moist	Dry	Parched
Skinfolds	Instant recoil	Recoil in <2 sec	Recoil in >2 sec
Capillary refill	Normal	Prolonged	Prolonged; minimal
Extremities	Warm	Cool	Cold; mottled; cyanotic
Urine output	Normal to decreased	Decreased	Minimal

Table 110–3 Conditions Altering Sodium and Total Body Water Balance

Total Body H ₂ O (Vol)	Serum Sodium		
	↑	Normal	↓
↑	Excess saline infusion Bicarbonate intoxication Salt poisoning Hyperaldosteronism	Congestive heart failure Liver disease Nephrotic syndrome Renal failure SIADH Glucocorticoid deficiency	Congestive heart failure Liver disease Nephrotic syndrome Renal failure SIADH
Normal	Insensible losses (skin and respiratory) Diabetic insipidus (central or nephrogenic)	Mild–moderate GI losses	Water intoxication
↓	Insensible losses (skin and respiratory) Water deprivation Vomiting, diarrhea	Vomiting Diarrhea Diuretics	Vomiting/diarrhea Cystic fibrosis Diuretics Renal losses Burns/heat stroke Ascites

Abbreviations: GI, gastrointestinal; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

determined to be dehydrated based on clinical criteria, assessment of serum sodium can be helpful in generating an appropriate differential diagnosis (Table 110–3).

Important Clinical Features and Considerations

There is no universally accepted group of signs and symptoms that accurately estimates the degree of dehydration in children. Even though broad categories are often used (e.g., mild, moderate, severe), children may fail to fall into a single category.¹⁵ Given the number of predictors examined, a child may fall into the mild category for some of them and the moderate category for others. This can be very confusing to families and clinicians. One strategy in dealing with this is to simply count the number of abnormal signs and symptoms. One suggested approach is to assess decreased skin elasticity, prolonged capillary refill time, general appearance, absence of tears, abnormal respirations, dry mucous membranes, sunken eyes, abnormal radial pulses, a heart rate greater than 150 beats/min, and decreased urine output. In one study, the presence of fewer than three of these signs and symptoms corresponded with mild dehydration, three to six signs or symptoms corresponded with moderate dehydration, and more than six signs or symptoms corresponded with severe dehydration.⁹

Another approach is to try to narrow the focus of the evaluation to those features most strongly associated with dehydration. One constellation of signs and symptoms suggested is general appearance, prolonged capillary refill time, dry mucous membranes, and reduced tears.⁹ Another recommendation is that general appearance, sunken eyes, dry mucous membranes, and decreased tears be the focus of the evaluation.²⁰ Yet another recommendation includes deep breathing, decreased skin turgor, and decreased peripheral perfusion.^{11,21} Still others have recommended focusing on prolonged capillary refill time as the sole factor used in estimated dehydration.^{22–26} Because researchers and clinicians are using different groupings of signs and symptoms, it is problematic to compare research studies or standardize clinical care.

Management

The treatment of dehydration is based on the estimated degree of dehydration^{12,14,27–34} (Table 110–4). In the last several years, a strong interest in utilizing oral rehydration in the emergency department has arisen.^{28–31,35,36} It is conceivable that the increasingly widespread use of oral ondansetron in the pediatric emergency department has positively contributed to the acceptance and success of oral rehydration in this setting.³⁷ A few studies performed in the emergency department have shown success and effectiveness of nasogastric rehydration.^{32,38–40} Although there is little controversy in initiating intravenous rehydration in severely dehydrated children, the exact point at which intravenous rehydration is preferred is unknown.

For children undergoing intravenous rehydration, determining the rate at which a child should be rehydrated is not always clear. Some children may receive one or two 20 mL/kg normal saline boluses, resume adequate oral intake, and be discharged home. For those requiring prolonged hydration due to poor oral intake or persistent vomiting, the “4-2-1” rule can be utilized to calculate an appropriate rate at which to administer intravenous fluids: for the first 10 kg of weight, administer 4 mL/kg/hr; for the second 10 kg of weight, administer 2 mL/kg/hr; and for the remaining weight, administer 1 mL/kg/hr. Using this calculation results in the generally accepted rate for “maintenance fluids.” To treat dehydrated children, it is customary to administer 1.5 times the maintenance rate. For a 26-kg child, the maintenance fluids would be administered at a rate of 66 mL/hr (40 + 20 + 6); thus 1.5 times the maintenance rate is 99 mL/hour (1.5 × 66). An order for 100 mL/hr would be appropriate for this 26-kg child.

The choice of fluid is controversial. Traditionally, hypotonic solutions have been selected, but some have advocated using isotonic solutions for ongoing intravenous infusions.⁴¹ For previously healthy children who are not critically ill, hypotonic 0.45 normal saline with 5% dextrose and 20 mEq (20 mEq) potassium per liter run at 1.5 times the maintenance rate is a reasonable starting point. Neonates and young infants are customarily given 0.2 normal saline with added dextrose and potassium. These fluids are not intended for

Table 110–4 Treatment for Dehydration*

	Minimal	Mild to Moderate	Severe
Primary phase	PO	PO	IV
Secondary phase (if primary phase fails)	NG	NG	Central line
Tertiary phase (optional)	IV	IV	Intraosseous (IO)
Laboratory studies	PO	PO	± PO after initial
	None	None [†]	Electrolytes, blood urea nitrogen, creatinine, calcium, glucose, urine
Fluid amounts	<50 ml/kg	50–100 ml/kg	>100 ml/kg
Treatment length	<4 hr	1–4 hr	>4 hr
Discharge criteria	Baseline or near-baseline vital signs Urine output during hydrating period Moist oral mucosa Streaming tears No or minimal ongoing losses Able to tolerate PO fluids (optional)		Not applicable
Treatment failure	Admit or observation unit		Admit

*PO: 5 ml (1 teaspoon) every 1–2 min; ↑ based on patient tolerance.
NG: 20 ml/kg/hr over 1–4 hr (ORS).

IV (moderate dehydration): 50–100 ml/kg over 1–4 hr (NS or LR).

IV (severe dehydration): 20 ml/kg over 5–30 min (NS or LR).

Aim for 60–100 ml/kg within the first hour. Contraindications include some forms of cardiac disease (e.g., cardiomyopathy) or neurologic disease.

[†]May need to obtain laboratory studies based on dietary history or disease state.

Abbreviations: IV, intravenous; LR, lactated Ringer's solution; NG, nasogastric; NS, normal saline; ORS, oral rehydration solution; PO, oral.

bolus therapy. Bolus therapy should be accomplished using normal saline without added glucose or potassium. Medically complicated children and those with conditions known to cause electrolyte abnormalities (e.g., children on dialysis) will require individualized approaches.

Treatment of mild derangements of sodium homeostasis can usually be accomplished by administering normal saline. Normal saline is hypertonic to hyponatremic serum and hypotonic to hypernatremic serum. Therefore, the administration of normal saline should be the appropriate treatment regardless of the serum sodium level. For more extreme sodium derangements, specific therapy may offer the opportunity for the best outcome. For symptomatic children with a serum sodium below 120 mmol/L (120 mEq/L), the administration of 5 ml/kg of 3% normal saline over several minutes can be used to treat seizures and other serious signs or symptoms. The goal for this type of treatment is to raise the serum sodium above the threshold for seizures or the concerning sign or symptom. Rapid correction of hyponatremia beyond this is to be avoided because permanent neurologic damage in the form of central pontine myelinolysis may occur. The treatment of hypernatremic dehydration should occur somewhat more slowly than that of hyponatremic or isotonic dehydration. Many times, providing an initial normal saline bolus followed by maintenance fluids (*not* 1.5 times maintenance) will be sufficient for the emergency department management of these children. Rapid rehydration may lead to cellular swelling and damage.

Summary

Dehydration is a common problem causing significant morbidity and mortality in children. With appropriate treatment, dehydration can be successfully treated in nearly all cases. Serious derangements of serum sodium are uncommon. With appropriate treatment, the prognosis of these electro-

lytes disturbances is excellent. An important task for the emergency physician is identifying the cause of the dehydration and initiating appropriate treatment for the underlying coexisting illness.

Metabolic Acidosis

John C. Brancato, MD

Key Points

Metabolic acidosis is commonly encountered in serious pediatric illnesses presenting to the emergency department.

The causes of metabolic acidosis can be categorized according to whether or not an elevation in the anion gap is present.

The treatment of metabolic acidosis is based on treatment of the underlying illness.

Administration of large volumes of normal saline can result in hyperchloremic acidosis.

Introduction and Background

Many of the more serious conditions for which children present to the emergency department manifest a metabolic acidosis. These include traumatic injuries,^{1,2} ingestions,³⁻⁶ inborn errors of metabolism,⁷⁻⁹ diabetic ketoacidosis,¹⁰⁻¹³ renal disorders,^{13,14} dehydration due to diarrheal illness,¹⁵ and septic shock.¹⁶⁻¹⁸ Understanding metabolic acidosis is the foundation for understanding the clinical manifestations, diagnostic approach, and management of these myriad conditions.

Recognition and Approach

The human body is designed to keep a tightly controlled acid-base environment. However, the body also continually produces acids both when healthy and to an even greater extent in certain illnesses. Many of these acids are generated during the metabolism of the basic components of food. For example, lactic acid and ketoacids are generated during the metabolism of fat. Sulfuric acid and phosphoric acid are generated during the metabolism of proteins. Various homeostatic mechanisms promote the buffering and excretion of excess acids to allow tight control of the pH of the blood and interstitial fluids. When these homeostatic mechanisms become dysfunctional or are overwhelmed, acidosis develops.

Recognized for the last half century, one of the key homeostatic mechanisms involves carbonic acid (H_2CO_3).¹⁹ H_2CO_3 is an intermediary in a bidirectional chemical reaction that converts water (H_2O) and carbon dioxide (CO_2) into a hydrogen ion (H^+) and bicarbonate (HCO_3^-) and vice versa. This homeostatic mechanism involving H_2CO_3 is the principal extracellular buffer allowing the body to accommodate fairly rapid, large increases in excess acid. When chemoreceptors in the brain encounter an increasingly acidic environment, increased respirations are generated to allow for greater expiration of CO_2 . To some degree, this increase in ventilation compensates for metabolic acidosis (Fig. 111–1). At the same time, receptors in the kidney are triggered leading to increased excretion of H^+ and retention of HCO_3^- (Fig. 111–2).

Clinical Presentation

The clinical presentation of metabolic acidosis is dominated by the signs and symptoms of the underlying illness. However, there are some features common to many of these illnesses. In particular, deep, rapid respirations are often present. The paradigm for this is Kussmaul's respirations seen in children with diabetic ketoacidosis.¹⁰ Dehydration, nausea, abdominal pain, vomiting, lethargy, and malaise are also common features in many cases of metabolic acidosis. In cases of inborn errors of metabolism, coma may dominate the presentation to the emergency department.⁷ In some cases, such as seen with septic shock, the signs and symptoms of metabolic acidosis and those of septic shock are intimately intertwined.¹⁸ As septic shock resolves, so does the metabolic acidosis. Determining if there are symptoms solely attributable to metabolic acidosis is of no clinical significance and not feasible.

The signs and symptoms of many of the conditions that cause metabolic acidosis are nonspecific and overlap. Given this, the emergency physician will encounter very ill patients for whom a metabolic acidosis has been identified, but for whom a specific diagnosis is not readily apparent.

One approach to refine the differential diagnosis for conditions presenting with a metabolic acidosis is to assess the serum for “unmeasured” anions. The term *unmeasured* is primarily of historical significance given that the measurement of important anions such as lactate is now routine. One approach to assessing serum for these excess anions is the anion gap.^{13,20,21} The anion gap is calculated as follows:

$$\text{Anion gap} = [\text{Na}^+] + [\text{K}^+] - [\text{Cl}^-] - [\text{HCO}_3^-]$$

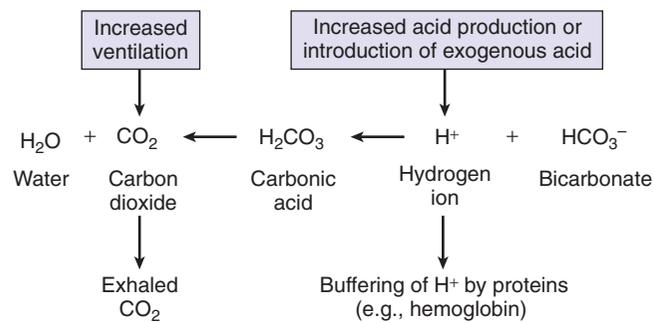

FIGURE 111-1. Simplified depiction of the basic chemical reactions involved in the immediate buffering of excess acids.

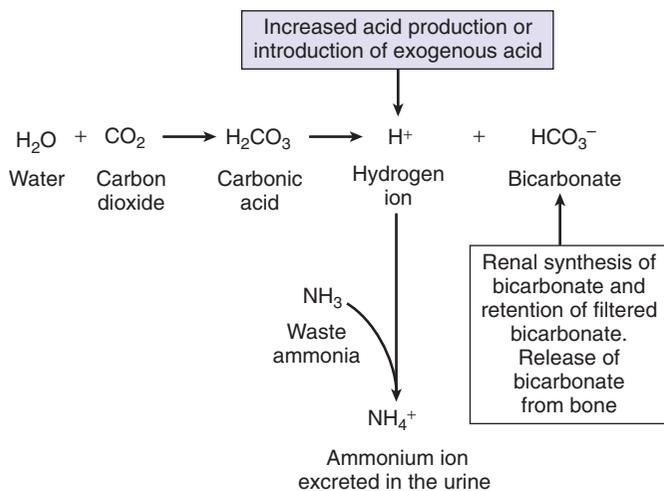

FIGURE 111-2. Simplified depiction of the basic chemical reactions involved in the renal excretion of excess acid.

where $[\text{Na}^+]$, $[\text{K}^+]$, and $[\text{Cl}^-]$ are the serum sodium, potassium, and chloride concentrations respectively.^{13,20} The numerical values for these electrolytes are the same whether conventional units (mEq/L) or Système International d'Unités (SI) (mmol/L) are used. An alternative form of the anion gap does not include potassium in the sum.^{22,23} There is not a universally agreed upon normal anion gap.²³ A reasonable approximation for a normal anion gap is in the range of 8 to 16.²⁴ Given differences in how individual hospital laboratories perform their electrolyte analyses, the exact values constituting a normal anion gap will vary.²⁴ Fortunately, many hospital laboratories report an anion gap along with their report on electrolyte measurements. The anion gap is useful in differentiating some relatively common and serious conditions that present to the emergency department with a metabolic acidosis (Table 111-1). One of the limitations of the anion gap is its inappropriate normalization in the setting of hypoalbuminemia.^{13,20,25-28} Adjustments to the anion gap calculation to take abnormalities of serum albumin into account have been proposed.^{26,27}

One alternative to the anion gap that adjusts for abnormalities in serum albumin is the strong ion gap.^{20,29,30} The strong ion gap is calculated as follows:

$$\text{Strong ion gap} = [\text{Na}^+] + [\text{K}^+] - [\text{Cl}^-] - [\text{HCO}_3^-] - 2.8 [\text{albumin (g/dL)}] - 0.6 [\text{phosphate (mg/dL)}]$$

Table 111-1 Anion Gaps of Conditions Likely to Present to the Emergency Department with a Metabolic Acidosis

Increased Anion Gap	Normal Anion Gap
Diabetic ketoacidosis	Diarrhea with dehydration
Septic shock	Renal tubular acidosis
Ingestions*	Inborn errors of metabolism
Hemorrhagic shock	
Inborn errors of metabolism	

*Includes carbon monoxide, cyanide, toxic alcohols, iron, isoniazid, paraldehyde, metformin, salicylates, and theophylline.

A normal strong ion gap is zero. A falsely negative strong ion gap occurs in the setting of an elevated serum chloride. The role, if any, of the strong ion gap in evaluating children in the emergency department has not been determined. Another proposed alternative is the chloride:sodium ratio.³¹

Important Clinical Features and Considerations

Adequacy of the specimen used to determine the serum pH is an important concern. Although many blood gas analyses utilize arterial blood to assess oxygenation, arterial blood gases can be painful and technically difficult in children. If oxygenation can be assessed with pulse oximetry, a venous blood gas would be adequate to assess the serum pH. There is evidence to suggest that venous blood gases correlate very well with arterial specimens and accurately reflect the serum pH.^{32,33} There is also evidence to support the use of capillary blood gases to assess the serum pH.^{34,35} Initial specimens obtained from intraosseous access, before medications are instilled, may also yield an accurate assessment of the serum pH.³⁶

Management

The key to treating a patient with a metabolic acidosis is to treat the underlying cause of the acidosis. Many children with metabolic acidosis will be dehydrated, intravascularly volume depleted, or both. Intravenous hydration with normal saline is generally indicated. It is useful to keep in mind that the administration of excessive volumes of parenteral normal saline may result in a hyperchloremic acidosis and an artificially normal anion gap.³⁷ For patients in shock, 20 ml/kg boluses of normal saline are indicated¹⁶ (see Chapter 8, Circulatory Emergencies: Shock).

The administration of parenteral sodium bicarbonate is appropriate in some circumstances. For example, in the setting of tricyclic antidepressant overdose, sodium bicarbonate has been shown to be effective.³³ In conditions such as diabetic ketoacidosis, the use of sodium bicarbonate is controversial^{11,12,38,39} (see Chapter 105, Diabetic Ketoacidosis). Similarly, in circumstances of severe hypoxic metabolic acidosis with excessive lactate formation, the use of sodium bicarbonate has not been shown to offer improved outcomes.^{40,41}

Summary

Many serious conditions for which children present to the emergency department manifest a metabolic acidosis. Calculating the anion gap may be helpful in refining the differential diagnosis. Establishing adequate perfusion by administering intravenous fluids is frequently indicated. However, large volumes of normal saline can result in a hyperchloremic acidosis. Sodium bicarbonate should be administered when clearly indicated based on the underlying illness. Successful management of the child with metabolic acidosis is most dependent upon successfully treating the confirmed or presumptive underlying cause.

Chapter 112

Metabolic Alkalosis

John C. Brancato, MD

Key Points

Metabolic alkalosis is a disturbance characterized by an increase in serum bicarbonate resulting from either a loss of hydrogen ions or a gain in bicarbonate.

Respiratory compensation for metabolic alkalosis is by hypoventilation.

Treatment depends on the underlying cause and the severity of the alkalosis.

Introduction and Background

Under normal circumstances, the body uses various homeostatic mechanisms to buffer and excrete the acid it produces daily. The carbonic acid system, for example, allows for large amounts of acid to be excreted through the ventilatory system as carbon dioxide (CO_2) and through the renal system as hydrogen ions (H^+) with conservation of bicarbonate (HCO_3^-).¹ However, either an excessive loss of H^+ or a gain of HCO_3^- results in alkalosis. As with acidosis, the alkalosis may be a primary metabolic process or it may be secondary to a respiratory derangement. In the latter instance, the retention of CO_2 is compensated for by an increased HCO_3^- . The excessive losses of H^+ that may lead to primary metabolic alkalosis can occur in several ways. Large amounts of gastric HCl may be lost through vomiting or nasogastric suctioning. Pyloric stenosis is often considered the prototype of processes characterized by gastric acid loss. Hyperaldosteronism or other mineralocorticoid excess causes an increase in renal sodium reabsorption with secretion of H^+ and potassium ions (K^+) into the tubular lumen.² Liddle's syndrome, through the action of a mutated sodium channel, and licorice ingestion, through the inhibition of cortisol metabolism, produce similar symptoms.³⁻⁵

An increase in HCO_3^- may occur through the administration of exogenous alkali as in antacid overdose, milk-alkali syndrome, large transfusions of blood with citrate anticoagulant, and parenteral therapy with acetate-, lactate-, or bicarbonate-containing fluids.⁶⁻⁸ A loss of chloride-rich fluid as may occur from heavy vomiting, congenital chloride diarrhea, or thiazide and loop diuretics may lead to a decreased

extracellular fluid volume.^{9,10} The remaining HCO_3^- is effectively increased in concentration, producing a modest "contraction alkalosis."

Once it is established, multiple factors contribute to the maintenance of a metabolic alkalosis. An important one is increased activity by the renin-angiotensin-aldosterone system. Hypovolemia stimulates aldosterone production, in turn increasing the rate of sodium ion (Na^+) reabsorption and H^+ secretion. The addition of H^+ into the tubular lumen leads to the exchange of chloride ions (Cl^-) and HCO_3^- , enhancing the alkalosis. In the distal tubule, increased mineralocorticoid activity causes increased sodium/potassium (Na^+/K^+) exchange, leading to hypokalemia. When the extracellular potassium concentration drops, K^+ move out of the cells. The movement of H^+ intracellularly maintains charge balance but also stimulates renal HCO_3^- reabsorption.¹¹ The collecting duct responds to hypokalemia by holding onto K^+ but excretes H^+ in the process. Hypochloremia, from inadequate ingestion, cystic fibrosis or other losses, further stimulates the renin-angiotensin-aldosterone system and inhibits the kidney's ability to secrete HCO_3^- and retain H^+ via the chloride/bicarbonate ($\text{Cl}^-/\text{HCO}_3^-$) exchanger.^{12,13} A reduced glomerular filtration rate due to hypovolemia, hypokalemia, or hypochloremia reduces the amount of HCO_3^- presented to the kidney and, therefore, available for excretion.¹⁴

Recognition and Approach

The causes of metabolic alkalosis are commonly classified by their responsiveness to saline therapy. Chloride-responsive alkaloses are those in which low extracellular fluid volume, hypochloremia, and hypokalemia predominate. Hyperaldosteronism occurs in these cases, but as a secondary process. Chloride-resistant alkaloses are those characterized by a primary increase in mineralocorticoid activity or by impaired chloride reabsorption. They are further divided into those causes with or without hypertension (Table 112-1).

Bartter's syndrome is a group of three inherited disorders caused by dysfunction of renal ion channels.¹⁵ Classic Bartter's syndrome is caused by impaired sodium chloride reabsorption, resulting in hypokalemic metabolic alkalosis with hypercalciuria. Presentation is in infancy. Loop and thiazide diuretics have similar effects on the kidney and lead to similar electrolyte abnormalities. Gitelman's syndrome is also caused by a defect in a Na^+/Cl^- transporter but is clinically milder than Bartter's syndrome.¹⁶ It is also

Milk-alkali syndrome
Organic acidosis recovery
Refeeding after prolonged fasting
Parenteral penicillin administration
Transfusion-related citrate administration

characterized by hypomagnesemia and hypocalciuria. Metabolic alkalosis, hypercalcemia, and renal insufficiency characterize the milk-alkali syndrome, more common prior to the development of proton pump inhibitors. Chronic ingestion of large amounts of calcium carbonate (e.g., antacid abuse, betel nut use) is the usual cause.¹⁷

Serious physiologic effects may ensue from metabolic alkalosis and the body's attempt to compensate through hypoventilation.¹⁸ For example, an elevated pH shifts the oxyhemoglobin dissociation curve to the left, impeding oxygen delivery to the tissues.¹⁹ Hypoventilation may worsen the hypoxemia. If alkalosis is secondary to protracted vomiting, significant dehydration and volume contraction are possible. Associated hypokalemia can cause muscle weakness and ventricular dysrhythmias. Secondary hypocalcemia may result from increased binding of calcium to serum proteins. Symptoms are most often related to the underlying process. Recognition rests with familiarity with likely clinical scenarios and subsequent laboratory testing.

Clinical Presentation

The history is important to the evaluation of a child with a suspected or confirmed metabolic alkalosis. Vomiting, regardless of etiology, is the most common cause in the emergency setting. A history of alkali ingestion may be present, and diuretic use, whether prescribed or surreptitious, should be determined. Weight gain and symptoms of hypertension may be present in conditions of elevated mineralocorticoid activity.

The physical examination may demonstrate weakness or neuromuscular excitability. An example of this is Chvostek's sign, spasm of the facial muscles brought on by tapping the patient's cheek in the area of the facial nerve near the parotid gland. Volume depletion is more common with chloride-

responsive alkaloses, while normovolemia or hypervolemia is seen with chloride-resistant alkaloses. Hypoventilation may be noted. The presence or absence of hypertension may narrow the differential diagnosis (see Table 112–1).

Laboratory tests are an important part of the evaluation of a child with a suspected metabolic alkalosis. Initial laboratory investigation with an extended serum chemistry panel is indicated. Key findings include hyponatremia, hypokalemia, hypochloremia, hypercalcemia, and hypomagnesemia. Results are not necessarily predictable. For example, pyloric stenosis may present with elevated, reduced, or normal potassium levels.^{20,21} An arterial blood gas determination is helpful in identifying mixed acid-base disorders. For a primary metabolic process, a 0.7-mm Hg rise in arterial partial pressure of carbon dioxide (PaCO_2) is expected for each 1 mEq/L rise in HCO_3^- . An elevated PaCO_2 (>55 to 60 mm Hg) is likely to reflect a concomitant respiratory component to the acid-base derangement. Determination of the spot urine chloride (U_{Cl}) level allows classification of the process as chloride responsive or chloride resistant. A urine chloride level less than 10 mEq/L indicates a chloride-responsive process, while a level greater than 20 mEq/L indicates a chloride-resistant alkalosis.⁹ Other values are indeterminate. However, diuretic use may give an unexpectedly elevated U_{Cl} .²² In contrast to the U_{Cl} , the spot urine sodium (U_{Na}) level may not be useful in the setting of alkalosis as the kidney may excrete excess HCO_3^- as a sodium salt. Additional laboratory studies may further help identify the cause of the alkalosis, but the results seldom directly impact emergency department management. Examples of these include renin and aldosterone levels, fasting cortisol level, and a urine screen for diuretics.

Important Clinical Features and Considerations

For children with metabolic alkalosis, it is prudent to remember to treat the patient and not just the laboratory numbers. Many times, the cause of the metabolic alkalosis is evident from the initial emergency department history and physical examination. Although vomiting children undoubtedly have at least some degree of metabolic alkalosis, the metabolic derangement is seldom the focus of the management for these children. Aggressive pursuit and treatment of metabolic alkalosis is seldom indicated in previously healthy children.

Management

Patients with severe alkalosis may present with hypoventilation and hypoxemia. Those with hypokalemia and hypocalcemia are at risk for ventricular dysrhythmias. As patients with chloride-responsive alkaloses are likely to present with significant volume depletion and even shock, intravenous fluid resuscitation with normal saline is essential.²³ It is important to add potassium chloride and follow with K^+ levels for those children who are also hypokalemic (see Chapter 113, Hypokalemia). If the initial serum K^+ is critically low, no glucose should be added to initial fluids to avoid stimulation of an insulin response and subsequent driving of K^+ into the cells. When the degree of alkalosis is critical (i.e., if arterial pH > 7.55) or renal failure prevents adequate

administration of crystalloid, the intravenous administration of HCl may be required. This situation is rare in children. When indicated, the administration of intravenous HCl may result in improved gas exchange and an increase in the arterial partial pressure of oxygen (PaO₂).²⁴

Acetazolamide, a carbonic anhydrase inhibitor, is especially useful in chloride-resistant alkalosis. It blocks HCO₃⁻ reabsorption by the proximal renal tubules.²⁵ The increased flow of HCO₃⁻ to the collecting duct causes an increase in K⁺ secretion. In absence of hyperkalemia, potassium chloride supplementation is indicated.

In cases of hyperaldosteronism or mineralocorticoid excess, spironolactone, a potassium-sparing diuretic, reverses the renal effects of the underlying process. Careful K⁺ repletion is necessary to correct the alkalosis, though attention must be paid to avoid hyperkalemia. Other available potassium-sparing diuretics such as triamterene or amiloride may be used as well, and are the drugs of choice in Liddle's syndrome.²⁶ Bartter's and Gitelman's syndromes are both treated with these diuretics and potassium and magnesium supplements. Proton pump inhibitors are helpful to decrease acid production and subsequent ongoing losses in the setting of persistent vomiting or suctioning of gastric secretions.

Summary

Generating a differential diagnosis and assessing the severity of a metabolic alkalosis relies on the history, physical examination, extended serum electrolytes, arterial blood gas determinations, and a urine chloride level. Treatment should be directed at the likely causes, with particular emphasis on addressing hypoxia and dehydration. The disposition will depend on the likely cause of the acid-base disturbance, local medical resources, and the overall clinical condition of the child. Children with severe metabolic derangements often benefit from transfer to a pediatric intensive care unit.

Hypokalemia

Eric T. Carter, MD

Key Points

Excessive potassium losses, decreased potassium intake, and intracellular electrolyte shifts are the three main processes that lead to hypokalemia.

Hypokalemia is frequently associated with other electrolyte abnormalities.

The most common clinically evident signs and symptoms of hypokalemia are neuromuscular and cardiac.

In general, children tolerate mild to moderate degrees of hypokalemia well and do not require potassium replacement.

Successful treatment of hypokalemia needs to be undertaken in the context of the overall management of the child's medical condition and not just as an isolated process.

Introduction and Background

Potassium homeostasis is crucial to the normal cellular function of every cell in the human body.^{1,2} The majority of potassium stores are located intracellularly.¹ Routine laboratory measurements of potassium only measure extracellular potassium. Therefore, routine laboratory testing may not correlate well with whole body stores. Hypokalemia refers to a lower than normal level of potassium in the blood and is defined as a serum or plasma level less than 3.5 mmol/L (3.5 mEq/L).³ Although potassium homeostasis plays an important role in all cellular function, neuromuscular and cardiovascular manifestations appear to have the greatest clinical impact on patients.^{1,2,4-8}

Recognition and Approach

The three general mechanisms through which hypokalemia may develop are excessive potassium losses, decreased potassium intake, and electrolyte shifts across cell membranes⁹

(Table 113–1). Various medications are well known to cause hypokalemia. Some of these medications are very commonly used to treat children, including albuterol.¹⁰⁻¹² Common examples of how excessive losses may occur include vomiting, diarrhea, and excessive sweating.^{1,6,13} Excessive renal losses of potassium may be due to primary renal disease (e.g., Bartter's syndrome, Gitelman's syndrome), medications, or excess mineralocorticoids (e.g., Cushing's syndrome, Conn's syndrome).^{4,14,15} Hypokalemia may result from long-term inadequate oral intake of potassium. In one study of otherwise healthy young women with anorexia nervosa, nearly 20% were found to have hypokalemia.¹⁶ Intracellular shifts of potassium from the extracellular spaces may result in decreased plasma levels in the face of either normal or abnormal whole body stores.¹⁷⁻¹⁹ Examples of clinical conditions in which there is an intracellular shift of potassium include alkalemia, hypothermia, the administration of albuterol, and periodic hypokalemic paralysis^{10-12,20,21} (see Chapter 47, Peripheral Neuromuscular Disorders). Traumatized children may have hypokalemia on laboratory testing.^{22,23} The significance of this finding and its cause are unknown.

The recognition of clinically significant hypokalemia may result from the constellation of presenting signs or symptoms, a history of chronic disease such as diabetes mellitus, or chronic medication usage, or may occur as an incidental laboratory finding.^{5,10-12,14,17-19,24} Useful diagnostic tests include a basic metabolic panel to evaluate for other clinically significant electrolyte abnormalities (e.g., hypomagnesemia, an elevated anion gap), an arterial or venous blood gas determination if an acid-base abnormality is suspected, and an electrocardiogram to detect cardiac conduction disturbances^{7,8} (Table 113–2).

Clinical Presentation

In general, children with mild to moderate degrees of hypokalemia do not manifest clinically appreciable signs or symptoms. Clinical experience suggests that many children with vomiting and diarrhea have some degree of hypokalemia when laboratory testing is performed. For the majority of children with vomiting and diarrhea, the assessment of electrolytes is not indicated. It is likely that even those children who do not have laboratory testing performed also have some degree of hypokalemia that is clinically unimportant and requires no specific treatment. If evident, signs and symptoms of hypokalemia include muscle cramps, hyporeflexia,

and weakness.¹ More severe presentations may include bradycardia, arrhythmias, hypotension, respiratory muscle paralysis, and even cardiovascular collapse.^{6–8,18–21}

Important Clinical Features and Considerations

Spuriously low potassium may occur if a blood specimen is drawn from a vein at a location proximal to an infusing

intravenous line. Multiple low laboratory values from that same specimen may be a useful clue if this is suspected.^{25,26}

Management

Hypokalemia can frequently be managed without primarily directing treatment at a specific potassium level. Clinical experience suggests that directing care at the underlying disease process usually leads to the proper identification of and treatment for hypokalemia. When indicated, potassium may be administered orally or intravenously. Some children, particularly those with renal disease, may require oral potassium supplementation when hypokalemia is identified. Coordinated care with a physician familiar with a particular child or with a pediatric nephrologist is prudent in many of these cases. There is no evidence-based potassium level at which oral potassium replacement should be initiated for children who were previously healthy and are not manifesting clinical findings attributable to hypokalemia. Clinical experience suggests that it is uncommon for children to present with a serum potassium level <2.5 to 3.0 mmol/L (2.5 to 3.0 mEq/L). This degree of hypokalemia may be a reasonable trigger point for pursuing a definitive diagnosis and initiating potassium replacement.

Intravenous potassium replacement needs to be provided in the context of overall fluid and electrolyte management. A good example of this is seen in the care of children with diabetic ketoacidosis (see Chapter 105, Diabetic Ketoacidosis). The American Diabetes Association has made specific recommendations regarding the management of potassium in children with diabetic ketoacidosis.²⁷ Although children with diabetic ketoacidosis typically have diminished whole body stores of potassium, the serum value may be high, low, or normal at the time the specimen is obtained. As fluid and insulin treatment is initiated, the serum potassium level will fall. In the context of hourly electrolyte assessments, the recommendation by the American Diabetes Association is for potassium replacement to be withheld if the serum potassium level is greater than 5 mmol/L (5 mEq/L), to replace potassium at 30 to 40 mmol/L (30 to 40 mEq/L) in the infusing intravenous fluids if the potassium level is between 3.5 and 5 mmol/L (3.5 and 5 mEq/L), and to replace potassium at 40 to 60 mmol/L (40 to 60 mEq/L) in the infusing intravenous fluids if the potassium level is between 2.5 and 3.5 mmol/L (2.5 and 3.5 mEq/L). In these instances, the potassium replacement should be performed using one third potassium phosphate (KPO₄) and two thirds potassium chloride (KCl). If the potassium level is less than 2.5 mmol/L (2.5 mEq/L), the potassium is to initially be replaced by 1 mmol/kg (1 mEq/kg) of KCl over 1 hour with insulin withheld until the potassium rises about 2.5 mmol/L (2.5 mEq/L).²⁷ This example illustrates how the treatment of hypokalemia needs to be undertaken in the context of the overall management of the child's condition. Infants and children receiving intravenous potassium replacement require continuous cardiac monitoring.

Summary

Hypokalemia is a relatively common electrolyte abnormality in children. The clinical importance of hypokalemia ranges from inconsequential to a life-threatening manifestation of

many disease states. Understanding potassium homeostasis and its relation to disease processes allows for the appropriate evaluation and management of hypokalemia. Using readily obtained laboratory tests, the presenting signs and symptoms, and occasionally an electrocardiogram will allow the clinician to determine the significance of the hypokalemia and whether replacement is warranted. The disposition decision in cases of hypokalemia is seldom based solely on the potassium level. Instead, the disposition is usually based on the working diagnosis, the known underlying disease process, or the overall clinical status of the child.

Chapter 114

Hyperkalemia

Eric T. Carter, MD

Key Points

Hemolysis of a laboratory specimen is probably the most common cause of an elevated potassium result.

Symptomatic hyperkalemia in previously healthy children who are not traumatized is rare.

The most expeditious test for assessing hyperkalemia is an electrocardiogram.

The degree of renal insufficiency a child is experiencing roughly correlates with the risk of hyperkalemia.

Introduction and Background

Hyperkalemia is an “abnormally high potassium concentration in the blood.”¹ A normal serum potassium ranges from 3.5 to 5.0 mmol/L (3.5 to 5.0 mEq/L).² Therefore, by definition, a serum potassium greater than 5.0 mmol/L (5.0 mEq/L) is indicative of hyperkalemia. Hyperkalemia is seldom an isolated problem. The overall approach to hyperkalemia depends on the degree of hyperkalemia and the underlying cause.

Recognition and Approach

Potassium homeostasis is integral to normal cellular function. Most of the body’s potassium is intracellular. Potassium is a major regulator of cellular resting membrane potentials. Clinical symptoms of hyperkalemia are most dramatic and serious when the cellular function of cardiac and neural tissues is disrupted.^{3–8} The epidemiology of hyperkalemia is unknown, but clinical experience suggests it is rare in previously healthy children who have not sustained trauma such as large burns or a crush injury.^{9,10}

Hyperkalemia may develop through three main processes (Table 114–1). The first process is decreased excretion of potassium. The kidneys are the dominant regulators of serum potassium levels. In particular, children who have poor renal function or end-stage renal disease are at risk for developing hyperkalemia through decreased excretion.¹¹ In neonates, hormonal alterations of the renal excretion of potassium

occur in endocrinologic conditions such as congenital adrenal hyperplasia.^{6,7} The second process is increased intake of potassium. Although excessive oral ingestion of potassium may lead to hyperkalemia,³ the digestive process seems to offer substantial protection in this regard. Iatrogenic hyperkalemia due to inappropriate intravenous fluid, for example, is probably a more likely route for the increased intake of potassium. Transfusion of packed red blood cells through a small-gauge needle has been identified as a cause of increased potassium intake.¹² The third process is fluid and electrolyte shifts. If potassium shifts from the intracellular compartment to the extracellular compartment (e.g., the circulating blood), then hyperkalemia usually develops. Examples of when this type of potassium and fluid shifting occurs include diabetic ketoacidosis,¹³ crush injuries,⁹ and succinylcholine-induced hyperkalemia.¹⁰ Because of this fluid and electrolyte shifting, hyperkalemia is not synonymous with increased total body stores of potassium.

Clinical Presentation

The clinical presentation of children with hyperkalemia is dominated by cardiac manifestations, neurologic manifestations, or the underlying illness. The most prominent cardiac manifestations are dysrhythmias.⁵ The conduction disturbances roughly correspond to the degree of hyperkalemia. There is a classic progression through which the electrocardiogram changes as potassium values rise (Fig. 114–1). This progression is not universal and has substantial variability from one patient to the next.¹⁴ Ventricular fibrillation and asystole occur with marked hyperkalemia.^{4,6,15} Since an electrocardiogram usually can be obtained much more quickly than a set of electrolytes, an electrocardiogram is the most expeditious test in cases of suspected hyperkalemia. The neurologic manifestations include paresthesias and weakness. With regard to underlying illnesses and associated hyperkalemia, clinical experience suggests that hyperkalemia is more often identified during the workup for an underlying condition and less often the starting point of an evaluation. Since renal excretion plays such an important role in potassium homeostasis, obtaining tests of blood urea nitrogen and creatinine is reasonable in cases of suspected hyperkalemia.^{11,16} The degree of hyperkalemia seen in children with renal insufficiency and end-stage renal disease roughly correlates with the degree of renal impairment.¹¹ Familiarity with the identification and management of specific conditions known

Table 114-1 Selected Causes of Hyperkalemia

Increased Intake

Inappropriate intravenous fluid preparation or administration
Medications containing potassium salts (e.g., penicillin)
Oral potassium ingestion
Transfusion of packed red blood cells through a small-gauge needle

Decreased Excretion

Congenital adrenal hyperplasia
Renal insufficiency or failure

Fluid and Electrolyte Shifts

Acidosis (e.g., diabetic ketoacidosis)
Burns involving a large body surface area
Crush injury
Heat stroke
Medications (e.g., succinylcholine)
Rhabdomyolysis
Tumor lysis syndrome

“Pseudohyperkalemia”

Hemolysis of the specimen
Laboratory error
Munchausen syndrome by proxy
Thrombocytosis

Table 114-2 Treatment Strategies for Hyperkalemia

Membrane Stabilization

- Calcium chloride (10%): 10–30 mg/kg per dose (0.1–0.3 ml/kg per dose) slowly IV (0.5–1 ml/min max), may repeat PRN. Not to exceed 5 ml (stop infusion if bradycardia develops).

Intracellular Shift

- Sodium bicarbonate: 1–2 mEq/kg per dose (1–2 ml/kg per dose of 1-mmol/ml solution) IV slowly. Incompatible with epinephrine, calcium, and atropine.
- Glucose and insulin: 0.5 g/kg (2 ml/kg) 25% dextrose solution + 0.1 unit/kg regular insulin IV
- Albuterol nebulized (unit dose); may repeat

Increased Elimination

- Furosemide: 0.5–2 mg/kg per dose IV; may increase by 1–2 mg/kg q6–8h. Limits: neonates, 2 mg/kg per dose; infants and children, 6 mg/kg per dose.
- Kayexalate: 0.5–1 g/kg PO or by retention enema
- Hemodialysis

Abbreviations: IV, intravenous; PO, per os (orally); PRN, as needed.

to be associated with hyperkalemia is prudent (see Chapter 88, Renal Disorders; Chapter 99, Rhabdomyolysis; and Chapter 105, Diabetic Ketoacidosis).

Important Clinical Features and Considerations

Serum potassium values obtained through laboratory testing may not reflect true hyperkalemia (see Table 114-1). One common cause of this “pseudohyperkalemia” is the hemolysis of laboratory specimens.¹⁷ Since relatively small needles and catheters are used to draw pediatric blood specimens, the process may cause red blood cell rupture.¹² The release of intracellular potassium into the specimen tube will result in an elevated potassium value. Of course, this laboratory result does not reflect the potassium level in the patient’s blood. Fortunately, laboratories report on whether or not specimens are hemolyzed.¹⁷ In most instances, this allows the emergency physician to differentiate pseudohyperkalemia from true hyperkalemia. Hemolysis is particularly frustrating when there is a high likelihood of true hyperkalemia. In other circumstances, pseudohyperkalemia arises as a laboratory artifact because of other components of blood. For example, patients with thrombocytosis may have artificially elevated

potassium values on laboratory testing.^{18,19} In a bizarre example of pseudohyperkalemia, a mother was suspected of adding urine to her child’s blood tubes in a case of Munchausen syndrome by proxy.²⁰

Management

The management of hyperkalemia depends on the underlying cause. An excellent example of this is the management of hyperkalemia identified during the evaluation of diabetic ketoacidosis. In this instance, the “treatment” of hyperkalemia is to simply avoid adding potassium to the intravenous fluids until the child demonstrates urinary output.¹³ Since children experiencing diabetic ketoacidosis have a total body depletion of potassium, enhancing potassium excretion would lead to serious hypokalemia as treatment progressed (see Chapter 105, Diabetic Ketoacidosis). In another example, administering corticosteroids to neonates with congenital adrenal hyperplasia should lead to normalization of the potassium level.⁶ For children with impeded excretion of potassium, particularly those with renal failure, temporizing measures will be followed by definitive care. The purpose of these temporizing measures is to stabilize cell wall electrical potentials, shift some of the serum potassium intracellularly, and enhance excretion (Table 114-2). Definitive care focuses on the prompt initiation of hemodialysis.

Summary

Hyperkalemia is a serious and potential life-threatening electrolyte abnormality. Hyperkalemia is usually a manifestation of another disease state. If treatment is guided by the underlying condition, the morbidity and mortality associated with hyperkalemia is low. Disposition is typically guided by the overall management of an underlying condition.

Hypocalcemia

Eric T. Carter, MD

Key Points

Symptomatic hypocalcemia primarily involves neuromuscular and cardiac symptoms

Once hypocalcemia has been identified, an ionized calcium level helps in identifying the cause.

Calcium homeostasis is complex and interconnected by multiple metabolic pathways.

Hypocalcemia is frequently associated with other electrolyte abnormalities.

Introduction and Background

Calcium is the most abundant mineral in the human body.¹ It is essential to cellular and enzymatic functions. Calcium is found primarily in bone, where 99% of the body's total calcium is stored. The remaining 1% either is bound to proteins or exists in the free ionized form. When a serum total calcium level is obtained, both the protein-bound and free ionized forms of calcium are measured. Ionized calcium is the physiologically active form of calcium. Calcium homeostasis is maintained by feedback loops that include parathyroid hormone, vitamin D, and calcitonin.¹ Parathyroid hormone acts to increase bone resorption and increase serum calcium. Vitamin D acts on the gastrointestinal tract to increase calcium absorption from the diet.¹ Calcitonin, in opposition to parathyroid hormone and vitamin D, acts to lower serum calcium levels. Magnesium and phosphate levels also directly affect calcium homeostasis. The normal range for total serum calcium is 2.2 to 2.6 mmol/L (9.0 to 10.5 mg/dl).² The normal range for ionized serum calcium is 1.1 to 1.4 mmol/L (4.5 to 5.6 mg/dl).² Since normal neonates may have a lower total serum calcium level than older children and adults, clinicians tend to use a somewhat lower age-specific threshold for defining hypocalcemia in neonates.³

Recognition and Approach

The multiple interconnected pathways associated with calcium regulation make recognition and diagnosis of the

underlying process somewhat complex (Table 115–1). Once hypocalcemia has been identified, a more thorough investigation is warranted. The most important initial laboratory value in this setting is an ionized calcium level.^{4,5} Low total serum calcium associated with a normal ionized calcium level suggests hypoproteinemia due to insufficient protein production (e.g., malabsorption, hepatic disease) or excessive protein loss (e.g., nephrotic syndrome).⁶ Hypocalcemia in which both the total and ionized calcium levels are low suggests hypoparathyroidism, vitamin D deficiency, magnesium or phosphate abnormality, a medication effect, or an underlying disease process (e.g., malignancy, pancreatitis, sepsis).⁶ Other laboratory studies helpful in identifying the cause of hypocalcemia include studies of renal and hepatic function, and magnesium, phosphate, and albumin levels.^{5,7–10} Radiographs may be indicated, particularly in cases of suspected rickets, nonaccidental trauma, or pathologic fractures.¹¹

Clinical Presentation

Because of calcium's ubiquitous involvement in many vital cellular functions, hypocalcemia results in a wide range of clinical presentations. Common neuromuscular manifestations seen with hypocalcemia include paresthesias, muscle cramping, carpedal spasm, generalized weakness, tetany, Chvostek's sign (i.e., spasm of the facial muscles when the facial nerve is tapped near the parotid gland), Trousseau's phenomenon (i.e., spasms of muscles elicited by applying pressure to the nerves innervating them), and seizures.^{11–13} Psychiatric manifestations include depression, anxiety, irritability, confusion, and progressive dementia. Cardiovascular manifestations include arrhythmias, hypotension, electrocardiographic changes including QT prolongation or ventricular dysrhythmias, and syncope.¹⁴ Respiratory manifestations include laryngeal spasm, bronchospasm, stridor, respiratory distress, and apnea.^{15,16} Gastrointestinal manifestations include abdominal distention, poor feeding, vomiting, excessive crying, and dysphagia. Chronic hypocalcemia leads to changes in the teeth, skin, and bones as well. Other diagnostic considerations include congenital syndromes, malnutrition, and neck surgery. A number of medications can affect calcium regulation, including phosphate-containing enemas^{17,18} (see Table 115–1). Calcium chelation, as occurs with blood transfusions or renal failure, and altered protein-binding states (e.g., alkalosis, hypoalbuminemia) may also cause hypocalcemia.

Table 115–1 Common Causes of Hypocalcemia

Surgical/postoperative damage to parathyroid glands
Vitamin D deficiency
Wilson's disease

*Medications associated with hypocalcemia include aminoglycosides, amphotericin, calcitonin, calcium channel blockers, cimetidine, cisplatin, citrate, furosemide, glucagon, glucocorticoids, heparin, magnesium, phenobarbital, phenytoin, phosphates, protamine, and theophylline.

Important Clinical Features and Considerations

Clinical experience suggests that the child's history and physical examination are important keys to suspecting clinically significant hypocalcemia. The use of medications, recent blood transfusions, a history of neck surgery, a history of renal failure, and seizures in a neonate should all be considered "red flags" for hypocalcemia. Acknowledging the varied manifestations may allow the emergency physician to suspect hypocalcemia in clinical scenarios that are not intuitively obvious.^{8,11} For example, physical examination findings such as wheezing and stridor, commonly associated with bronchiolitis and croup, have been described as being associated with hypocalcemia in children.^{15,16}

Management

The management of a child with hypocalcemia is directed at identifying and treating the underlying cause. Given the varied causes of hypocalcemia, there is no standard approach to all children with hypocalcemia. Calcium replacement may be achieved via the oral route in mild or asymptomatic cases of hypocalcemia or in chronic disease states such as renal failure, vitamin D deficiency, and parathyroid hormone deficiency. Clinical experience suggests that appropriate follow-up with the patient's primary physician or endocrinologist should be arranged, and it is seldom, if ever, necessary to begin oral calcium therapy in the emergency department.

In contrast, life-threatening hypocalcemia should be treated in the emergency department. Cardiac monitoring is prudent given the known effects of hypocalcemia on ventricular function. Intravenous calcium chloride and calcium gluconate are both available for emergent calcium replacement. Calcium chloride, commonly stocked in "crash carts," contains three times the elemental calcium and is also more

caustic to infuse in peripheral veins compared to calcium gluconate. Calcium chloride is typically available in a 10% solution and may be given intravenously at a dose of 0.2 to 0.3 ml/kg slowly over 5 to 20 minutes. Continuous cardiac monitoring during intravenous calcium replacement is indicated. Calcium gluconate, also typically available in a 10% solution, may be given intravenously at a dose of 0.5 to 1 ml/kg slowly over 5 to 20 minutes with continuous cardiac monitoring. Neonatal hypocalcemic seizures may be treated with 1 to 2 ml/kg of calcium gluconate over 5 to 10 minutes.³

Summary

Calcium is the most abundant element in the body, and its regulation is vital to cellular function. Calcium homeostasis is maintained via multiple interconnected metabolic pathways. Hypocalcemia affects multiple organ systems and therefore results in a wide range of clinical presentations. Intravenous replacement is indicated in life-threatening or severe hypocalcemia. Any child receiving intravenous calcium replacement warrants admission to the hospital and monitoring. Appropriate consultation and disposition are dependent on the suspected underlying cause of hypocalcemia and its clinical manifestations.

Psychobehavioral Disorders

Thomas H. Chun, MD

Key Points

Psychobehavioral disturbances can be caused by both psychiatric and medical conditions. These patients need a careful assessment for possible medical causes for their symptoms, especially younger patients and those with acute changes in their symptoms.

Patient safety is paramount; every patient and his or her caregiver(s) need a comprehensive assessment of their ability to safely manage the patient's symptoms.

Symptoms may be situation dependent; patients may be able to control their symptoms/behavior and act in a safe manner in the emergency department (ED), yet be unable to do so in other settings.

“Medical clearance” and assessing patient safety are the keys to successfully managing these ED patients and are far more important than making a psychiatric diagnosis or differentiating between comorbid psychiatric conditions.

Selected Diagnoses

- Violent and/or agitated behavior
- Psychosis
- Other psychiatric conditions
 - Behavioral disorders (attention-deficit/hyperactivity disorder, attention-deficit disorder)
 - Pervasive developmental disorder
 - Acute anxiety
 - Obsessive-compulsive disorder
 - Posttraumatic stress disorder
 - Conduct disorders
- Somatiform disorders
 - Conversion disorder
 - Munchausen syndrome
 - Munchausen syndrome by proxy

Discussion of Individual Diagnoses

Violent and/or Agitated Behavior

Violent or agitated behavior is not a diagnosis unto itself but the final common pathway for a number of medical and psychiatric conditions.¹ Unfortunately, every year emergency department (ED) staff are injured or threatened by such patients. Violence has a much higher association with substance abuse than with mental illness in general. When it occurs with mental illness, it is greater in the presence of other acute psychiatric symptoms.^{2,3}

Violent behavior includes verbal threats, destruction of property, and/or physical violence toward oneself or others. Agitation may present with these symptoms but may also present without any violence. Agitation can be so severe as to cause extreme distress or to impair the patient's ability cooperate.

Ensuring the safety of the patient, ED staff, and others is critical. All patients need to be carefully assessed for suicide (see Chapter 117, Major Depression and Suicidality), homicide, or plans for revenge, and any current violent thoughts or impulses. Equally important is identifying and treating potential organic etiologies of the behavior.

Management includes verbal, chemical, and physical restraint. Training in verbal restraint has been shown to decrease the need for chemical or physical restraint. Techniques common to all verbal restraint strategies include a calm, nonjudgmental manner; asking the patient to verbalize what is bothering him or her; active, empathetic listening; offering the patient as many treatment options as is reasonably possible while setting clear limits; and avoiding “bargaining” and punitive treatment(s).⁴

Many agents are available for chemical restraint (Table 116–1). None has been approved by the U.S. Food and Drug Administration for this purpose in pediatric patients. All, however, have been widely used and are considered safe and efficacious by experienced psychiatrists and emergency physicians. If a patient is already taking one of these medications, the current dose or a larger dose may be necessary. All medication doses should be rounded to the nearest half or whole milligram, or to the nearest whole-pill dose.^{5–15}

A minimum of five personnel are needed to adequately physically restrain a patient, one to control each limb and one for the head. Padded leather restraints are recommended. The choice between positioning the patient supine or prone

Table 116–1 Chemical Restraint Medications

Medication	Starting Dose	Onset of Action (min)	Comments/Adverse Effect
Diphenhydramine	1.25 mg/kg (IV/IM/PO) Adolescent: 25–50 mg	5–15 (IM/IV); 20–30 (PO)	
Hydroxyzine	0.5–1.0 mg/kg (IV/IM/PO) Adolescent: 25–50 mg	5–15 (IM/IV); 20–30 (PO)	
Lorazepam	0.05–0.1 mg/kg (IV/IM/PO) Adolescent: 0.07 mg/kg	5–15 (IM/IV); 20–30 (PO)	Slowly over 5 min (IV); may redose q60 min
Midazolam	0.05–0.15 mg/kg (IV/IM), 0.5–0.75 mg/kg (PO) Adolescent: 2–4 mg	5–15 (IM/IV); 20–30 (PO)	Over 2–3 min (IV); may redose q60 min
Haloperidol	0.1 mg/kg (PO) Adolescent: 1–5 mg (PO) or 2–5 mg per dose (IV/IM)	15–30 (IM); 30–60 (PO)	May redose q60 min; may prolong QTc
Risperidone	<12 yr: 0.5 mg (PO) Adolescent: 1 mg (PO)	45–60 (PO)	
Olanzapine	<12 yr: 2.5 mg (IM/PO) Adolescent: 5–10 mg (IM/PO)	30–60 (IM); 45–60 (PO)	
Quetiapine	25 mg/dose (PO)	45–60 (PO)	
Zispradone	<12 yr: 5 mg/dose (PO) Adolescent: 10–20 mg per dose (PO)	30–60 (IM); 60 (PO)	May prolong QTc

Abbreviations: IM, intramuscularly; IV, intravenously; PO, orally.

Adapted from Allen MH: Managing the agitated psychotic patient: a reappraisal of the evidence. *J Clin Psychiatry* 61(Suppl 14):11–20, 2000.

must be individualized to each patient. The prone position is safer but more restrictive than the supine position. Close observation and documentation of vital signs, assessment of behavioral status, and regularly offering food, water, and access to bathroom facilities are all mandated by law, as is regular reassessment of all parameters. Physical restraint is not without risk. A government analysis of a series of reported deaths following restraint identified three major risk factors for death: excessive weight being placed on the backs of prone patients, objects being used to cover patients' mouths to prevent spitting or biting, and airway obstructions due to placing patient's arms across their neck.^{8,16}

The least restrictive means of treatment should always be tried first, a practice that represents an optimal clinical approach as well as compliance with the law. Once a patient has calmed, removal of physical restraints may be considered. There is no standard procedure for removing restraints. Some prefer removing one restraint at a time, to determine if the patient has regained control of him/herself. Others prefer to remove all restraints at once. The same type of personnel who were present when the restraints were placed should be present when they are removed, in case the restraints need to be reapplied.^{8,16}

Psychosis

Psychosis specifically refers to a syndrome of significant alterations in cognition, perception, reality testing, mood, and/or impulse control, resulting in impaired social functioning. Psychosis can be seen in a large number of psychiatric and medical conditions (Table 116–2).

Classically the symptoms of psychosis include hallucinations and/or delusions, along with other changes in cognitive functioning, mood, and behavior. However, symptoms may vary considerably depending on the patient's developmental status and cultural background. In young children, it may be particularly challenging to differentiate between developmentally appropriate “magical thinking” and true psychosis.^{17–19}

Table 116–2 Conditions That May Lead to Psychosis

Central Nervous System Lesions

- Tumors
- Brain abscess
- Cerebral hemorrhage
- Meningitis or encephalitis
- Temporal lobe epilepsy

Cerebral Hypoxia

- Pulmonary insufficiency
- Severe anemia
- Cardiac failure
- Carbon monoxide poisoning

Drug Intoxications

- Accidental ingestion
- Drug abuse/experimentation
- Alcohol abuse (alone or with other drugs)
- Deliberate suicide attempt
- Prescribed medications (toxicity/side effects/withdrawal)

Infections

- Malaria
- Typhoid fever
- Subacute bacterial endocarditis

Metabolic and Endocrine Disorders

- Electrolyte imbalance
- Hypoglycemia
- Hypocalcemia
- Thyroid disease (hyper and hypo)
- Adrenal disease (hyper and hypo)
- Uremia
- Hepatic failure
- Diabetes mellitus
- Porphyria

Rheumatic Diseases

- Systemic lupus erythematosus
- Polyarteritis nodosa

Miscellaneous Conditions

- Wilson's disease
- Reye's syndrome

Trauma

Table 116–3 Medical Screening Tests

Complete blood count with differential
Blood chemistries, including electrolytes, glucose, calcium, magnesium, and tests of hepatic and renal function
Thyroid function tests
Rapid plasma reagin or Venereal Disease Research Laboratory tests (syphilis)
Urinalysis
Toxicology screening and/or drug levels
Electrocardiogram
Infectious disease workup
Lumbar puncture
Brain imaging (computed tomography or magnetic resonance imaging)

The most critical role of the ED physician is a thorough and comprehensive evaluation to rule out potential medical causes of the patient's symptoms. The psychiatric literature is rife with case reports of adverse outcomes in patients misdiagnosed as having a psychiatrically based psychosis. There is no standard medical evaluation for a patient with psychosis. The ED workup of such patients should be tailored to each individual patient, and there are many possible relevant laboratory investigations (Table 116–3).^{20,21}

Psychotic patients may be agitated or violent. A careful safety evaluation (i.e., harm to self or others) is mandatory. Ultimate treatment and disposition decisions will hinge on whether acute medical conditions have been successfully ruled out. An inpatient medical admission may be needed to accomplish this goal. Psychiatric consultation should be obtained only after acute medical conditions have been ruled out.²²

Other Psychiatric Conditions

Behavioral Disorders (Attention-Deficit/Hyperactivity Disorder or Attention-Deficit Disorder)

The cardinal features of attention-deficit/hyperactivity disorder (ADHD) are symptoms of inattention, developmentally inappropriate hyperactivity with impulsivity, or both. The symptoms must be present in at least two different settings and cause clear impairment in social or academic functioning. Symptoms will vary by age/developmental stage, subtype of ADHD, and whether other comorbid psychiatric conditions are present.^{23–26}

Pervasive Developmental Disorder

Pervasive developmental disorder (PDD) encompasses a number of different conditions, the best known of which is autism. All types of PDD involve early onset of impairment in social interaction and communication, and stereotypic or restricted behavior.

Patients' presentations will vary by age/developmental stage, gender, type of PDD, and whether other comorbid psychiatric conditions are present. Severity of symptoms is highly variable. Some patients are severely incapacitated, while those with mild symptoms will seem largely normal. Some degree of mental retardation is frequently (but not always) associated with PDD.^{27–29}

Acute Anxiety

The precise psychiatric term for episodes of acute anxiety is *panic attacks*.^{30,31} A panic attack is not itself a codable

Table 116–4 DSM-IV-TR Criteria for Panic Attack*

A discrete period of intense fear or discomfort, in which four (or more) of the following symptoms develop abruptly and reach a peak within 10 minutes:

1. palpitations, pounding heart, or accelerated heart rate
2. sweating
3. trembling
4. sensations of shortness of breathing or smothering
5. feeling of choking
6. chest pain or discomfort
7. nausea or abdominal distress
8. feeling dizzy, unsteady, light-headed, or faint
9. derealization or depersonalization
10. fear of losing control or going crazy
11. fear of dying
12. paresthesias
13. chills or hot flashes

*DSM-IV-TR, *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision*.

disorder but may be a part of any of the recognized anxiety disorders. Panic attacks (Table 116–4)³² are especially seen in panic disorder and agoraphobia, but can also be a part of other phobia disorders, obsessive-compulsive disorder (OCD), and posttraumatic stress disorder (PTSD) (discussed later), acute stress disorder, generalized anxiety disorder, and anxiety disorders due to medical causes or substance use.³³

A panic attack can present in a highly variable manner. In mild cases, the panic attacks may be infrequent and minimally incapacitating. Severe cases may result in significant debilitation. The presence of comorbid anxiety or other psychiatric disorders may add to the complexity of the patient's presentation.²³

Obsessive-Compulsive Disorder

A person with OCD must have either obsessions or compulsions, and at some point recognize that the symptoms are excessive or unreasonable (this symptom is not necessary in children). The obsessions/compulsions must cause the patient distress, be time consuming, or cause significant impairment in an important area of functioning. Patients with mild OCD may appear to be normal. Severe OCD can literally be all-consuming: patients cannot even perform basic functions of daily living. OCD symptoms can be mistaken for tics or simple "eccentricities."^{34–36}

Posttraumatic Stress Disorder

The diagnosis of PTSD requires a person to have been exposed to a traumatic event, to persistently reexperience the event, to continually avoid stimuli associated with the trauma, to have "emotional numbing" (not present before the trauma), and to have physical and/or emotional hyperarousal. The presentation of PTSD can be highly variable, depending on which symptoms are present and/or prominent. Patients can present looking primarily "depressed" (e.g., moody, irritable, withdrawn), agitated, angry, or aggressive; anxious or "jumpy"; or even psychotic (e.g., hallucinations, illusions, dissociative phenomena).^{37–39}

Conduct Disorders

The current diagnostic criteria for conduct disorder emphasizes a repeated pattern of aggression (verbal, physical, or sexual) toward people or animals, destruction of property, deceitfulness or theft, or serious violations of societal rules, resulting in a significant impairment in functioning. The context in which these behaviors occurred and how long these behaviors have been present are important factors in assessing the severity of the patient's symptoms. Patients with later onset of symptoms and symptoms occurring only in group settings are more likely to have a better prognosis than those with early onset of symptoms and exclusively solitary antisocial behavior.^{40,41}

Management

These psychiatric conditions may be the sole presenting problem of an ED patient, but are more likely to be one of many presenting problems. Comorbid psychiatric problems are the rule, not the exception. As such, the presenting complaints/symptoms with which patients come to the ED often do not easily lend themselves to a single, simple diagnosis or management plan.

As with all psychiatric patients, ED management should focus on ruling out possible medical causes for the patient's presenting complaints and a careful safety evaluation. There is no standard set of laboratory tests that should be obtained to "medically clear" a patient. The workup should be individualized to each patient. Pregnancy testing and drug screens are the most commonly obtained laboratory studies. Patients with new onset or acute changes in their symptoms warrant a meticulous evaluation for underlying medical conditions (see Table 116–3). If there are safety concerns, a psychiatric consultation should be obtained. If such a consultation is not available, the patient should be transferred to a facility where a psychiatric evaluation can be obtained. If there are no acute medical or safety issues, consultation with the patient's existing mental health care provider(s) is appropriate. If the patient does not have a mental health provider, a referral for timely outpatient services should be arranged before the patient is discharged from the emergency department.²³

Somatoform Disorders

Somatoform disorders include a number of conditions in which patients present with somatic complaints that are primarily due to psychological causes. This category of disorders includes somatization disorder (chronic, multiorgan system complaints), conversion disorder (see later), pain disorder, hypochondriasis, and body dysmorphic disorder. The presenting complaints can encompass every type of physical complaint. The most common types of complaint are pain, gastrointestinal symptoms, sexual dysfunction, and pseudo-neurologic symptoms.^{42,43}

Conversion Disorder

In conversion disorder, symptoms or deficits of a voluntary motor or sensory function are reported. The symptoms are not intentionally or consciously produced or feigned. After appropriate evaluation, a medical cause or culturally sanctioned reason for the behavior cannot be found. The symptoms distress the patient and/or result in significant functional

impairment. Any voluntary motor or sensory function may be the object of a conversion disorder. *La belle indifférence* (i.e., the patient does not appear distressed by the symptoms) is a classic sign of conversion disorder.

Munchausen Syndrome

The accepted term in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) for Munchausen syndrome is *factitious disorder*. In this condition, physical or psychological symptoms are intentionally manufactured. The motivation for this behavior is solely for the purpose of assuming the role of an ill person. Factitious disorder may present with any type of physical or psychological complaint. The symptoms may fit classic medical or psychological conditions, but may also represent bizarre diagnostic dilemmas. Some patients may administer harmful substances to or perform harmful acts upon themselves, resulting in serious illness or injury. The lack of external "rewards," such as economic gain, avoiding responsibilities, or improving physical well-being, differentiates factitious disorder from malingering.^{44,45}

Munchausen Syndrome by Proxy

"Munchausen syndrome by proxy" is the historical term for a subtype of factitious disorder. In this condition, the physical or psychological symptoms are intentionally produced in or attributed to another person; for example, a parent (most often the mother) deliberately causes or reports ill symptoms in his or her child. As with all factitious disorders, there is no external reward or gain for this behavior other than assuming the "sick role." Patients may present in many ways. Some will appear healthy with no findings on physical examination. Conversely, some patients will be gravely ill and some may even die as victims of Munchausen-by-proxy.

Management

Patients with these conditions can be particularly vexing to ED physicians, who must strike a balance between the need for a careful medical workup and the potential harm of unnecessary tests and treatment. If there is no established history of any of this group of diagnoses, the most prudent course for an ED physician is an appropriate medical evaluation of the patient's complaints. If the evaluation is nondiagnostic and one of these diagnoses is strongly suspected, further medical and psychological evaluation, on either an in- or outpatient basis, should be arranged.

If there is an established history or diagnosis, the ED evaluation should be tailored to individual circumstances. As with any ED patient, if there is a reasonable possibility that an acute medical condition may exist, that possibility should be explored. However, if acute medical conditions are considered to be unlikely and if the patient has a primary care provider, mental health clinician, or consistent, responsible caregiver, that individual may be an invaluable resource and may obviate the need for extensive and unnecessary testing.

In suspected cases of Munchausen-by-proxy, consultation with a child abuse service and/or governmental agencies (e.g., child protective or social services, law enforcement) is mandatory. Unfortunately, these conditions are often chronic and difficult to treat, requiring multidisciplinary services well beyond the scope of the ED.^{44,45}

Chapter 117

Major Depression and Suicidality

Jacqueline Grupp-Phelan, MD, MPH and Sergio V. Delgado, MD

Key Points

The most common emergency department presentations of major depression in children are somatic complaints, and feeding disorders.

The most common emergency department presentations of major depression in adolescents are sleep disorders, aggressive/violent behavior, eating disorders, and superficial cutting on arms and/or legs.

Frequent reasons why children and adolescents present to the emergency department for treatment of major depression are fear of death, wish for problem relief, fear of reaction of parents, and suicidality.

The major focus of evaluation is assessment of suicidal risk, and the major focus of management is averting suicidal behavior and its acute consequences.

Introduction and Background

Major depression has become an important cause of emergency department (ED) utilization. The prevalence of depression increases throughout the lifespan, with approximately 1% of preschoolers, 2% of school-age children, and almost 8% of adolescents having major depression in the general population.¹⁻³ Depression in children is often unrecognized and inadequately treated.^{4,5} The prevalence of mental illness in U.S. EDs has been increasing over the past decade, representing approximately 5% of all visits by children for mental health reasons.^{6,7} The frequency of positive screens for depression across all age groups is about 4%.⁸ The ED can play an important role in the detection and referral of children with depression.

Recognition and Approach

There is no single cause of depression; rather, a combination of predisposing factors, including genetics, neurobiologic factors, and environmental variables, is likely responsible.⁹⁻¹¹ Depressed children present differently according to age;

however, there is no gender differentiation until adolescence, where the incidence doubles for females.^{5,12} Obsessive-compulsive disorder and learning disabilities are often precursors to major depression in children.¹²⁻¹⁴ Suicide is the third leading cause of death in the 10- to 24-year-age group and has been increasing over the last decade. Suicide remains the most critical management issue for ED providers.¹⁵

Clinical Presentation

The clinical presentations for depressive disorders in children and adolescents are similar across health care venues and are similar to adult presentations with respect to irritable mood, failure to achieve, and significant weight gain or loss. However, the ED presentation of depressed school-age children does differ from that of adults in that children often present with somatic complaints or disorders of feeding. Adolescents are more likely to present with sleep disorders, aggressive behavior, and self-mutilation. Acute presentations in the adolescent age group include fear of death, wish for problem relief, fear of reaction of parents, and the most concerning presentation, suicidal ideation. Depressed preschoolers present with sadness or irritability, which is the most sensitive symptom, although lack of enjoyment or interest in play is the most specific symptom.¹⁶⁻¹⁸

The ED provider should be highly suspicious of depression when a younger child presents with extreme irritability, conflict with parents, fear of death, inappropriate guilt, or selective mutism. Older children display more traditional signs of depression, including dysthymia, hopelessness, self-mutilation, and suicidal ideation. Adolescents or their parents may report conflict in important social relationships. Finally, a significant change in weight or fears of returning home should cue ED providers to perform a mental health screen.¹⁹ It is important to note that parents may underreport their child's depression and not take the early signs seriously if it does not directly affect them.^{20,21} For example, in these situations the child frequently reports that "my parents would be better off without me," and the parents feel "he/she has everything, I don't understand what he/she has to be depressed about."

Preschoolers and school-age children through the age of 14 are less able to accurately describe their internal state of sadness and often communicate in concrete terms: "I feel down, bad, sad." This explains the need for parental presence during the interview.

Table 117–1 Assessment of Suicidal Patients**Assessing Circumstances of an Attempt**

Precipitating humiliating event
 Preparatory actions: acquiring a method, putting affairs in order, suicide talk, giving away prized possessions, suicide note
 Use of a more violent method
 Precautions taken against discovery

Presenting Symptoms

Hopelessness
 Depressed mood
 Suicidal thoughts

Psychiatric Illness

Previous suicide attempt
 Affective disorders
 Alcoholism or substance abuse
 Conduct disorder

Psychosocial History

Parents recently divorced
 Multiple life stressors
 Chronic medical history

Personality Factors

Impulsivity, hostility
 Negativity
 Borderline or antisocial personality disorder

Family History

Family history of suicidal behavior
 Family history of affective disorder

Children with special health care needs are also at risk for depression and often are more difficult to assess. This group of children may present to the emergency department in a medical crisis, often after a period of noncompliance with medications. This may be a mechanism to ask for help and should prompt ED providers to perform a mental health screen.

The suicidal patient presents to the emergency department in crisis. A rigid algorithmic approach in the ED is unlikely to be beneficial due to the unique characteristics and risk factors of the individual patient. In the assessment of the suicidal patient, the emergency physician must utilize information about risk factors (Table 117–1) in consultation with a mental health professional to determine the appropriate disposition of the patient. Indications for psychiatric evaluation include acute suicidality, a combination of risk factors for suicide, recurrent ED visits over a short period of time, poor or nonexistent social and mental health supports, and a specific plan with lethal means.

As in any medical examination, the physician will start with the chief complaint and a review of present illness, including what brought the patient to the ED. Patients at high risk of suicide frequently present with nonspecific somatic complaints ranging from vague digestive problems and aches and pains to other symptoms more directly linked to depression—changes in appetite, fatigue, and insomnia. A staged suicide risk assessment with brief screening questions should be undertaken. Risk factors that increase the likelihood of suicide, such as recent drug use or trauma (domestic violence or rape), a previous suicide attempt, or gender identity issues, should prompt the ED provider to continue with a more in-depth assessment of suicidal risk (see Table 117–1). Unfortunately, structured instruments have shown high false-positive

and false-negative rates in general medical practice, requiring further research on the best way to classify patients with suicidal behavior.

A physical examination should be performed to rule out medical causes for psychiatric complaints. A mental status examination should be done evaluating mood, content of thought (hallucinations or delusions), and whether speech is pressured. Explicit questions about suicidal ideation, plans, attempts, and notes should be asked in a direct, compassionate, and confidential manner. Most importantly, the patients should be asked whether he or she can promise to contract for safety, control his or her behavior, and not act on impulses. Although confidentiality is imperative, patient safety may dictate the notification of family and psychiatric personnel even against the child's or adolescent's wishes.

Important Clinical Features and Considerations

Suspicion of suicidality or depression should be aroused when patients fear or are reluctant to allow a medical examination or discuss their problem with a nurse or physician. During the physical examination in children who present with risk factors for depression, it is important to ask and look for superficial cuts on arms and legs, particularly around the area of the thighs and hips. For children or adolescents being admitted for observation, it is important to completely check for abrasions or lacerations by performing a complete examination while the patient is in a hospital gown. Acute presentation to the ED is often in the evening, after parents return from work, after school hours, or anytime during the summer. In the review of systems, it is important to ask about preexisting or recent stressors that may have exacerbated an underlying depression, such as poor performance in school or a recent relationship difficulty (e.g., break up with a significant other). The educational level of parents has been found to be a risk factor associated with severe adolescent depression. Patients have a higher risk of depression if parents did not graduate from high school.²² Pitfalls in the diagnosis may include dismissing somatic presentations of children who are high-achieving straight A students, described by their parents as “perfect” or “never angry.” In a child with a bipolar disorder, a potential complication may be missing the depressive phase during which the risk for suicide is greatly increased.²³ It is important to ask about cycles of mania (not sleeping for days, hypersexuality, or spending sprees) and depression. Finally, there are a number of conditions that mimic acute depression in children and adolescents, including infections, neurologic disorders, and medication reactions²⁴ (Table 117–2).

Management

Although the child may be presenting for the first time with depressive complaints, it is mandatory to develop a biopsychosocial treatment plan beginning with the ED visit. Assessment of family willingness to participate in the treatment plan is essential for appropriate decisions with respect to the timeliness of the treatment plan and disposition. Individual psychotherapy, behavioral therapy, cognitive psychotherapy, and family therapy are the major nonpharmacologic treatments. Laying the groundwork for the initiation of

Table 117–2 Conditions Mimicking Depression in Children and Adolescents

Infections	Neurologic Disorders/Tumors	Endocrine	Medications	Others
Infectious mononucleosis Influenza	Epilepsy Postconcussion	Diabetes Cushing's disease	Antihypertensives Barbiturates	Alcohol abuse Drug abuse and withdrawal Cocaine Amphetamine Opiates
Encephalitis	Subarachnoid hemorrhage	Addison's disease	Benzodiazepines	Electrolyte abnormality Hypokalemia Hyponatremia Failure to thrive
Subacute bacterial endocarditis Pneumonia Tuberculosis Hepatitis Syphilis (CNS) AIDS	Cerebrovascular accident Multiple sclerosis Huntington's disease	Hypothyroidism Hyperthyroidism Hyperparathyroidism Hypopituitarism	Corticosteroids Oral contraceptives Cimetidine Aminophylline Anticonvulsants Clonidine Digitalis Thiazide diuretics	Anemia Lupus Wilson's disease Porphyria Uremia

therapy is an essential part of the ED management of acute depression.

Moderately to severely depressed children and adolescents should leave the emergency department with psychopharmacologic intervention. This is particularly important if there will not be urgent outpatient access to a child or adolescent psychiatrist. Mental health access has been a major problem in rural settings and increasingly has become a problem in urban centers. Thus, moderately depressed patients who are safe to go home are often unable to see a psychiatrist or psychologist for a full evaluation for weeks to months. For this reason, the emergency department visit may need to include the initiation of antidepressants in conjunction with mental health providers. Therefore, an understanding of the contraindications and potential complications regarding their use is imperative.

The most frequently prescribed pharmacologic agents for depression in children and adolescents continue to be the selective serotonin reuptake inhibitors (SSRIs), primarily because of their safety profile. Careful attention should be paid to U.S. Food and Drug Administration (FDA) “black box” warnings. Fluoxetine, at present, is the only medication approved for the use in major depressive disorders in children and adolescents.²⁵ Psychopharmacologic and psychotherapeutic approaches are often used together, with evidence supporting combination therapy.²⁶ Nevertheless, over 60% of depressed children have a positive response to the use of fluoxetine alone.

Of major concern in the initiation of SSRIs is the recent evidence surrounding increased adverse events in the initiation phase of therapy. Adverse events are defined as suicidal thinking or suicidal behavior. The average risk of adverse events in patients on SSRIs is 4%, twice the 2% risk in patients who received placebo in clinical trials. Although no deaths occurred, the FDA elected to present a black box warning, which mandates that clinicians have the duty to warn patients and their families about the risk associated with the medication, and to develop a clear way to follow up

and monitor the response to the medication. The monitoring should include “daily observations by families and frequent (weekly) contact with a physician during the first month of therapy.”²⁵ Parents of children who receive antidepressant therapy with SSRIs must provide informed consent, recognizing that the FDA has not approved any of these medications for use in children for depression, aside from fluoxetine.²⁷ The primary goal is to maximize benefits and minimize potential side effects. Immediate consultation with a psychiatrist is highly recommended if using any other SSRI than fluoxetine.

An SSRI is contraindicated if the patient has known hypersensitivity or had received a monoamine oxidase inhibitor within the previous 2 weeks.²⁸ In general, tricyclic antidepressants may have serious cardiac effects and should be avoided.^{29,30} Bupropion hydrochloride is contraindicated if the patient has a history of seizures.²⁸

The emergency physician must gather information, weigh risk factors, and formulate a plan for managing suicidal behavior. The most important question is whether or not the patient can be managed as an inpatient or outpatient. Although hospitalization has no clear association with improved outcome in suicidal youth, it remains the most common risk management tool in the acute suicidal setting. For acutely suicidal patients who cannot contract for safely, inpatient care is mandatory. Suicidal patients are at risk for hurting themselves or eloping. As the number of suicidal and mentally ill youth increases, many EDs are investigating the use of locked rooms or psychiatric observation areas on site. Care must be taken to protect the patient from self-harm (see Chapter 154, The Child-Friendly Emergency Department: Practices, Policies, and Procedures). Some patients can be discharged from the ED based on absolute risk of suicide, the social and school supports available, and the availability of outpatient care. In all cases of patients who have a serious plan for suicide or who have made an attempt, psychiatric consultation is important in understanding an underlying psychiatric diagnosis, developing a confidential treatment

plan, and managing the immediate psychiatric needs of the patient. Once patient safety is addressed and a decision regarding disposition is made, follow-up must be facilitated with the family.

Summary

For children and adolescents presenting with acute depression, referral to an outpatient therapist for patient and/or family counseling should ideally be arranged within 1 week. If a timely mental health evaluation is not possible, the ED physician should consider the initiation of psychopharmacologic treatment with return to the primary care physician for urgent follow-up of medication and therapeutic complications within several days.

For suicidal patients, emergency providers must be able to provide effective and appropriate identification and referral for mental, physical, and substance abuse disorders. In addition, the family must restrict access to highly lethal methods of suicide. Finally, a family-centered approach taking advantage of family and community support and support from ongoing medical and mental health care relationships is mandatory.

Chapter 118

Sexual Abuse

Mathew A. Seibel, MD and Deborah Scott, RN, ARNP

Key Points

An understanding of normal prepubertal gynecologic anatomy can help distinguish abnormal anatomy associated with abuse from other genital complaints.

Due to the dynamics of prepubertal sexual abuse, children will often present with a variety of minor or superficial complaints masking the real problem

Many children who have been sexually abused will have normal examinations.

Knowledge of the differences between a purely medical examination and an examination in which forensic issues are to be considered is essential and can completely alter the provider's approach to diagnostics and documentation.

Introduction and Background

Physicians in the emergency department may be asked to evaluate and examine children and adolescents who may have been sexually abused. Such complaints evoke strong, emotional responses in professionals treating these patients and their families. Knowledge of sexual abuse in children has grown rapidly in the past 20 years. Numerous studies of normal genital findings, findings associated with genital trauma and abuse, where and when to perform sexual abuse exams, and what should be included in a complete sexual abuse examination have increased our understanding of the problem.¹⁻¹⁴ Many medical and community leaders are continually working to define protocols for medical and forensic evaluations.¹⁵⁻²⁰

The dynamics of child sexual abuse are unique in the spectrum of human crisis response. Child sexual assault rarely involves "stranger danger." Currently available data from many sources indicate that over 80% of perpetrators are known to the child victim, and many sexually abused children are related to the perpetrator by blood or parental remarriage. Fathers are equally likely to be perpetrators as stepfathers. Children also frequently report assault by other close relatives such as siblings, uncles, cousins, and grandfa-

thers. Perpetrators also include nonfamilial persons who are in a position of trust by the child and family, such as teachers, clergy, scoutmasters, coaches, and mentors. Less than 5% of reported child sexual assaults involve total strangers. The number is a bit higher for adolescents, though relatives and acquaintances remain the predominant source of origin. Interfamilial factors such as the divisiveness of allegations, denial, financial considerations, social isolation, loss of domicile, and threat of incarceration, make it difficult to assume that nonabusing parents and family members will step into the protective supportive roles that are readily seen in a family in crisis from a disease. Alternately, some children may present to the emergency department with a description of symptoms of sexual abuse that are aggressively pursued by a caregiver despite significant information to the contrary. The dynamics of this type of presentation may include factitious disorder, attempts to create custody barriers, and projection of the caregiver's own sexual abuse history onto the child. However, this scenario still leaves significant concerns for the emergency physician as to the physical and emotional safety of the child.

Recent articles have suggested that up to 1 of every 4 females and 1 of every 7 males will be a victim of some form of inappropriate sexual contact by the age of 18 years.¹ Some emergency physicians will experience contact with these types of cases monthly and others much less frequently. In either case, one must be aware of both the immediate medical treatment responsibilities and responsibilities to local law enforcement agencies, social services agencies, and the legal system. Many communities now have experts who specialize in evaluation of sexually abused children and adolescents. Under these conditions, recognition of the problem and appropriate referral is the standard of care. Other communities rely on emergency medical professionals to identify, evaluate, and treat these children at their most vulnerable time.

Recognition/Approach

Recognition of signs and symptoms of child sexual abuse involves an awareness of the types of behaviors that are typically reported by children to have occurred so as to better understand the types of findings that may or may not be present. Younger children will use terms and descriptions that make sense to them to explain incidents and events that have occurred. For example a child may describe an

encounter as “X’ put a stick in my butt.” While the child may not have actually seen a stick, he or she may be trying to explain the insertion of a rigid, stick-sized object into the rectum and that this triggered a sharp sensation. A child may give details as simple as “white pee” or as involved as “choking his pee-pee by the neck until it throws up” to describe witnessing ejaculation. Many of the types of behavior described are physically noninjurious, and the examiner may be left with a feeling of helplessness in trying to evaluate something that does not create any physical findings.¹⁴

In male children, sexual abuse may involve fondling, pinching, squeezing, or oral manipulation of the penis, testicles, and anal area, or tying off of the penis with a ligature. It can also involve penetration of the anus or mouth. Children can be forced to assist in masturbating their assailants. In cases in which a boy is describing an event that happened in the past, a thorough external physical inspection of the child is typically all that is required. Cultures and DNA evidence are not typically necessary. The normalcy of the examination should be considered to be consistent with the child’s statements, documented fully, and turned over to the legal and social services agencies for the remainder of the investigation.¹⁰

The approach to the evaluation of the sexually abused female child is more complicated and must be based on an understanding of normal pediatric and adolescent behavior as well as normal pediatric and adolescent genital anatomy and physiology (Fig. 118–1). In female sexual abuse, common complaints include touching, fondling, and putting things into various orifices such as the mouth, anus, and vagina. Again, the descriptions may involve the child’s normal vocabulary to explain her perceptions and understandings of events beyond her full scope of comprehension. A detailed history of any symptoms that occurred at the time of this event will help to formulate an impression for different types of injuries and findings. Frequently the opportunity to clarify the initial description occurs during the actual examination.

Anatomic differences among newborn, prepubertal, and adolescent females are striking. Normal newborn female anatomy is strongly influenced by maternal hormones, and at birth the anatomic structures appear almost “adolescent like.” The external labia and the prepuce are somewhat

edematous, causing a more pronounced appearance. The clitoris is frequently prominent. The hymen is fuller and petaled or ruffled in appearance, and has a pale, whitewashed pink color. Physiologic leukorrhea is often present. As estrogen withdrawal progresses, discharge becomes serous in some infants. After several months, the anatomy changes and maternal hormone depletion allows the anatomy to become that of a prepubertal female. The labia, prepuce, and clitoris become smaller, and the minor labia and perivaginal structures become somewhat atrophic.²¹

Contrary to many layperson assumptions, an imperforate hymen is a medical anomaly, not the norm. The hymen is a ring of tissue that sits at the opening of the vagina and has a central opening creating an annular, crescentric, or fimbriated appearance. It often contains clefts and tags along the hymenal rim where longitudinal ridges form within the vagina to meet the hymen. The hymen itself can vary from thin and translucent to a thicker, more fascia-like appearance. Less frequently the hymenal opening may be divided by one or more bands of tissue, creating a septate appearance. Rarely the hymen may appear more like a solid sheet with multiple holes and areas of varied thickness, described as a cribriform hymen.^{22,23}

During the peripubertal period, as external genitalia progress through the Tanner 2 and 3 stages, changes will also be noted in the appearance of the minor labia and the hymen. The labia begin to elongate until they meet posterior to the hymen (Tanner stages 4 and 5). The hymen becomes thicker and less translucent and develops a more rubbery appearance. The tissue continues to develop until it creates a mature, petaled or redundant mass that to varying extents occludes the opening of the vagina. It will again have a physiologic leukorrhea and a pale, whitewashed pink color. Children at the Tanner 2 and 3 stages may be aware of some vaginal discharge. Menarche ensues in late Tanner 3 to Tanner 4 stages of development.

Clinical Presentation

Sexually abused children and adolescents frequently present with a history of anogenital symptoms or trauma.²⁴ With toddlers, the disclosures frequently are triggered by

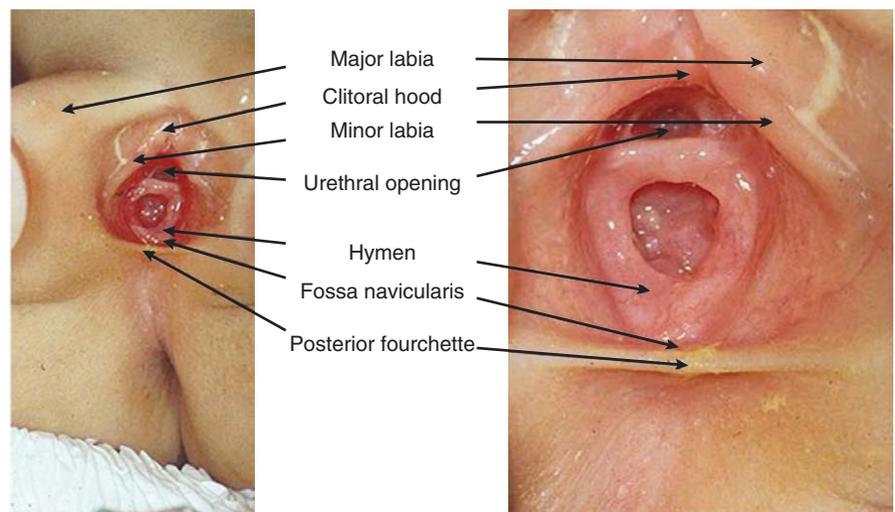

FIGURE 118–1. Normal genital anatomy of the child (left) and adolescent (right).

Table 118–1 Typical Presenting Symptoms of Acute Sexual Abuse

Genital or rectal pain
Genital or rectal bleeding
Vaginal discharge
Genital or rectal inflammation or redness
History of abuse with or without symptoms
Constipation
Dysuria
Acute behavioral changes

discomfort in the genital area during bathing. After gathering more history, this is often determined to be the result of trauma that actually occurred at some time in the past. In these cases the emergency is more frequently a parental emergency, rather than an actual medical emergency. In other cases patients with genitourinary, rectal, or abdominal complaints have in fact been acutely sexually molested. Some may present with symptoms of anxiety (Table 118–1).

History should optimally be taken after one has established some type of rapport with the patient. The appearance of the interviewer (male vs. female, older vs. younger) can be an issue to the patient and may affect the quality of the history obtained. A quiet environment is preferable, and parties present must be supportive and nonjudgmental in their approach. Involved parties present during the interview or history may significantly affect the content of any history obtained. It is important to excuse all suspected or involved parties from the examination room throughout the evaluation. This may be a problem with special needs children or children who are minimally verbal. This can also trigger a very strong separation anxiety for the parent who is already feeling insecure in his or her ability to protect the child; however, there needs to be an opportunity for the child to provide his or her version of the history without cues, interruptions, or interjections by the adult. Along with providing an environment away from the parent or caregiver, the interviewer must be careful to limit his or her own emotional responses. Children frequently shut down communication when they notice that the information they are providing upsets the caregiver or interviewer.

Document accurately all historical statements made by the child. Include quotes and the exact wording of comments made by the patient whenever possible. Open-ended, age-appropriate questions are best, but may not provide the information needed to assess the child's situation if there is significant apprehension. Direct questions may need to be asked, and then followed up with an open-ended "tell me more about that" or "then what happened?" Framing the questions from the context of medical concern and the need to appropriately provide treatment will often allow the child to overcome initial reluctance to talk and often allow for inclusion in the future legal process. Asking questions that facilitate differential diagnostics are appropriate and necessary in these cases just as with any other medical diagnosis and should not be avoided.

It is important to understand how children deliver a history regarding emotionally difficult issues. Younger children have difficulty with time and often give a history that is factually correct but easily misleading or misinterpreted by adults when it seems to change. It is not uncommon for a child to

mix several events that have occurred at different times and thus appear to give untruthful histories, when actually they are telling several "truths" simultaneously. Children can also give a history of events that did not occur due to suggestions by adults who may have secondary gain issues. These patients will have great difficulty with specifics and frequently be much less clear about the specific details of the allegations. Careful use of developmentally appropriate vocabulary and a simple question format can slow the history but is much more accurate.

When there are concerns for sexual abuse, the physical examination should be comprehensive.²⁵ By focusing on the patient's genitals alone, signs and symptoms pertinent to the final diagnosis may be overlooked, such as cutaneous injury, tonsillar contusions, grip marks, and abrasions. Sedation is only rarely necessary to complete the examination, but can be considered when fear or pain is severe enough to prevent a thorough medical examination. The need for collection of forensic evidence or to fully visualize or culture the vaginal orifice also increases the need for sedation. More often than not, time and a calming atmosphere is all that is necessary to perform an appropriate examination. When sedation is necessary, short-acting benzodiazepines or barbiturates are most frequently used.

Examine the perineum and the introitus in the supine lithotomy or frog leg position. Older texts defer the use of stirrups; however, many children are quite comfortable when the stirrups are shortened to accommodate the shorter leg length. Supine inspection should reveal most traumatic findings. The labia may appear either closed or gaping and need to be separated to reveal the vestibule and structures including the urethra and hymen. Use gentle outward and downward traction of the major labia to flatten the pelvic floor and allow optimal visualization of the vaginal area. Be careful not to pull laterally as this can sometimes tear posterior labial adhesions not initially recognized, causing pain or bleeding from the posterior fourchette. In prepubescent children, vaginal speculums are almost never required. Occasionally nasal speculums can be used to further spread the opening, but this should only occur under anesthesia and after carefully documenting the preprocedural state of the child's anatomy and the presence and location of any bleeding. This prevents the examination itself from clouding the diagnosis.

It is important to document the hymenal shape and configuration. The size of the hymenal opening is relatively unimportant. It is considered normal when there is a 1-mm rim of hymen present.^{16,17} The anterior-posterior diameter can normally be elongated in overweight girls.

The vaginal examination can be enhanced by placing the child in the prone knee-chest position. Separating the buttocks upward and outward can provide the best view of the hymen. Loose or redundant hymens are also best visualized in this position. This position is not always required if the supine examination is adequate. The rectal examination can be performed supine but is best done in the prone knee-chest position. Separation of the buttocks will provide an excellent view of the rectum. Relaxation by the patient can allow dilation of the rectal opening. Visualization of the skin and mucosa inward to the dentate line is appropriate. Circumferential vascular congestion in the perianal area will increase during the examination and should not be confused with contusion. Instrumentation is rarely needed even for forensic

sample collection. Sedation is necessary to evaluate and repair more extensive trauma, if suspected.

Examination of the adolescent female is essentially equivalent to the examination of an adult female. Tanner stage 3 through 5 females can be evaluated with a routine gynecologic examination, recognizing that this will be the first such exam in many traumatized girls. Detailed attention to the external and prevaginal anatomy should precede the speculum insertion. Translucent disposable speculums greatly facilitate the thorough inspection of the entire vaginal canal, as well as the cervix. Adolescents may be physiologically mature but emotionally immature or regressed during crisis, and these developmental and psychological issues need to be considered and accommodated prior to initiating the examination. Many locations have victim advocates who assist with this during the examination. In other locations, another staff person or a support person brought to the emergency department by the victim can assist in this role.

Penile examinations typically involve inspection only. Retraction of the foreskin in uncircumcised boys may reveal trauma to the glans. In circumstances in which repair is required, sedation will be necessary during repair and again at the time of suture removal to prevent further psychological trauma, especially if the initial injury involved any form of instrumentation. Certain physical findings are diagnostic of sexual abuse, while others only raise suspicion of sexual abuse (Table 118–2).

Photographic documentation of any abnormal finding is the standard of care for a forensic examination. This can be done using video or still photography. In specialized sexual trauma evaluation centers, colposcopes are frequently used, though a camera with a macro lens can also be used with excellent results. The purpose is to document a magnified image of any perineal, vaginal, penile, or rectal physical findings. Multiple images from different angles, with different

amounts of traction, and while the child is in different positions are needed. This is due in part to medicolegal requirements and the desire to prevent a need for a second examination. Labeled drawings should also accompany the photographs as a part of the medical record.

Testing and treatment for sexually transmitted infection (STI) is not necessary or appropriate in every case. In the prepubescent child, data currently suggest a 1% to 5% STI transmission rate related to sexual abuse. STI testing should be reserved for children with acute vaginal injury, body fluid contamination, children who are symptomatic, and children who are found to be pregnant. Anytime a prepubescent child is determined to need testing, genital cultures should be obtained. Do not rely solely on polymerase chain reaction or DNA testing for a child, as many of the nonculture tests have been studied only in adults, causing a potential legal pitfall. With a cooperative child, a swab can be threaded into the vaginal orifice from an anterior angle, thus avoiding the highly sensitive posterior hymenal rim. Cultures can often be obtained with a cotton-tipped swab by obtaining cells from discharge external to the hymen. Infection with *Neisseria gonorrhoeae* will cause vaginitis, and cervical specimens are not needed in prepubescent children. The laboratory can be instructed to obtain a DNA analysis from a culture sample, but a culture cannot be obtained from a DNA specimen. This applies to both *N. gonorrhoeae* and Chlamydia testing. Genital herpes and Chlamydia can frequently be tested from the same specimen. Blood testing for syphilis (rapid plasma reagent) and human immunodeficiency virus (HIV) should also be obtained.²⁶

In situations in which the history provided by the child indicates that the event was extremely recent, there may be DNA evidence from the assailant on the child's body. Suspected areas can be swabbed with a dry, cotton-tipped applicator to attempt evidence collection. Suspected areas can often be identified by the use of a black light. If the area being swabbed is already moist (i.e., a rectal vault, oral cavity, or a wet fold on the skin), using a dry cotton-tipped applicator is all that is necessary. It should be moved across the area in a gentle rolling motion to lift rather than smash the secretions onto the swab. If the area is already dried, moisten the swab with a small amount of sterile saline before collecting the evidence. Cultures and DNA collection are necessary only when the child describes a perpetrator's bodily fluid as having had contact with the skin, and there has been no time for the evidence to be removed through bathing, urinating, defecating, or eating or drinking, depending on the orifice involved.²⁷ DNA collection swabs should be fully dried prior to submitting the specimen to law enforcement. Specialized equipment for this process is commercially available. Detailed instructions for specimen collection are included in most evidentiary rape kits, but these are often based upon adult examinations. Only the portion of the kit that is medically indicated by history and physical examination findings should be utilized.

Important Clinical Features and Considerations

There are multiple emergency department presentations that may or may not represent child sexual abuse (Table 118–3).

Table 118–2 Physical Findings

Physical Findings DIAGNOSTIC of Sexual Abuse

Pregnancy in a child under the age of legal consent
Gonorrhea, syphilis, or HIV in a prepubescent child, other than a neonate
Semen in the vaginal vault of a child under the age of consent
Sperm, motile cells, or evidence of acid phosphatase
Acute laceration of the hymen with a history of sexual assault
A witnessed event of sexual assault
Photographic documentation of the sexual assault occurring

Physical Findings SUSPICIOUS FOR Sexual Abuse

Acute bruising of thigh, labia, and/or vestibule
Acute laceration of labia and/or external genitalia
Acute laceration of hymen
Nonacute hymenal changes
Presenting with genital inflammation and/or discharge
Acute and nonacute rectal findings
Penile injuries
Associated nongenital injuries
STIs

- *Chlamydia* and condylomata in children can be from abuse or present in children of up to 2–3 years of age from vertical transmission that has been dormant prior to presentation.
- Herpes can present from abuse or autoinfection.

Abbreviations: HIV, human immunodeficiency virus; STI, sexually transmitted infection.

Table 118–3 Signs and Symptoms Concerning for Possible Sexual Abuse**Bleeding (Rectal/Vaginal)**

Nonsexual trauma—abrasions or lacerations of the vestibule or labia
 Prolapsed urethra—seen as hemorrhagic tissue that often fills the area in front of the vestibule, obscuring the hymen
 Straddle injury—seen as laceration or bleeding from the area of the posterior fourchette; often there is associated bruising
 Precocious puberty—menstrual bleeding
 Maternal estrogen withdrawal—neonates only
 Gastrointestinal infections such as *Shigella*, *Salmonella*, or *Escherichia coli*
 Rectal fissure—very common, especially in younger children
 Hemorrhoid—not common in younger healthy children

Pain (Vaginal/Rectal/Penile)

Bacterial infections, such as with β -hemolytic streptococcus
 UTI or urethritis
 Perirectal abscess
 Pinworms—can involve the rectum or vagina
 Periurethral cyst
 Nonsexual trauma with or without bruising
 HSV infection—can be secondary to abuse or spread from oral lesions by patient

Discharge (Vaginal/Penile)

Nonspecific vaginitis—often seen with small amounts of green or yellow discharge
 Balanitis
 Hygiene—poor care can allow for nonspecific discharge
 Physiologic leukorrhea
 Foreign body—presents with recurrent discharge; sometimes examination under anesthesia is required for diagnosis

Redness or Swelling (Vaginal/Penile/Rectal)

Contact dermatitis
 Thermal injury
 Irritation from soaps, detergents
 Infections such as yeast, *staphylococcus*, *streptococcus*
 Laxative use causing perirectal burning
 Lichen sclerosis—long-term irritation with itching

Abnormal Appearance (Vaginal/Rectal/Penile)

Septum—most often vertical but can also be horizontal
 Gaping or “too big” vaginal opening
 Dilated rectal opening when in knee-chest position
 Imperforate anus with anterior fistula
 Imperforate hymen
 Labial adhesions—both posterior and anterior connections
 Healed hymenal transection
 Lesions—warts, molluscum contagiosum, Bartholin’s gland cyst

Behavioral Changes “Suggestive of Sexual Activity”

Masturbation—many normal children masturbate
 Inserting foreign objects into the vagina or rectum
 Acting out of a sexual act with dolls, pets, or other children

Knowledge of Sexual Activity Abnormal for Age and Known Lifestyle Exposures

Abbreviations: HSV, herpes simplex virus; UTI, urinary tract infection.

As with any other medical evaluation, an appropriate differential diagnosis must be explored while fully assessing the child’s symptoms, findings, and safety risk. In areas where an advocacy center or rape crisis center is available, the emergency department may defer forensic evaluation and focus strictly upon making sure that the patient is stable for transport to that center. In situations in which nonsexual sources of the complaint are the primary concern, the emergency

Table 118–4 Circumstances in Sexual Abuse That Warrant Hospitalization

- Trauma so severe as to require surgical repair and postoperative observation
- Severe bleeding requiring observation for hemostasis
- Multidimensional trauma in which the need to care for other physical injuries, such as fractures, head injuries, dehydration, and chest and abdominal trauma, is a higher level of concern
- Social instability—the safety of the child in these situations is imperative and, if the social instability is potentially hazardous to this child, medical admission is appropriate; coding guidelines are inclusive of this.
- Treatment of unstable unassociated findings

physician may be better equipped to perform the differential evaluations for urinary tract infection, gastrointestinal bleed, constipation, hemorrhoids, diaper dermatitis, and other conditions.

Management

Management of a child who has been sexually assaulted or abused depends in large part on the community or geographic area where the patient is seen. While the specific wording may vary and different age cutoffs are used, all states mandate the reporting of cases in which there is a suspicion of child abuse and/or neglect. Failure to report is a crime that in some areas is punishable by fine and imprisonment. Awareness of the statutory requirements for the location is critical for both the physician’s decision process and the legal process.

In areas in which specialized experts are not available, the emergency physician is the most accessible and appropriate person to evaluate and intervene on behalf of children who may be sexually abused. In areas in which specialized experts are available, the patient is stable, and forensic evidence will not be lost, referral to a trained specialist in a child advocacy center or other child abuse evaluation unit not only is appropriate for the child, but also frequently allows for more appropriate use of the emergency physician’s time and resources. Admission to a medical facility is rarely medically necessary. Certain circumstances do warrant hospitalization. (Table 118–4).

Discharge from the emergency department is appropriate only after all evaluations are complete; the findings are documented; forensic evidence has been appropriately collected, labeled, and turned over to the appropriate law enforcement agency; and mandatory reports are made. Many areas have crisis intervention teams whose mission is to deal with sexual abuse victims. This evaluation should take place prior to discharge. Follow-up arrangements should be made for counseling, therapy, or immediate acute behavioral interventions. Arrangements should also be made for follow-up of culture results or other medical findings.

At this time the Centers for Disease Control and Prevention does not recommend HIV prophylaxis for all prepubescent sexual abuse victims. There is a move toward recommending a 1-month course of postexposure prophylaxis for the adolescent and adult sexual assault victim that is the same as the “needlestick” prophylaxis used in hospitals (see Chapter 156, Postexposure Prophylaxis). The local

pediatric infectious disease physician is an excellent resource for the most current recommendations for the prepubescent child and should be consulted in any case in which this is being considered. Decisions regarding the treatment of suspected STI need to be made on suspicion or likelihood of positive findings and likely ability for medical follow-up.

Law enforcement officers are often present in the emergency department. Communication with law enforcement is an integral part of the care of the sexual abuse/assault victim because of the criminal act involved and for maintaining a safe environment for the patient. The emergency physician should expect discussions with law enforcement and social services. The history and physical must be obtained and documented with the presumption that it will be reviewed by the law enforcement agent, the state prosecutor, a defense attorney, and a defense-sponsored medical expert. Deposition and criminal courtroom testimony by the examining physician will certainly occur when the child gives a positive history and/or when physical findings are present. Juvenile courts may also require testimony if an extended investigation shows a need to consider alternate living arrangements for the child.

Summary

Overall, medical prognosis from sexual abuse is excellent. Life-threatening injury is extremely rare. The psychological impact of these events is much more profound and, due to the fact that so many of these events are intrafamilial, the allegations alone will potentially permanently alter family dynamics and structure. Even under the best circumstances with widespread support of the victim, optimal medical care, available counseling, and swift and effective prosecution, many of these children will go on to have problems with interpersonal relationships and have a higher potential for self-destructive behaviors such as alcoholism, drug dependency, sexual promiscuity, and self-mutilation. These problems can present months or years later as posttraumatic stress disorder or other psychological abnormalities. The initial contact with the emergency department is often the place where the child's emotional healing can begin. As a medical authority figure, the emergency physician may be able to empower the victim to realize that he or she is not responsible for the actions of others, is healthy and "whole" as a person, and has a right to pursue a happy, fulfilling life. The emergency provider should take the time to communicate these basic tenants to the child whenever possible.

Chapter 119

Physical Abuse and Child Neglect

Irene Tien, MD, MSc

Key Points

Physical abuse should always be considered in children presenting to the emergency department for a traumatic injury.

The American Academy of Pediatrics recommends that the evaluation of infants and young children for physical abuse should include a skeletal survey if the child is 2 years old or younger and retinal examination if 3 years old or younger. A head computed tomography scan should be considered if there is suspicion of abuse and the child has neurologic signs or symptoms, is under 6 months old, has fractures suggestive of abuse, or has bruises on the face.

A child may be neglected if his or her basic needs are not being met, including clothing, food, and shelter as well as adequate supervision, emotional needs, and education.

It is the ethical and legal obligation of health care providers to report cases of suspected child abuse or neglect to child protective services.

Introduction and Background

Of the 4.5 million children who were reported to child protective services (CPS) in 2002, 896,000 were abused.¹ Thirty-four percent of neglect and 10% of physical abuse cases were reported to CPS by medical professionals in 2002.¹ It is especially important that abused children are not misdiagnosed and are not returned to a dangerous environment, because abuse does not occur in isolation. Many abused children have a past history of hospitalization and many who are returned to the custody of their parents are subsequently abused.^{2,3} Furthermore, studies have shown that some infants who are seen by a physician who did not recognize the diagnosis of abuse were subsequently re-injured, resulting in preventable deaths.⁴ Abused children suffer higher in-hospital mortality and morbidity rates than children with accidental injuries.⁵⁻⁷ Those who recover are more likely to have residual neurologic deficits, behavioral problems, mental health problems,

and substance abuse disorders, and to become adult abuse perpetrators or victims.⁸⁻¹⁶

The federal Child Abuse Prevention and Treatment Act (CAPTA) of 1976 established CPS agencies that were vested with the responsibility of investigating suspected child abuse and protecting children.^{8,17} In the United States, all physicians are legally required to report cases of suspected abuse to their local CPS agency.¹⁸ It is the ethical and legal obligation of all physicians to be aware of how to identify abused children and to know what to do when they think they are taking care of a child who has been injured from abuse.

During 2002, 61% of victims suffered physical abuse and 19% suffered neglect.¹ Federal legislation describes a minimum set of acts or behaviors that define child abuse and neglect: “any recent act or failure to act on the part of a parent or caretaker which results in death, serious physical or emotional harm, sexual abuse or exploitation or an act or failure to act which presents an imminent risk of serious harm.”¹⁹ Specific definitions of what constitutes abuse or neglect vary between states.

Recognition and Approach

History Gathering

The key to the diagnosis of physical abuse and child neglect is to always consider it in the differential diagnosis of childhood injury. The importance of a complete history cannot be overemphasized. The clinician must ask enough questions in order to clearly understand how an injury occurred and to resolve apparent discrepancies. In general, adults and children should be individually questioned in their primary language in a quiet, private space. Extended questioning of children is discouraged as they are especially vulnerable to distortions of memory. Children often perceive repeated questioning as a sign that their previous answers were wrong.²⁰ This may lead to a distortion of a child’s account of his or her abuse during subsequent questioning by investigative officials. The approach should be supportive and neutral, using open-ended questions.²¹ Appropriate preparation of the child for questioning is also necessary and important (Table 119–1).

General Approach to Physical Abuse

When evaluating any injured child, the clinician should consider the six core questions listed in Table 119–2. Answers to these questions will depend upon the understanding of the

Table 119–1 Recommended Approach to History Gathering for Child Abuse Concerns**Who Should Be Interviewed**

- Parents and other witnesses to the injury or those present at the time when the injury was first noticed.
- Children, only if it is necessary to determine safety or immediate medical needs.

How To Conduct Interview**General considerations:**

- Interview in the respondent's first language when possible. Use interpreter services.
- Use a quiet and private space.
- Interview the adults out of earshot of the child and vice versa.
- Give adolescents the option of being interviewed with or without the parents.
- Obtain the history of the events through open-ended statements, such as "Tell me why you are here."
- Avoid leading questions.
- Remain calm and sensitive.
- Minimize the number of interviews.

Special considerations for questioning children:

- Children are especially vulnerable to distortions in their recall of an event.
- Repeated questioning may be interpreted by the child that his or her previous answers were wrong.
- Do not question unless it is necessary for identification of immediate medical needs or assessment of safety in returning the child home from the emergency department.
- Interview in a supportive but neutral manner.
 - Do not suggest that you know what the child is thinking, how he or she should feel, or what has happened.
 - Show interest in the child's statements, and praise the effort in giving responses (not the content of the responses).
 - Use predominantly open-ended questions.
- Prepare the child for the interview.
 - Introduce yourself.
 - Give an age-appropriate explanation of what is going to happen.
 - Instruct the child that it is fine to say that he or she doesn't understand a question, doesn't know the answer, or doesn't wish to respond.

What Information Should Be Asked

- Obtain the details of who, what, when, where, and how.
- Ask enough questions that the story makes sense to you. For example, if the parent states that the child fell off of the bed, ask how they know that. Did they witness the fall? Did they find the child on the floor and presume the child fell?
- Obtain an extended social history.
 - Names, ages, addresses, and phone numbers of guardians, parents, other caregivers, and other children potentially at risk.
 - Details of the caregiving and custody arrangements for this child.
- Use screening questions for domestic violence (DV). There is concurrent DV in up to 50% of child physical abuse cases.²³
 - Have you been hit, kicked, or punched by a partner in the past year?
 - Do you feel safe in your current relationship?
 - Is there a partner from a past relationship who is making you feel unsafe right now?
- Include other questions you feel necessary to ask to assess the child's immediate safety and the safety of other possibly involved children.

patterns of the presentation of abuse and the epidemiology, biomechanics, pathophysiology, and differential diagnosis of childhood injuries. A detailed history and physical examination are pivotal to arriving at an accurate conclusion about the likelihood of an injured child having been abused. This may differ from a more focused emergency department (ED) evaluation for other conditions.

General Approach to Neglect

Child neglect comes in many different forms, including emotional neglect, educational neglect, medical neglect, failure to provide health care, supervisory neglect, abandonment, inability to provide basic needs (food, shelter, clothing), inadequate protection from environmental hazards (e.g., failure to secure in a car seat, allowing access to a loaded gun), and drug exposure of neonates and children (Table 119–3).²² An initial assessment of neglect should begin by answering the six core questions listed in Table 119–2.²²

Filing with Child Protective Services

Definitive proof of abuse or neglect is not required to make a report to CPS. It is the job of CPS to follow up on all cases in which there is reasonable concern of abuse or neglect. Physicians are legally required to report suspicions of neglect.

This may include a report to law enforcement in addition to CPS. Specific procedures for reporting vary by state, and emergency physicians must be knowledgeable about these procedures. The Child Welfare Information Gateway provides information about reporting laws in each state on its web site (www.childwelfare.gov/systemwide/laws_policies/search/index.cfm).

Clinical Presentation**Physical Abuse**

The identification of child abuse is very challenging. Health care providers traditionally begin their medical decision making based upon a gathered history. Children injured from abuse, however, often present for medical care without an accurate history.²³ Abused infants may present with vague signs and symptoms. Many of the injuries sustained from child abuse are also sustained through accidental mechanisms or may be confused with nontraumatic findings.^{5,10,20,23–30} Clinicians must become familiar with the patterns of child abuse and neglect presentation and with recommendations for screening for occult injuries in order to identify abuse.^{31,32} This requires that a detailed history and examination be performed in the evaluation of every injured child.

Table 119–2 Six Core Questions to Ask during an Assessment for Physical Abuse and Neglect

Physical Abuse

- How did the injury happen?
 - A first-hand account by whoever witnessed the injury or the first signs of injury is preferable.
- When did the injury happen?
- Could it be abuse?
- What medical and social considerations make you more or less concerned about abuse?
 - Consider the biomechanics and epidemiology of this injury for a child of this age given the mechanism described.
 - Consider the family's history of having been reported to child protective services (CPS) in the past; approximately 30% of families reported to CPS once will be reported again in 18 months.⁴⁸
- What is the medical prognosis for this child?
- What is the safety prognosis for this child?

Neglect

- Are the child's needs not being adequately met?
 - Has this led to demonstrable harm?
 - If not, what is the evidence of potential harm?
- Has there been a pattern of neglect?
 - For how long?
 - What types?
 - Has CPS been involved?
- What is contributing to the neglect? Consider child, parent, family, and community factors.
- What strengths and resources are available?
- What interventions have been tried? What were the results?
- What is the likelihood that changes will occur?
 - Is the family motivated?
 - Do they understand the concern?
 - Are resources available?

Adapted from Dubowitz H, Giardino A, Gustavson E: Child neglect: guidance for pediatricians. *Pediatr Rev* 21:111–116, 2000.

There is no comprehensive list of historical indicators of physical abuse or child neglect. Patterns of presentation that should increase concern for child abuse include (1) a child who presents for medical care of a significant injury for which there is no history of trauma; (2) the history provided does not explain the injury based upon knowledge of the biomechanics and epidemiology of that injury; (3) the history of how the injury occurred changes significantly over time; (4) the history of self-inflicted injury does not correlate with the child's developmental abilities; (5) there is a delay in seeking medical care that is unexplained or unexpected; and (6) the child discloses abuse or neglect (Table 119–4).²³

Worrisome historical indicators of abuse are not necessarily in themselves enough to result in a report to CPS. A detailed history and examination should be completed first. Considerations of cultural beliefs as well as specialized challenges associated with poverty or immigration should be taken into account. Reporting of suspected abuse or neglect should be based upon factual information and not “gut feelings,” which are subject to personal biases. Biased reporting of child abuse has been shown to be affected by a reporter's perception of a family's ethnicity or socioeconomic status, type and severity of injury, age of the child and parents, and urban location.^{23–25} The morbidity associated with report-

ing cases of nonabuse should be kept in mind. The need for social services support versus CPS investigation should be differentiated.

Child Neglect

Neglected children seek care in the ED for several reasons. Children left home alone may be reported by neighbors and brought into the ED by prehospital providers. Primary care pediatricians may be concerned about failure to thrive and refer children to the ED, or a child may become acutely ill because of dehydration associated with poor nutrition. A child may present with an acute injury related to poor supervision. Familiarity with the types of neglect will help identify cases of neglect (see Table 119–3).

Conditions That May Be Mistaken for Physical Abuse or Child Neglect

Many conditions have been mistaken for physical abuse or child neglect. These include ethnic therapies, mongolian spots, photodermatologic reactions, disorders leading to inadequate bone mineralization and increased susceptibility to fractures, organic causes of failure to thrive, organic causes of subdural hemorrhage, and organic causes of retinal hemorrhage (Table 119–5).

Important Clinical Features and Considerations

The frequent absence of an accurate history and the potential for confusion with nonabusive illness in cases of suspected child abuse require a more aggressive diagnostic evaluation that is not only based upon gathered history and examination findings, but also conducted with consideration of occult injuries (Table 119–6). The American Academy of Pediatrics (AAP) recently published guidelines recommending a skeletal survey in all cases of suspected abuse in children 2 years old or younger.³¹ Approximately 15% of physically abused infants will have occult fractures diagnosed on skeletal survey. Thirty to 70% of infants with abusive head trauma will have a fracture on skeletal survey. Skeletal surveys may be considered in children up to 5 years of age, depending on the clinical scenario. For example, children with a predisposition to more easily broken bones (e.g., cerebral palsy) may be more likely to sustain abusive fractures than healthy children of the same age. Repeat skeletal surveys in 2 weeks may also be considered in cases of unclear findings or high risk. An additional 27% of children may have newly identified fractures on repeat skeletal survey.³³

The AAP also recommends an ophthalmologic examination by an ophthalmologist familiar with retinal findings in child abuse in all children under 3 years of age who are suspected of having been physically abused.³² As many as 65% to 90% of children with abusive head injury have retinal hemorrhages when examined by an ophthalmologist.^{10,26,34–36} In one study, non-ophthalmologist retinal assessments were only accurate in identifying the presence or absence of retinal hemorrhages 87% of the time. An examination was attempted only in 63% of children, and 81% of these attempts resulted in a visualized retina.³⁷ Characterization of the type, number, and location of retinal hemorrhages is important when determining possible etiologies.^{27,38–44}

Table 119–3 Types of Child Neglect*

Type	Definition	Example
Emotional neglect	Inadequate provision of affection, nurturance, or love.	Infant of a mentally ill mother who doesn't provide comfort when the infant cries.
Educational neglect	Failure to enroll a child in school, failure to assure adequate attendance at school without a satisfactory reason, or when special educational needs are not being met.	Teenager expelled from school, but parents do not enroll her in another school.
Medical neglect	Nonimplementation of health care recommendations leading to actual or potential significant harm.	Child with insulin-dependent diabetes not getting or taking prescribed treatments.
Failure or delay in getting health care	Delay or failure in getting health care that results in actual or probable significant harm.	Young child with second-degree burns to his hands who presents several days after the injury.
Supervisory neglect	Inadequate supervision in accordance with the child's developmental needs, resulting in clear risks to his or her health and well-being.	A toddler left unattended near a swimming pool; a preschooler left home alone.
Abandonment	Extreme form of supervisory neglect wherein children are not "claimed" within 2 days or teenagers are forced out of the home.	Parent gets angry at their 12-year-old child, locks him out of the house and does not allow him to return home.
Inability to provide basic needs[†]	Inadequate provision of food, clothing, shelter, or hygiene.	Child presents with failure to thrive (growth less than 5th percentile for age) for which no medical cause has been identified. Child inadequately dressed for the weather or dressed with poorly fitting clothes (e.g., no jacket in snowy weather; extremely tight-fitting, painful shoes). Child is homeless and sleeping on the street or in a car. Child repeatedly does not meet the basic standards of hygiene (e.g., obviously filthy, not just dirty).
Inadequate protection from environmental hazards	Failure to protect from avoidable environmental hazards.	Failure to use a car seat or seatbelt; riding a bike without a helmet; poisonous household substances left within reach of a child; access to a loaded gun.
Drug exposure of neonates and children	In utero exposure to illegal drugs and alcohol, indirect exposure in infants and older children.	Woman gives birth to a heroin-addicted baby; young child is exposed to second-hand marijuana smoke; child living in a home with a methamphetamine lab.

*A determination of the presence of neglectful behavior by a caregiver toward a child involves a degree of judgment on the part of the clinician. This table is not meant as an all-inclusive definition of child neglect, but rather should serve as a guide as to what could be considered neglectful behavior requiring consideration of a report to CPS.

[†]Please refer to your state statute for allowances made for poverty.

Table 119–4 Patterns of History or Injury That Should Increase Concern for Physical Abuse or Child Neglect***Historical Patterns**^{20,23}

- Significant injuries for which no history is given.
- The history provided does not explain the injury identified. Take into consideration the biomechanics and epidemiology of the injury.
- The history of injury changes significantly over time.
- A history of self-inflicted trauma that doesn't correlate with the child's developmental abilities.
- Delay in seeking treatment for an injury or illness for which there is an inadequate or implausible explanation.
- Disclosure by the child that he or she has been physically, emotionally, or sexually abused by a caregiver.
- Frequently missed health care appointments that can reasonably be expected to result in additional injury to or illness in the child.

Injury Patterns

- Bruising in preambulatory children⁴⁹
- Bruising in ambulatory children in areas not usually associated with normal activities (e.g., inner arms, inner thighs, buttocks, behind the ears, pinnae, trunk)⁴⁹
- Laceration of the inferior or superior frenulum of the lips or the frenulum of the tongue
- Hematoma of the tragus of the ear⁵⁰
- Scars or injuries in the shape of objects
- Traumatic intracranial injuries in children under 2 years for which there is no plausible mechanism, or in a child under 2 years in whom there is no external evidence of injury⁵¹⁻⁵⁶
- Long bone or pelvic fractures in preambulatory children or for which there is no plausible explanation⁵⁷⁻⁶⁷
- Rib or metaphyseal fractures in young children⁶⁸⁻⁷⁰
- Multiple fractures or fractures of varying ages for which there is no plausible explanation
- Traumatic intra-abdominal injuries (e.g., pancreatic laceration, duodenal hematoma) without appropriate history
- Concerning patterns of burns⁷¹⁻⁷⁵:
 - Bilateral burns of lower extremities
 - Burns localized to the perineal area or buttocks
 - Burns that are circumferential, have a clear tide mark, or do not present with splash marks if they were reported as liquid thermal burns
 - Burns in the shape of an object such as a cigarette or iron
 - "Doughnut sign"—an area of spared skin around which is scalded skin as a result of a child being held down in hot water where the part in contact with the bottom of the tub does not burn
 - Suspicious burns associated with restraint injuries on the upper limbs
- Infant or young child who is less than the 5th percentile on growth chart for weight, height, or head circumference for whom there is no medical history explaining failure to thrive or for whom there is an identified medical cause that the parent(s) are not appropriately managing

*These findings strongly suggest abuse or neglect. This is not intended to be an all-inclusive list of indicators of abuse or neglect.

Table 119–5 Nonabuse/Non-neglect Causes of Findings Mistaken for Abuse/Neglect

Condition	Examples	Differentiation from Abuse/Neglect
Ethnic therapies	Coining Cupping	Characteristic diagonal bands of ecchymotic and/or petechial lesions in rows over the child's back measuring the approximate width of a coin. Characteristic uniformly sized, round, ecchymotic and/or petechial lesions over the child's back.
Mongolian spots		Well-demarcated, blue-grey to deep brown or black, irregularly shaped skin lesions most commonly seen in babies of Asian, East Indian, Latino, or African descent. There may be multiple spots on the child that are most commonly seen on the buttocks and back but may be seen on the ankles and wrists. They have a normal overlying skin texture. They appear at birth or shortly after birth and often resolve by puberty. These do not resolve as a bruise would be expected to.
Phytophotodermatitis	Common offending substances: • Meadow grass • Parsley • Parsnips • Celery • Carrots • Limes	Refers to a cutaneous inflammatory rash caused by contact of the skin with a light-sensitizing botanical substance followed by exposure to ultraviolet light. ⁷⁶ The rash begins as a delayed burning erythema 24–48 hr after exposure followed by frank blisters in 48–72 hr. Postinflammatory hyperpigmentation may last weeks to months. This reaction may be confused with a burn or injuries from being struck.
Increased susceptibility to fractures due to decreased bone mineralization	Rickets Premature or low birth weight infants (<1500 g) Osteogenesis imperfecta (OI) Hypophosphatemia Neuromuscular diseases Menkes' syndrome Osteoporosis	These children have a history consistent with a bone disease. Family history of bone disease should also be sought (OI). Menkes' syndrome is limited to boys and is associated with other problems, including poor tone, failure to thrive, and abnormal skin and hair. Bones of abnormal mineralization are identifiable on radiograph. Consultation with a pediatric radiologist is recommended when there is a concern for abuse and for abnormal bone mineralization.
Conditions with radiographic findings confused with abusive fractures ⁷⁷	Hypervitaminosis A Rickets Congenital syphilis Skeletal dysplasias Scurvy (vitamin C deficiency) Copper deficiency	Diffuse periosteal reaction associated with pain and swelling. Child may have anorexia, irritability, and itching. Hard and tender swellings may be palpable over the extremities. Cupping and fraying of the costochondral junctions and long bone metaphyses. Destructive lesions of the metaphyses from osteomyelitis associated with symptoms from multiple organ systems. May be associated with metaphyseal irregularities. Bones are otherwise not normal in appearance (shortened and dysplastic). Usually seen in children older than 6 mo who receive milk formulas without vitamin supplements. Metaphyseal fractures and large calcific cloaks may be seen along long bone shafts. Rare. Associated with neurologic symptoms, pallor, neutropenia, anemia, and hepatosplenomegaly. Metaphyseal cupping and spurring and occasionally rib fractures may be seen.
Decreased intestinal absorption of nutrients, leading to failure to thrive (FTT)	Gluten-sensitive enteropathy Food allergies Gastroesophageal reflux Cystic fibrosis Lactose intolerance Enteric pathogens Renal tubular acidosis Urinary tract infections	Medical causes of FTT are often accompanied by signs and symptoms beyond simply poor growth. Poor growth will be identified at a young age in the vast majority of children presenting for regular medical care. An evaluation for FTT by the child's pediatrician should be initiated at the time of the identification of FTT. Discussion with the child's pediatrician will provide information important to the full evaluation of FTT concerns in the emergency department.
Nonabusive causes of subdural hemorrhages	Birth trauma Ateriovenous malformations Glutaric aciduria type 1 Coagulation disorders	Subdural hemorrhages after birth trauma may be normal. These resolve by 3 wk of age and are not associated with neurologic signs/symptoms. ⁵³ Other nonabusive causes of subdural hemorrhages may be differentiated based upon history, examination, and diagnostic studies.
Nonabusive causes of retinal hemorrhages	Birth trauma Severe accidental head trauma Severe compressive chest trauma Coagulopathies Blood dyscrasias Meningitis Severe hypertension Vasculitis Thromboembolic phenomena Middle cerebral artery aneurysm	Retinal hemorrhages commonly occur after birth. These should be resolved by 4 wk of age. Other non-birth related causes of retinal hemorrhages have an associated history of severe trauma, illness, or laboratory findings suggestive of a blood dyscrasia.

Table 119–6 Diagnostic Evaluation of Suspected Physical Abuse or Neglect**Physical Abuse**

- **Skeletal survey:** Recommended by the American Academy of Pediatrics (AAP) for all children under 2 yr of age when there is a suspicion of physical abuse. Skeletal survey may be performed selectively in children between 2 and 5 yr of age.³¹ A 2-wk follow-up skeletal survey may be considered.³³
- **Bone scan:** Bone scan may be a useful adjunct to skeletal survey when specifically attempting to delineate posterior rib fractures or other nonmetaphyseal fractures. It should not be used alone in evaluation of the skeleton in cases of suspected physical abuse.⁷⁸
- **Retinal examination:** Recommended by the AAP in all children under 3 yr of age when there is a suspicion of physical abuse.³² This should be performed by an ophthalmologist.
- **Computed tomography (CT):** In one series, 37% of infants meeting high-risk criteria (rib fractures, multiple fractures, facial injury, or age < 6 mo) had an occult head injury.⁴⁶ Head CT should be strongly considered in infants meeting these high-risk criteria.
- **Magnetic resonance imaging (MRI):** Currently there are insufficient data to support routine use of MRI to identify abusive injuries. There is some evidence to support usefulness in differentiating abusive from accidental head injury.⁷⁹ There is no evidence to support routine MRI imaging of the cervical spine.⁸⁰
- **Biochemical markers:** Currently there are insufficient data to reliably use biochemical markers in evaluation for abusive head trauma in children. Future studies will likely lead to usable markers.⁸¹
- **Hight's burn criteria:** (1) burn attributed to sibling; (2) unrelated adult seeking medical attention; (3) differing historical accounts; (4) treatment delay > 24 hr; (5) history of prior accidental injuries; (6) inappropriate affect of the parent; (7) inappropriate affect of the child; (8) history incompatible with physical examination; (9) burn incompatible with developmental age; (10) mirror-image burns; (11) localized burns of perineum, genitalia, and/or buttocks; (12) burns older than history given; and (13) other injuries. In one series, 37% of children with 1 criterion and 67% with 2 criteria had abusive burns.⁴⁷

Neglect: Special Considerations for Evaluating Failure to Thrive (FTT)

- **Growth parameters:** Infants and young children in whom there is a concern for nutritional neglect should have their head circumference, length, and weight plotted on a growth chart. Data for other points on the growth chart, if available in the child's medical records or from the primary care physician, should also be included.
- **Documentation:** Documentation of previous FTT medical evaluations should be included. This information should be sought from the primary care physician and the child's medical records.
- **Preliminary ancillary testing for medical causes of FTT:** This may include complete blood count, electrolytes, lead, tuberculosis skin testing, and urinalysis and culture.²² Additional testing is often beyond the scope of the emergency department visit. An admission to the hospital for a complete FTT evaluation and nutritional supplementation is warranted in severe cases.
- **Documentation of feeding issues:** Include information about what the child is fed, how much, how often, and by whom. Specifically ascertain the caregiver's perceptions of how feeding is going: Is the child a finicky eater? Does the caregiver often become frustrated with feeding time? Does the caregiver actively engage the child in feeding or is the child left with a plate of food and expect to feed him- or herself? Is there a feeding schedule?

Identification of abusive head injuries in infants can be very difficult. Significant numbers of infants are misdiagnosed because of a lack of history of trauma, vague or no neurologic symptoms, and no external evidence of trauma.^{4,45,46} In one series, 37% of children under 2 years of age who met one of four “high risk” criteria, were admitted because of injuries suspicious for abuse, and underwent computed tomography (CT) of the head had an occult head injury.⁴⁶ “High risk” criteria included rib fractures, multiple fractures, facial injury, or age less than 6 months. Use of skeletal survey or retinal examination as a screening tool to identify the head-injured infants in this series was not effective. In another series of 38 children under 2 years old who were suspected of having been abused, 29% had traumatic intracranial injury without associated neurologic signs.⁴⁵ While there are no formal guidelines for when to perform a head CT in suspected abuse, the study should be performed any time there is suspicion of head injury, even if low, especially for children under 2 years of age.

Intentionally inflicted burns are more likely to be fatal than accidental burns.²⁸ Hight's burn criteria, a set of 13 factors based upon epidemiologic burn data, were determined to have a positive predictive value of 40% when any one criterion was present and 62% when any two criteria were present (see Table 119–6).^{45,46} Consideration should be given to these criteria when evaluating children for burn injuries. One study demonstrated that inclusion of a checklist of Hight's criteria on an ED record increased reporting of suspicious burns to CPS from 3% to 12%.³⁰

Management

Immediate Interventions

Evaluation and stabilization of the airway, breathing, and circulation occurs first. As soon as the patient is stable, a thorough examination should be completed because some cutaneous findings may progress or even disappear during the course of the child's stay in the ED. A focused, but detailed history as described in Table 119–1 must be done during the initial stages of evaluation. This will allow for follow-through by other members of the health care team as well as CPS and other investigative personnel, if they become involved.

Secondary Therapeutic Interventions

Once the child is medically stabilized, the situation should be evaluated on several levels. First, the clinician must make sure enough information has been gathered to form an opinion about the safety of the child as well as any other potentially vulnerable children. Second, appropriate medical, psychiatric, and social service referrals should be considered. Finally, a determination should be made as to whether a report should be filed with CPS. Types of responses by CPS will vary. Clinicians should be familiar with state statutes regarding the identification and reporting of child abuse.

Therapeutic Complications

One of the most dreaded consequences of considering child abuse in the differential diagnosis is addressing concerns with parents. The clinician should always consider that a

family may become violent. The circumstances of this conversation with the family should be tailored to keep one's own personal safety and the safety of the staff in mind. It is preferable that discussions about concerns of abuse be conducted in a private, quiet environment. The clinician should be familiar with his or her rights as a physician over the legal guardian of a child in his or her care. A legal representative of the hospital may be consulted if necessary. Clinicians should become familiar with laws and hospital policies before there is an emergent issue.

There are some situations in which complete evaluation of a potentially abused child is not possible because of limitations in local resources. If specialized services, such as pediatric surgery, pediatric ophthalmology, or pediatric radiology, are required and not available, the child should be transferred to a hospital that does provide these pediatric-specific services. Transferring a child does not relieve the emergency physician of the responsibility of filing a report with CPS. Personnel at the accepting facility often are unable to obtain detailed information about what happened at the originating institution and information about the child's first presentation.

Documentation

Accurate, detailed documentation is paramount. Photographic documentation is especially helpful in circumstances in which cutaneous findings may be transiently visible, or may change over time. For example, if a child presents with an erythematous mark that resembles a handprint, it would be helpful to photograph the handprint because these types of injuries often fade over a few hours and may completely resolve before CPS or other investigators have an opportunity to examine and confirm the finding. The procedure for photographic documentation of this type varies between states and institutions. An overall algorithm for the approach to suspected child abuse and neglect is provided in Figure 119-1.

Summary

Prognosis

Abused children are more likely to suffer immediate and long-term medical and psychological consequences of greater severity than accidentally injured children. Abused children are also likely to be reabused if returned to the care of abusive caregivers. The key to protection of this vulnerable population is abuse prevention and prompt abuse and neglect recognition. Emergency physicians carry a large part of the burden of ensuring that abused children are placed in safe environments.

Disposition and Follow-up

Most children for whom the emergency physician has a concern of abuse or neglect may be safely sent home with a caregiver if the alleged perpetrator can be reliably kept away from the child, a safety plan can be established, and a report to CPS has been made. If there is concern that the child may return to an unsafe environment, an immediate response by CPS may be necessary to evaluate the home situation, or to establish temporary CPS custody in more severe cases. If there is concern about the immediate safety of the child and no mechanism by which CPS can respond to perform an

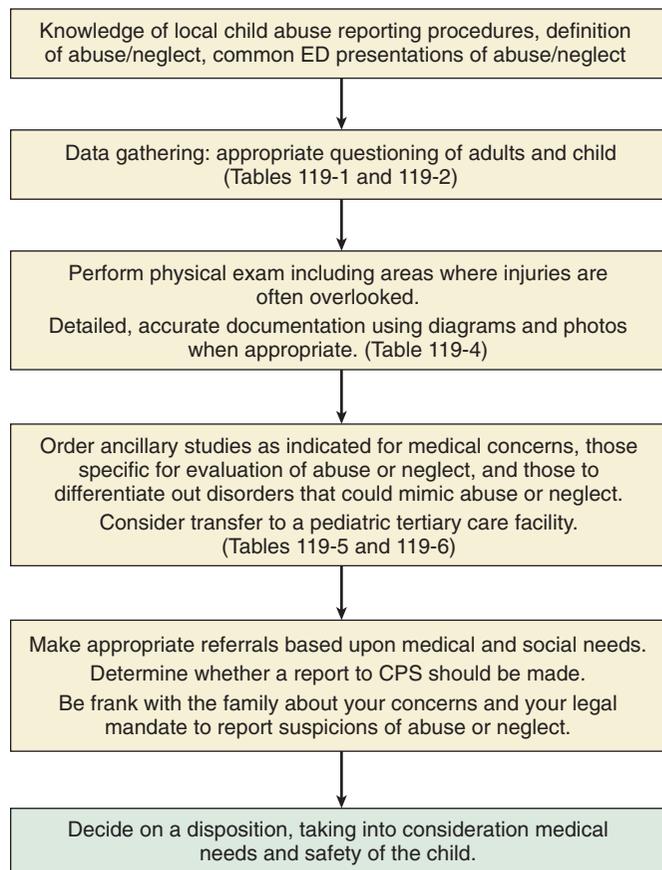

FIGURE 119-1. Algorithm for the emergency department (ED) evaluation and management of suspected child physical abuse or neglect. Abbreviation: CPS, child protective services.

immediate safety evaluation of the child's home situation, then the child should be admitted to the hospital. Admission is also indicated for medical or psychiatric care.

The emergency physician should communicate with the child's primary care physician to provide more reliable follow-up for the family. An initial determination of the family's psychosocial needs should be made in conjunction with a hospital social worker, if available. Appropriate medical follow-up should be discussed with the child's parents and CPS.

Future Directions

As CPS continues to strive to meet the prevention and investigation initiatives set forth to them by CAPTA, the medical community must continue to accumulate information that will allow for more timely and accurate identification of abused and neglected children. Studies of the epidemiology and biomechanisms of childhood injury, the use of radiographic studies, new biochemical markers for differentiating abusive and nonabusive head injuries, child abuse prevention measures, and improved physician education, among other topics, are being actively pursued.

Skin and Soft Tissue Infections

Michael J. Muszynski, MD

Key Points

Unusual pathogens may occur when skin infections are associated with human or animal bites, contaminated wounds, puncture wounds, or compromised hosts.

Resistant pathogens such as methicillin-resistant *Staphylococcus aureus* have become commonplace in skin and soft tissue infections in the community at large, leading to the need for more aggressive diagnostic approaches such as needle aspiration for culture.

In cases of moderate to severe disease or in cases demonstrating rapid clinical progression, accurate empirical therapy can be life saving.

The initial presentation of necrotizing fasciitis may be nondescript, suggesting more common and less serious conditions, such as cellulitis or benign muscular pain; unfortunately this may delay recognition and result in high mortality rates.

Selected Diagnoses

- Cellulitis
- Wound infections
- Necrotizing fasciitis
- Atopic dermatitis with bacterial superinfection
- Eczema herpeticum
- Folliculitis
- Furuncles and carbuncles
- Hidradenitis suppurativa
- Lymphangitis

Discussion of Individual Diagnoses

Cellulitis

Cellulitis is a suppurative, inflammatory process of connective tissue within the subcutaneous space that has a varying degree of dermal involvement, and is most often infectious. The epidermis is generally spared. The process most commonly begins at the point of a wound or breach of the integu-

ment, such as folliculitis or a furuncle. However, the portal of entry might not be obvious in some cases. Other mechanisms include extension from a deeper infectious focus, such as the teeth and paranasal sinuses, or from hematogenous seeding associated with systemic infection due to *Streptococcus pneumoniae*, *Streptococcus pyogenes* (group A streptococcus), *Staphylococcus aureus*, or *Haemophilus influenzae* type b. The latter is now rare due to the effectiveness of the *H. influenzae* type b conjugate vaccine.¹ The classic violaceous hue of *H. influenzae* type b cellulitis is rapidly approaching historical interest only. Hematogenously derived facial and periorbital cellulitis due to *S. pneumoniae* may clinically mimic that seen with *H. influenzae*. Other areas of the body may be involved as well, especially in patients with collagen vascular disorders or immune deficiency.²

Clinical Presentation

Cellulitis is clinically recognized as an area of erythema, edema, warmth, and tenderness with a gradual, tapered edge, distinguishing it from the abrupt, well-demarcated edge of erysipelas, which is an inflammatory condition of the epidermis. Cellulitis severity ranges from mild and limited to severe and extensive, and onset and progression can be slow or rapid. Presentation depends on multiple factors, which may be used as important predictors of severity (Table 120–1).

Wound cultures are strongly recommended, especially if methicillin-resistant *S. aureus* (MRSA) or unusual pathogens are suspected. Unusual pathogens may occur when skin infections are associated with human or animal bites, contaminated wounds, puncture wounds, or compromised hosts. Needle aspiration of the cellulitis site can be informative but is often not performed due to reported low yield of 5% to 36%.^{3–5} Microbiologic yield does increase with disease severity. One study showed that aspiration identified bacterial etiologies in 4 of 7 patients with cellulitis and abscess (57%) compared to 9 of 56 patients with uncomplicated cellulitis (16%), and in 11 of 15 patients with necrotizing infections (73%).⁶ Nonetheless, resistant pathogens such as MRSA have become commonplace in skin and soft tissue infections in the community at large,⁷ leading to the need for more aggressive diagnostic approaches such as needle aspiration for culture. This is especially true in cases of moderate to severe disease or cases demonstrating rapid clinical progression, in which accurate empirical therapy can be life saving.

The needle aspiration procedure starts with cleansing the site with povidone-iodine solution and allowing the solution

Table 120–1 Factors Associated with Increased Severity of Soft Tissue Infections**Host**

Young age (neonates, infants)
 Immunocompromised states (congenital and acquired immune deficiency, asplenia, cancer, diabetes, renal disease, collagen vascular disease, burns)

 Toxin-producing strains (group A streptococcus, *Staphylococcus aureus*)
Haemophilus influenzae type b
Vibrio species
 Anaerobes

to dry. Locally injected anesthesia is generally avoided, since these agents have in vitro antibacterial activity; however, topical anesthesia is often employed. The area is aspirated using a 22-gauge needle for sites on the face and a 20-gauge needle elsewhere. The needle is attached to a 1- to 3-ml syringe with 0.5 ml of sterile, nonbacteriostatic saline. The saline is used to expel aspirated material from the needle and syringe hub onto plate media or a suitable transport vessel. Some authorities recommend aspirating the “leading edge” of the cellulitis, but a comparative study has shown that aspirating the point of maximal inflammation is superior in yield of the pathogen (45% versus 5% from the leading edge).⁸ Blood cultures are recommended in seriously ill patients and anytime bacteremia is suspected.⁹

Management

The management of cellulitis is based on an assessment of risk factors, disease severity, and potential etiologies. As with other significant skin and soft tissue infections, patients should be risk-stratified for serious illness with consideration of hospitalization and intravenous therapy. Many cases of cellulitis are minor and will respond to local measures and oral antimicrobial therapy. Table 120–2 outlines a general management scheme for cellulitis, skin, and soft tissue infections. Empirical antibiotic choice depends on suspected pathogens, clinical presentation, patient age, and historical clues. Historically, antimicrobials active against *S. aureus*, group A streptococcus (e.g., first-generation cephalosporin [cephalexin], amoxicillin/clavulanate, or clindamycin) have been prescribed for uncomplicated and minor wound-associated infections. Dicloxacillin has also been used, but is difficult to prescribe as the suspension because of concentration and palatability issues. Mild infections due to MRSA may respond to antistaphylococcal agents demonstrating

Table 120–2 Management Scheme for Skin and Soft Tissue Infections**Assess Need for Incision and Drainage****Obtain Culture Specimens**

Wound
 Material from incision and drainage
 Consider needle aspiration of cellulitis
 Blood
 If sepsis or bacteremia suspected

Assess Local MRSA Rate and Clindamycin Resistance Prevalence**Define Disease Severity**

Mild (afebrile, healthy child with minor clinical findings)
 Incision and drainage alone for abscesses if cellulitis < 5 cm
 Incision and drainage plus antimicrobial therapy if cellulitis > 5 cm
 Cephalexin or amoxicillin/clavulanate
 If MRSA suspected, oral clindamycin (when community resistance rate < 10%) or trimethoprim-sulfamethoxazole, or doxycycline (if > 8 years of age)

Ensure follow-up

Moderate (febrile, healthy child or more extensive involvement)
 Incision and drainage plus antimicrobial therapy as for mild disease; ensure follow-up

Incision and drainage, hospitalization, parenteral antimicrobial therapy if extensive cellulitis or poor adherence to therapy or follow-up suspected

Severe (toxicity, immune compromised, limb-threatening process, rapid progression, periorbital/facial, neonate)

Incision and drainage as needed, hospitalize for parenteral antimicrobial therapy

Clindamycin if community clindamycin resistance rate < 10%, vancomycin if > 10%

Add third-generation cephalosporin if periorbital/facial cellulitis or neonate

Critical (sepsis, shock, toxic shock syndrome)

Resuscitate, incision and drainage if focus of infection found, ICU admission, parenteral antimicrobial therapy

Vancomycin plus nafcillin plus gentamicin regardless of local resistance rate data

Abbreviations: ICU, intensive care unit; MRSA, methicillin-resistant *Staphylococcus aureus*.

poor in vitro MRSA activity. MRSA demonstrates a heterogeneity of susceptibility in infected sites. A subpopulation of bacteria at the site can be susceptible to an agent while the remainder of the bacterial inoculum is not. Thus, in mild infections, the antibiotic employed may simply decrease the total bacterial inoculum to the point at which immune responses can effect a cure.

Patients with simple abscesses and no surrounding cellulitis do not require antibiotics. Those who have cellulitis and an associated abscess require incision and drainage (see Chapter 166, Incision and Drainage and Supplemental Antibiotics).

Severely ill patients and moderately ill patients with extensive areas of involvement have always required intravenous antibiotic therapy. In these cases an antibiotic with activity against streptococci and *S. aureus*, including MRSA, is preferred. Seriously ill patients who may be infected with *S. aureus* should be empirically treated for MRSA with intravenous clindamycin,¹⁰ provided that there are no risks for hospital-acquired MRSA (HA-MRSA) and local clindamycin resistance rates for community-associated MRSA (CA-MRSA) strains are less than 10%. Clinicians may obtain antibiotic susceptibility information for their community from local hospital infection control programs, local hospital laboratory antibiogram reports, local and state health departments, and

the Centers for Disease Control and Prevention (<http://www.cdc.gov>). Local laboratories and clinicians must be aware that clindamycin resistance will be underestimated if the laboratory does not employ the “D test” for susceptibility testing. MRSA strains that are resistant to erythromycin and apparently sensitive to clindamycin by routine susceptibility assays may exhibit inducible resistance to clindamycin *in vivo*. Thus, when clindamycin is prescribed in these cases, resistance will emerge during therapy, which may lead to treatment failure. The D test utilizes an erythromycin disk placed 15 mm from a clindamycin disk on the susceptibility test agar plate. MRSA that exhibits inducible clindamycin resistance will show a zone of bacterial growth inhibition around the clindamycin disk affected by the presence of erythromycin that forms the shape of a “D” rather than the expected circle, hence the name “D test.” Strains that form a circular shape of inhibition at a prescribed diameter are clindamycin sensitive without inducible resistance. Clindamycin therapy can be expected to be efficacious for infections due to these strains. Seriously ill patients infected with MRSA strains demonstrating any type of clindamycin resistance must be treated intravenously with an alternative agent such as vancomycin. This also includes all HA-MRSA cases and those with clindamycin resistant or inducible-resistant CA-MRSA. Antibiotic therapy choices for moderately ill patients and patients with potentially serious infections require coverage for CA-MRSA or HA-MRSA to avoid risk of mortality and serious morbidities. Serious infectious complications (shock, disseminated intravascular coagulation [DIC]), additional metastatic sites of infection, and death have been reported with delays in instituting an antibiotic effective against MRSA.¹¹

CA-MRSA infection differs from HA-MRSA in that CA-MRSA is not associated with classic HA-MRSA risk factors (hospitalization, contact with a health care worker, dialysis, history of intensive care admission, recent surgery, long-term care facility residence).¹² CA-MRSA is also more likely than HA-MRSA to cause skin and soft tissue infections. CA-MRSA patients are more likely to have household members with similar infectious problems, such as recurrent boils and soft tissue infections. Infections due to CA-MRSA require surgical intervention more commonly than infections due to methicillin-sensitive *S. aureus* (MSSA). CA-MRSA is inherently resistant to antistaphylococcal β -lactams, cephalosporins, erythromycin, and quinolones. It is sensitive to vancomycin and linezolid and generally sensitive to clindamycin, trimethoprim-sulfamethoxazole, tetracyclines, and gentamicin. HA-MRSA is resistant to most antimicrobials except vancomycin and linezolid. Critically ill children with suspected *S. aureus* infection require the triple combination of vancomycin, nafcillin, and gentamicin.

Linezolid is an oxazolidinone with excellent activity against MRSA and MSSA, *S. pneumoniae* (penicillin/cephalosporin-sensitive and -resistant strains), group A streptococcus, and enterocci (including vancomycin-resistant strains). Linezolid has no gram-negative antibacterial activity. It has been shown to be safe and effective for uncomplicated skin and soft tissue infections in children.¹³ It may become an attractive choice for the treatment of skin and soft tissue infections, since it is effective against both CA-MRSA and HA-MRSA by both intravenous and oral routes. Linezolid is costly, and experience with this drug as a first-line agent in children is somewhat limited, which leads some

experts to discourage routine use, instead using an infectious disease expert for guidance for its application.¹⁴

Other Forms of Childhood Cellulitis

Several other forms of childhood cellulitis deserve specific mention. Periorbital cellulitis, buccal cellulitis, and cellulitis without an obvious wound precipitant generally require treatment with a parenteral third-generation cephalosporin plus clindamycin. Panniculitis of the cheek due to freeze injury, as can occur with popsicle eating in young children, mimics infectious buccal cellulitis.¹⁵ Cellulitis of the face and neck of suspected odontogenic origin (e.g., tooth abscess) should be treated with antimicrobials effective against mouth anaerobes.¹⁶ Oral amoxicillin/clavulanate or parenteral ampicillin/sulbactam are excellent choices. Penicillin-allergic patients may be treated with clindamycin either parenterally or orally as the situation requires.

ERYSIPELAS

Erysipelas is a superficial infection commonly involving the face or legs in children, although any area of the body can be affected. The involved skin has an orange peel appearance and is intensely red, warm, and very painful. The lesion displays significant edema with sharply defined and raised borders. Rapid spread is the rule, and blistering of the lesion can occur. Patients are commonly febrile and ill appearing. When positive, culture of aspiration of the lesion yields group A streptococcus. Patients tend to respond quickly to antibiotic therapy, but erysipelas must be respected as a potentially serious condition, especially in patients with immunodeficiency or malignancies such as lymphoma. The condition is especially worrisome in neonates and may be also due to group B streptococcus. Treatment with penicillin plus clindamycin is recommended for the most serious group A streptococcal infections and appears to be associated with a better clinical outcome than that seen with monotherapy.¹⁷ Clindamycin inhibits bacterial protein synthesis and suppresses production of bacterial virulence factors, overcoming the deleterious effect of a large bacterial inoculum. It possesses a longer postantibiotic effect than penicillin (continued antibacterial effect after the antibiotic concentration falls below inhibitory levels in tissue). However, clindamycin cannot be used alone in serious group A streptococcal infections, since 1% to 2% of strains are resistant. Penicillin or cephalosporin resistance in group A streptococcus has not been described.

PERIANAL CELLULITIS

Perianal cellulitis or perianal dermatitis presents with rectal pain with sitting or defecation and is characterized by intense edema and erythema of perirectal tissues. The borders of inflammation are sharply demarcated, reminiscent of erysipelas, in an otherwise well-appearing child. Rectal swab cultures nearly always yield group A streptococcus.¹⁸ There may be concomitant balanitis or vulvovaginitis.¹⁹ Oral penicillin and cephalosporins are effective for perianal infection with or without genital involvement. Topical agents such as mupirocin and erythromycin ointment have also been used.²⁰ Relapses often require treatment with clindamycin or a combination of penicillin plus rifampin, or consideration of *S. aureus* as the cause (including MRSA).²¹ Ongoing recurrences require inquiry for potential household or day care contacts with the same condition.^{19, 22}

CELLULITIS OF THE EXTERNAL EAR

Cellulitis of the external ear may result from trauma, infected atopic dermatitis, or ear piercing. Infections of the earlobe tend to be relatively minor and are generally due to *S. aureus*, and respond to local measures of cleansing and warm compresses and oral antistaphylococcal antibiotics. More serious infections that involve the upper ear and its cartilage are associated with high risk for cosmetic deformation. Infections from ear cartilage piercing are most often due to *Pseudomonas aeruginosa*.²³ Wound culture is important to guide therapy. Empirical intravenous antibiotic coverage for *P. aeruginosa*, *S. aureus*, and group A streptococcus is often recommended to lessen the chance of a poor cosmetic result. Cefepime, piperacillin/tazobactam, or ceftazidime are good choices, but ceftazidime is a less potent gram-positive agent. Severe lesions or lesions failing to respond to initial therapy require consideration of MRSA as outlined for other forms of cellulitis.

BLISTERING DISTAL DACTYLITIS

Blistering distal dactylitis is a localized infection of the distal volar fat pad of the digits. Fingers are affected more commonly than toes. Most cases present in children 2 to 16 years of age. The condition has also been described in infants less than 9 months of age.²⁴ Patients develop superficial, tender bulla on the fat pad of the digit up to 2 cm in size. The process occasionally extends further up the fingers to involve the palms.²⁵ The primary etiology is group A streptococcus, which can be isolated from culture of the blisters. *S. aureus* has also been described, and may be more common with blisters on multiple digits or with more extensive disease.²⁵ Blistering distal dactylitis must be differentiated from herpetic whitlow, as the two conditions may have a similar appearance but differ greatly in management. Dactylitis is treated with antibiotics active against group A streptococcus and *S. aureus* (amoxicillin/clavulanate, a first-generation cephalosporin, or a macrolide), plus drainage of the blisters. Draining a herpetic whitlow is hazardous and will spread herpes simplex virus (HSV) found in the blisters more widely into surrounding tissue. The two conditions can be distinguished by the appearance of gram-positive cocci on Gram stain in blistering dactylitis and the presence of HSV by direct immunofluorescent antibody staining of cells from the base of a vesicle or blister in herpetic whitlow.²⁶ Although frequently recommended, the Tzanck smear is inferior when compared to direct fluorescent assays because of an unacceptable low sensitivity. A negative Tzanck preparation cannot definitively rule out herpes simplex infection.

Wound Infections

Wound care involving special circumstances, such as snake and spider envenomations, are described elsewhere in this text (see Chapter 141, Bites and Stings). Mammalian bite wounds sustained from unusual domesticated and wild animals are associated with particular organisms (see Table 120–5). Consider consulting an infectious disease specialist for management recommendations if such a situation is encountered. The same wound management principles discussed in this chapter and in Chapter 160 (Wound Management) apply to the management of wounds sustained from wild or domesticated animals and humans. Both common

and unusual organisms may be present in infected bite wounds, and polymicrobial infections are the rule rather than the exception. Prophylactic treatment strategies depend on the type of bite sustained (see Table 120–6).

Classic water-contaminated wound pathogens include *Aeromonas* species, *P. aeruginosa*, a host of gram-negative enteric bacteria, and *Mycobacterium marinum*. The latter is also associated with skin injuries associated with maintaining home and commercial aquaria. *Chromobacterium violaceum* infections are related to stagnant, freshwater wounds mainly in the southeastern United States.²⁷ Marine water harbors the same list of potential pathogens as fresh water with the important addition of *Vibrio* species. Infected soil-contaminated wounds are characterized by a large number of etiologic possibilities and are often polymicrobial in nature. They present special challenges in the choice of empirical antimicrobial therapy. At the minimum, broad-spectrum coverage for organisms such as *S. aureus* and group A streptococcus, a variety of gram-negative enteric bacteria (especially *Enterobacter* species), enterococci, and anaerobes should be provided. If the contaminating soil was wet or mixed with vegetable matter, then *P. aeruginosa* and *Aeromonas hydrophila* must be kept in mind.²⁸ Soil also harbors *Nocardia*, *Actinomyces*, nontuberculous mycobacteria (especially *Mycobacterium fortuitum* complex), and a variety of fungi (*Aspergillus*, *Zygomycetes*, *Fusarium*, *Acremonium*, *Bipolaris*). Wound cultures must be obtained before starting therapy and must employ specific media for the isolation of aerobic, anaerobic, mycobacterial, and fungal organisms. Empirical therapy for serious infections may include the broad-spectrum choices of imipenem (or meropenem), piperacillin/tazobactam, or clindamycin plus cefepime or ceftazidime. Each of these regimens covers the common anaerobic and aerobic bacteria, including *Pseudomonas* and *Aeromonas*. Therapy is based on the initial culture results as they become available. Simple wound infections with soil contamination can be managed with wound cleansing and oral antimicrobial therapy such as amoxicillin/clavulanate or a cephalosporin. Careful follow-up should be arranged for all cases. All patients should be evaluated for tetanus immunity and vaccinated if indicated.

Puncture wounds, particularly of the foot, are common emergency department presentations. These injuries are prone to infection due to the innate characteristics of the wound, specifically deep penetration, injury to underlying structures (fascia, vessels, muscle, tendons, cartilage, bones and joints), possible retained foreign body, and a small entrance with little chance of spontaneous drainage. The clinical presentation is the same as for any cellulitis with additional findings when other structures are affected (e.g., fasciitis, septic arthritis, osteomyelitis, deep abscesses, pyomyositis). The infecting agents are related to skin flora (staphylococci and streptococci) and contaminating material. Infected punctures of the foot through shoes, especially rubber-soled (e.g., tennis) shoes, are most likely due to *P. aeruginosa* and *S. aureus*. Rapid progression of infection is highly suggestive of a common bacterial etiology, whereas a subacute or delayed presentation raises suspicion for unusual pathogens such as nontuberculous mycobacteria, *Nocardia*, *Actinomyces*, and some fungi. Infectious disease consultation is helpful in these cases. As with all wound infections, cultures should be attempted before antibiotics are administered. Sonography is

a sensitive and specific modality for evaluation for retained foreign bodies, especially wood.²⁹ Computed tomography (CT) and magnetic resonance imaging can provide additional information concerning extent of infection or purulent collections. Surgical or orthopedic consultation is commonly needed in these conditions to explore for foreign bodies, drain abscesses, and débride affected tissues. Pseudomonas infections due to puncture wounds of the foot require surgical intervention as the primary therapeutic approach, since cartilage and bone involvement is common. Aggressive surgical débridement of all infected material, including bone, combined with parenteral antipseudomonal therapy of just 7 days' duration, results in excellent clinical outcome.³⁰ The same is not true for other organisms, such as *S. aureus*. *P. aeruginosa* is a true opportunistic pathogen that can be effectively treated with short courses of antibiotics if the predisposing factor or infected nidus is removed.

Necrotizing Fasciitis

Necrotizing fasciitis is a rapidly spreading, fulminant infection in the subcutaneous space that involves the superficial fascia. The process initially spares adjacent muscle and overlying skin. Associated thrombosis of subcutaneous vasculature eventually leads to cutaneous gangrene and rapid destruction of deeper tissues. Missed diagnosis in the early phase can have disastrous consequences. This relatively rare but fearsome condition carries a mortality rate of about 25% even with application of modern therapeutic measures. Timely diagnosis followed by prompt surgical débridement and antibiotic therapy are required to save life and salvage limb.

Clinical Presentation

The initial presentation of necrotizing fasciitis may be nondescript, suggesting more common and less serious conditions such as cellulitis or benign muscular pain. Unfortunately this may delay recognition. One study of 39 pediatric cases found that 28% were missed at initial evaluation.³¹ The most difficult challenge is to distinguish necrotizing fasciitis from benign inflammatory conditions during the early phase. Clues may come from the presence of underlying medical conditions or risk factors, suspected pathogenesis, and historical and clinical findings. Diabetes and peripheral vascular disease are common associations in adult patients, whereas typical predisposing conditions in children are malnutrition, neoplasia (especially leukemia), recent surgery (especially procedures in the inguinal region), omphalitis in infants, breast abscess in infants, and balanitis associated with circumcision. An association with *Vibrio* species has been reported in pediatric patients with iron overload.³² Fasciitis has also been described after major trauma, soft tissue foreign bodies, minor injuries, and even insect bites. Fasciitis in the neck has been associated with lymphadenitis, dental infection, or tonsillopharyngitis. Some cases of necrotizing fasciitis have no predisposing factor. Of all associated conditions, chickenpox is the most important in childhood.³³ Varicella greatly increases the overall risk for invasive group A streptococcal disease, which is a major etiology of necrotizing fasciitis in children. In a large surveillance study, necrotizing fasciitis occurred in 4% of invasive group A streptococcus cases.³⁴ The varicella vaccine shows great promise in the prevention of the serious bacterial complications of chickenpox.

Use of nonsteroidal anti-inflammatory drugs (NSAIDs) has been suspected to increase the risk of developing necrotizing fasciitis with invasive group A streptococcal disease. Prospective studies have not borne this out; however, NSAIDs may increase risk of poor outcome in fasciitis by reducing pain and causing delay in seeking medical care. NSAID use is associated with the increased likelihood of renal failure as part of the systemic presentation of necrotizing fasciitis.³⁵

Clinical manifestations of necrotizing fasciitis begin with pain followed by induration, edema, and erythema within 24 to 48 hours. In a report of 15 patients in whom group A streptococcal necrotizing fasciitis was missed at initial evaluation, unremitting pain out of proportion to physical findings was not appreciated.³⁶ Pain commonly extends beyond the area of suspected inflammation. Signs of necrosis such as purple skin coloration, ecchymosis, and blisters are seen much later. Presence of paresthesia or anesthesia is an ominous sign of severe underlying necrosis. Tissue crepitance is an infrequent but specific indicator of necrotizing fasciitis. Toxic appearance, generalized erythematous rash, and low platelet count or other findings suggestive of toxic shock are independent predictors of necrotizing fasciitis.³⁷ A scoring system termed the "Laboratory Risk Indicator for Necrotizing Fasciitis" was recently proposed as a tool to distinguish necrotizing fasciitis from other forms of cellulitis.³⁸ The scoring system uses total white cell count ($>15,000/\text{mm}^3$), hemoglobin (<11 to 13.5 g/dl), sodium (<135 mmol/L), glucose (<10 mmol/L), serum creatinine (>141 $\mu\text{mol/L}$), and C-reactive protein (>150 mg/L) as risk factors but awaits further validation, and it has not been applied to children. Ultrasound as a diagnostic tool for suspected necrotizing fasciitis has a sensitivity of 88%, a specificity of 93%, a positive predictive value of 83%, and a negative predictive value of 95%.³⁹ CT scan may also suggest the diagnosis, especially if air is seen in the tissues.⁴⁰ Contrast-enhanced magnetic resonance imaging has been shown to differentiate fasciitis from cellulitis and is helpful in evaluating deep structures and fascial layers,⁴¹ but requires more to complete. Imaging should not be allowed to delay definitive surgical management of patients suspected to have necrotizing fasciitis. Tissue biopsy is the most accurate diagnostic method. Frozen surgical sections allow rapid decision making for proceeding with further exploration and aggressive débridement.⁴²

Management

Prompt surgical intervention is paramount. In a report of 20 pediatric cases, all survivors had aggressive surgical débridement within 3 hours of admission. Delay in surgical management occurred in the five patients who died.⁴³ In another study of 29 patients, aggressive surgical approaches instituted within 24 hours of admission decreased the mortality rate from 25% to 6%.⁴⁴ Aerobic and anaerobic cultures of blood, wounds, and needle aspiration of compartments should be obtained when fasciitis is suspected and before starting antibiotic therapy. Gram stain should guide antibiotic choice when possible. Repeat cultures of the site are obtained at surgery. Fluid resuscitation with or without vasopressors, correction of electrolyte imbalances and hypoglycemia, and treatment of coagulopathy are often required for very ill patients. Polymicrobial infections are common, necessitating broad-spectrum antibiotic coverage including anaerobic bacteria. If *S. aureus* is suspected, vancomycin should be added. Antimicrobial choices are similar to those for serious

Table 120–3 Etiologic Considerations in Wound Infections

Associated Clinical Condition	Common Pathogens
Varicella	GABHS, MSSA, MRSA
Cervical adenitis	GABHS, MSSA, MRSA
Neck space infection	GABHS, MSSA, MRSA, anaerobes
Tonsillopharyngitis	GABHS, MSSA, MRSA
Jugular thrombosis	<i>Fusobacterium necrophorum</i>
Surgical wounds	
Uncomplicated	GABHS, MSSA, MRSA
Abdominal, inguinal, perineal, circumcision	GABHS, MSSA, MRSA, enteric gram-negative bacilli (esp. <i>Proteus</i> spp.), anaerobes
Omphalitis, breast abscess	MSSA, MRSA, group B streptococcus, GABHS, enteric gram-negative bacilli (esp. <i>Escherichia coli</i>), anaerobes
Traumatic wounds	GABHS, MSSA, MRSA
Aquatic	MSSA, MRSA, streptococci, <i>Pseudomonas aeruginosa</i> , <i>Aeromonas</i> spp., <i>Vibrio</i> spp. (salt water), <i>Chromobacterium violaceum</i> (stagnant freshwater)
Soil and wood	MSSA, MRSA, streptococci, gram-negative bacilli (esp. <i>Enterobacter</i> spp., <i>P. aeruginosa</i>), fungi (esp. Zygomycetes, <i>Acremonium</i> , <i>Fusarium</i>)
Neutropenia	Clostridia, gram-negative bacilli (esp. <i>P. aeruginosa</i>), GABHS, MSSA, MRSA
Neutrophil oxidative disorders	MSSA, MRSA, <i>Serratia</i> spp., <i>C. violaceum</i> , <i>Pseudomonas</i> spp.
Iron overload syndromes	<i>Vibrio</i> spp.
Vasculitis	<i>Streptococcus pneumoniae</i> , <i>Serratia</i> spp., GABHS, MSSA, MRSA
Injection drug use	Bacillus spp., <i>P. aeruginosa</i>

Abbreviations: GABHS, group A β -hemolytic streptococcus; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *Staphylococcus aureus*.

or complicated cellulitis and are directed at potential causes related to the clinical situation (Table 120–3). When group A streptococcus is suspected, the combination of clindamycin and a β -lactam is optimal.¹⁷ Early administration of intravenous immune globulin (0.5 to 1 g/kg) is recommended by some authorities, especially if there are signs of toxic shock due to group A streptococcus or *S. aureus*.⁴⁵

Atopic Dermatitis with Bacterial Superinfection

Infectious complications of atopic dermatitis are common and present as bullous lesions, pustular lesions, increased erythema and discomfort, and increased oozing and crusting, as well as skin erosions and ulcerations. It is important to differentiate between possible bacterial and herpesvirus etiologies, since therapeutic misadventures can have significant consequences.

S. aureus and group A streptococcus are the most important bacterial causes of atopic dermatitis superinfection. Over 90% of individuals with atopic dermatitis are colonized with *S. aureus*. Increased colonization is known to correlate with increased disease severity, thus antistaphylococcal topical and oral antibiotic therapies are widely prescribed. As with other skin and soft tissue infections, CA-MRSA has become a major problem. Atopic dermatitis has clearly been identified as a risk factor for CA-MRSA infection.⁴⁶ Therefore, bacterial cultures are important to effective management. MSSA may be treated with topical mupirocin or oral antibiotics; cephalosporins and dicloxacillin are popular choices, but dicloxacillin suspension is especially unpalatable. Mupirocin cream and oral cephalexin have been shown to be equally effective; mupirocin is superior in reducing bacterial inoculum on the skin.⁴⁷ Cephalosporins may be used in patients with non-type I penicillin allergy, and clindamycin for patients with type I allergy. Trimethoprim-sulfamethoxazole should be used only in patients in whom *S. aureus* is the sole pathogen, due to lack of efficacy in group A streptococcus infections. Treatment and control of super-

infection also includes optimizing the treatment of atopic dermatitis using skin hydration and topical steroids. Nasal mupirocin therapy twice a day in each naris for 5 days is recommended by some authorities to reduce *S. aureus* carriage.

Disseminated viral infection is the other concern in atopic dermatitis superinfection. Molluscum contagiosum is a benign, self-limited skin condition in most children characterized by a few skin lesions. Patients with atopic dermatitis are more likely to exhibit widespread skin involvement with hundreds of lesions.⁴⁸ The latter has been termed *eczema molluscatum* and presents as a heavy concentration of 2- to 3-mm umbilicated, skin-colored papules in areas of affected skin with occasional scatter elsewhere. Patients are otherwise well appearing. The condition resolves on its own, except in individuals with T-cell immune deficiency, in particular that related to human immunodeficiency virus (HIV) infection. Curettage, cryotherapy, and laser vaporization have been used in minor cases. Patients with disseminated disease should be referred to a dermatologist, who may recommend topical imiquimod or related agents.⁴⁹

Similarly, severe and disseminated varicella infection may occur in atopic dermatitis patients. Lesions similar to eczema herpeticum occur and are strikingly concentrated in areas with significant disease. Both of these viral infections have been termed *Kaposi's varicelliform eruptions*. Intravenous or oral acyclovir is indicated depending on disease severity. Infected atopic dermatitis that does not respond to standard therapy for a suspected etiology raises the possibility of a different or resistant pathogen, or a serious, previously unrecognized, underlying disorder (HIV infection, Wiskott-Aldrich syndrome, hyperimmunoglobulinemia E syndrome, histiocytosis, or zinc deficiency).

Eczema Herpeticum

HSV may infect eczema by auto-inoculation from oral lesions, by contact with HSV skin lesions (as seen in wrestlers), or

from kissing. Crops of tiny vesicles develop in areas of eczema and become pustular, then ulcerated, and finally crusted. Normal skin tends to be spared. Constitutional symptoms are common. Eczema herpeticum is often misdiagnosed as bacterial superinfection. The vesicular and pustular appearance may be brief due to intense scratching by the patient. Concomitant bacterial infection may further confuse the clinician. Diagnosis is based on clinical appearance and the tendency for the lesions to recur on the same areas of the skin. Diagnosis is confirmed by viral culture of lesions or HSV direct fluorescent antibody immunostaining of cells scraped from the base of lesions.

Eczema herpeticum is a potentially severe condition. Systemic acyclovir therapy is required. For children under 12 years of age, the recommended dose is 750 mg/m² administered intravenously every 8 hours for 7 days. Oral acyclovir bioavailability is low, but this formulation can be prescribed as 20 mg/kg per dose four times daily for mild disease. Topical antivirals are ineffective.

Folliculitis

Folliculitis is a superficial infection of hair follicles that presents as small, discrete, pustules on an erythematous base. Skin irritation is a common cause. Usual etiologies are *S. aureus* and other staphylococcal species. Treatment with topical antiseptics (chlorhexidine, hexachlorophene, or clindamycin) suffices in most cases. More extensive presentations may require oral antibiotic therapy and consideration of MRSA. Chronic folliculitis responds to daily application of a benzoyl peroxide lotion or gel. *Candida* and *Malassezia furfur* may cause folliculitis in patients being treated with topical corticosteroids. Topical selenium sulfide, azoles, and tolnaftate have all been prescribed with success. Gram-negative organisms are found in patients with concomitant acne vulgaris. Standard therapies for acne are recommended in those cases. “Hot tub folliculitis” is due to *P. aeruginosa* found in hot tubs with suboptimal chemical maintenance. Lesions develop 8 to 48 hours after exposure and may be quite pruritic. Diagnosis is confirmed by culture of pustules. This is a benign, self-limited condition that resolves in 1 to 2 weeks, but treatment with an oral quinolone may be considered in teenagers and those with constitutional symptoms. Immunocompromised hosts may progress to more serious disease such as cellulitis, ecthyma, systemic infection, and even sepsis. Cancer patients and immune-deficient patients should avoid hot tubs. Immunocompromised children are frequently treated empirically with antipseudomonal agents (oral quinolones for well patients and parenteral agents in patients with illness or complications).

Furuncles and Carbuncles

Furuncles develop in a fashion similar to folliculitis but represent a more extensive infectious process in hair follicles. Furuncles may also develop as skin abscesses after minor skin injury. As the furuncle develops, infection progresses to deeper dermal levels with potential extension into subcutaneous tissues. Carbuncles are collections of two or more neighboring furuncles forming a confluence of purulent pockets, which eventually drain from several sites to the surface. As seen in folliculitis, furuncles and carbuncles have a predilection for hair-bearing skin and areas subject to rubbing and skin friction. Common sites in children are the

buttocks, perineum, and axillae. The extremities are also commonly affected, resulting from minor, everyday skin trauma and insect bites. Furuncles present as painful areas of erythema with increasing edema. The discomfort can be distressing for the child. Lesions progress to abscess with eventual thinning of the overlying skin and rupture of the purulent contents. They often drain and heal spontaneously to leave a slightly depressed scar. In some cases lesions cause significant cellulitis and constitutional symptoms, including fever. Deeper underlying tissues may be threatened. Furuncles and carbuncles must be differentiated from a kerion of the scalp, inflamed epidermal and pilar cysts, acne vulgaris, and hidradenitis suppurativa.

S. aureus is the major cause of furunculosis. The incidence of furunculosis appears to be increasing due to the emergence of CA-MRSA.^{7,50} These strains may also cause more severe skin disease and invasive infection due to ability to produce virulence factors, including Panton-Valentine leukocidin.⁵¹ Outbreaks have occurred in day care and detention facilities and among competitive sports participants.⁵² Wrestlers and rugby and football players have been increasingly affected, but the problem has occurred even in sports with little direct participant contact or physical trauma, such as fencing. An athletic outbreak can also be a marker of a community-wide outbreak.⁵³ Community and sports outbreaks have been shown to have been caused by specific CA-MRSA clones limited to a certain geographic area.⁵⁴ Because of epidemiologic and treatment implications, cultures of furunculosis and skin abscesses are mandatory in modern management.

Management

The treatment approach for furuncles and carbuncles is the same as that outlined for other potentially serious skin and soft tissue infections (see Table 120–2). As previously noted, furuncle management depends on clinical presentation, disease severity, and local antibiotic resistance rates. Simple incision and drainage alone suffices for the vast majority of cases. Patients often recover after incision and drainage even when no antibiotic is prescribed or an agent ineffective against CA-MRSA in vitro is used. A prospective study suggested that antimicrobial therapy is most likely to be helpful in cases in which cellulitis surrounding a furuncle is greater than 5 cm.⁵⁵ This group of patients were at risk for eventual hospitalization and parenteral therapy. This approach may not apply to infants and ill or immunocompromised patients, who are likely to require the most aggressive management, especially if they are febrile. Antibiotic choice depends on the severity of illness and local antibiotic resistance patterns (Table 120–4). The possibility of CA-MRSA infection should be considered when choosing. Seven to 10 days is the usual length of treatment.

Recurrent furunculosis is most often a benign condition and reflective of patient and familial colonization with a troublesome isolate of *S. aureus*. This, too, is becoming much more common with the rise of CA-MRSA. These patients tend to have heavy nasal colonization with *S. aureus* as well as colonization of other body sites. Nasal mupirocin (application into each naris twice daily or more for at least 5 days)⁵⁶ along with daily bathing with a chlorhexidine cleanser⁵⁷ has been recommended with some success. Oral rifampin has been used in combination with other antibiotics depending

Table 120–4 Antibiotics Useful in Skin and Soft Tissue Infections (see text)

Drug	Route	Dose	Max dose	Comments
Dicloxacillin	PO	25–50 mg/kg/day in 4 doses	1–2 g/day	MSSA, GABHS; poorly palatable suspension
Penicillin VK	PO	25–50 mg/kg/day in 3–4 doses	2 g/day	GABHS, Eikenella, Pasteurella
Penicillin G	IV	250,000–400,000 U/kg/day in 4–6 doses	24 million U/day	
Amoxicillin/ clavulanate (14 : 1)	PO	90 mg/kg/day of amoxicillin in 2 doses	2 g/day	MSSA, GABHS, Haemophilus, Pneumococcus, Pasteurella, anaerobes
Ampicillin/ sulbactam	IV	3 mo–12 yr: 100–200 mg/kg/day of ampicillin in 4 doses Older: 200–400 mg/kg/day of ampicillin in 4 doses	6–12 g/day	MSSA, GABHS, Haemophilus, Pneumococcus, Pasteurella, anaerobes
Piperacillin/ tazobactam	IV	150–200 mg/kg/day of piperacillin in 3 doses	240 mg/dose	Not licensed for use in children; MSSA, GABHS, gram-negative enterics, Pseudomonas, anaerobes
Imipenem	IV	50–100 mg/kg/day in 4 doses	4 g/day	Many gram-negative and positive organisms, Aeromonas, Pseudomonas, anaerobes; no MRSA activity
Cefepime	IV	150 mg/kg/day in 3 doses	4 g/day	MSSA, GABHS, gram-negative enterics and Pseudomonas
Ceftazidime	IV	150–200 mg/kg/day in 3 doses	6 g/day	Gram-negative enterics and Pseudomonas, many Aeromonas; fair MSSA and GABHS coverage
Cephalexin	PO	25–50 mg/kg/day in 3–4 doses	1–4 g/day	MSSA, GABHS; no MRSA
Nafcillin	IV	150 mg/kg/day in 4 doses	12 g/day	MSSA, reasonable GABHS; no MRSA
Cefazolin	IV	50–100 mg/kg/day in 3 doses	6 g/day	MSSA, GABHS; no MRSA
Clindamycin	PO	25–40 mg/kg/day in 3–4 doses	2 g/day	MSSA, CA-MRSA, anaerobes, most GABHS, penicillin-resistant pneumococcus; no HA-MRSA
	IV	25–40 mg/kg/day in 3–4 doses	2.7 g/day	Do not use alone for serious GABHS infection (see text)
Linezolid	PO	20–30 mg/kg/day in 3 doses	1200 mg/day	MSSA, CA-MRSA, HA-MRSA, GABHS, Enterococcus (including vancomycin-resistant); no gram-negatives; very expensive
	IV	20 kg/day in 2 doses	1.2 g/day	
Trimethoprim- sulfamethoxazole	IV	20–30 mg/kg/day in 3 doses 8–12 mg/kg/day of trimethoprim, 40–60 mg/kg/day of sulfa in 2 doses	1200 mg/day 300 mg/1.6 g per day	Expert infectious disease advice helpful MSSA, CA-MRSA, Aeromonas; no GABHS
Doxycycline	PO	5 mg/kg/day in 1–2 doses	200 mg/day	CA-MRSA, Vibrio; limited to > 8 yr old
Ciprofloxacin	PO	30 mg/kg/day in 2 doses	1.0–1.5 g/day	Selective indications in children; expert infectious disease advice helpful
	IV	20–30 mg/kg/day in 2 doses	400–800 mg/day	Gram-negatives, Pseudomonas, Aeromonas; no anaerobes, poor MSSA
Azithromycin	PO	5–12 mg/kg once daily	600 mg/day	MSSA, GABHS; no MRSA; reserve for penicillin allergy
Vancomycin	IV	40 mg/kg/day in 3–4 doses; 40–60 mg/kg/day in 4 doses (severe cases)	2 g/day; 4 g/day	MSSA, CA-MRSA, HA-MRSA, GABHS, penicillin-resistant Pneumococcus
Rifampin	PO	10–20 mg/day in 1–2 doses	600 mg/day	Synergy against MSSA, CA-MRSA, HA-MRSA
Gentamicin	IV	3–7.5 mg/kg in 3 doses or 5–6 mg/kg every 24 hr	N/A	Used in combinations for synergy versus staphylococci, enterococci, Pseudomonas, gram-negative enterics

Abbreviations: GABHS, group A β -hemolytic streptococcus; CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; HA-MRSA, hospital-acquired methicillin-resistant *Staphylococcus aureus*; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *Staphylococcus aureus*.

on the antimicrobial susceptibility pattern of the patient's isolate in attempts to decolonize patients. Data are not currently sufficient to allow recommendation of such approaches as routine care. The emergency physician should seek infectious disease expertise in these situations.

Patients who do not respond to therapy or worsen despite use of effective antimicrobial agents, or continue to have significant recurrent disease, may have an underlying predisposing condition. *S. aureus* disease is most troublesome to patients with neutropenias (familial, cyclic, acquired), neutrophil disorders (oxidative burst deficiencies, myeloperoxidase deficiency, glucose-6-phosphate dehydrogenase deficiency, chemotactic disorders, leukocyte adhesion defects),

HIV-related immune deficiency, hyperimmunoglobulinemia E syndrome, and common variable immune deficiency.

Hidradenitis Suppurativa

Hidradenitis suppurativa is a chronic, often progressive, severe inflammatory disease of apocrine glands mainly in intertriginous areas such as the axillae, groin, perineum, and rectum. Disease severity is often cyclic and remitting; flare-ups can be debilitating. The spectrum of disease ranges from inflammatory nodules to nodules with draining wounds and sinus tracts. With each cycle of inflammation the extent of the lesions increases. The condition is commonly confused with furuncles and carbuncles, progressive folliculitis, and

Table 120–5 Organisms Associated with Unusual Domesticated and Wild Animal Bite Wounds

Animal	Organism	Treatment Should Include*
Horses	Similar to dog and cat	Amoxicillin/clavulanate
Pig/sheep	Dog/cat flora + <i>Francisella tularensis</i> and others	Amoxicillin/clavulanate, gentamycin
Rat	Dog/cat flora + <i>Streptobacillus moniliformis</i> , <i>Leptospira</i>	Amoxicillin/clavulanate
Ferret/gerbil	Rat flora + <i>Acinetobacter anitratus</i>	Antipseudomonal penicillin
Monkeys	Human flora + herpesvirus B	Antiviral therapy
Coyote	<i>Francisella tularensis</i>	Gentamycin
Wolf	<i>Pasteurella multocida</i>	Amoxicillin/clavulanate
Cougar	<i>Pasteurella multocida</i>	Amoxicillin/clavulanate
Panther	<i>Pasteurella multocida</i>	Amoxicillin/clavulanate
Lion	<i>Pasteurella multocida</i> , <i>Staphylococcus aureus</i> , <i>Escherichia coli</i>	Amoxicillin/clavulanate
Tiger	<i>Pasteurella multocida</i> , <i>Acinetobacter</i> , <i>Escherichia coli</i> , streptococci, staphylococci	Amoxicillin/clavulanate
Skunks	Rabies	RIG, HDCV
Raccons	Rabies	RIG, HDCV
Bats	Rabies	RIG, HDCV
Foxes	Rabies	RIG, HDCV
Opossum	<i>Pasteurella multocida</i>	Amoxicillin/clavulanate
Squirrel	<i>Francisella tularensis</i>	Gentamycin

*Consult with infectious disease specialist for total management strategy.

Abbreviations: HDCV, human diploid cell rabies vaccine; RIG, rabies immune globulin.

Table 120–6 Prophylactic Antimicrobial Strategy for Mammalian Bite Wounds (Domesticated Animals and Humans)

	Commonly Associated Organisms	First Choice	Other Choices	Penicillin-Allergic Patient*
Empirical therapy for most bites		Amoxicillin/clavulanate 25–40 mg/kg bid	Cefuroxime [†] 50 mg/kg divided bid <i>or</i> Ceftriaxone [†] 50–75 mg/kg IM qd × 2–3 days	Clindamycin 15–25 mg/kg divided tid <i>plus</i> Trimethoprim/sulfamethoxazole 6–12 mg/kg divided bid <i>or</i> Doxycycline [‡] 50–100 mg bid
Dog bites	<i>Pasteurella multocida</i> <i>Streptococcus</i> species <i>Staphylococcus aureus</i> <i>Neisseria</i> species Anaerobes: <i>Bacteroides</i> , <i>Fusobacterium</i> Other: <i>Eikenella</i> , <i>Capnocytophaga canimorsus</i>	Amoxicillin/clavulanate	Penicillin V 25–50 mg/kg divided tid–qid <i>or</i> Amoxicillin 40 mg/kg divided tid [§]	Clindamycin plus trimethoprim/sulfamethoxazole <i>or</i> Doxycycline [‡]
Cat bites	<i>Pasteurella multocida</i> <i>Streptococcus</i> species <i>Staphylococcus aureus</i> <i>Neisseria</i> species Anaerobes: <i>Bacteroides</i> , <i>Fusobacterium</i> Other: <i>Eikenella</i> , <i>Capnocytophaga canimorsus</i>	Amoxicillin/clavulanate	Penicillin and/or dicloxacillin 25–50 mg/kg, divided qid for both	Clindamycin plus trimethoprim/sulfamethoxazole <i>or</i> Doxycycline [‡]
Human bites	Many aerobic/anaerobic bacteria, esp. <i>Streptococcus</i> , <i>Staphylococcus</i> , <i>Eikenella corrodens</i> , <i>Corynebacterium</i> , <i>Bacteroides</i> , <i>Clostridium</i>	Amoxicillin/clavulanate	Penicillin and/or dicloxacillin	Clindamycin plus trimethoprim/sulfamethoxazole <i>or</i> Doxycycline [‡] <i>or</i> Erythromycin [¶] <i>or</i> Macrolide

*Should consult with infectious disease expert.

[†]Effective against *S. aureus*, anaerobes, *E. corrodens*, and *P. multocida*.

[‡]Not for use in prepubertal children or pregnant women.

[§]Lower incidence of *P. multocida*.

[¶]*Pasteurella multocida* only moderately sensitive, with known treatment failures; *Eikenella* with slightly increased sensitivity.

epidermoid or dermoid cysts. Hidradenitis suppurativa is differentiated from these other conditions by its chronicity, cyclic presentation, and progressive nature. Differentiation of perianal hidradenitis from perianal complications associated with inflammatory bowel disease may be difficult. Acne conglobata is similar in appearance to hidradenitis suppurativa but lacks cyclic features.

Over 98% of hidradenitis suppurativa cases present after the age of 11 years, and hormonal influences may play an important role. Oral contraceptives, pregnancy, and the latter portion of the menstrual cycle are known to worsen disease in females. Hidradenitis is more common in patients with a variety of endocrinopathies, including diabetes mellitus and adrenal gland diseases. The etiology of hidradenitis suppurativa remains largely undefined; however, apocrine gland duct obstruction and superinfection play roles in pathogenesis. A variety of organisms have been isolated from wound drainage, including *Staphylococcus* species, *Streptococcus* species, *Escherichia coli*, *Klebsiella* species, *Proteus* species, *Corynebacteria*, and anaerobes.^{58,59}

Treatment of patients with flare-ups of hidradenitis involves warm baths, local antiseptics, and cleansing with mild antibacterial agents. Oral and topical antistaphylococcal antimicrobial agents are commonly prescribed, with anaerobic coverage added in cases of perianal disease. Topical clindamycin or an oral tetracycline has some efficacy.⁶⁰ Oral clindamycin has also been used. Cultures should guide the ultimate antibiotic choice. There are no data to support a recommendation for chronic, suppressive antimicrobial therapy. Patients should be advised to wear loose-fitting clothes that will not rub and traumatize affected areas. Incision and drainage of lesions or unroofing of closed lesions to encourage marsupialization may speed healing, but has no effect on recurrence, prognosis, or disease severity. Referral to a dermatologist or surgeon is necessary since treatment with retinoids or immunomodulating medications such as cyclosporin, or local to wide surgical incision and even skin grafting, may be warranted.

Lymphangitis

Lymphangitis is an inflammatory process of the lymphatic system that drains an area of infection. Regional lymph nodes are often involved and may become suppurative at later stages. Physical examination reveals tender, erythematous streaks extending from the primary site of infection and along the tracts of the lymphatics. Group A streptococcus is the leading cause, with *S. aureus* implicated in most other cases; however, infection with a variety of other organisms may also present in a similar fashion. For example, lymphangitis may be seen with puncture and contaminated wound infections. Wound and blood cultures are recommended in children due to the risk of bacteremia and sepsis, especially when febrile. Therapy is directed against the primary infection and stratified by the general approach to soft tissue infections (see Table 120–2).

Chapter 121

Erythema Multiforme Major and Minor

Antonio E. Muñoz, MD

Key Points

Erythema multiforme consists of “target” skin lesions and may have involvement of one mucous membrane, usually the oral mucosa.

The diagnosis of Stevens-Johnson syndrome requires that at least two mucous membranes are affected in addition to the “target” skin lesions.

Ophthalmologic consultation is required if there is ocular mucosa involvement.

Stevens-Johnson syndrome requires hospitalization, intravenous fluid and electrolyte replacement, and meticulous skin care.

Introduction and Background

Erythema multiforme (EM) and Stevens-Johnson syndrome (SJS) are hypersensitivity syndromes that can be caused by infections, drugs, vaccinations, malignancy, and connective tissue disorders. EM is defined as an acute, self-limiting vesiculobullous disorder characterized by the formation of symmetrically distributed erythematous macules and papules, some of which evolve into the classic “target” lesions (Table 121–1).¹ On occasion it can involve one mucosal surface, particularly the oral mucosa.² It is seen most commonly in the second to fourth decade of life, but 20% of cases occur in children.

SJS is a potentially life-threatening condition with mortality up to 15%. By definition, it requires involvement of at least two mucous membranes, most often the conjunctivae and oropharynx, although the nasal, urethral, vaginal, and rectal mucosa can also be affected³ (Table 121–2). The respiratory and gastrointestinal tracts are occasionally involved. As opposed to EM, mucosal and cutaneous involvement in SJS is severe with extensive necrosis. For many years EM was classified into minor and major forms, the major variant being SJS. However, recent consensus states that SJS is best

regarded as a different entity than EM, despite clinical and histologic similarities.^{1,4} In addition, no one has been able to demonstrate that EM evolves into SJS.^{4,5}

Recognition and Approach

The pathogenesis of EM is unknown, but it is considered to be a delayed hypersensitivity immune response to a number of different stimuli, particularly the herpes simplex virus (HSV) antigen in children.^{6–8} Cytotoxic effector cells (CD8⁺ T lymphocytes in the epidermis) induce apoptosis of scattered keratinocytes, which leads to cell necrosis. The diagnosis is often made by clinical assessment but can be confirmed by biopsy of a typical lesion, which shows T-lymphocyte infiltration.

Unlike EM, in SJS there is an excessive overexpression of tumor necrosis factor- α in the epidermis.^{8,9} This may account for the greater degree of epidermal necrosis seen in SJS. Skin biopsy is characterized by a perivascular mononuclear infiltrate with some eosinophils in the dermis, variable hydrops degeneration of the basilar layer, and subepidermal blister formation in severe cases.

The list of putative trigger factors for EM and SJS in adults is an extensive one, but in children it seems that the majority of cases of EM are the result of a preceding recrudescence of HSV.^{1,10} SJS in adults is usually drug induced, but in children it is associated with infections, especially *Mycoplasma pneumoniae*, as well as drugs, most notably antibiotics, anticonvulsants, and nonsteroidal anti-inflammatory drugs.^{1,10–13}

Clinical Presentation

Erythema Multiforme

EM is often preceded by a herpes simplex infection, usually localized to the face but potentially occurring in any location. Prodromal symptoms are absent or mild and may consist of low-grade fever, cough, and anorexia. Myalgias or arthralgias are rare accompanying symptoms. Typically, crops of lesions develop over a few days in acral regions, especially the palms and dorsa of the hands, wrists, feet, and extensor surfaces of elbows and knees, and occasionally on the face. EM may manifest Koebner’s phenomenon—target lesions appearing within areas of cutaneous trauma such as

Table 121-1 Clinical Features of Erythema Multiforme

- Benign, self-limited, and occasionally recurrent disorder
- Cutaneous lesions consisting of symmetric, fixed macules or papules evolving into “target” lesions
- Mucous membrane absent or limited only to the oral cavity
- Minimal or no prodromal symptoms
- Supportive treatment (antihistamines, acyclovir)

Table 121-2 Clinical Features of Stevens-Johnson Syndrome

- Prodromal symptoms
- Severe mucous membrane involvement (at least two)
- Much larger cutaneous involvement
- Treatment includes fluid and electrolyte replacement and meticulous skin care
- Other treatment may include corticosteroids and immune globulin
- Life threatening (mortality up to 15%)

Table 121-3 Differential Diagnosis of Erythema Multiforme

Giant urticaria
 Drug reactions
 Bullous pemphigoid
 Chronic bullous dermatosis of childhood (CBDC)
 Polymorphic light reaction
 Systemic lupus erythematosus (SLE)
 Urticarial vasculitis
 Erythema annulare centrifugum

scratches.^{13,14} The cutaneous eruption of EM generally resolves in 1 to 2 weeks, but occasionally may be present for 4 weeks.

EM in childhood is frequently initially misdiagnosed as urticaria^{14,15} (Table 121-3). The lesions in urticaria are transient and migratory and have a clear central zone, not a dusky one. In addition urticarial lesions will resolve with the administration of subcutaneous epinephrine, and EM will not.^{14,15}

Stevens-Johnson Syndrome

SJS is usually preceded by a prodromal illness lasting up to 2 weeks and consisting of high fever, cough, coryza, sore throat, headache, chest pains, malaise, arthralgias, myalgias, vomiting, and diarrhea. Toxicity and generalized lymphadenopathy are common. Occasionally the child has hepatosplenomegaly or evidence of hepatitis. Myocarditis, pneumothorax, nephritis, and gastrointestinal bleeding are rare complications. After 1 to 14 days, the rash starts suddenly and occurs in the face, trunk, and limbs. Mucous membrane involvement, especially of the oral, conjunctival, and urethral mucosa, is typical and often severe. Oral mucous lesions may be confused with aphthous ulcers, herpes simplex infection, pemphigus, bullous pemphigoid, epidermolysis bullosa, and paraneoplastic pemphigus, and the differential diagnosis for SJS involves these and other serious disorders (Table 121-4).

Table 121-4 Differential Diagnosis for Stevens-Johnson Syndrome

Burns or scalds
 Staphylococcal scalded skin syndrome (SSSS)
 Toxic epidermal necrolysis (TEN)
 Kawasaki disease
 Toxic shock syndrome
 Acute graft-versus-host disease
 Paraneoplastic pemphigus

**FIGURE 121-1.** Typical target lesions in erythema multiforme.**FIGURE 121-2.** Concentric rings of target lesion in erythema multiforme.

Important Clinical Features and Considerations

Cutaneous lesions start as dull red macules or maculopapules, which may increase in size up to 3 cm in diameter within 24 to 48 hours. The lesions are usually asymptomatic, but some patients complain of itching. The lesions may evolve into target-shaped (or iris) plaques, which are the hallmark of EM⁴ (Fig. 121-1). The target lesions consist of two or three concentric rings (Fig. 121-2). The central portion starts as a dusky red or purple macule before evolving into tense bullae with clear or hemorrhagic contents. There is usually a middle pale zone of edematous skin and an outer halo of well-demarcated erythema. As the name implies, there may be a variable pattern of lesions ranging from necrotic macules to an exclusively blistering disorder, but most have approximately 100 lesions¹⁶ (Fig. 121-3). In SJS, depending on the severity, the

FIGURE 121-3. A, Close-up of extensive erythema multiforme. B, Stevens-Johnson syndrome demonstrating extensive skin lesions.

epidermis begins to separate from the basal layer as a result of very minor frictional forces (Nikolsky's sign), and large flaccid blisters that resemble scalds rupture, leaving sheets of necrotic epidermis with a moist erythematous base (Fig. 121-4). Complications that occur with large areas of skin sloughing include fluid and electrolyte losses, secondary bacterial infections, scarring, and dyspigmentation.^{1,17}

The primary oral lesion consists of an erythematous macule that evolves centrally into a thick-walled vesicle or bulla. The blisters last a brief period and, after rupture, leave the characteristic irregularly shaped ulcer with indistinct margins and a yellow necrotic base. Unlike EM, mucosal involvement in SJS is confluent and widespread. The lips are often covered with hemorrhagic crusts (Fig. 121-5). These lesions are extremely painful and may become covered with a pseudomembrane prior to healing. In severe cases, erosion of the pharynx and esophagus leads to necrotizing esophagitis (Fig. 121-6). Swallowing is so painful that dehydration is a common sequela.

Genital involvement induces urethritis, balanitis, and vulvovaginitis, which are associated with dysuria and purulent discharge (Fig. 121-7). The skin eruption consists of symmetric red macules that progress to central blister formation and extensive areas of epidermal necrosis. Erosions may also bleed. Genitourinary lesions may be so painful that urinary retention occurs. On occasion the rectal mucosa is also inflamed and ulcerated. Complications such as adhesions may develop.¹⁸

FIGURE 121-4. Large desquamation in Stevens-Johnson syndrome.

FIGURE 121-5. Hemorrhagic crusts of oral mucosa in Stevens-Johnson syndrome.

FIGURE 121-6. Extensive painful necrotic lesions of Stevens-Johnson syndrome.

Ocular lesions constitute the most severe mucous membrane involvement. The early phase consists of a mucopurulent conjunctivitis with inflamed, edematous papillae and photophobia (Fig. 121-8). Focal ulcerations can occur and lead to formation of pseudomembranes and synechiae between the eyelids and conjunctiva. Other reported complications include entropion, keratitis, symblepharon,

FIGURE 121-7. Penile mucosal involvement in Stevens-Johnson syndrome.

FIGURE 121-8. Involvement of the conjunctiva in Stevens-Johnson syndrome.

trichiasis, corneal pannus, uveitis, panophthalmos, and stricture of the lacrimal puncta.^{19,20} Severe involvement may lead to loss of vision and even blindness.²¹

There are no specific laboratory abnormalities in EM, but SJS has been associated with elevated sedimentation rate, leukocytosis, eosinophilia, anemia, elevated hepatic transaminases, proteinuria, and hematuria.^{1,22}

Management

Patients with EM require only symptomatic care, in addition to withdrawing any drugs suspected of initiating the eruption. If pruritus is prominent, oral antihistamines, calamine lotion, or oatmeal baths may be useful. Painful oral lesions may be treated with topical analgesic mouthwash (equal mixture of Maalox, 60 ml, and diphenhydramine, 15–30 ml), which is placed on the lesions with a Q-Tip. Viscous xylocaine should not be included since as little as 1–2 ml can be toxic to young children. HSV-associated EM does not usually respond to acyclovir, but prophylactic acyclovir, if given early enough, can prevent recurrences.^{2,23,24}

Those patients with more extensive skin involvement, such as those with SJS, must be hospitalized for intravenous fluids,

correction of dehydration from transepidermal fluid losses, replacement of electrolytes, maintenance of nutrition, and pain control. These patients are best managed in a burn unit or pediatric intensive care unit with meticulous skin care for prevention of secondary bacterial infection, which can lead to sepsis, a leading cause of mortality. In addition, sulfonamide-containing ointments should be avoided since they have been implicated in causing these disorders.^{18,25} Surgical débridement and whirlpool therapy to remove necrotic epidermis are recommended. Prompt withdrawal of the causative agent should be a priority since the course of the illness may be shortened.²⁶ Immediate ophthalmologic evaluation is mandatory if there are conjunctival lesions. Frequently applied lubrication with artificial tears and ophthalmic antibiotic drops or ointments (not containing sulfonamide) are necessary, with daily blunt disruption of synechiae.

The controversy over whether systemic corticosteroids should be used to attenuate progression of disease is still unresolved, since there are no large prospective, double-blind, multicenter controlled trials.^{17,27} In small trials, corticosteroids have been shown to decrease the duration of fever and lesions.²⁷⁻²⁹ Systemic corticosteroids do increase the risk of infection; however, their advocates suggest tapering the dose quickly once disease progression has ceased, and perhaps combining their use with a prophylactic antibiotic. High-dose intravenous immune globulins have been shown to improve some cases, with faster resolution of fever and skin lesions and shortened hospital stays.³⁰⁻³³

Summary

In EM, disease tends to be mild and attacks tend to subside within 1 to 3 weeks, usually without sequelae, except for an occasional pigmentary change. A follow-up visit in 24 to 48 hours is advisable to determine the progress of EM. In SJS, prognosis depends on prompt diagnosis and meticulous care for patients with extensive disease. Mortality is generally less for children than adults, but may be as high as 15%, and is worse with increasing body surface area involvement. In most cases recovery occurs within 3 to 6 weeks.

Henoch-Schönlein Purpura

Antonio E. Muñoz, MD

Key Points

Palpable petechiae or purpura symmetrically distributed over the buttocks and extensor surfaces of the legs is the characteristic rash distribution of Henoch-Schönlein purpura.

In children with severe colicky abdominal pain, an ileoileal intussusception must be excluded.

Major morbidity is due to renal involvement, which may lead to chronic renal disease.

Treatment is supportive with nonsteroidal anti-inflammatory drugs and occasionally systemic corticosteroids or cytotoxic drugs.

Introduction and Background

Henoch-Schönlein purpura (HSP), also known as anaphylactoid purpura or allergic vasculitis, is the most prevalent cause of leukocytoclastic vasculitis in children, particularly between 3 and 10 years of age. It can occur in adults but is associated with a worse prognosis, more renal involvement, and increased use of aggressive therapeutic regimens, including corticosteroids and cytotoxic drugs.^{1,2} The disorder is characterized by a tetrad consisting of a distinctive purpuric rash, colicky abdominal pain, arthralgias or arthritis, and in some cases renal disease.

Recognition and Approach

A history of an antecedent upper respiratory tract infection preceding the onset of illness, seen in up to 75% of cases, suggests a hypersensitivity reaction to a virus resulting in vascular damage. Other entities implicated in the pathogenesis have included drugs, foods, insect bites, immunizations, cold exposure, tumors, pregnancy, and chemical toxins.³⁻⁵

The disorder appears to be initiated by deposition of immune complexes on the basement membrane, mainly of the immunoglobulin A (IgA) class, which activates complement leading to systemic inflammation of small vessels in the

upper dermis, gastrointestinal tract, synovial membranes, renal glomeruli, and occasionally the lungs and central nervous system.⁶⁻⁸ The deposition of IgA occurs as a consequence of abnormal glycosylation of O-linked oligosaccharides of IgA1.⁹

Clinical Presentation

The eruption is frequently preceded by a prodrome consisting of fever, headache, malaise, nausea, and vomiting. Subsequently a characteristic rash, abdominal pain, and/or joint symptoms occur. In most children, HSP is a self-limited illness with no significant sequelae; however, in a small minority renal disease can occur.

The major diagnostic feature is that of palpable petechiae or purpura. Individual lesions vary in size from 2 to 10 mm in diameter. They are most commonly found in a symmetric distribution over the buttocks and extensor surfaces of the legs (Figs. 122-1, 122-2, and 122-3). Children younger than 2 years of age have lesions in atypical locations, such as the face, upper extremity, and trunk (Fig. 122-4). Individual lesions occur in successive crops, tend to fade after 5 days, and eventually are replaced by areas of brownish pigmentation, purpura, or ecchymosis. New crops of lesions frequently occur over the next 2 to 4 weeks over the fading lesions of a previous episode, thereby giving a polymorphous appearance to the disorder. Less than 5% of patients have associated edema of the hands, feet, or face, and few have lesions consisting of urticaria.¹⁰

The differential diagnosis of HSP is variable^{3,4,11} (Table 122-1).

Important Clinical Features and Considerations

Fifty percent to 80% of affected children also have involvement of joints, gastrointestinal tract, and kidneys, with lesser involvement of the cardiopulmonary, genitourinary, and central nervous system (Table 122-2).

The diagnosis of HSP is made by clinical features. Confirmation of the diagnosis of HSP requires evidence of tissue deposition of IgA in the skin or kidney by IgA immunofluorescence microscopy. Biopsy of skin lesions demonstrates a leukocytoclastic vasculitis, or white blood cells surrounding dermal blood vessels. These are more prominent in the post-capillary venules.

Table 122–2 Organ Systems Affected by HSP

Associated Features	Description
Joints (80%)	Warm, tender, and painful swelling of joints, with or without overlying purpura ¹¹ Primarily in knees and ankles, but may be seen in elbows, hands, and feet Joint symptoms generally last a few days but have a high recurrence rate
Gastrointestinal symptoms (75%)	Symptoms from edema of the bowel wall, hemorrhage as a result of vasculitis, and thrombosis of the microvasculature Typically occur 1 wk after the rash but may precede in 14%–36% ³¹ Colicky abdominal pain, vomiting, visceral infarction or perforation, pancreatitis, cholecystitis, hydrops of the gallbladder, colitis, protein-losing enteropathy, appendicitis, pseudomembranous colitis, chronic intestinal obstruction with ileal stricture, intussusception, hemorrhage (melena or hematochezia), or shock ^{18,32-37} Location of intussusception is usually ileoileal and is diagnosed initially by ultrasound (“donut” or “pseudokidney” sign); may require surgical reduction but spontaneous reduction has occurred with conservative therapy, consisting of nasogastric drainage, corticosteroids, and intravenous fluids ³⁸⁻⁴⁰
Kidney (25–50%)	Most serious cause of morbidity Occurs few days to 1 mo after onset May present with gross or, more commonly, microscopic hematuria, with or without casts and proteinuria Often self-limited; if proteinuria persists, may progress to advanced glomerular disease and acute or chronic renal failure Chronic renal disease in up to 15% with hematuria and proteinuria; if evidence of nephritis or nephrotic syndrome, end-stage renal disease in up to 50% ⁴¹ Overall, 1.7% of all patients develop chronic renal failure. ⁴² Children at higher risk for renal disease include those with hypertension, proteinuria > 1 g/L, elevations of serum blood urea nitrogen and creatinine, decreased fibrin-stabilizing factor (factor XIII) activity, glomerular crescents on biopsy, and rash greater than 1 month’s duration. ^{41,43-48}
Central nervous system	Headache, diplopia, cerebral or cerebellar hemorrhage, subarachnoid hemorrhage, seizures, focal neurologic deficit, mononeuropathy, and coma ⁴⁹⁻⁵²
Cardiopulmonary	Asymptomatic pulmonary infiltrate or recurrent episodes of pulmonary hemorrhage ^{53,54} Cardiac involvement is rare; may include myocarditis, coronary artery vasculitis resulting in acute myocardial ischemia or infarction, and cardiac tamponade ^{48,55,56}
Genitourinary (20%)	Scrotal hemorrhage may cause intense pain from severe scrotal swelling ^{57,58} Rare report of a simultaneous torsion of the testes; ultrasound or nuclear scan is recommended ^{59,60}

Management

Complete recovery occurs in 94% of children; therefore, most receive no specific therapy.² Bed rest and general supportive care are helpful. Analgesia with nonsteroidal anti-inflammatory drugs may reduce joint and soft tissue discomfort. For significant gastrointestinal hemorrhage, fluids and blood should be replaced as required. The degree to which diagnostic testing is performed in the emergency department depends on symptoms, but in all cases a urinalysis is warranted as a screening test for possible renal complications. Need for hospitalization is also dictated by severity of symptoms and the presence of complications. Most children can be managed as outpatients, but parents should be counseled that symptoms may wax and wane for several weeks before remitting entirely, and can be debilitating.

The efficacy of corticosteroids is controversial.¹²⁻¹⁵ Although there is little evidence that corticosteroids alter the prognosis of HSP, they suppress and improve the acute manifestations, and hence may be justified for short periods in severe cases, especially those with significant gastrointestinal complications (except bleeding, perforation, intussusception) or chronic glomerulonephritis.^{16,17} In this setting, a regimen of phased intravenous methylprednisolone followed by oral prednisone for 3 months may be beneficial.¹⁸ This regimen is useful in reversing the anti-inflammatory process but not the IgA deposition. Dapsone, azathioprine, cyclophosphamide, cyclosporine, methotrexate, intravenous immune globulins, plasmapheresis, anticoagulation, and dipyridamole have been tried with varying success in severe and refractory cases.^{8,19-28} Renal transplantation can be performed in those

patients who progress to end-stage renal disease; however, recurrent disease can occur.^{29,30} A pediatric nephrologist or rheumatologist should be consulted for guidance on the use of steroids and other medications.

Summary

HSP generally subsides within a few days to weeks, with some patients having recurrent attacks lasting weeks or months. The prognosis for most patients with HSP is excellent, with full recovery without sequelae in most cases. In children younger than 2 years of age, the disease is generally milder and of shorter duration, with fewer systemic complications.

Patients should be hospitalized if complications develop, such as significant bleeding, intussusception, renal disease (especially with hypertension), and pulmonary or central nervous system hemorrhages. All patients with an abnormal urinalysis should be referred for urgent follow-up so that the urine may continue to be frequently monitored.

Chapter 123

Classic Viral Exanthems

Antonio E. Muñoz, MD

Key Points

Measles causes a prodrome, Koplik's spots, and a 10-day maculopapular rash.

Rubella usually is a benign disease, but can result in thrombocytopenia and arthralgias.

Roseola infantum may present as febrile seizure.

Fifth disease can result in aplastic anemia in patients with shortened life span or abnormal red blood cells.

Gingivostomatitis is the primary presentation of herpes simplex virus infection in children.

Selected Diagnoses

- Measles (rubeola, first disease)
- Rubella (German measles, third disease)
- Roseola infantum (exanthem subitum, sixth disease)
- Erythema infectiosum (fifth disease, human parvovirus B19)
- Herpes simplex (human herpesvirus 1 and human herpesvirus 2)
- Varicella-zoster virus (human herpesvirus 3)
- Coxsackievirus (hand-foot-and-mouth disease)

Introduction and Background

Any generalized cutaneous erythematous eruption associated with an acute viral syndrome is known as a viral exanthem. If the mucosa is involved, it is called an enanthem. The exact incidence of viral exanthems is unknown, and the most common are caused by enteroviruses.¹ A majority of childhood exanthems are nonspecific and cannot be accurately assigned to a discrete etiologic diagnosis. These exanthems are usually self-limited, resolving spontaneously in 1 week without long-term sequelae, and require only symptomatic therapy. Multiple viral agents are capable of causing a nonspecific exanthem, including nonpolio enteroviruses (i.e., coxsackievirus, echovirus, and enterovirus) and respiratory viruses (i.e., rhinovirus, adenovirus, parainfluenza virus,

respiratory syncytial virus, and influenza virus).^{2,3} In general, most nonspecific exanthems occurring in the warmer months are caused the enteroviruses, and those occurring during the winter months by the respiratory viruses.

Discussion of Individual Diagnoses

Measles (Rubeola, First Disease)

Classic features of measles include a prodrome of fever, cough, coryza, conjunctivitis, and Koplik's spots, followed by an exanthematous phase. During the entire course of the illness, the child appears quite ill. Despite active immunization in the United States, outbreaks continue to occur.⁴

Measles is caused by an RNA virus, *Paramyxovirus*, that is highly contagious and is spread by direct contact with infectious droplets or, less commonly, by airborne spread. The incubation period, as defined by days prior to appearance of the rash, is 8 to 12 days. It is contagious 1 to 2 days before the prodrome and 4 days after the rash develops. It is most prevalent in late winter and spring. With the recommended two-dose vaccination schedule, first at 12 to 15 months and the second at 4 to 6 years of age, the incidence of measles in the United States has decreased to 100 cases per year.^{5,6} Up to 67% are caused by importation of the virus from other countries.⁷

Typical measles infects the epithelial cells of the respiratory tract and binds to a cell surface glycoprotein, CD46.^{8,9} This is followed by spread to lymphoid tissue, where it replicates, and eventually a primary viremia occurs. The virus disseminates to multiple sites, including skin, the liver, and the gastrointestinal tract.¹⁰ Infection of the oral mucosa leads to the enanthem. The cutaneous eruption is related to the presence of the measles virus within keratinocytes and endothelial cells of the superficial dermal vessels.¹¹ The virus replicates within keratinocytes, leading to multinucleated giant cells, called Warthin-Finkeldey cells.¹¹ The clinical lesions are believed to be due to the host response to the virus within the skin.

Clinical Presentation

A prodrome occurs for 3 to 5 days of high fever, chills, systemic toxicity, headache, malaise, anorexia, and the "three Cs" (cough, coryza, and conjunctivitis). The cough is described as brassy or barking, and an initial diagnosis of croup or bronchitis may be made. The conjunctivitis is characterized by severe lacrimation with mild photophobia. The

FIGURE 123-1. Koplik's spots on buccal mucosa seen in measles.

FIGURE 123-2. Erythematous macules and papules in measles.

coryza consists of copious mucopurulent discharge. Enlarged cervical and preauricular lymph nodes are present.

The exanthem follows the prodrome but is preceded by an enanthem. The enanthem is composed of intense erythema of the mucous membranes with focal 1- to 3-mm punctuate white-gray papules (Koplik's spots) usually adjacent to the lower premolars. These resemble a grain of salt on a red background (Fig. 123-1).

The exanthem begins at the hairline and behind the ears as blotchy erythema and spreads centrifugally and in a cephalocaudal direction to involve the face, trunk, and extremities, with multiple discrete macules and papules (Fig. 123-2). These gradually coalesce, and, by the third day, the entire body is involved and lesions are intensely erythematous, and at times purpuric (morbilliform). Usually by the fourth day, the rash begins to fade, with a coppery-brown discoloration

Table 123-1 Differential Diagnosis of Morbilliform Rashes

Differential Diagnosis	Causes
Viruses	Measles Rubella Roseola infantum Erythema infectiosum Infectious mononucleosis Pityriasis rosea HIV (primary) Infectious hepatitis
Bacterial infections	Scarlet fever Rocky Mountain spotted fever Syphilis
Drug eruptions	Ampicillin, penicillin Nonsteroidal anti-inflammatory drugs Salicylic acid Phenytoin, barbiturates Phenothiazines Thiazide diuretics Isoniazid
Papulosquamous disorders	Guttate psoriasis Graft-versus-host disease
Reactive erythemas	Urticaria Papular urticaria Erythema multiforme Henoch-Schönlein purpura Kawasaki disease

Abbreviation: HIV, human immunodeficiency virus.

and desquamation, in the same order as it appeared. The rash fades by the 10th day ("10-day rash").

Complications of measles are infrequent but may be life threatening, especially in children less than 1 year of age, patients who are immunosuppressed, or the elderly.¹² Bacterial otitis media, bacterial pneumonia, bronchitis, laryngotracheobronchitis, diarrhea, myocarditis, and encephalitis may complicate measles.^{1,13} Severe pneumonia and encephalitis are primary causes of death and are more likely to complicate measles in young infants and malnourished or immunocompromised children. Other rarely reported complications include thrombocytopenia, Stevens-Johnson syndrome, gangrenous stomatitis, appendicitis (lymphoid hyperplasia), hepatitis, laryngotracheal bronchitis, acute glomerulonephritis, pericarditis, lymphadenitis, and subacute sclerosing panencephalitis.¹⁴ Mortality related to measles in the United States is estimated to be 1 per 1000.⁴ Low vitamin A levels have been implicated in the severity of measles.¹⁵

The differential of morbilliform exanthems is vast and include viruses, bacterial infections, drug eruptions, papulosquamous disorders, and reactive erythema (Table 123-1). The typical features of measles are easily recognized. When the diagnosis is in doubt, viral isolation from mucosa or the nasopharynx, although difficult, will distinguish measles from other morbilliform exanthems. Acute and convalescent sera, obtained at 1 week and 3 weeks after the onset of the illness, showing a fourfold rise in immunoglobulin G antibodies assist with a retrospective diagnosis.¹⁶ Laboratory diagnosis can be accomplished by serologic assays, including complement fixation, hemagglutination-inhibition (HAI) titer, direct immunofluorescence, and enzyme-linked immunosorbent assay (ELISA).¹⁷ Leukocytosis is common.

Management

No specific treatment is available, only supportive therapy in most cases. Using two doses of vitamin A (200,000 IU) on consecutive days is associated with a reduction in the risk of mortality in children under the age of 2 years as well as a reduction in the risk of pneumonia-specific mortality.¹⁸ Those with suspected vitamin A deficiency should have a second dose on the following day and at 4 weeks. Others who should receive vitamin A include immunosuppressed or malnourished patients or those with impaired intestinal absorption, or patients recently emigrated from an area with high mortality due to measles. Vitamin A reduces mortality in hospitalized children up to 60%.¹⁹ If bacterial pneumonia or otitis media occurs, appropriate antibiotics are indicated. Children with significant pulmonary symptoms or central nervous system (CNS) involvement should be hospitalized.

In areas where other patients are not immunized against measles, any patient with measles should be isolated during the contagious period, from onset of respiratory symptoms through the fourth day of the exanthem. Postexposure prophylaxis in susceptible individuals includes measles vaccine, if given within 72 hours of exposure, and immune globulin (0.25 ml/kg intramuscularly [IM]), which can be given up to 6 days following exposure to prevent disease or modify its course. Immune serum globulin should be administered to unimmunized infants less than 1 year of age or to those who are immunosuppressed at a dose of 0.5 ml/kg IM (maximum 15 ml) as soon as possible after exposure. Outbreaks should be reported to local public health authorities. Measles virus is susceptible in vitro to ribavirin, which has been given to patients with severe infection and immunocompromised children. Close follow-up should be arranged to observe for the development of severe pneumonia or encephalitis. Parents should be advised to return immediately if there is fever recurrence, headache, or a change in mental status, or if seizures or motor deficits develop.

Rubella (German Measles, Third Disease)

Rubella is a viral illness characterized by a maculopapular rash and enlargement of the posterior occipitocervical lymph nodes. Rubella is caused by an RNA virus, *Rubivirus*, that is transmitted by contact with aerosolized particles from an infected person. It can also be transmitted transplacentally. Rubella occurs most commonly in late winter and early spring, and the incubation period ranges from 14 to 21 days. The patient is contagious a few days before illness and up to 1 week after the onset of the rash. The primary site of infection is the nasopharynx, followed by spread to regional lymphatics and eventually viremia. Virus replicates in the reticuloendothelial system. The rash appears as the serum antibody titer is rising, suggesting a potential contribution of antigen-antibody interactions in the skin.

Clinical Presentation

Classic rubella is a mild illness in most children and usually not diagnosed unless an epidemic exists.²⁰ Rubella acquired postnatally in infants and children is accompanied by few or no prodromal symptoms, and up to 50% of rubella infections may be asymptomatic.^{20,21} In children with clinical symptoms (10%), rubella presents insidiously with a mild prodrome of headache, low-grade fever, malaise, sore throat,

FIGURE 123-3. Rose-pink macular and papular eruption in rubella.

anorexia, conjunctivitis, cough, and coryza. These are more common in adolescents or adults.^{20,21} Mild lymphadenopathy may precede the exanthem by several days and occurs in the occipital, posterior auricular, and posterior cervical lymph nodes. An exanthem characterized by erythematous and petechial macules on the soft palate (Forschheimer spots) may be present.

The rash occurs 1 to 5 days after onset of illness. A faint rose-pink, macular or papular eruption appears first on the face and spreads downward to the trunk and proximal extremities (Fig. 123-3). Within 48 hours, the face and trunk rash has faded and the eruption involves the distal extremities. Rarely, petechiae or purpura may be seen. In cases of extensive eruption, a fine, flaky desquamation may occur. The eruption is usually completely resolved by the third day (“3-day measles”), but occasionally may last 5 days. As opposed to measles, the child appears well.

A monoarticular arthritis or arthralgia may accompany rubella, especially in adolescent girls.^{20,21} The fingers, wrists, and knees are most often affected, and symptoms resolve by 1 month. Occasionally the elbows, shoulders, and spine are involved. It may present as the so-called STAR (sore throat, arthritis, rash) complex.²² Other viruses associated with the STAR complex include human parvovirus B19, hepatitis B, adenovirus, echovirus, coxsackievirus, and Epstein-Barr virus. Other less common complications include encephalitis, myocarditis, pericarditis, hemolytic anemia, thrombocytopenic purpura, and hepatitis.

In distinguishing rubella from measles, the clinician should look for the absence of fever and toxicity. It may be difficult to distinguish rubella from enterovirus exanthems, infectious mononucleosis, cytomegalovirus, reovirus,

adenovirus, measles, scarlet fever, roseola infantum, parvovirus B19, syphilis, toxoplasmosis, or mild drug reactions.²³ The diagnosis may be made from recovery of the organism from the nasal mucosa, blood, urine, or cerebrospinal fluid, but such tests are superfluous in most cases. Serologic diagnosis can be performed with the HAI titer, latex agglutination, direct immunofluorescence, ELISA, and passive HAI antibody test or by serologic acute and convalescent titers.¹⁷ In infants with congenital rubella, the virus may be recovered from peripheral blood leukocytes, stool, or urine for months to years after birth. Leukopenia is common.

Rubella acquired during the first trimester of pregnancy may result in intrauterine transmission, and congenital rubella is seen 10% to 20% of cases.²³⁻²⁵ The earlier in the pregnancy that the transmission occurs, the greater the risk to the fetus. The skin manifestations include purpura and petechiae from thrombocytopenia, and may recur any time during the first 5 years of life. Other features include sensorineural hearing loss, congenital heart defects (i.e., patent ductus arteriosus, pulmonary stenosis), cataract, retinopathy, glaucoma, pigmentary retinopathy, growth retardation, behavioral disorders, meningoencephalitis, pneumonia, intrauterine growth retardation (IUGR), psychomotor retardation, hepatosplenomegaly, hepatitis with jaundice, and “blueberry muffin” spots.^{20,23-25}

Management

There is no specific treatment for rubella. If the patient is febrile, fever control measures will suffice. Oatmeal baths and antihistamines are helpful for pruritus. Nonsteroidal anti-inflammatory agents may be prescribed for arthritis. Administration of the rubella vaccine after exposure has not been demonstrated to ameliorate illness.

When a pregnant woman is exposed to rubella, a serum specimen should be obtained and tested for rubella antibody. If antibody is present, there is no risk of infection. If no rubella antibody is detectable, a second blood specimen should be obtained 2 or 3 weeks later. If antibody is present in the second specimen and not the first, infection is presumed to have occurred, and termination of pregnancy may be considered. If termination of pregnancy is not an option, serum immune globulin (0.55 ml/kg IM) should be given.

Roseola Infantum (Exanthem Subitum, Sixth Disease)

Roseola occurs predominantly in infants 6 months to 3 years of age, with a peak age of 6 to 7 months.²⁶⁻²⁹ It is characterized by 2 to 3 days of sustained fever in an infant who otherwise appears well, after which the infant becomes afebrile and a pink, morbilliform exanthem appears transiently and fades within a few days. Roseola is caused by human herpesvirus 6 (HHV-6), a double-stranded DNA virus, and occasionally by human herpesvirus 7 (HHV-7).^{30,31} It can occur at any time of the year, but is more common in the spring.³² The incubation period is 5 to 15 days. Transmission is airborne and from contact with infected respiratory droplets and, rarely, transplacentally.³³

Clinical Presentation

The illness begins with high fever that lasts 3 to 7 days, cough, and otitis media, but patients appear well.^{26,27,34} Mild edema of the eyelids and posterior cervical lymphadenopathy

FIGURE 123-4. Rose-pink macules and papules in roseola infantum.

are occasionally seen. A seizure with the onset of fever is noted in 25% to 36% of cases.^{27,29,35} A bulging fontanelle is also a common physical finding. An enanthem of erythematous papules on the mucosa of the soft palate and uvula (Nagayama's spots) may be seen in 65% of cases.³²

The rash of roseola usually coincides with cessation of fever, or may follow it by 1 to 2 days. It is characterized by rose-pink macules and papules, and occurs predominantly on the neck and trunk, but occasionally involves the face and proximal extremities (Fig. 123-4). The eruption fades over a few days, rarely persisting for up to a week. Differential diagnosis may include other viruses (Table 123-2).

HHV-6 can be recovered from cultures of peripheral blood leukocytes, by serology with a fourfold increase in HHV-6 immunoglobulin G antibodies, by antigen detection by polymerase chain reaction (PCR) or immunofluorescence studies, or from skin lesions by molecular diagnosis.³⁴ Leukopenia with relative lymphocytosis develops on day 3 of illness.

Complications are uncommon and include seizures, hyperpyrexia, vomiting, diarrhea, cough, fulminant hepatitis, thrombocytopenia, disseminated infection, and hepatosplenomegaly. Rarely encephalitis or encephalopathy occurs.³⁶

Management

There is no specific treatment for roseola. Antipyretics can be used for fever. Patients with severe disease or immunocompromised hosts may benefit from administration of ganciclovir, foscarnet, or cidofovir.^{37,38} If an infant presents with a febrile seizure and the appropriate diagnostic studies reveal no source, it is prudent to inform parents that the child may have the roseola exanthem after the fever subsides.

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum (fifth disease) is a viral infection caused by human parvovirus B19, which causes an intense,

Table 123–2 Differential Diagnosis of Roseola Infantum

 Epstein-Barr virus
 Adenovirus
 Cytomegalovirus
 Parvovirus B19
 Rubella
 Measles
 Parainfluenza virus

confluent erythema on both cheeks, followed by a lacy rash on the rest of the body.³⁹ Human parvovirus B19, a single-stranded DNA virus, has been isolated within the skin lesions of patients with erythema infectiosum.³⁹ The organism replicates in erythroid bone marrow cells, accounting for its role in red-cell aplasia of immunodeficient patients or those with chronic hemolytic anemia.⁴⁰ It occurs more frequently in winter and spring. It can present at any age but is most common in children 4 to 10 years of age.⁴¹ Transmission is via respiratory droplets or blood products, or vertically from mother to fetus. The incubation period is 6 to 14 days but can be as long as 21 days, and patients are contagious prior to the start of the eruption and up to 7 days posteruption.

Clinical Presentation

In most patients the first reported manifestation is the characteristic rash. Prodromal symptoms may occasionally occur, and include low-grade fever, coryza, headache, sore throat, chills, nausea, myalgias, and malaise. The exanthem of erythema infectiosum is divided into three stages. Initially a bright, fiery red macular erythema appears on the cheeks (“slapped-cheek” or “sunburned” appearance) (Fig. 123–5). It is often associated with a rim of sparing around the nose and mouth (“circumoral pallor”). The second stage occurs 1 to 4 days later when the rash may spread to involve the arms, legs, chest, and abdomen. It consists of a pink to dull red macular eruption. Fading of the central portion gives a lacy, reticulate pattern. Pruritus is unusual.⁴² The third stage varies in duration from 1 week to several weeks and is characterized by waxing and waning intensity of the eruption. The exanthem generally lasts from 3 to 5 days, but may last up to 4 months.^{39,40} The rash increases in intensity from vigorous exercise, overheating of the skin, sun exposure, or crying. Occasionally, morbilliform, vesicular, or purpuric skin eruptions are seen. A purpuric hand and foot eruption (purpuric gloves-and-socks syndrome) may develop.^{39,43} The differential diagnosis may include drug reactions, other viral entities, and collagen vascular diseases (Table 123–3).

Diagnosis can be confirmed by analysis of serum obtained within 30 days of the onset of illness for the presence of immunoglobulin M B19 antibodies via ELISA or radioimmunoassay.⁴⁴ For immunocompromised hosts with chronic infection, nucleic acid hybridization or PCR assays are recommended.⁴⁵

Symmetric arthritis of the hands, wrists, or knees has been described, especially in adolescent and adult females.^{22,40,46} The STAR complex is caused by parvovirus B19 as often as by rubella.²² Joint symptoms usually resolve by 1 to 2 months. Joint involvement worsens over the day.

**FIGURE 123–5.** Slapped-cheek appearance of erythema infectiosum.**Table 123–3** Differential Diagnosis of Erythema Infectiosum

Differential Diagnosis	Causes
Viruses	Echovirus Rubella Epstein-Barr virus Measles Coxsackievirus Dengue Hepatitis
Bacteria	Scarlet fever
Drug eruption	
Collagen vascular disease	Polyarteritis nodosa Lupus erythematosus Juvenile rheumatoid arthritis

Unusual complications may include encephalopathy, aseptic meningitis, neuropathy, cerebellar ataxia, seizures, myocarditis, and hepatitis.⁴⁷ In children with acquired or hereditary hemolytic anemias or any condition that results in red blood cell destruction (i.e., hereditary spherocytosis, sickle cell disease, glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency) or decreased red blood cell production (i.e., iron deficiency anemia or thalassemia), parvovirus B19 is associated with a poorer prognosis and results in transient aplastic crisis.^{40,48} It can occur under conditions of erythroid stress, such as during hemorrhage, during a state of iron deficiency anemia, and following kidney or bone marrow transplant. These episodes are accompanied by symptoms of anemia, such as dyspnea, lassitude, and confusion, and can last 10 to 15 days. Rarely congestive heart failure develops, which can be fatal.

In immunocompromised patients, such as those with human immunodeficiency virus infection, congenital immunodeficiencies, acute leukemia, organ transplants, or systemic lupus erythematosus, or in infants less than 1 year old, parvovirus B19 can cause a serious, prolonged chronic anemia due to persistent lysis of red blood cell precursors and bone marrow suppression. In pregnant women, parvovirus B19 infection may result in fetal anemia, high-output cardiac failure,

pleural effusions, polyhydramnios, nonimmune hydrops fetalis, and fetal demise.⁴⁸⁻⁵⁰ Fetal loss occurs in 8% to 10% of pregnancies complicated by parvovirus and is highest if infection is acquired prior to 20 weeks' gestation.^{51,52}

Management

There is no specific treatment for erythema infectiosum. Isolation for 2 weeks of patients at risk for complications, such as pregnant women, immunosuppressed patients, or patients with chronic hemolytic anemia, is recommended. Administration of intravenous (IV) immune globulins may be used in these high-risk groups,⁵³ leading to a marked increase in reticulocyte counts and corresponding rise in hemoglobin. Blood transfusions may be required. Those with arthritis symptoms may gain relief with nonsteroidal anti-inflammatory drugs.

The risk of exposure should be explained to pregnant females, and serologic testing offered. If acute infection is confirmed, serial fetal ultrasonography should be performed, assessing for congestive heart failure, IUGR, or fetal hydrops. Management of severely affected fetuses has included in utero blood transfusion.

Herpes Simplex (Human Herpesvirus 1 and 2 Infections)

Grouped vesicles on an erythematous base are the characteristic lesions of herpes simplex virus (HSV) in the skin, regardless of location.⁵⁴ On mucous membranes, the blister roof is easily shed and an erosion is seen. The infection may be primary or recurrent.⁵⁴ Initial infection is termed *primary* if it occurs in a host with no prior HSV infection or *recurrent* in a host previously infected with HSV. Recurrent infections represent reactivation of latent herpesvirus.

Human herpesvirus 1 (HHV-1, or herpes simplex virus 1 [HSV-1]) and human herpesvirus 2 (HHV-2, or herpes simplex virus 2 [HSV-2]) are double-stranded DNA viruses. They are epidermotropic, and productive viral infection occurs within keratinocytes. Initial infection is characterized by viral replication at the initial site of contact, such as skin, mucous membranes, or eyes. The virus then travels along the regional nerves to the ganglia and establishes a latent infection, where it remains for life. The incubation period ranges from 2 days to 2 weeks. Transmission in neonates is during birth through contact with an infected maternal genital tract, or by direct contact with infected oral secretions or lesions.

Clinical Presentation

After initial exposure, HSV may persist in nerve ganglia and be reactivated by a number of factors, including fever, emotional disturbances, ultraviolet light, menses, and trauma.^{54,55} Once recurrent skin involvement appears, the disease is contagious and can be transmitted to other areas of the skin or to other persons. Sites of involvement vary, but the most common are the lips, eyes, cheeks, and hands.^{54,55} Regional lymphadenopathy may occur in all forms of herpes simplex. Distinct clinical features of the various types are listed in Table 123-4 and shown in Figures 123-6 through 123-9.

Herpes virus may be recovered from vesicles during the first 24 hours after their appearance. Other locations for recovery include conjunctivae, nasopharynx, rectum, urine, cerebrospinal fluid, and blood.⁵⁶ A Tzanck preparation (scraping from an intact blister treated with Geimsa or

FIGURE 123-6. Herpetic gingivostomatitis: vesicular lesions on the lips and oral mucosa from herpes simplex virus.

FIGURE 123-7. Herpes labialis: grouped vesicles on the lips.

Wright stain) will show the characteristic epidermal giant cells. Rapid diagnostic tests using direct fluorescent antibody or dye-labeled monoclonal antibodies are 90% accurate.⁵⁷ Some institutions may perform a PCR for detection of HSV DNA, especially in the setting of CNS infection.⁵⁸

Many other viruses and diseases should be considered in the differential diagnosis of herpes simplex (Table 123-5).

The most common complication is secondary bacterial superinfection. Immunosuppressed patients or pregnant patients may have disseminated disease involving multiple organs, including the liver, lung, brain, heart, and adrenal glands. It presents as a sepsis-like syndrome with jaundice, progressive hepatosplenomegaly, hepatitis, poor feeding, dyspnea, pneumonia, adrenal necrosis, hypothermia, seizures, encephalitis, evidence of disseminated intravascular coagulopathy, and death, which may occur in 48 to 96 hours.

Management

Oral acyclovir, famciclovir, valcyclovir, or penciclovir, foscarnet, or cidofovir are specific therapies for localized cutaneous herpes simple infections⁵⁴ (Table 123-6). Antiviral

Table 123–4 Clinical Features of Herpes Simplex Virus (HSV) Disease in Children

Forms of HSV	Clinical Features
Herpes Gingivostomatitis (caused by HSV-1)	<p>Most frequent clinical presentation of primary HSV infection in children (6 mo–5 yr)</p> <p>Transmitted by infectious saliva</p> <p>Incubation: 2–12 days</p> <p>Primary form: fever, irritability, malaise, refusal to eat or drink</p> <p>Vesicular lesions on tongue, buccal mucosa, gingiva, and palate (Fig. 123–6) become eroded and ulcerated, appearing as 1- to 3-mm shallow gray ulcers on a red base; gums become mildly swollen, red, ulcerated, exudative, and friable.</p> <p>Tender submandibular and cervical lymphadenopathy are common.</p> <p>Dehydration is the most common complication.⁸³</p> <p>Acute disease lasts 3–7 days but may persist up to 3 wk.</p>
Herpes Pharyngotonsillitis Herpes Labialis (Fig. 123–7)	<p>Fever, malaise, odynophagia, and headache</p> <p>Vesiculoulcerative lesions develop on tonsils and pharynx.</p> <p>Recurrent infection of the lip</p> <p>Occurs in up to 20% of infants and children⁵⁴</p> <p>Prodrome of pain, tingling, or itching</p> <p>Grouped vesicles on one portion of the lip, usually lower, typically follow an acute febrile illness or intense sun exposure.</p> <p>Lesions last up to 8 days.</p>
Herpes Keratitis (Fig. 123–8)	<p>Corneal involvement in <10% (must be ruled out in presence of any lesion around the eye)</p> <p>May lead to corneal scarring and permanent loss of vision</p> <p>Usually remains unilateral</p> <p>Blepharitis, conjunctivitis, superficial or deep keratitis, and anterior uveitis may occur.</p> <p>Pain, blurred vision, eyelid swelling, and itching</p> <p>May produce severe purulent conjunctivitis (edema, erythema, and vesicles with opacity and superficial erosion or ulceration of the cornea); dendritic ulcers may be seen.</p> <p>Ophthalmologic consultation is mandatory.</p> <p>Most lesions heal within 2 wk without residual damage.</p>
Herpetic Whitlow (Fig. 123–9)	<p>Occurs in 10% of patients with predilection for thumb sucking</p> <p>Inoculated into the skin</p> <p>Superficial vesiculopustules or extremely painful deep vesicular, bullous, or pustular eruption</p> <p>Often initially considered pyoderma or cellulitis</p> <p>Accompanied by regional lymphadenopathy</p>
Herpes Facialis	<p>Recurrent infection of grouped vesicles on the cheek or forehead</p> <p>May be confused with impetigo</p> <p>Acquired during wrestling (herpes gladiatorum)</p> <p>May result in endemic spread of HSV, with lesions more commonly on the head, neck, and shoulders⁸⁴</p>
Herpes Progenitalis (HSV-2)	<p>Predominantly in adolescents and young adults⁵⁴</p> <p>Appears 2–8 days following contact with infected individual</p> <p>Prodrome of fever, malaise, myalgias, and headaches</p> <p>Involves penile shaft and, less frequently, the glans, urethra, or scrotum. Single or multiple painful vesicles (2–4 mm) are transformed to painful shallow ulcers covered with exudates; these coalesce to form large ulcerations.</p> <p>Severe genital edema, ulceration, and pain</p> <p>Exclude gonococcal or chlamydial infection in presence of exudate.</p> <p>Recurrent case presents with a painful prodrome followed by eruption of grouped vesicles on an erythematous base in a localized area of genitalia.</p> <p>Contagious and sexually transmitted (in young children should raise question of abuse)</p> <p>Fever and symptoms last 5–7 days; lesions resolve in 10–14 days.</p>
Herpes Vulvovaginitis	<p>Severe pain associated with vulvovaginitis, urethritis, cervicitis, and cystitis</p> <p>Produces vesicles that coalesce to form large, painful ulcerations with edema of the genitalia</p>
Herpes Encephalitis	<p>From primary or recurrent infection</p> <p>Associated with fever, alteration in consciousness, personality changes, seizures, and focal neurologic findings</p>
Neonatal Herpes	<p>Fulminant course leading to coma and death in untreated patients</p> <p>Occurs in 10% of infants born to parents with active HSV-2 infection⁸⁵</p> <p>Two thirds of cases caused by HSV-2, rest by HSV-1</p> <p>Grouped vesicles on an erythematous base may be present at birth or appear up to 7 days after birth.</p> <p>In severe cases, central nervous system involvement or dissemination may occur.^{86,87}</p> <p>Can be localized to skin, eyes, and mouth (SEM disease)</p> <p>Oral mucous membrane involvement may manifest as vesicles, erosions, or ulcers and ocular involvement with conjunctivitis or keratitis.⁸⁸</p> <p>If untreated, can lead to progression of more severe disease</p> <p>Neonates present with focal encephalitis or meningoencephalitis or nonspecific fever, decreased sensorium, irritability, poor feeding, seizures, bulging fontanelle, and lethargy or coma.⁵⁶ Skin manifestations are usually absent or develop late. Consider in differential of sepsis, especially with negative cultures and/or liver dysfunction.</p> <p>Cerebrospinal fluid shows lymphocytic pleocytosis.</p>

agents given within 72 hours of the onset of the rash decrease severity or duration of the infection and are associated with less feeding difficulty and shorter duration of viral shedding. However, famciclovir, valacyclovir, foscarnet, and cidofovir are not approved for use in children.

In neonatal HSV, IV acyclovir is efficacious. The dose for preterm infants of 34 to 36 weeks' gestation is 10 mg/kg per dose IV every 8 hours, and that for premature infants less

Table 123-6 Antiviral Agents for Herpes Simplex Virus

Agents	Doses
Acyclovir	200 mg 5 times per day for 7 days 30–80 mg/kg divided q8h IV
Valacyclovir (>12 yr)	1000 mg PO 1–2 times per day for 7–10 days

Abbreviations: IV, intravenously; PO, orally.

than 34 weeks' gestation, 10 mg/kg per dose IV every 12 hours. The dose for term infants is 20 mg/kg per dose IV every 8 hours for 14 days. For infants with encephalitis or disseminated HSV, recommended treatment is up to 21 days. Although most neonates with encephalitis survive, most have substantial neurologic sequelae. Approximately 25% of neonates with disseminated disease die despite treatment. Supportive measures, such as fever control, maintenance of fluid and electrolyte balance, and thermal regulation, should be instituted immediately. Infected patients must be isolated as they shed virus. Pain relief should be provided for gingivostomatitis with acetaminophen and an analgesic mouth wash (equal parts of aluminum hydroxide and diphenhydramine plus viscous xylocaine added when age appropriate, but this should be done with extreme caution since as little as 1–2 ml may be toxic in young children), which is applied with a cotton swab onto lesions or, in older children, rinsed and expectorated. Patients should avoid citrus fruits and spicy or hot liquids.

Careful daily ophthalmologic follow-up is required for ocular keratitis. Corticosteroid therapy, either topical or systemic, should be avoided. Topical corticosteroids may be required after several days of antiviral therapy in patients with marginal ulcers or associated stromal disease, but these agents should be given only in consultation with an ophthalmologist. Antiviral agents may include trifluridine (1%) drops, vidarabine (3%) ointment, 0.1% iododeoxyuridine, or acyclovir ophthalmic ointment. In severe cases, oral or IV acyclovir or vidarabine and a cycloplegic may be required.⁵⁹ Disseminated infections require hospitalization and intensive supportive therapy.

Treatment of genital herpes consists of warm sitz baths, topical anesthetics, oral analgesics, wet compresses with aluminum acetate (Burow's solution), and topical antibacterial ointment to prevent secondary infection. For severe cases, oral acyclovir can accelerate healing and shorten duration of symptoms and viral shedding.⁶⁰ The majority of children with HSV require supportive care, and follow-up is indicated in cases in which the lesions persist or in patients who are hospitalized with severe disease.

Varicella-Zoster Virus (Human Herpesvirus 3 Infections)

Varicella-zoster virus (VZV) or human herpesvirus 3 (HHV-3) is a double-stranded DNA virus producing an abrupt onset of crops of grouped vesicles.^{61,62} It is highly contagious, with an incubation period of 14 to 16 days (range 10 to 21 days)²⁶ and occurs primarily in children from 2 to 8 years old, with 90% of cases occurring before the age of 14 years. It is most prevalent in late winter and early spring. The disease is spread through person-to-person contact and airborne spread, and occurs from 1 to 2 days before the onset of rash to 5 to 6 days

after onset or when lesions have crusted.⁶² Transplacental infection may also occur.

HHV-3 enters via the respiratory route and replicates in the lymph nodes. Viremia follows with entry into reticulo-endothelial cells. A second viremia results in spread into the skin and organs. In keratinocytes, HHV-3 produces ballooning degeneration of cells and an interepidermal blister. Primary infection is known as chickenpox. After an initial varicella infection, the VZV remains dormant in cells of the dorsal root ganglia or cranial nerve ganglia until reactivation. Subsequent propagation of the virus along the nerve to the skin gives rise to grouped vesicles. The reactivation stage is known as herpes zoster or shingles.^{61,62} Reactivation may result from reexposure to varicella, physical trauma to the spinal column, radiation therapy, immunosuppressant drugs, cancer, leukemia, or Hodgkin's lymphoma.

Clinical Presentation

A prodrome consists of low-grade fever, malaise, headache, anorexia, cough, coryza, and sore throat. In normal children, systemic symptoms are mild and serious complications are rare. In immunocompromised patients, the disorder is more likely to be characterized by an extensive eruption that is often hemorrhagic, severe constitutional symptoms, and occasionally pneumonia and death.⁶³

Individual lesions begin as faint erythematous macules that progress to edematous papules and then to delicate vesicles (“dewdrop on a rose petal”) within 24 to 48 hours (Figs. 123–10 and 123–11). The exanthem usually begins on the scalp, face, and trunk and less commonly on the extremities. Intense pruritus commonly accompanies the vesicular stage of the rash. The vesicles develop moist crusts that dry and are shed, leaving a shallow erosion. Successive crops of lesions appear during the next 2 to 5 days, so that at any one time several stages of skin lesions can be seen concomitantly. The lesions spread centripetally. Lesions frequently involve mucous membranes, and isolated erosions may be seen in the conjunctiva, oral mucosa, or nasal cavity and occasionally in the vagina.⁶² Lesions may vary from as few as 10 to greater than 100. The lesions disappear in 7 to 10 days and usually heal without scarring. In patients with thrombocytopenia, lesions may appear hemorrhagic.⁶⁴

While smallpox has been eradicated, there is still concern regarding its use as a biological terrorism agent. In contrast to varicella, it causes a vesicular rash that evolves at the same rate for all lesions as opposed to the successive crops that occur with chickenpox.

Herpes zoster in prepubertal children is usually mild. Neuralgia, common in the elderly, is rarely seen in children and occasionally occurs in adolescents. Maternal varicella infection during pregnancy and varicella occurring in the newborn period represent risk factors for childhood herpes zoster. Malaise, headache, and fever may precede the rash, especially in young children. Herpes zoster is a unilateral eruption that involves one to three dermatomes, most commonly the thoracic and the ophthalmic branch of the trigeminal nerve (Fig. 123–12). Infection of the ophthalmic branch of the Vth cranial (trigeminal) nerve may involve the cornea with keratitis and uveitis and lead to permanent damage (zoster ophthalmicus). It is suspected when the nasociliary branch is involved and, accordingly, is present in those who have cutaneous involvement of the nose

FIGURE 123–10. Papules, vesicles, and pustules seen in varicella-zoster virus infection.

(Hutchinson's sign). Involvement of the geniculate ganglion results in pain in the ear with vesicles on the pinnae, tongue, ear, and skin of the auditory canal. When accompanied by facial palsy and disturbances of hearing and equilibrium, it is part of the Ramsay Hunt syndrome (Fig. 123–13).

In herpes zoster, grouped lesions appear within several adjacent dermatomes. They begin as macules and edematous papules and progress to vesicles on an erythematous base. Intense pruritus occurs during the vesicular stage. As the eruption resolves, vesicles open up, become crusted, and slowly heal. The eruption tends to appear first at a point nearest the CNS and extends peripherally along the course of the nerve, thus producing the characteristic bandlike distribution of lesions. Generally the eruption is unilateral, but it may cross the midline and, at times, may involve the contralateral side. Successive crops continue to appear from 5 to 7 days. They resolve by crusting over in the course of another 7 to 10 days, and occasionally up to 3 weeks. In children, rarely dermatomal pain may precede the eruption.

Typical varicella is seldom confused with other illnesses, but some viruses may mimic the lesions (Table 123–7).

HHV-3 may be recovered from the vesicles during the first 72 hours after the onset of the eruption. A Tzanck

preparation (scraping from an intact blister treated with Geimsa or Wright stain) will show the characteristic epidermal multinucleated giant cells containing intranuclear viral inclusions. Direct fluorescent antibody examination using a swab specimen taken from the base of a freshly opened lesion can distinguish HSV from HZV. Other laboratory tests include fluorescent antibody to membrane antigen, neutralization test, latex agglutination, ELISA, and demonstration of VZV DNA from vesicular fluid with PCR; identification of viral particles by direct electron microscopy; and serologic studies of acute and convalescent sera for VZV antibody.⁶⁵ Laboratory abnormalities usually show leukocytosis and elevated hepatic transaminases.

Secondary bacterial infection of varicella skin lesions is common.⁶⁶ It is generally caused by *Staphylococcus aureus* or group A β -hemolytic streptococci. The presence of fever after 4 or 5 days of illness or unusually indurated skin lesion should alert the clinician to the possibility of cellulitis. Life-threatening toxic shock syndrome, gangrenous cellulitis, and necrotizing fasciitis have all been described.⁶⁷ Data suggest that the use of ibuprofen may be associated with necrotizing fasciitis.⁶⁸ Pneumonia may complicate varicella, especially in adolescents. Other complications include otitis media, Reye's syndrome, acute postinfectious cerebellar ataxia, encephalitis, aseptic meningitis, transverse myelitis, Guillain-Barré syndrome, arthritis, nephritis, carditis, myositis, appendicitis, orchitis, nephritis, hepatitis, purpura fulminans, and thrombocytopenia.^{69,70}

In immunocompromised patients or those with Hodgkin's lymphoma or leukemia, hematogenous spread of herpes zoster occurs 1 to 5 days after the dermatome infection begins.⁷¹ This results in a generalized eruption. Most children recover without sequelae, but visceral involvement can occur. Some may have severe disease with high fever, encephalitis, pneumonia, hepatitis, or disseminated intravascular coagulation.⁶² Congenital varicella syndrome occurs in 2% of infants in whom exposure to varicella occurred during the first or second trimester. It consists of IUGR, microcephaly, cortical atrophy, limb hypoplasia, microphthalmia, cataracts, micrognathia, chorioretinitis, and cutaneous scarring.⁷²

Management

Healthy children with varicella do not require specific therapy. Treatment is supportive and aimed at decreasing pruritus and minimizing the risk of secondary infection. Wet dressing, soothing baths, and calamine lotion with oral antihistamines will provide symptomatic relief of pruritus.⁷³ Topical antihistamines containing diphenhydramine have the potential to cause sensitization and should probably be avoided. Acetaminophen can be used to control fever or pain; salicylates should be avoided due to the associated risk of

Reye's syndrome. Secondary bacterial infection is treated with antistaphylococcal drugs such as cephalexin, amoxicillin/clavulanate, or dicloxacillin. In penicillin-allergic patients, azithromycin, clarithromycin, or clindamycin can be used.

In immunocompetent hosts, most viral replication stops 72 hours after the onset of the eruption; however, it is extended in immunocompromised hosts. Oral acyclovir is not recommended for routine use in otherwise healthy children with varicella. Systemic antiviral agents, such as acyclovir and vidarabine, have been used with success in children.⁷⁴⁻⁷⁶ If given within the first 24 hours of the exanthema, they can shorten the duration and magnitude of fever, accelerate healing time, and decrease the number of skin lesions. Since VZV is less sensitive to acyclovir than HSV, levels of acyclovir two to eight times greater are required. Oral acyclovir should be considered for patients at increased risk for moderate to severe varicella, such as those less than 6 months old or greater than 12 years old, those with chronic cutaneous or pulmonary disease, those on long-term salicylate therapy or corticosteroids, immunocompromised children, and children with ophthalmic involvement, Ramsay Hunt syndrome, disseminated zoster, and possible pregnancy. Children on corticosteroids or other immunosuppressive agents and exposed to varicella should have the dosages of these drugs reduced or discontinued whenever possible.

Passive immunization with varicella-zoster hyperimmune globulin has been shown to modify or prevent illness in high-risk individuals if given with 48 to 72 hours of exposure.^{73,74} It is recommended for patients with immunodeficiencies, leukemia, or lymphoma, and in those receiving chemotherapy or other immunosuppressive agents, with seronegative pregnancy, or with disseminated disease. It is indicated for newborns whose mothers have developed primary varicella within 5 days before or 2 days after delivery and in neonates who develop varicella by the 10th day of life, as they are at increased risk of disseminated, fulminant infection.

In the rare case of postherpetic neuralgia, treatment consists solely of analgesics. Analgesics used primarily in adults have included tricyclic antidepressants, gabapentin, lidocaine patch, opioids, and capsaicin, but none of these has been studied for use in children.⁷⁷

All patients with complications such as fasciitis, Reye's syndrome, pneumonia, or encephalitis should be hospitalized. The highly contagious nature of the infection should be emphasized, and child should be isolated until the lesions are crusted, which usually occurs 5 to 7 days after the eruption occurs. A follow-up visit within 48 hours should be scheduled for children who are discharged home from the emergency department to assess for any development of secondary bacterial infection. Children with disseminated zoster, ophthalmic zoster, or Ramsay Hunt syndrome should be seen daily until symptoms resolve.

Coxsackievirus (Hand-Foot-and-Mouth Disease)

Abrupt onset of scattered papules that progress to oval or linear vesicles in an acral distribution with oral involvement suggests hand-foot-and-mouth disease. The epidemic form is almost always caused by coxsackievirus A16 or enterovirus 71, but coxsackieviruses A2, A4 through A7, A9, A10, B1 through B3, and B5 have also been isolated.⁷⁸ The incubation period is 3 to 6 days, and patients are highly contagious from 2 days before to 2 days after onset of the eruption, with viral

excretion in feces persisting for 2 weeks. Coxsackievirus is transmitted transplacentally, by direct contact with nasal or oral secretions, through fecal material, or in aerosolized droplets. It is more prevalent during late summer or early fall. The virus enters the buccal or ileal mucosa and spreads to the lymph nodes. Viremia ensues with spread to the oral mucosa and skin. By day 7 after infection, serum antibody levels increase, and the virus disappears.

Clinical Presentation

A brief prodrome may occur, characterized by low-grade fever, anorexia, abdominal pain, cough, mouth soreness, and malaise, followed by the appearance of the enanthem and exanthem. The enanthem is the most characteristic finding and begins as small red macules that evolve into small vesicles, 1 to 3 mm to 2 cm in diameter, that rapidly rupture to leave behind erosions and ulcers superimposed on an erythematous base. They occur over the buccal mucosa and tongue as well as the palate, uvula, gingiva, and anterior tonsillar pillars (Fig. 123-14). These lesions are painful, and children refuse to eat or drink; therefore, dehydration is a common sequela.

The exanthem is maculopapular at first, then evolves into gray-white vesiculopustules ranging from 3 to 7 mm in diameter, with variable amounts of associated erythema. They are thin walled and contain a clear fluid, sometimes coalesce to form bullae, and are occasionally tender or pruritic. Lesions are usually elliptical or football shaped and surrounded by a red areola, and are found most commonly on the palms and soles, less often on the dorsal or lateral surfaces of the hands and feet, and occasionally on the buttocks and perineum (Fig. 123-15). Lesions clear within 2 to 7 days. Children with coxsackievirus infection are generally not ill appearing. Other findings include occasional lymphadenopathy in submandibular and cervical regions.

In the early nonvesicular stage, rubella and other morbilliform lesions must be considered, and in the vesicular stage the disease can be mistaken for varicella. The enanthem may be mistaken for several other entities (Table 123-8).

Occasionally coxsackievirus infections may cause myocarditis, pneumonia, meningoencephalitis, and aseptic meningitis.^{79,80} In addition, there have been reports of fatal cases from enterovirus 71.⁸¹ Infection in the first trimester may lead to spontaneous abortion or IUGR.

Table 123-8 Differential Diagnosis of the Enanthem of Coxsackievirus Infection

Varicella
Aphthous ulcers
Erythema multiforme
Herpes simplex virus
Herpangina

Management

No treatment is necessary in mild cases. Treatment is symptomatic and aimed at providing relief of painful oral lesions with topical agents, such as anesthetic mouth wash. In severe illness with enterovirus 71 infection, immune globulin or the antiviral agent pleconaril may be effective.⁸²

Dermatitis

Antonio E. Muñiz, MD

Key Points

The main treatment for atopic dermatitis is topical corticosteroids.

Diaper dermatitis of longer than 3 days' duration is usually superinfected with *Candida*.

Seborrheic dermatitis responds to tar shampoos and ketoconazole topically and only occasionally requires topical corticosteroids.

Removal of the offending agent responsible for the eruption in contact dermatitis is curative, but symptomatic treatment includes corticosteroids and antihistamines.

Selected Diagnoses

- Atopic dermatitis
- Diaper dermatitis
- Seborrheic dermatitis
- Contact dermatitis

Discussion of Individual Diagnoses

Atopic Dermatitis

Atopic dermatitis (AD) is a chronic, inherited, relapsing skin condition characterized by xerosis, pruritus, inflammation, and lichenification. Associated findings include a family history of AD, asthma, or allergic rhinitis. Eczema (“boiling over”) in the acute setting refers to a morphology of erythema, scaling, vesicles, and crusts. In the chronic state, eczema refers to a morphology of scaling, lichenification, and pigmentary changes (either hypo- or hyperpigmentation). Eczematous lesions are found in conditions other than AD, including seborrheic dermatitis, contact dermatitis, scabies, autosensitization reactions, tinea pedis, immunodeficiencies, nummular eczema, dyshidrotic eczema, and lichen simplex chronicus. Eczema is essentially the morphologic skin finding to a number of different stimuli.

AD occurs during the first year of life in 60% of patients, generally appearing at 2 to 6 months of age. Approximately 70% to 95% develop AD by the age of 5 years. The lifetime prevalence of AD is 5% to 20% in children and 1% to 3% in adults.¹ There are three distinct phases of AD, in which both the location and morphology of the lesions change with age.²⁻⁵ The infantile phase occurs in children up to 2 years of age; the childhood phase from 2 years of age to puberty; and the adult phase from puberty onward. The etiology of AD is still unknown; however, atopic dry skin is characterized by a decrease in skin lipids, an altered water-binding capacity of the stratum corneum, and increased transepidermal water loss with marked skin dehydration.⁶ This impaired barrier function leads to increased skin irritability with subsequent scratching, which leads to the development of the typical lesions of AD. An immunologic etiology also has been suggested because many children with AD have chronic elevation of immunoglobulin E.^{6a}

Clinical Presentation

INFANTILE PHASE

The quintessential feature and morbidity of AD is pruritus from dry skin, which may be unbearable and interferes with daily activity and normal sleep patterns. The eruption begins on the cheeks, forehead, scalp, and lateral aspects of the extensor surfaces of the legs⁶ (Fig. 124-1). The trunk may also be involved (Fig. 124-2). The lesions are symmetric and ill defined, and consist of scaly, erythematous papules, patches, or vesicles that are sometimes covered with areas of crusting and excoriation. It spares the tip of the nose and the perioral and periorbital regions. Generalized xerosis is a prominent feature.

CHILDHOOD PHASE

The flexural areas are the sites of predilection. The antecubital and popliteal fossae are most affected, with the neck, flexural surfaces of the wrists and ankles, and buttock and thigh creases also commonly involved. The lesions are pruritic, ill-defined, scaly, erythematous patches, often covered with crusts and excoriations (Fig. 124-3). The childhood phase is when lichenification (thickening of the skin and accentuated skin markings) is first observed and is most prominent in the antecubital and popliteal fossae and around the wrists (Figs. 124-4 and 124-5). Nummular

FIGURE 124-1. Symmetrical scaly, erythematous papules, patches, and vesicles on the cheeks seen in the infantile phase of atopic dermatitis.

FIGURE 124-2. Symmetrical scaly, erythematous papules, patches, and vesicles on the cheeks and trunk seen in the infantile phase of atopic dermatitis.

FIGURE 124-3. Scaly, erythematous patches covered with crusts and excoriations seen on childhood phase of atopic dermatitis.

(coin-shaped) exudative patches may be seen. The nails maybe shiny and buffed and the eyebrows sparse and broken off from constant rubbing. In dark skin, the lesions are more papular with follicular accentuation and hyperpigmentation.

FIGURE 124-4. Lichenification seen in atopic dermatitis.

FIGURE 124-5. Lichenification seen in atopic dermatitis.

ADULT PHASE

After the child reaches puberty, the lesions are once again located on the face, neck, and body, with a more diffuse distribution with erythema and scaling, but with less exudation. Xerosis and lichenification are prominent features. The face continues to have a typical central pallor.

ASSOCIATED FINDINGS AND DIFFERENTIAL DIAGNOSIS

There are many associated findings with AD⁷⁻¹² (Table 124-1). Children with AD also have a tendency to develop secondary viral and bacterial skin infections. Herpes simplex virus infection is known as eczema herpeticum or Kaposi's varicelliform eruptions¹³ (Fig. 124-6). The child is usually febrile and develops small, grouped vesicular lesions in the area of eczema, which subsequently spreads to normal skin. These vesicles form small erosions that crust over 24 to 48

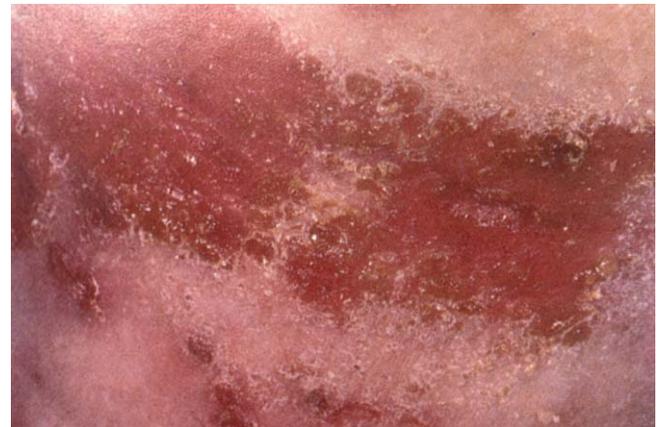

Table 124–1 Associated Findings in Atopic Dermatitis (AD)

Findings	Descriptions
Ichthyosis vulgaris	Extensor surfaces of the extremities are dry, scaly, and hyperkeratotic.
Dennie-Morgan fold	Extra crease line found under the lower eyelid. Originally thought to be pathognomonic for AD, but may be seen with other inflammatory conditions around the eye or in Down syndrome.
Hertoghe's sign	Lateral thinning of eyebrows from rubbing
Allergic shiners	Hyperpigmentation under the eyes caused by chronic edema, lichenification, and postinflammatory hyperpigmentation
"Nasal salute"	Exaggerated linear nasal crease caused by frequent rubbing of the nose
Eye findings	Keratoconjunctivitis, which may occur in a painful form known as vernal conjunctivitis. Other eye findings include cataracts, keratoconus (elongation of corneal surface), and retinal detachment.
Keratosis pilaris	The lesions consist of asymptomatic hyperkeratotic follicular papules ("chicken-skin appearance"). It is found on extensor aspects of upper arms and anterior aspects of the thigh. It begins early in life and improves with age. In young children, the lateral aspects of the cheeks near the hairline are often involved, which may be mistaken for acne.
Pityriasis alba	Slightly scaly and dry hypopigmented patches on the cheeks and upper trunk. The lesions are ill defined and often misdiagnosed as tinea corporis. Mainly seen in children 6–12 years of age, especially in warm weather when the rest of the face is tanned.
Dyshidrotic eczema	The lesions consist of small pruritic, multiloculated vesicles. These rupture, leaving crusts and scales with erythema. It affects the palms, soles, and sides of the fingers and toes and is associated with hyperhidrosis.
Juvenile plantar dermatitis	Scaling, cracking, and painful fissuring on both feet that markedly improves in puberty

**FIGURE 124–6.** Infection with herpes simplex virus (eczema herpeticum) in a child with atopic dermatitis.

hours. Tzanck smears and viral cultures will confirm the diagnosis.

Ninety-three percent of patients with AD have significant *Staphylococcus aureus* colonization of the skin.¹⁴ On occasion impetigo can occur in areas of eczema (Fig. 124–7). Widespread honey-colored crusting, erosions, oozing, follicular pustules, and furuncles suggest staphylococcal infection.

**FIGURE 124–7.** Secondary impetigo infection.

Chronic infection may lead to osteomyelitis. Infection with the nephritogenic M strain of streptococcus may lead to the development of glomerulonephritis.

The differential diagnosis of AD includes other eczematous disorders (Table 124–2).

Management

Effective management of AD hinges upon good rapport with the affected child and parents and education about the nature of the disease, potential aggravating factors to avoid, and treatment strategies.¹⁵ Bubble baths and excessive exposure to soap, shampoo, and detergents aggravate dryness and should be discouraged. However, daily bathing is no longer considered to be harmful for atopic dry skin. Bathing in lukewarm water for 5 to 15 minutes rehydrates the stratum corneum, although benefits are only seen if an emollient is applied immediately after leaving the water to prevent evaporation.^{16,17} Bathing once or twice daily is soothing during an acute flare, helps reduce bacterial counts, and aids in penetration of topical steroids applied after the bath. Soaps should be mild and unscented with a neutral pH (Dove, Oil of Olay, Caress, Camay, Aveeno, and Purpose). If soaps are too

irritating to the skin, hydrophobic lotions or creams (Cetaphil, Diprobase, and Unguentum Merck) may be used.

Many emollients are available that are suitable for use on atopic dry skin. These are best administered over slightly moistened skin, which seals in the moisture, rehydrates, lubricates, and moisturizes the skin and decreases inherent dryness and itchiness that appear to trigger the eczematous eruptions. They also aid in improving skin barrier function.¹⁸ In general, ointments are better than creams and are more beneficial than lotions. Ointment-based emollients include Vaseline petroleum jelly, Aquaphor, and Elta. However, these can be too greasy for everyday use; cream-based alternatives include DML Forte, Moisturel, Aveeno, Curél, Purpose, Dermasil, Neutrogena, and Eucerin. Lotions are better tolerated but trap less water and are less effective than ointment. Lotions include many brands such as Nivea, Aveeno, Curél, Vaseline, Lubiderm, Neutrogena, Dermasil, Suave, Olay, Jergens, and Moisturel. The moisturizer should be applied two to three times daily and after steroid application, so as not to impede steroid absorption.

Topical corticosteroids are the mainstay of treatment for AD.¹⁹ In general, corticosteroids should be used intermittently to control exacerbations. Inflammation should be treated aggressively initially, with the aim of complete clearance. Topical steroids should be applied only in areas of acute exacerbation, while emollients should be used over the remainder of the skin. Topical steroid ointment preparations are preferable to creams as they penetrate more efficiently and produce less stinging. Ointments, however, tend to occlude eccrine pores and may induce sweat retention and pruritus, and are less tolerable during the summer months. Creams are more practical in warm, humid weather and for the scalp, although lotions and gels are more aesthetically acceptable; however, their alcohol content may produce burning and discomfort.

For mild cases of AD, a low-potency (class VI or VII) topical steroid should be used (Table 124–3). A 1% hydro-

cortisone ointment is adequate for thin skin areas such as the face, neck, axilla, and groin, all areas prone to atrophy if more potent preparations are used. Potent steroids are not usually required, except for localized areas of long-standing dermatitis where significant lichenification has occurred. For moderate cases of AD, intermediate-potency (class III, IV, and V) topical steroids may be used for brief periods (<2 weeks) to control flares. The steroid preparation is applied one to three times daily until resolution. Once areas of inflammation have completely cleared, the steroid should be stopped and the skin moisturized regularly. For moderate to severe atopic dermatitis, maintenance therapy with application of topical steroid approximately twice weekly is effective.¹⁷ Prolonged use of corticosteroids should be avoided since side effects are common, including skin atrophy, striae, telangiectasia, hypopigmentation, tachyphylaxis, hypothalamus-pituitary-adrenal axis suppression, Cushing's syndrome, intracranial hypertension, and growth delay.²⁰ Systemic steroids are rarely indicated in the management of chronic atopic dermatitis. Although a course of oral steroids will rapidly settle an acute flare, there is often a rebound flare after discontinuation. Oral steroids should be reserved for only those few extremely severe cases that cannot be controlled by other means, and the dose slowly tapered over time.

Wet dressings for 15 to 30 minutes three times a day (modified Burow's solution 1 : 40, 1 packet of Domeboro [aluminum acetate topical] powder per 12 ounces of water) are a useful adjunct to topical steroids during acute flares. The evaporation of water from the skin surface results in vasoconstriction and affords cooling to inflamed tissue, relief of pruritus, and débridement of crusts from the skin surface. Percutaneous penetration of topical steroids is increased, and the amount of steroids required to treat an acute flare is reduced, with wet dressings.

Localized infections should be treated during acute flares. Treatment with topical steroids has been shown to reduce the density of staphylococcal organisms on the skin, but the clinical course is improved only if combined with oral antibiotics effective against *S. aureus*,²¹ such as cephalexin, dicloxacillin, and amoxicillin/clavulanate (Table 124–4). For penicillin-allergic patients, choices of antibiotics include azithromycin, clarithromycin, and clindamycin. Topical mupirocin can be used for impetigo involving a small surface area and is as effective as oral therapy.²² Localized eczema herpeticum is treated with oral acyclovir, and more extensive skin involvement requires intravenous acyclovir.

Controlling the itch is also an important aspect in minimizing flares. A mild detergent should be used to wash clothes. Bleach, fabric softeners, and perfumed products should be avoided. Clothing is also an important factor in controlling pruritus. Cotton should be worn all year long. Synthetic fabrics and wool are irritating to the skin and should be avoided. Antihistamines have long been used in AD to prevent the scratch-itch cycle^{23,24} (Table 124–5). Anecdotally, sedating antihistamines can be helpful in promoting sleep during a flare. Hydroxyzine has excellent antihistaminic and antipruritic qualities with fewer tendencies to sedation. Overuse of these medications should be avoided since side effects may occur, such as paradoxical agitation, fatigue, and decreased attention, cognitive, motor, and intellectual performance.^{25,26}

Table 124–3 Classification of Topical Steroids

Steroid Potency	Name	Preparation*	Dosage	
Class I: highest potency	Betamethasone dipropionate (Diprolene) (0.05%)	oint, gel	qd–bid	
	Clobetasol (Clobex, Embeline, Olux, Temovate) (0.05%)	crm, gel, oint	qd–bid	
	Halobetasol (Ultravate) (0.05%)	crm, oint	qd–bid	
Class II: high potency	Amcinonide topical (Cyclocort) (0.1%)	oint	bid–tid	
	Betamethasone dipropionate (Diprosone) 0.05%	oint	qd–bid	
	Desoximetasone topical (Topicort) 0.05%, 0.25%	crm, oint, gel	bid	
	Diflorasone topical (ApexiCon, Maxiflor, Psorcon) 0.05%	oint	bid–tid	
	Fluocinonide topical (Lidex) 0.05%	crm, gel, oint	qd–qid	
	Halicinonide topical (Halog) 0.1%	crm	bid–tid	
	Mometasone (Elocon) 0.1%	oint	qd	
Class III: high/medium potency	Amcinonide topical (Cyclocort) 0.1%	crm, lot	bid–tid	
	Betamethasone dipropionate (Diprosone) 0.05%	crm	qd–bid	
	Betamethasone valerate 0.1%	oint	qd–bid	
	Desoximetasone (Topicort) 0.05%	crm	bid	
	Diflorasone topical (ApexiCon, Maxiflor, Psorcon) 0.05%	crm	bid–qid	
	Fluticasone (Cutivate) 0.005%	oint	bid	
	Fluocinonide topical (Lidex) 0.05%	lot	qd–qid	
	Flurandrenolide (Cordran) 0.025%, 0.5%, 0.05%	lot, oint	qd–qid	
	Halicinonide topical (Halog) 0.1%	oint, sol	bid–tid	
	Triamcinolone (Aristocort A, Kenalog) 0.5%	crm, aerosol	qd–qid	
	Betamethasone valerate 0.1%	foam	bid	
	Clocortolone (Cloderm) 0.1%	crm	tid	
	Fluocinolone (Synalar) 0.025%	oint	bid–qid	
Class IV: medium potency	Hydrocortisone valerate (Westcort) 0.2%	oint	qd–qid	
	Mometasone (Elocon) 0.1%	crm, lot	qd	
	Prednicarbate (Dermatop) 0.1%	oint	bid	
	Triamcinolone (Aristocort, Kenalog) 0.1%	crm	qd–qid	
	Class V: medium/low potency	Desonide (Tridesilon) 0.05%	oint	bid–tid
		Fluticasone (Cutivate) 0.05%	crm	bid
		Fluocinolone (Synalar) 0.025%	crm	bid–qid
		Hydrocortisone butyrate (Locoid) 0.1%	oint, sol	bid–tid
		Hydrocortisone valerate (Westcort) 0.2%	crm	qd–qid
Class VI: low potency	Triamcinolone (Aristocort, Kenalog) 0.1%	lot	bid–qid	
	Alclometasone (Aclovate) 0.05%	crm, oint	bid–tid	
	Desonide (Desowen, LoKara) 0.05%	crm, lot	bid–tid	
	Fluocinolone (Synalar) 0.01%	crm, sol	bid–qid	
Class VII: lowest potency	Triamcinolone (Aristocort, Kenalog) 0.025%	crm	qd–qid	
	Hydrocortisone (Hytone) 1%, 2.5%	crm, oint	bid–qid	
	Hydrocortisone/pramoxine (Pramosone) 1%/1%	crm	tid–qid	
	Hydrocortisone/urea (Carmol HC) 1%/10%	crm	bid–qid	

*Crm, cream; lot, lotion; oint, ointment; sol, solution.

The newest form of therapy includes the topical immunomodulator agents. Tacrolimus ointment inhibits calcineurin, which results in decreased T-lymphocyte activation; especially CD4⁺ cells, and suppression of cytokine release.^{27–29} It has been safely used in children greater than 2 years of age, and results suggest it to be as effective as and possibly better than corticosteroids.^{30–34} The main adverse effects are stinging, burning, and erythema on application.³⁵ It has been shown to result in over 90% improvement in skin lesions.³⁶ Because tacrolimus ointment does not cause skin atrophy, it may be safely used for prolonged periods on all skin areas, including the face and intertriginous areas. Pimecrolimus has the same mechanism as tacrolimus and has been shown to be effective in children older than 3 month of age but is approved for use in children over 2 years of age.^{37–39} It is a cream that is less potent, but has less stinging upon application. The use of these agents early in flares has been shown to decrease the amount of corticosteroids required and has been more effective than corticosteroids and emollients.^{40,41}

Table 124–4 Drugs for Secondary Bacterial Infections

Antimicrobials	Dose
Cephalexin	25–100 mg/kg/day PO divided q6h
Amoxicillin-clavulanate	25–45 mg/kg/day PO divided q12h
Dicloxacillin	12.5–25 mg/kg/day PO divided q6h
Azithromycin	5 mg/kg/day PO qd
Clarithromycin	15 mg/kg/day PO bid
Clindamycin	25–40 mg/kg/day divided q6–8h

Abbreviation: PO, orally.

Theoretically, the topical immunomodulators may increase the risk of cutaneous infections by altering local cutaneous response. However, controlled trials do not show an increase in bacterial, fungal, or viral infections.⁴² Recently there has been a concern of an association between the development

Table 124–5 Common Antihistamines Used in Children

Antihistamine	Dosage
Diphenhydramine	5 mg/kg/day (maximum dose 300 mg/day and 50 mg per dose) divided q6h PO/IM/IV
Chlorpheniramine maleate	2–6 yr: 1 mg PO/IM/IV q4–6h (maximum dose 6 mg/day) 6–12 yr: 2 mg PO q4–6h (maximum dose 12 mg/day) >12 yr: 4 mg PO q4–6h
Hydroxyzine	2–4 mg/kg/day PO divided q4–6h (maximum dose 400 mg/day) 0.5–1 mg/kg IM q4–6h
Cetirizine	6 mo–2 yr: 2.5 mg PO qd 2–5 yr: 2.5–5 mg PO qd ≥6 yr: 5–10 mg PO qd
Loratadine	2–6 yr: 5 mg PO qd >6 yr: 10 mg PO qd
Fexofenadine	6–11 yr: 30 mg PO bid ≥12 yr: 60 mg PO bid or 180 mg PO qd
Desloratidine	6–11 mo: 1 mg PO qd 1–5 yr: 1.25 mg PO qd 6–11 yr: 2.5 mg PO qd >12 yr: 5 mg PO qd

Abbreviations: IM, intramuscularly; IV, intravenously; PO, orally.

of skin cancer and lymphoma and use of these agents; therefore, they should be prescribed only if other therapies are ineffective or inappropriate and when patients have well-established follow-up care.⁴³

Other agents tried for severe recalcitrant AD include cyclosporine, methotrexate, azathioprine, and phototherapy; however, their use is associated with significant adverse reactions such as renal damage, hypertension, infections, premature aging, and malignancy.^{44–48} High-dose intravenous immune globulins have been used successfully in recalcitrant atopic dermatitis.⁴⁹

Diaper Dermatitis

The term *diaper dermatitis* includes all inflammatory eruptions that occur in the area covered by the diaper. The etiology of irritant diaper dermatitis (IDD) is multifactorial and only partially understood, and includes recent antibiotic use, diarrhea, occlusion, overhydration of skin, maceration, prolonged contact with urine and feces, and the interaction of *Candida* and bacterial organisms.^{50–53} The critical step in the development of diaper dermatitis is the occlusion of the skin under the diaper.⁵⁴ Infrequent diaper changes create overhydration and maceration of the stratum corneum, which makes the skin more sensitive to friction. Elevations in the pH of the diaper area from feces mixed with urine activate fecal lipases and proteases; this together with *Candida albicans* causes damage to the epidermis, resulting in loss of the barrier function and fostering increased susceptibility to irritation.⁵⁵ The incidence of IDD is equal between the sexes and begins around 3 to 18 months of age, peaking at 6 to 9 months of age. The prevalence in infants is 7% to 35%.^{52,53,56}

Clinical Presentation

Friction dermatitis presents on areas where friction is most pronounced, such as the inner surfaces of thighs, genitalia,

FIGURE 124–8. Friction diaper dermatitis.

FIGURE 124–9. Irritant contact diaper dermatitis.

buttocks, and abdomen. It appears as a confluent shiny erythema with occasional papules that spares the intertriginous folds of the skin (Fig. 124–8).

Irritant contact dermatitis is generally asymptomatic and presents with erythema on the convex surface of the inner and upper thigh area, buttocks, and lower abdomen. The intertriginous creases are spared, as is the area over the mons pubis in boys. The eruption subsequently becomes deeply erythematous with a typical glistening or glazed appearance and with a wrinkled surface (Fig. 124–9). Papules, vesicles, and secondary erosions may occur in severe cases.

Candida diaper dermatitis presents with a diffuse erythematous patch extending over the genitalia with a peripheral scale. At the periphery of the patch it characteristically displays satellite red pustules or papules⁵⁴ (Fig. 124–10). The anterior perineal and perianal area are either both or separately involved, as are the intertriginous creases, which helps differentiate this from IDD. In cases in which diaper dermatitis has been present for 3 or more days, *C. albicans* has been isolated in up to 80% of infants.⁵⁴ Children with oropharyngeal candidiasis often have candidal diaper dermatitis due to excretion of *C. albicans* in the feces.⁵⁷ *Candida* growth is more common after taking antibiotics.

The differential diagnosis of diaper dermatitis is extensive (Table 124–6).

FIGURE 124-10. *Candida* diaper dermatitis.

Miliaria
Herpes simplex virus
Varicella
Epidermolysis bullosa
Dermatitis herpetiformis
Chronic bullous dermatosis of childhood
Child abuse
Perianal cellulitis (streptococcal)

Candidal dermatitis with psoriaform id reaction represents a candidal infection in the diaper area followed by an explosive erythematous papulosquamous eruption resembling psoriasis on the cheeks and body⁵⁸ (Fig. 124-11). An id reaction occurs from generalized and symmetric response to severe local inflammation.

Management

Attempts should be made to prevent all inciting factors.⁵⁹ Frequent diaper changing is one of the most important factors in curing and preventing diaper dermatitis.^{54,60} Using diapers made of sodium polyacrylate polymers that form a gel when hydrated to keep liquid away from the skin has been shown to decrease the incidence and severity of diaper dermatitis compared with the use of cloth diapers or other disposable diapers.⁶¹ The diaper area should be gently cleaned at each diaper change. This is best done by immersing the area in lukewarm water in a basin. Harsh rubbing should be avoided. The area should be gently but completely dried. Use of cornstarch was believed to increase growth of *C. albicans*,

Table 124-7 Topical Antifungal Agents for *Candida* Diaper Dermatitis

Agents	Dosage
Nystatin (Mycostatin) cream, ointment, powder	bid or tid
Clotrimazole (Lotrimin) 1% cream, lotion, solution	bid
Econazole (Spectazole) 1% cream	bid
Sertaconazole (Ertaczo) 2% cream	bid
Sulconazole (Exelderm) 1% cream, solution	bid
Ciclopirox (Loprox) 0.77% cream, gel, suspension	bid
Miconazole (Micatin, Monistat-Derm) 2% cream, lotion, spray	bid

Table 124-8 Oral Antifungal Agents for *Candida* Diaper Dermatitis

Agents	Dosage
Nystatin	2 ml PO qid (1 ml in each side of mouth after feeding)
Fluconazole	6 mg/kg PO once, then 3 mg/kg/day PO (maximum 200 mg/day)

Abbreviation: PO, orally.

but recent studies refute this, and its use does decrease moisture.⁶² Use of emollients, particularly zinc oxide preparations and petrolatum, will prevent overhydration of the skin and provides protection from urine and feces. Other topical barriers with proven efficacy include cod liver oil, dimethicone, and lanolin.⁶³ A nonfluorinated corticosteroid (hydrocortisone 1%), covered by the emollient, may be applied three times a day if emollients are ineffective. Their use, however, should be stopped after 14 days since overuse of corticosteroids can lead to skin atrophy or striae.⁶⁴

Candidal superinfection is treated with topical anticandidal therapy, such as nystatin or an imidazole, two to three times daily in order to produce resolution in under 2 weeks (Table 124-7). If *Candida* is resistant to topical therapy or if there is evidence of *Candida* in the mouth as well as the perineal area, topical therapy may be supplemented with oral nystatin or fluconazole (Table 124-8). Adding

hydrocortisone 1% to these agents may provide an anti-inflammatory effect and promote more rapid healing. The treatment of the id reaction involves a low-potency corticosteroid ointment on the face and a mid-potency corticosteroid ointment on the body (see Table 124–3).

Seborrheic Dermatitis

Seborrheic dermatitis refers to a chronic inflammatory disease with remissions and exacerbations, characterized by an erythematous, scaly, or crusting eruption that occurs primarily in the seborrheic areas, where the highest concentration of sebaceous glands exists. These areas include the scalp, face, and postauricular, presternal, axillary, and intertriginous folds. Seborrheic dermatitis is a disease of unknown etiology that affects infants from 3 weeks of age onward, is uncommon after 6 months of age, and usually clears by 12 months of age. It then can reoccur in adolescents.

The organism *Pityrosporum ovale* (*Malassezia furfur*) has been implicated in the etiology of adult seborrheic dermatitis, but its role in the infantile form of the disease is yet to be proven.^{65–67} It has, however, been recovered more often in patients with seborrheic dermatitis than in controls.⁶⁸ In addition, some patients improve with topical or systemic ketoconazole.⁶⁹

Clinical Presentation

The first area of involvement is generally the scalp. Here the lesions consists of diffuse greasy, yellow or white scales, frequently called “cradle cap” (retention hyperkeratosis) (Fig. 124–12).^{69a} Lesions may spread to involve the face, especially

the hairline and eyebrow area, where the scale is yellow and greasy and the underlying skin becomes erythematous (Fig. 124–13). The intertriginous, flexural, axillary, and postauricular areas and neck are involved in more severe cases, with scaling and linear erythema. In the diaper area, well-demarcated erythematous plaques are topped by a thin white scale or covered with thick, yellowish brown, greasy crusts. The lesions may become macerated, crusted, and superinfected with *C. albicans*. Pruritus is usually absent in comparison to AD. Infants are usually asymptomatic, and it is the parents who are dismayed by the cosmetic appearance. However, in one study up to 33% were seemingly itchy.⁷⁰

In children between middle school age and puberty, seborrheic dermatitis may appear on the scalp as a dry, fine, flaky desquamation known as pityriasis sicca or dandruff. Erythema and scaling may also involve the supraorbital region, nasolabial crease, lips, pinna, retroauricular area, aural canal, and chest (Fig. 124–14). Pruritus is common.

The differential diagnosis of seborrheic dermatitis includes atopic dermatitis, contact dermatitis, tinea facialis, tinea capitis, psoriasis, Langerhans cell histiocytosis (Letterer-Siwe disease), and Leiner’s disease.

Management

These lesions respond quickly to treatment with bathing in soothing oatmeal baths once or twice a day and shampooing with a tar shampoo daily. Shampoos containing salicylic acid should be avoided as they may be irritating and absorption may cause problems with salicylism. The use of ketoconazole

FIGURE 124–12. Seborrheic dermatitis (“cradle cap”).

FIGURE 124–13. Yellow and greasy rash from seborrheic dermatitis.

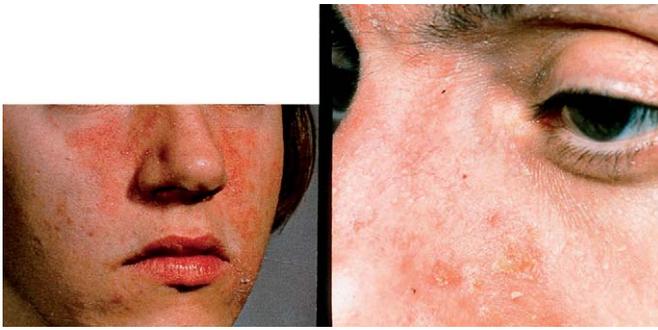

FIGURE 124-14. Erythematous scaly patches in an adolescent with seborrheic dermatitis.

2% results in clinical cure in patients with seborrheic dermatitis and has been found safe in infants.^{71,72} Itraconazole has been shown to be effective in adults.⁷³ If the scale is extremely thick and adherent, it can be loosened by warmed mineral oil massaged into the scalp and then removed with a comb. In stubborn cases, a topical corticosteroid lotion may be used on the scalp one to three times daily.

Adolescents with seborrhea of the scalp may use antiseborrheic shampoos, which include zinc pyrithone (Head & Shoulders, DHS Zinc, Zincon, or XSeb), selenium sulfide (Exsel or Selsun), ketoconazole (Nizoral), corticosteroids (FS Shampoo), and tar (T/Gel). Recently, the immunomodulators pimecrolimus and tacrolimus have been shown to be effective in improving lesions of seborrheic dermatitis.^{74,75} However, these agents have been associated with the development of dermal cancer and lymphoma and should be considered only for resistant cases.⁴³ Ciclopirox (Loprox) shampoo, which has anti-*Malassezia* activity, will improve lesions in seborrheic dermatitis. Topical lithium gluconate and topical metronidazole (MetroCream, MetroGel, MetroLotion, Noritate) have also been shown to be effective.^{76,77}

Contact Dermatitis

Contact dermatitis may be defined as an eczematous eruption produced either by local exposure to a primary irritating substance (irritant contact dermatitis) or by an acquired allergic response to a sensitizing substance (allergic contact dermatitis).⁷⁸⁻⁸⁰ Irritant contact dermatitis requires an irritant—any agent that is capable of producing cell damage in any individual if applied for sufficient time and in sufficient concentration. Common substances include harsh soaps, bleaches, detergents, acids, alkalis, solvents, fiberglass, bubble baths, certain foods, saliva, talcum, urine, feces, and intestinal secretions.

Allergic contact dermatitis (ACD) is unusual in children less than 10 years of age. It is a type IV hypersensitivity reaction only affecting previously sensitized individuals. There are two phases, the induction or sensitization phase and the elicitation phase.^{78,80} During the induction phase, an allergen, or hapten, penetrates the epidermis, where a cascade of events causes T lymphocytes to become memory cells. The elicitation phase occurs when the sensitized individual is reexposed to the antigen. The antigen causes T lymphocytes to produce lymphokines that mediate the inflammatory response that is characteristic of an allergic contact dermatitis. The elicita-

FIGURE 124-15. Allergic contact dermatitis from poison ivy.

FIGURE 124-16. Köbner's phenomenon from contact dermatitis.

tion phase requires several hours to develop, and as a result symptoms are delayed. In infants, the only ACD seen with any frequency is nickel dermatitis, while in children ACD may include poison ivy, nickel, preservative or fragrances used in cosmetics, topical medications, and rubber (Figs. 124-15, 124-16, and 124-17). Teenagers may react to cosmetics and to formaldehyde used to size clothing. Flowers and pollens may all cause allergic reactions, but rarely in children. Adhesive tape reactions may occur in all ages.

Several dermatitis conditions in children have characteristic presentations (Table 124-9). The differential diagnosis of contact dermatitis is lengthy (Table 124-10).

Management

Once the diagnosis of contact dermatitis has been made and the causative agent elicited, elimination of the offending substance results in cure within 2 to 3 weeks, but during this time patients may be severely incapacitated. Symptomatic treatment should be initiated as soon as the diagnosis is made.

For relief of pruritus, antihistamines (see Table 124-5) can be given, and calamine lotion and oatmeal baths are soothing for the skin, but systemic corticosteroid therapy is the treatment of choice. If there is widespread skin involvement, corticosteroids should be given orally and tapered over 2 to 3

FIGURE 124-17. Contact dermatitis caused by nickel.

weeks to avoid a rebound flare. If the skin involvement is small, topical corticosteroids are used. As in other acute eczematous eruptions, wet dressings for 15 to 30 minutes three times a day (modified Burow's solution 1 : 40, 1 packet of Domeboro [aluminum acetate topical] powder per 12 ounces of water) are a useful adjunct to topical steroids. The crusts can be gently loosened from affected sites, followed by the application of a thin layer of emollient or antibacterial ointment.

Table 124-9 Common Pediatric Dermatitis Conditions

Poison Ivy Dermatitis

- Most common ACD in children
- Caused by the plant of the *Rhus* or *Toxicodendron* genres (poison ivy, oak, or sumac). Poison ivy occurs in all parts of the United States as a shrub or vine. Poison oak, an upright shrub, appears only on the West Coast. Poison sumac grows as a shrub or tree in Mississippi
- Sensitizing agent is an oleoresin (urushiol).
- Occurs in spring, summer, and autumn
- Sensitization may take 5–25 days and may be followed by the development of an acute pruritic dermatitis.
- Reexposure will always result in an eruption within 24–48 hours. Initial lesions consists of erythematous vesicular streaks mainly on the lower legs, but any area may be involved (see Fig. 124-15).
- A few hours to days later, other erythematous patches, papules, and bullae may develop.
- Linear distribution of papules or vesicles after minor epidermal trauma (Köbner's phenomenon) is highly characteristic of contact dermatitis (see Fig. 124-16).
- Allergen may be washed off within 20 minutes without causing an eruption.
- Oleoresin may remain in clothing for months to years, causing a typical dermatitis if contacted by a sensitized person.

Nickel Allergy

- Earrings with nickel result in bilateral dermatitis consisting of erythema, scaling, vesicles, and crusts on the back and less often on the front of the earlobe.
- Also widely used in bracelets, necklaces, watches, and rings as a hardening agent for gold (see Fig. 124-17).
- Area immediately below the umbilicus where the nickel snap on blue jeans comes in contact with the skin is commonly involved.⁸¹
- Areas of inflammation may become chronic with shiny lichenoid papules from constant rubbing.

Shoe Dermatitis

- Acute or subacute dermatitis along the dorsa of the toes and foot
- Erythema, lichenification, and, in severe cases, weeping and crusting
- Webs of the toes not involved
- Ball and heel also involved when rubber is the causative agent
- Most common cause is rubber, but other agents include chromates, adhesives, and dyes.
- Commonly misdiagnosed as tinea pedis (usually involves toe web spaces and is rarely seen prior to puberty).

Infestations

Antonio E. Muñiz, MD

Key Points

The hallmark symptom of scabies is intense pruritis.

Failure to find mites on microscopic examination does not rule out scabies.

Empirical treatment after a tick bite is not recommended.

Rocky Mountain spotted fever occurs in many geographic areas and must be considered in a child with a tick exposure who presents with fever, headache, myalgias, and rash.

Selected Diagnoses

- Scabies
- Tick bites
- Lyme disease
- Rocky Mountain spotted fever
- Pediculoses (louse infestations)

Discussion of Individual Diagnoses

Scabies

Scabies is a highly contagious, papular, pustulovesicular and occasionally crusting, pruritic eruption of the skin caused by the release of toxic or antigenic secretions of the eight-legged human female arachnid mite *Sarcoptes scabiei* var *hominis*.¹ The organism is an obligate parasite, requiring an appropriate host for survival. The life cycle begins with the mating of adult male and female mites, after which the adult male dies. The female mite tunnels into the stratum corneum and deposits up to 90 eggs during its life span of 30 to 40 days. The eggs reach maturity in 10 to 14 days, and a new cycle begins. The average patient is infected with about 10 to 15 live adult female mites.²

A delayed type IV hypersensitivity reaction to the mites, their eggs, or scybala (fecal pellets) that occurs approximately 30 days after infestation is responsible for the intense pruritus, the hallmark of the disease. Transmission of scabies requires prolonged human contact, although female mites can survive 2 to 3 days off the human body and theoretically

lead to infestation by contact with objects or clothing containing the mites.²

Clinical Presentation

The earliest symptom is itching, especially at night. Primary lesions include burrows, papules, vesicles, and pustules (Fig. 125–1). Secondary lesions occur from scratching and include excoriated papules with honey-colored exudates and crusts (Figs. 125–2 and 125–3). Lesions are commonly located on the abdomen, dorsa of hands, flexural surfaces of the wrists and elbows, periaxillary skin, areolae, genitalia, ankles, feet, and interdigital web spaces of the hands.^{2a} In infants, eczematous eruptions of the face and trunk are seen. In older children, adolescents, and adults, the head and neck regions are almost never involved. A few patients develop a nodular form of scabies, exhibiting firm, erythematous, pruritic, dome-shaped lesions 5 to 6 mm in diameter. The genitalia, groin, buttocks, and axillary folds are the usual sites of involvement. Some patients present with urticaria as the initial manifestations of scabies.³

S-shaped burrows are diagnostic, but not commonly seen in children⁴ (Fig. 125–4). Occasionally the burrows are straight or curved, and they are usually 2 to 5 mm in length. A burrow is caused by the female mite when it tunnels into the skin, and appears as a white or gray threadlike, linear, wavy papule with a small vesicle at one end. It is most often found in the interdigital web spaces of the hand, flexural surfaces of the wrists and elbows, areolae in women, penis, scrotum, and belt line area.⁵

The term *scabies crustosa* (formerly known as Norwegian or crusted scabies) is used to describe heavy infections with severe cutaneous crusting and hundreds to thousands of adult mites on a patient's body.⁶ Patients with this form of scabies are usually immunocompromised, debilitated, or developmentally disabled, but it has also been encountered among indigenous Australians with no known immune deficiency.⁷ It begins with poorly defined erythematous patches that quickly develop a prominent scale. Any area may be affected, but the scalp, hands, and feet are particularly susceptible. Untreated, it spreads rapidly and may eventually involve the entire integument. Scales become warty and crusts appear.

Scabies may be confused with other pruritic conditions (Table 125–1).

The most common complication is secondary bacterial infection with *Staphylococcus aureus*, which is clinically suspected when there is pustule formation, bullous impetigo,

FIGURE 125-1. Excoriations, pustules, and vesicles on the hand from scabies.

FIGURE 125-2. Excoriations, pustules, and vesicles on the feet from scabies.

severe crusting, cellulitis, ecthyma, paronychia, or furunculosis.⁸ Another organism causing secondary skin infection is *Streptococcus pyogenes*. Poststreptococcal glomerulonephritis may follow if nephritogenic strains of streptococci are involved.⁹ Other complications may include lymphangitis, suppurative lymphadenitis, staphylococcal scalded skin syndrome, scarlet fever, rheumatic fever, osteomyelitis, septic arthritis, pneumonia, and sepsis.

The diagnosis of scabies is confirmed by scraping an unscratched burrow that is covered with a drop of microscopic immersion oil and placing the scrapings on a glass slide with a cover slip. Placing a drop of oil on the lesion prior to scraping with a number 15 scalpel blade improves the chance of obtaining a good specimen. Using the 10× magnification objective of the microscope, the female mite and/or

its eggs or excreta (scybala) should be visible. Failure to find the mite does not rule out scabies, since it is difficult to obtain adequate scrapings from an uncooperative, crying and moving child or infant. Videodermoscopy has been demonstrated to be an effective and sensitive diagnostic tool, allowing for noninvasive in vivo visualization of the skin at magnifications of up to 600 times to detect signs of infestations.¹⁰

Management

Treatment of scabies involves the control of symptoms, prevention of secondary infection, and eradication of the mites. Antihistamines, oatmeal baths, and calamine lotion may be

used to help alleviate pruritus. Persistent itching after appropriate therapy may respond to topical corticosteroids. Secondary bacterial infections are treated with antistaphylococcal antibiotics.

Application of a scabicide (Table 125–2), such as 5% permethrin (Elimite) cream, is considered the treatment of choice.^{1,4} It is recommended for infants older than 2 months of age but has been reported to be safe in neonates.¹¹ It can be used in pregnant patients and those who are breast-feeding. In children, the scabicide is applied to the entire body, including the scalp and face, and washed off in 8 to 14 hours. The treatment is repeated in 1 week to ensure complete eradication. In adults, the scabicide is applied to areas below the head, since scabies rarely involves the face; a 30-g tube is usually sufficient for an average adult. Permethrin produces a 98% cure rate.^{1,11,12}

In the past, 1% gamma benzene hexachloride (lindane; Kwell) lotion has been used. Although equally effective in eradicating scabies, prolonged absorption or repetitive use of gamma benzene hexachloride, especially in infants less than 6 months of age, concentrates the compound in the central nervous system and may cause seizures and rarely death.^{13,14} Other adverse effects include headache, nausea, vomiting, dizziness, restlessness, tremors, disorientation, weakness, twitching of eyelids, and respiratory failure.^{15,16}

In addition to the patient, all family members and close contacts should be treated with a scabicide.^{1,4} Normal laundering or dry cleaning of clothing is sufficient to prevent the potential reinfection with the mite. Potential fomites that cannot be laundered or dry cleaned should be sealed in plastic bags for 1 week, since the adult mite cannot survive more than 3 to 4 days when separated from humans.

For crusted scabies, crust and scale removal is necessary for scabicide penetration. Permethrin is the topical medication of choice, but when used by itself, topical treatment requires weeks of repeated application, and the failure rate is high. Oral ivermectin is rapidly becoming the treatment of choice for scabies crustosa¹⁷ (see Table 125–2).

Follow-up within 2 weeks should be arranged to ascertain success of therapy. Many patients experience persistent

symptoms for up to 2 weeks after curative treatment. This is likely due to the ongoing immune response to mite antigens. However, if symptoms persist beyond this period, one must consider other possibilities, such as an incorrect diagnosis, incorrect application of the topical scabicide, poor penetration of the agent into scaly skin, reinfection from untreated contacts or contaminated fomites, contact dermatitis from the topical agent, or drug-resistant infection.

Tick Bites

Tick bites are usually painless and inconspicuous in children and not noted until several hours to days later when pruritus becomes prominent. Tick bites are acquired when children play in woods or when ticks are transferred from animals to children. The tick attaches itself to the skin by its head in an effort to suck blood. The tick cuts the skin surface with chelicerae, introduces its proboscis, and secretes saliva into the wound. The saliva contains a cement substance, anesthetic, anti-inflammatory agent, and anticoagulant, and may also include a neurotoxin responsible for tick paralysis or other infections, such as agents for relapsing fever, rickettsial infections (Rocky Mountain spotted fever, typhus, trench fever, Q fever, ehrlichiosis, boutonneuse fever), Lyme disease, Colorado tick fever, babesiosis, and tularemia.

After a tick bite, a localized urticarial reaction occurs. The most common sites for tick attachment are the occiput, ear canal, axilla, groin, and vulva.^{18,19} On rare occasions a systemic reaction consisting of fever, nausea, abdominal pain, and headache may occur. A persistent pruritic nodule with surrounding alopecia may be the result of an incompletely removed tick in which mouth parts remain in the skin.

Lyme Disease

Ticks may carry the spirochete *Borrelia burgdorferi*, which is responsible for Lyme disease (see Chapter 71, Selected Infectious Diseases). The predominant tick in the northeastern and midwestern United States is the deer tick, *Ixodes dammini* (or *Ixodes scapularis*). In the northwestern United States, *Ixodes pacificus* is the vector, and *Amblyomma americanum* (Lone Star tick) is the vector in the southern United States.²⁰

Table 125–2 Medications for the Treatment of Scabies⁶⁴⁻⁶⁶

Agent	Application	Cautions
Permethrin 5% (Elimite) cream	Apply and wash off in 8–14 hr; repeat in 1 wk	>2 mo old (reported safe in neonates), safe in pregnancy and breast-feeding
1% gamma benzene hexachloride (lindane; Kwell) lotion	Apply and wash off in 8–12 hr; repeat in 1 wk	Repeated use may cause seizures and death (<6 mo old); avoid if seizure disorder, pregnant, breast-feeding, or with extensive dermatitis
Precipitated sulfur (3–10%) in petrolatum ointment	Apply for 3 consecutive days; can be washed off after every 24 hr	Safe in pregnancy, breast-feeding and infants <2 mo of age; bad odor and messy; in hot or humid climate may lead to irritant dermatitis; less effective than permethrin
Crotamiton 10% (Eurax) cream or lotion	Apply and repeat in 24 hr, then washed off in 48 hr. Better results occur if applied for 5 days	Safe in pregnancy and infants; irritating in patients with eczema or with weeping wounds and associated with increased treatment failures
Benzyl benzoate (12.5–25%)	Apply three times in a 24-hr period, then wash off	Can cause irritant dermatitis
Ivermectin (Mectizan, Stromectol)	150–200 mcg/kg/day PO as a single dose; repeat 2 wk later	>5 yr old; not FDA approved; consider for treatment failures or immunosuppressed patients; deaths reported in elderly

Abbreviations: FDA, Food and Drug Administration; PO, orally.

Bacteria are introduced into the skin by a bite from an infected tick. It generally takes more than 24 hours of tick attachment for the transmission to occur.²¹ Once in the skin, the spirochete can be overwhelmed and eliminated by host defense mechanisms, can remain viable but localized at the site of inoculation, or can disseminate via blood and lymphatics. Hematogenous spread can occur within days or weeks of the initial infection. The organism may travel to other parts of the skin, heart, joints, and central nervous system.

Three stages are usually described: stage I (early localized infection; onset days to weeks after infection), stage II (early disseminated infection; onset days to months), and stage III (late or persistent infection; onset months to many years). Early disseminated Lyme disease produces various neurologic syndromes, cardiac disease, multiple skin lesions, and sometimes early synovitis. Later manifestations are primarily neurologic and rheumatologic. Most tick bites occur from April through September. The highest attack rate occurs in children between 5 and 10 years of age.²² The incubation period is 7 to 14 days. Only about one third of patients distinctly recall a tick bite.^{18,23}

The pathognomonic skin manifestation of Lyme disease is erythema migrans (EM), formerly called erythema chronicum migrans. It begins as a red papule at the site of the bite, and then slowly enlarges over several weeks to form an annular ring with a flat red border, with less than 40% showing central clearing (Fig. 125–5).^{23a} The most common lesion in the United States is round morphology with a homogeneous or central erythema.²⁴ Its size ranges from 5 cm up to 70 cm.^{25,26} It is commonly found in the axilla, inguinal region, popliteal fossa or belt line. EM is usually asymptomatic, although it may itch or burn. Fifty percent will develop multiple secondary annular rings, which begin 1 to 6 days after the primary ring.¹⁸ EM may spontaneously regress within weeks or months but may persist and spread. Patches remaining for 4 weeks or longer are referred to as erythema chronicum migrans. Two other less common skin findings, mostly seen in Europe, are borrelia lymphocytoma and acro-

FIGURE 125–5. Acute erythema migrans.

dermatitis chronica atrophicans (ACA). Lymphocytoma consists of a bluish red papule, plaque, or nodule, most often located at the earlobe or nipples.²⁷ ACA is seen years after EM and is characterized by a bluish red discoloration, often with a doughy infiltration that progresses to atrophy of the skin, and is sometimes complicated by sclerodermic changes. It is usually found on the dorsal portion of the hand, elbow, foot, or knee.²⁸

Other associated findings may include headaches, fatigue, malaise, myalgias, stiff neck, arthralgias, low-grade fever, nausea, vomiting, sore throat, and lymphadenopathy.^{18,29} Untreated, EM lasts about 3 to 4 weeks but may recur with arthritis, and in some cases neurologic or cardiologic complications occur.²⁷ Lyme arthritis is often monoarticular or oligoarticular, most commonly involving the knee joint. Neurologic manifestations occur in less than 10% of cases and consist of lymphocytic meningitis, encephalopathy, cerebritis, transverse myelitis, mononeuritis multiplex, and cranial nerve palsies, especially of cranial nerve VII.^{22,30} Tertiary neuroborreliosis occurs in late disease and consist of encephalopathy, neurocognitive dysfunction, and peripheral neuropathy. Cardiac manifestations are less common, occurring in less than 10% of cases, and include electrocardiographic signs of myocarditis, such as atrioventricular block, left ventricular dysfunction, pericarditis, or fatal pancarditis.³¹

The expanding annular rings of EM may be confused with tinea corporis, urticaria, nummular eczema, erythema multiforme, erythema marginatum, erythema annulare centrifugum, granuloma annulare, fixed drug reaction, cellulitis, and insect or spider bites. The diagnosis of EM is purely clinical. Disseminated or late Lyme disease can be diagnosed by polymerase chain reaction detection of *B. burgdorferi* DNA, enzyme-linked immunosorbent assay, immunofluorescence antibody, and Western immunoblot assay.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever (RMSF) is caused by the obligate intracellular bacteria *Rickettsia rickettsii*. The clinical spectrum of human infection ranges from mild to fulminant disease. It is primarily a disease of the southeastern and south central United States, but has been reported in every state except Vermont. It also occurs in Canada, Mexico, Central America, and parts of South America. The ticks that serve as vectors and reservoirs include *Dermacentor variabilis* (American dog tick) in the eastern and south central United States, *Dermacentor andersoni* (wood tick) in the mountain states west of the Mississippi river, and *Amblyomma americanum* (Lone Star tick) in the southern United States.³² It is transmitted by a bite from an infected tick or contamination of the skin when the arthropod is being crushed. It generally takes more than 6 hours of tick attachment for transmission. Occasionally the disease is transmitted by blood transfusions.

Following inoculation, *R. rickettsii* multiplies in the endothelial cells of small blood vessels and disseminates widely via the bloodstream. It attaches to and invades the vascular endothelial and smooth muscle cells of many organs, including the brain, liver, skin, lungs, kidneys, and gastrointestinal tract. The essential pathologic lesion is an anti-inflammatory reaction of the endothelium and smooth muscle of the arterioles and endothelia of capillaries. This leads to swelling,

necrosis, thrombosis, and finally occlusion of the vascular lumen.

CLINICAL PRESENTATION

A history of a tick bite can be elicited in 50% to 80% of cases. The longer the infected tick feeds, the greater the chance of infection. The incubation period ranges from 2 to 12 days, with most cases occurring between 5 and 7 days after exposure. The symptoms of the prodrome phase include headache, malaise, anorexia, photophobia, conjunctival hyperemia, chills, low-grade fever, arthralgias, myalgias, nausea, vomiting, and abdominal pain. The presence of headache, fever, and myalgias should always alert one to the possibility of RMSF. Gastrointestinal involvement may be severe and lead to erroneous diagnoses such as cholecystitis, appendicitis, and even bowel obstruction.³³

The classic triad includes fever, headache, and rash. The rash is seen in 90% of cases and occurs 1 to 4 days after onset of symptoms. It starts in the ankles and feet, and spreads within hours to the wrists and hands and then centripetally toward the head and trunk.³⁴ At first the rash is small, discrete, macular, and rose colored, with blanching on pressure. It soon becomes papular and assumes a darker hue. In 2 to 3 days, it develops a petechial or purpuric character³⁵ (Fig. 125–6). The rash may desquamate and leave hyperpigmented areas. Generalized nonpitting edema is present, especially in children.³⁶ Lymphadenopathy, hepatosplenomegaly, and nuchal rigidity may occur. The differential diagnosis is extensive (Table 125–3).

FIGURE 125–6. Petechial rash of Rocky Mountain spotted fever.

The diagnosis of RMSF is based largely on clinical presentation in a patient with history of tick exposure. There is no completely reliable diagnostic test in the early phases of illness when therapy should be initiated to prevent complications. Later, the diagnosis can be made by skin biopsy and confirmed serologically. Punch biopsy of the skin can be examined for *Rickettsia* using direct immunofluorescence or immunoenzyme methods. Serologic diagnosis includes a fourfold increase in acute and convalescent titers using indirect immunofluorescence antibody assay, enzyme immunoassay, complement fixation, latex agglutination, indirect hemagglutination, or microagglutination. Laboratory tests are nonspecific but might show anemia, an elevated or depressed white blood cell count, thrombocytopenia, coagulation abnormalities, elevated hepatic transaminases, an elevated blood urea nitrogen, and a lymphocytic cerebrospinal fluid pleocytosis.

Complications of RMSF include thrombocytopenia, disseminated intravascular coagulation, gangrene, acute disseminated encephalomyelitis, meningoencephalitis, seizures, coma, acute renal failure, aseptic monarticular arthritis, ataxia, hyperreflexia, paraparesis, hearing loss, peripheral neuropathy, pneumonia, respiratory failure, myocarditis, and bowel and bladder incontinence.^{37,38}

MANAGEMENT

Removal of the tick is the treatment of choice. The preferred method of removal is with a blunt instrument, such as a forceps or tweezers, between the tick head and the child's skin. Gentle outward traction will cause the tick to be pulled out. This will prevent retention of tick parts within the skin. All methods that will injure the skin, such as burning the tick or using noxious substances on the skin, are not recommended. The body of the tick should not be squeezed; if there is a remnant of the tick in the skin, a simple surgical excision may be performed with local anesthetic.³⁹

Routine administration of oral antibiotics after tick removal is not recommended for prophylaxis against Lyme disease since the infection rate is low.⁴⁰ However, one study showed that a single dose of doxycycline given within 72 hours after a tick bite can prevent the development of Lyme

disease.⁴¹ If the child develops EM, then appropriate antibiotics, such as amoxicillin, azithromycin, doxycycline, or cefuroxime axetil for 10 days, should be given.^{42,43} If the child develops fever, frontal headache, myalgias, and petechiae, then RMSF should be considered and doxycycline should be given. Early therapy of RMSF is important because delay beyond the fifth day of illness is associated with an increased risk of a fatal outcome.^{44,45} The dose of doxycycline in children less than 45 kg is 0.9 mg/kg divided in two doses (maximum 200 mg/day), and in children greater than 45 kg, 2 mg/kg orally (PO) as a loading dose followed by 1 mg/kg PO every 12 hours. It should be given for 7 days or until 2 days after the patient becomes afebrile. Doxycycline does not stain the teeth when given for a short period of time. In pregnant patients with RMSF, chloramphenicol is the preferred drug, but it is associated with toxic effects on the baby (gray baby syndrome) when given close to delivery.⁴⁶

Prevention is the best method for avoiding tick bites. Children should avoid tick habitats, such as dense brush or tall grass, and stay in the center of the path on wooded trails. They should wear protective clothing, such as long-sleeved tops, long pants, and caps, preferably of light color so ticks are easily seen, and should tuck pants into boots or socks. In endemic areas, regular and careful use of insect repellants during tick season is recommended. Caution should be exercised not to use DEET (*N,N*-diethyl-*m*-toluamide) on large areas of skin or in concentrations greater than 10% because of neurotoxicity.⁴⁷ Pretreatment of clothing with permethrin spray is also useful. Children and pets should be routinely inspected for ticks if they have been in wooded areas.

A follow-up visit in 2 weeks after a tick bite to observe for signs of EM should be considered in areas endemic for Lyme disease. Admission is indicated in all patients with RMSF with clinical evidence of toxicity, encephalitis, seizures, hypotension, thrombocytopenia, prolonged clotting factors, hyponatremia, or marked gastrointestinal symptoms. Patients who survive the initial episode generally go on to complete recovery and cure, although a small percentage of patients with severe RMSF develop long-term sequelae such as peripheral neuropathy, hemiparesis, or deafness.⁴⁸

Pediculosis (Louse Infestations)

Pediculosis is an infestation of humans by lice. The human louse, an ectoparasite, is a six-legged insect. It attaches itself to the skin, ingests blood, and produces skin lesions by mechanical puncture and by injecting toxic substances.⁴⁹ The clinical signs and symptoms arise from host reaction to louse saliva injected at the time of feeding. The hallmark of all types of pediculosis is pruritus. There are two species of human lice, *Pediculus humanus* (body louse), which has subspecies *capitis* (head lice) and *corporis* (body lice), and *Pthirus pubis* (crab louse). The body louse is 2 to 4 mm in length, while the pubic louse is 1 to 2 mm in length. The female attaches to the hair and slides along it, laying eggs or nits that are white and less than 1 mm long. Nits are firmly attached to one side of the hair.⁵⁰ If hair is not available to the lice, clothing fibers are used.

The female produces new offspring every 2 weeks and up to 80 offspring during her life span. Newly hatched lice mate with older lice, and hundreds of nits result every 2 weeks. Transmission is by person-to-person contact or by fomites, such as hairbrushes, caps, clothing, or carpets.⁵¹ Lice die

within 10 days of removal from their human host. Head lice are uncommon in African Americans because they have oval-shaped hair shafts that are harder for lice to grasp.⁵²

The differential diagnosis of human louse infestations is limited (Table 125–4).

Clinical Presentation

PEDICULOSIS CORPORIS

Pediculosis corporis is infestations of humans and their clothing by *P. humanus* (body louse). Body lice spend most of their lives in clothing and only go back to the body to feed. The lice lay their eggs on fibers in the fabric seams. The louse can carry *Bartonella*, can cause fever and endocarditis, and is a vector for relapsing fever, trench fever, and epidemic typhus.^{53,54} The bites of body lice are relatively painless. Skin lesions include excoriated papules and pustules on the trunk and perineum. With chronic infestations, the skin may be thickened and hyperpigmented.⁵⁵ On occasion, the louse may be discovered by closely examining the seams of the patient's clothing.

PEDICULOSIS CAPITIS

Pediculosis capitis is an infestation of the scalp by *P. capitis*. The gelatinous nits of the head louse appear as white, ovoid bodies tightly adherent to the hair shafts (Fig. 125–7). The nits move away from the scalp as the hair grows. The nits fluoresce a pale blue color under a Wood's lamp and are usually located in the occipital and retroauricular areas. Patients present with nocturnal pruritus, excoriations, con-

junctivitis, and posterior neck lymphadenopathy.^{49,56} A hypersensitivity rash may mimic a viral exanthem.

PEDICULOSIS PUBIS

Pediculosis pubis is an infestation of the pubic hair with *P. pubis*. It is commonly spread as a sexually transmitted disease, and up to 30% of patients have another concomitant sexually transmitted infection.⁵⁷ The pubic (crab) louse may be seen crawling among pubic hair. It may also attach to eyelashes (pediculosis palpebrarum) and beard, mustache, and axillary hairs.⁵⁸ The lice lay their eggs at the base of hair fibers. Patients typically present with pruritus of the pubic region. On occasion there is a blue-black crusted macule (macula cerulea) in the pubic area, thighs, trunks, or upper arms.⁵⁰ Nits may be seen attached to pubic hair.

Management

Permethrin is the drug of choice for treatment of head lice,⁵⁹ although other agents are available (Table 125–5). After the hair has been washed with shampoo, rinsed with water, and towel dried, the scalp should be saturated with the pediculicide. Permethrin remains on the hair for 10 minutes before rinsing off with water. All agents can be repeated in 1 week to kill any newly hatched nymphs. Cutting of the child's hair should be avoided. Resistance of head lice to these agents has been reported, and ivermectin has been used with success in these cases.^{60,61} Antihistamines are used to control itching.

Shampoo treatments will not remove the gelatinous nits. The use of warm, damp towels or towels saturated in white vinegar (dissolves chitin, which binds nits to hair shafts) for 30 minutes on the scalp will loosen nits and allow their mechanical removal with a fine-toothed comb. Petroleum jelly massaged on the entire surface of the hair and scalp and

left overnight with a shower cap has been shown to be effective by obstructing the respiratory spiracles of the louse, causing the lice to die of suffocation and desiccation.⁶² Fine-toothed combs and brushes can be treated by soaking at least 5 minutes in hot water (>131° F or 55° C). Potential fomites such as towels, pillow cases, hats, and children's stuffed animals may benefit from washing in hot water. Because adult lice cannot survive more than 6 to 10 days when separated from humans, sealing potential fomites in plastic bags for 12 to 14 days is effective when they cannot be laundered or dry cleaned.

For treatment of body lice, the most important therapy is disinfection of all contaminated clothing and linens.^{62a} The clothing may be dry cleaned, steam fumigated, or washed in hot water and dried on high heat. Furniture in the house should be sprayed with agents specifically approved for disinfecting lice, such as permethrin spray. The patient should be treated from head to toe with a pediculicide. Permethrin 5% topical cream is the safest agent and should be applied for 8 to 14 hours and repeated in 1 week to ensure appropriate cure.

Treatment of pubic lice with permethrin or pyrethrin applied for 10 minutes and repeated in 1 week is sufficient. Sexual contacts should be treated, and laboratory tests for other sexually transmitted infections should be performed.

The safest and most effective treatment for *P. pubis* of the eyelashes is petrolatum (Vaseline). The ointment is applied three to five times daily. Physostigmine 0.25% (Eserine) has been used successfully, but has the major drawback of miosis from an anticholinergic effect. For severe resistant cases, ivermectin has been successful.^{62,63}

Human louse infection causes an annoying pruritic sensation. When treated with appropriate agents, the infection can easily be controlled.

Table 125–5 Treatment of Head Lice⁶⁷⁻⁷²

Agents	Instructions for Use	Precautions
Permethrin (Elimite 5%, Nix 1%) cream	Apply to hair for 10 min and wash; repeat in 1 wk	Approved for > 2 mo old
Piperonyl butoxide 4%/pyrethrins 0.33% (RID Mousse, RID shampoo, A-200 shampoo, R & C, Pronto, Clear lice system, End Lice)	Apply to hair for 10 min and wash; repeat in 1 wk	Approved for > 2 yr old; 80% cure rate
1% gamma benzene hexachloride shampoo and cream (lindane; Kwell, G-well)	Apply for no more than 4 min and wash; repeat in 1 wk	Not recommended due to neurotoxic adverse effects, such as seizures if used repeatedly; avoid if seizure disorder, pregnant, or breast-feeding
Malathion 0.5% (Ovide) lotion	Apply and leave for 8–12 hr, then wash; repeat in 1 wk	Approved for > 6 yr old; high alcohol content makes it flammable, may cause respiratory depression if ingested
Crotamiton 10% (Eurax) cream and lotion	Apply and leave for 24 hr, then wash	Not FDA approved and safety in children unknown
Ivermectin (Mectizan, Stromectal)	200 mcg/kg PO; repeat in 1 wk	Not FDA approved; use in resistant cases and if > 15 kg
Sulfamethoxazole/trimethoprim (co-trimoxazole)	8–10 mg/kg/day of trimethoprim q12h PO for 3 days; repeat in 1 wk	Not FDA approved; increased effectiveness if given with permethrin
Precipitated sulfur (3–10%) in petrolatum	Apply daily for several days	Safe in pregnancy, breast-feeding, and infants < 2 mo of age; bad odor and messy; in hot or humid climate may lead to irritant dermatitis; less effective than permethrin

Abbreviations: FDA, Food and Drug Administration; PO, orally.

Chapter 126

Other Important Rashes

Antonio E. Muñiz, MD

Key Points

Scarlet fever is treated with penicillin to prevent local suppurative complications and the development of acute rheumatic fever.

Staphylococcal scalded skin syndrome and toxic shock syndrome require antistaphylococcal antibiotics, fluid and electrolyte replacement, and meticulous skin care.

Tinea capitis is the most common cause of hair loss in children and is usually treated with prolonged oral antifungal therapy.

Tinea corporis is the most common fungal skin infection in children and is usually treated with topical antifungal therapy.

Kawasaki disease is treated with aspirin and intravenous immune globulin to prevent formation of coronary artery aneurysms.

The disease is rare under 2 years of age presumably due to the presence of maternal antitoxin antibodies.

Most cases of scarlet fever are due to group A β -hemolytic streptococcal pyrogenic exotoxin-producing strains.² Occasionally cases are caused by strains of group C or G streptococci. Its highest incidence is in the late fall, winter, and early spring. Transmission occurs through person-to-person contact with infectious respiratory droplets. The incubation period prior to appearance of the rash is 2 to 5 days.

The most common infection that leads to scarlet fever is tonsillopharyngitis, but the rash develops in less than 10% of cases.³ It can also occur after a streptococcal skin and soft tissue infection, or infection of surgical wounds (surgical scarlet fever) or the uterus (pubertal scarlet fever).

Clinical Presentation

The illness begins with nonspecific signs and symptoms: fever, headache, malaise, nausea, vomiting, abdominal pain, and myalgias. Exudative tonsillopharyngitis is characterized by an erythematous oral mucosa, petechiae, and punctate erythematous macules on the palate and uvula (Forschheimer spots). The tongue is covered initially by a yellowish white coat; protruding red papillae give it the appearance of a “white strawberry tongue.” Within 2 to 4 days, disappearance of the white coating reveals a beefy red tongue with enlarged papillae known as a “red strawberry tongue” (Fig. 126–1).

The exanthem appears 24 to 48 hours afterward and consists of erythematous macules and papules, beginning on the neck, face, and upper trunk and spreading downward to the extremities over the next 1 to 2 days. Generalized erythroderma is punctuated by numerous pinpoint, erythematous, blanchable papules, imparting a sandpaper-like texture (Fig. 126–2). Occlusion of sweat glands produces the papular rash. In severe cases the exanthem may be petechial and worsened by the application of a tourniquet. Capillary fragility causes petechiae in a linear pattern along major skinfolds, such as the axilla, antecubital fossa, and inguinal fossa, known as Pastia’s lines. The palms and soles are generally spared, and there is a facial flush with circumoral pallor. Generalized adenopathy is common, but particularly inguinal nodes and splenomegaly may occur.

The rash fades over 5 to 7 days, and is followed by fine superficial desquamation of the face, trunk, axilla, groin, and extremities. Desquamation may continue for weeks, especially in the hands and feet.

Selected Diagnoses

- Scarlet fever (scarlatina, second disease)
- Staphylococcal scalded skin syndrome
- Staphylococcal toxic shock syndrome
- Tinea capitis
- Tinea corporis
- Pityriasis versicolor
- Molluscum contagiosum
- Pityriasis rosea
- Kawasaki disease (mucocutaneous lymph node syndrome)
- Impetigo

Discussion of Individual Diagnoses

Scarlet Fever (Scarlatina, Second Disease)

Scarlet fever is a toxin-mediated disease characterized by fever, oral mucous membrane changes, and an exanthem. It occurs most often in children between 2 and 10 years of age.¹

FIGURE 126-1. Red strawberry tongue in scarlet fever.

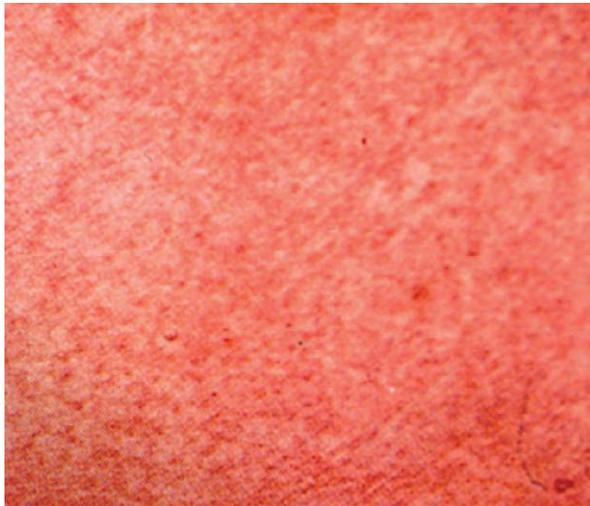

FIGURE 126-2. Papular rash in scarlet fever with sandpaper-like texture.

The differential diagnosis for scarlet fever includes other papular eruptions⁴ (Table 126-1).

Complications of scarlet fever are unusual but include bacteremia, sepsis, pneumonia, myocarditis, hepatitis, otitis media, meningitis, and toxic shock syndrome (TSS). Late complications include acute rheumatic fever and acute post-streptococcal glomerulonephritis.⁵

Leukocytosis with a left shift is common, and eosinophilia may also occur. Diagnosis is generally made on clinical grounds and confirmed by culture of *Streptococcus pyogenes* from a focal infection such as the throat or skin. Highly specific rapid antigen detection technology is available for detection of *S. pyogenes*. False negatives can occur with a low level of infection and with infection caused by the non-group A streptococcus. Consequently, a negative antigen detection test should be followed up with a confirmatory throat culture. One can also confirm the diagnosis with an anti-streptolysin O titer that is noted to be rising.

Table 126-1 Differential Diagnosis for Scarlet Fever

Staphylococcal scarlet fever
Viral hepatitis
Infectious mononucleosis
Kawasaki disease
Toxic shock syndrome
Measles
Rubella
Staphylococcal scalded skin syndrome
Roseola infantum
Erythema infectiosum
Echovirus 14
Drug-associated eruptions
Secondary syphilis
Juvenile rheumatoid arthritis
<i>Streptobacillus moniliformis</i> (rat bite fever)
<i>Arcanobacterium haemolyticum</i>

Table 126-2 Antimicrobial Agents Effective for Scarlet Fever

Antimicrobials	Doses
Penicillin V potassium	25–50 mg/kg/day qid PO for 10 days
Benzathine penicillin	Single daily dose: <1 mo old: 50,000 U/kg IM <27 kg: 600,000 units IM >27 kg: 1,200,000 units IM
Cephalexin	25–100 mg/kg/day qid PO for 10 days
Azithromycin	12 mg/kg/day qd PO for 5 days
Clarithromycin	15 mg/kg/day bid PO for 10 days

Abbreviations: IM, intramuscularly; PO, orally.

Management

Early treatment of scarlet fever is associated with reduced infectivity, more rapid resolution of disease, and prevention of acute complications as well as acute rheumatic fever.⁶ Penicillin is the treatment of choice; it can be given orally as penicillin VK for 10 days or intramuscularly as benzathine penicillin⁷ (Table 126-2). Narrow-spectrum oral cephalosporins, such as cephalexin, are also effective therapies.⁸ For penicillin-allergic patients, azithromycin, or clarithromycin is effective. Erythromycin should no longer be used for Group A *Streptococcus* infections due to resistance rates that approach 50%.

During the later stages of desquamation, antihistamines and bland ointments applied to wet skin will restore the skin integrity and ameliorate discomfort.

Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome (SSSS) is a toxin-mediated disease characterized by cutaneous tenderness and widespread blistering and/or desquamation.⁹ A spectrum of clinical presentations of SSSS is recognized, ranging from purely localized forms (bullous impetigo) to generalized involvement (Ritter's disease). It generally occurs in children less than 5 years of age, and is postulated to be due to reduced renal clearance and lack of immunity to the toxins. It has occurred in adults with immunosuppression, malignancy, chronic alcohol abuse, intravenous drug use, or renal

impairment and is associated with greater than 50% mortality.¹⁰⁻¹² In children the mortality is approximately 4%.¹³

Staphylococcus aureus is an aerobic, gram-positive coccus that is ubiquitous and a virulent pathogen. It causes a wide range of infections from folliculitis and skin abscess to endocarditis and sepsis. SSSS is caused by phage II staphylococci, particularly strains 71 and 55, and occasionally strains 3A, 3B, and 3C.^{14,15} *Staphylococcus aureus* elaborates two exotoxins, epidermolytic toxin A and epidermolytic toxin B, which are carried via the blood to the skin, where they act on the cell surface of the epidermal granular cells and activate serine proteinases.^{16,17} Minor trauma to these keratinocytes results in intraepidermal separation of the cells within the granular layer and subsequent shedding of the skin.

Clinical Presentation

Foci of infection where the toxins are generated include the nasopharynx, umbilicus (neonates), urinary tract, cutaneous wounds, conjunctiva, and blood. Onset of the rash may be preceded by a prodrome of fever, malaise, and irritability. A faint erythematous eruption that resembles a sunburn begins, and is most intense on the central face, neck, axilla, and groin.^{1,18} The skin rapidly becomes acutely tender, which is responsible for the marked irritability in many affected patients. The exfoliative phase is heralded by crusting around the mouth, eyes, and neck (Fig. 126-3). Often a purulent discharge emits from the eyes. Mild rubbing of the skin results in epidermal separation, leaving a shiny, moist, red surface (Nikolsky's sign).¹⁸ Large fragments of crusts often become separated, leaving radial fissures surrounding the mouth that give the disorder its characteristic appearance. In infants and preschool children, lesions are usually limited to the upper body, while in newborns, the entire cutaneous surface may be involved (Ritter's disease) (Fig. 126-4). With severe involvement, large sheets of skin shear away, leaving a denuded oozing surface similar to the reaction that occurs after a burn or scald. Vesicles, pustules, and bullae can also occur during the exfoliative phase. Most children do well,

FIGURE 126-3. Exfoliative phase with crusting around mouth and eyes seen in staphylococcal scalded skin syndrome.

with resolution in 12 to 14 days with no residua. Intact bullae are consistently sterile. Occasionally the organism can be recovered from pyogenic foci on the skin, conjunctivae, or nasopharynx, from the stool, and rarely from the blood.

In the newborn, SSSS may be confused with diffuse cutaneous mastocytosis. In older children, the differential diagnosis is more broad (Table 126-3).

Complications may include sepsis and respiratory distress.¹⁹

Management

Therapy is directed against *S. aureus* to eliminate bacterial toxin production. For localized skin involvement, oral antibiotics such as cephalexin, amoxicillin-clavunilate, or dicloxacillin may be used. Those patients allergic to penicillin can be given azithromycin, clarithromycin, or clindamycin. Theoretically, clindamycin suppresses protein synthesis and further toxin production; therefore, its use may be more efficacious than bacterial cell wall inhibitor agents, such as β -lactamase antibiotics.²⁰ Neonates and infants less than 1 year old, and patients with extensive involvement, should be hospitalized and given parenteral antibiotics such as nafcillin or cefazolin. With the increasing prevalence of MRSA, consider administration of antibiotics effective against this organism (see Chapter 120, Skin and Soft Tissue Infections).

Replacement of fluid and electrolytes is required for patients with extensive skin involvement. The skin should be handled minimally, especially during the first 24 hours.

Table 126-3 Differential Diagnosis for SSSS

Drug-induced (toxic epidermal necrolysis, Stevens-Johnson syndrome)
Diffuse cutaneous mastocytosis
Exfoliative erythroderma
Sunburn
Thermal burn or scalds
Toxic shock syndrome
Streptococcal scarlet fever
Scarlet fever
Bullous impetigo
Epidermolysis bullosa
Epidermolytic hyperkeratosis
Pemphigus foliaceus

FIGURE 126-4. Scalded appearance from widespread desquamation seen in staphylococcal scalded skin syndrome.

Newborns may require burn therapy protocols, with careful attention to fluid and electrolyte losses and prevention of secondary infection.¹⁷ During the desquamation stage, application of emollients twice a day may be helpful in restoring the skin surface and reducing dermal pain.

Staphylococcal Toxic Shock Syndrome

Staphylococcal TSS is characterized by the acute onset of high fever, diffuse erythroderma followed by desquamation, hyperemic mucous membranes, hypotension, and multiorgan compromise. Prolonged tampon use with superinfection by *S. aureus* is the classic history, but many other sources have been implicated.

TSS is due to infection or colonization with a toxin-producing strain of *S. aureus*, especially phage types 29, 52, and 29/52 of phage group I, in a susceptible host with low to absent levels of specific antitoxin antibody.^{21,22} The exotoxins include toxic shock syndrome toxin-1 (TSST-1), staphylococcal enterotoxin B (SEB), and staphylococcal enterotoxin C (SEC). TSST-1 occurs 75% of the time, SEB 25%, and SEC 2%. These toxins are associated with massive release of tumor necrosis factor- α (TNF- α) and interleukin-1. These substances have been shown to produce the features of TSS, including, fever, rash, hypotension, shock, and tissue injury.

Clinical Presentation

A typical presentation of TSS involves a menstruating adolescent female who presents with a high fever, generalized erythroderma, and hypotension.^{1,23} Prominent desquamation of the palms and soles follows the acute eruption by 1 to 2 weeks. Additionally, in the nonmenstruating female or in males, sinusitis, otitis media, tracheitis, burns, minor skin infections, nasal packing, herpes zoster infection, cellulitis, osteomyelitis, bursitis, and uterine infection are sources for *S. aureus* to elaborate toxins.²⁴ Nonmenstrual TSS has less frequent central nervous system manifestations and anemia, but more frequent musculoskeletal involvement.²³

High fever, malaise, chills, headache, myalgias, weakness, abdominal pain, vomiting, and diarrhea frequently precede the hypotensive state.²⁵ Hypotension ensues rapidly, leading to tissue ischemia and multiorgan injury.²⁶ The hypotension is caused by a decrease in systemic vascular resistance as well as nonhydrostatic leakage of fluid from the intravascular space to the interstitial space, both of which occur from massive cytokine release induced by the responsible exotoxins.²⁶ Patients typically present without focal neurologic or meningeal signs, but confusion and disorientation can occur, and may progress to seizures and coma. Persistent neuropsychological sequelae can develop, such as headaches, memory loss, and poor concentration.²⁷ Acute renal failure, adult respiratory distress syndrome (ARDS), myocardial dysfunction, hepatic dysfunction, and disseminated intravascular coagulation may be life threatening. Mortality occurs in up to 10% to 15% of cases without treatment and 3% to 5% with treatment.²³

The rash develops in all patients within 1 to 3 days of the prodrome. A diffuse, macular, erythrodermic, scarlatiniform eruption develops on the trunk and spreads to the extremities²⁸ (Fig. 126–5). It resembles a sunburn that involves the palms and soles. Typically the rash fades over a few days, but on occasion it becomes petechial, purpuric, vesicular, or bullous.

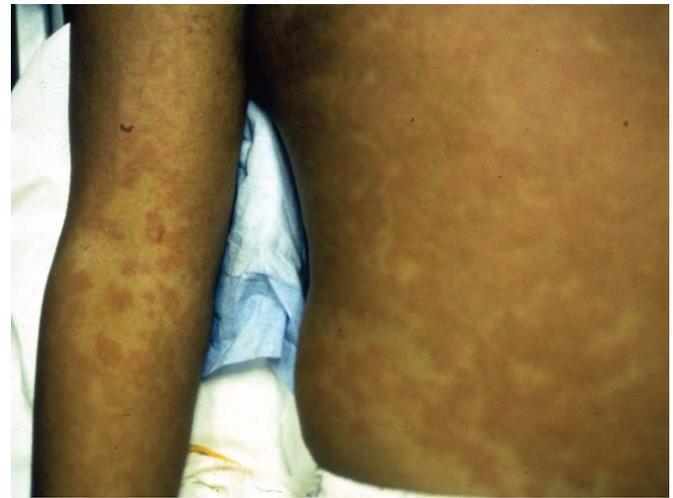

FIGURE 126–5. Diffuse erythrodermic rash seen in staphylococcal toxic shock syndrome.

Diffuse erythema of the pharyngeal, oral, conjunctival, and vaginal mucosa occurs and may progress to ulcerations.²³ A strawberry tongue and palatal petechiae may be seen.²⁹ One to 2 weeks after the onset of illness, approximately 50% of patients develop a diffuse, pruritic, maculopapular rash, which is sometimes urticarial, typically involving the palms and soles.³⁰ This secondary eruption lasts 2 to 7 days and is accompanied by edema of the face, hands, and feet as a consequence of increased interstitial fluid. Full-thickness desquamation of the skin, especially in the subungual, palm, and sole regions, occurs 10 to 21 days after onset of illness. The nails may be shed, and telogen effluvium or temporary cessation of hair growth may occur 2 months later.

Laboratory abnormalities reflect the multisystem involvement, shock, and endogenous cytokine release. They include low serum protein and albumin, leukocytosis with a left shift, anemia, thrombocytopenia, and evidence of disseminated intravascular coagulation. Renal abnormalities include reduced urine output, sterile pyuria, proteinuria, and elevated blood urea nitrogen and creatinine. Electrolyte abnormalities include hypocalcemia, hyponatremia, hypoalbuminemia, hypophosphatemia, and hypomagnesemia. Cerebrospinal fluid pleocytosis may occur. Hepatic enzymes, bilirubin, muscle creatinine, and serum lactate are elevated.

Diagnosis is usually based on the clinical features. *Staphylococcus aureus* is recovered from the cervix or vagina in more than 85% of patients with menstrual TSS and from the focus of infection in patients with nonmenstrual TSS. It is recovered from blood cultures in less than 5% of cases.³¹

The differential diagnosis for scarlet fever includes the entities listed in Table 126–4.

Complications include hypotension, myocardial dysfunction, acute renal failure, ARDS, disseminated intravascular coagulation, and fluid and electrolyte imbalances.

Management

Treatment of TSS centers on intensive supportive management of shock and multiorgan failure, identification and drainage of infection, and prompt institution of antibacterial therapy. Prompt replacement of fluids to correct hypotension

Abbreviations: IM, intramuscularly; IV, intravenously; PO, orally.

and shock is essential to achieve adequate tissue perfusion, as are other general supportive measures for shock. Treatment with an antistaphylococcal antibiotic is necessary to eliminate bacterial toxin production, but is unlikely to alter the acute course of the disease unless given early, before significant amounts of toxin can reach the circulation. The choice of antibiotics may include nafcillin or cefazolin (Table 126–5). Penicillin-allergic patients can be given azithromycin, clarithromycin, or clindamycin.³² Theoretically, clindamycin suppresses protein synthesis and further toxin production; therefore, its use may be more efficacious than bacterial cell wall inhibitor agents, such as β -lactamase antibiotics.²⁰ Clindamycin is generally effective for patients with community-associated methicillin-resistant *S. aureus* (MRSA), and vancomycin is recommended for those with hospital-acquired MRSA.³³ Administration of intravenous immune globulin (IVIG) or TSST-1–specific monoclonal antibody may be considered for treatment of TSS with unrelenting shock and organ failure despite optimal management.^{26,34–36} The use of high-dose corticosteroids, such as methylprednisolone 10 to 30 mg/kg/day for 2 to 3 days, is controversial. In a retrospective trial, corticosteroids reduced the severity of illness and duration of fever but had no effect on mortality.³⁷ If a tampon or nasal packing is present, it should be removed and the cavity irrigated in an effort to remove the organism, toxins, and possible retained pieces of tampon or packing. Drainage of a focus of infection is necessary to remove the offending *S. aureus*. Bland lubricants should be used on the desquamating skin.

Tinea Capitis

Tinea capitis is the most common dermatophytosis in children and is a fungal infection of the scalp characterized by scaling and alopecia. It is the most common cause of hair loss in children. Dermatophytes are fungi that invade and proliferate in the outer layer of the epidermis (stratum corneum). Some species can invade the hair and nails. Because of the annular appearance of the lesion, they are known as “ringworm.” Dermatophytes can be of three types: geophilic organisms that live in the soil, zoophilic organisms that live on animals, and anthropophilic organisms that live on humans. These infections are common and increase with increasing age, in hot humid climates, and in crowded living conditions.^{38,39} Hair involvement is usually seen in prepubertal children and is largely due to *Trichophyton tonsurans* and less often to *Microsporum audouinii* and *Microsporum canis*.^{38,39} Each infection has a noninflammatory stage lasting 2 to 8 weeks, followed by an inflammatory stage.

Most cases occur in children ages 4 to 7 years with a prevalence of 2.5% in African Americans and less than 1% in whites.³⁴ The fungus is transmitted by person-to-person contact or animal-to-person contact.⁴⁰ The incubation period is 1 to 3 weeks, and the infection occurs more commonly in boys.⁴¹

Fungal infections of the scalp occur when hyphae invade the stratum corneum and then grow down a follicular wall between the skin and hair shaft until they reach the midfollicle. At this point they invade the hair itself and continue the downward invasion of the hair until they reach Adamson’s fringe, where keratinization first occurs within the hair. If the infection is endothrix in nature, the hyphal element segments into arthroconidia inside the hair, which become replete with spores. These hairs are severely damaged, and tend to break off close to the scalp because of their fragility. In an ectothrix infection, the hyphae fragment into spores on the surface of the hair shaft, rather than within it.

Clinical Presentation

Hair loss is a regular feature of tinea capitis. *Microsporum canis* infections are noninflammatory and characterized by scaling and patchy hair loss. The infected areas are round, oval, or irregular and 1 to 6 cm in diameter, and multiple patches are common (Fig. 126–6). “Black dots,” which are short (1- to 3-mm), broken-off hairs, may be noted in areas of alopecia. In some patients, no discrete hair loss is noted, and these cases may be misdiagnosed as seborrheic dermatitis or dandruff. Some hair follicles may be tinged gray as a result of the spores coating the outside of the hair shaft. Accompanying posterior cervical adenopathy is common.⁴²

In contrast, *T. tonsurans* produces several distinct clinical presentations.⁴³ There is a “seborrheic” form in which scales occur without noticeable hair loss (Fig. 126–7). The inflammatory disease form is characterized by papules, pustules, erythema, and significant crusting (Fig. 126–8); it is very pruritic. An initial cluster of small follicular papules or pustules may gradually expand and coalesce, and at this stage the infection may be mistaken for folliculitis. Hair loss follows, which may be discrete and patchy or confluent. The most severe reaction consists of a tender, red, sometimes oozing, boggy mass known as a kerion (Fig. 126–9). The kerion may be misdiagnosed as a bacterial abscess. Severe

FIGURE 126-6. Annular patch of alopecia with scales and “black dots” seen in tinea capitis.

FIGURE 126-7. Patchy alopecia with scales in tinea capitis (“seborrheic” form).

FIGURE 126-8. Inflammatory tinea capitis showing papules, pustules, erythema, and crusting.

scarring and permanent hair loss may occur even if proper therapy is given, but are more likely if therapy is delayed. A “black dot” variety of *T. tonsurans* infection is also seen. An extensive pruritic, eczema-like eruption on the trunk and extremities (dermatophytid or id reaction) may develop,

FIGURE 126-9. Kerion seen in tinea capitis.

especially after institution of antifungal therapy.⁴⁴ This occurs from an interaction between the host and fungal antigens.

Wood’s lamp examination in *Microsporum* species is positive (fluoresces yellow-green) because it is an ectothrix infection of hairs, while *T. tonsurans*, an endothrix infection does not fluoresce. Culture in Sabouraud’s agar is the “gold standard” for diagnosis. Potassium hydroxide (KOH) examination will reveal tiny arthrospores surrounding the hair shaft in *Microsporum* infection (ectothrix) and chains of arthrospores within the hair shaft (endothrix) in *T. tonsurans*. Dermatophyte test medium is a culture technique that changes color to deep red when the culture is positive.

The differential diagnosis includes alopecia areata, trichotillomania, traction alopecia, friction alopecia, seborrheic dermatitis, psoriasis, bacterial folliculitis, yeast folliculitis, impetigo, discoid lupus, and secondary syphilis.

Management

Topical therapy may be helpful, but is not sufficient to penetrate the hair shaft; therefore, systemic treatment is essential for eradication of the organism. Griseofulvin is still considered first-line therapy because of its efficacy, safety profile, and cost.^{44a} However, a decreased sensitivity to this agent is emerging.⁴² Increasing the dose to 20 to 25 mg/kg (maximum 1 g) of the microsize formulation has been shown to once again be efficacious.⁴⁵ Treatment consists of 6 to 12 weeks of therapy, and continuing for 2 weeks after clinical resolution. Accumulating experience with systemic terbinafine, itraconazole, and fluconazole indicates that they may be more effective and require shorter course of therapy^{46,47,47a} (Table 126-6). Ketoconazole is the least effective agent and has a higher adverse effect profile, and is not recommended.

Rapid elimination of contagion risk is best achieved through systemic treatment in conjunction with twice-weekly use of a spore-inhibiting shampoo containing selenium sulfide, ketoconazole, or zinc pyrithione.⁴⁸ Contaminated hairbrushes, towels, pillowcases, or other fomites may spread infection and should be disinfected. Therefore, scalp grooming items and hats from infected patients should not be shared.

Table 126–6 Antifungal Therapy for Tinea Capitis

Drug	Dose	Duration
Griseofulvin	20–25 mg/kg/day PO of microsize or 5–10 mg/kg/day PO of ultramicrosize qd or bid	6–12 wk; continue 2 wk after clinical resolution Take with fatty foods, eggs, or milk (improves absorption)
Terbinafine	3–6 mg/kg/day <20 kg: 62.5 mg/day 20–40 kg: 125 mg/day >40 kg: 250 mg/day	2–3 weeks <i>M. canis</i> may require 8 wk
Itraconazole	5 mg/kg/day PO qd or bid	2–4 wk
Fluconazole	8 mg/kg/day	2–4 wk

Abbreviation: PO, orally.

Treatment of the id reaction consists of topical or systemic corticosteroids. Kerions respond best by treating the underlying fungal disorder. Some advocate 3 to 4 weeks of oral corticosteroid therapy in patients with large and painful kerions; however, a randomized trial of corticosteroids plus oral antifungal agents versus antifungal agents alone showed no difference in cure rates.^{49,50} If treated with oral antifungal agents, follow-up should occur in 2 to 3 months to ensure eradication of the infection.

Tinea Corporis

Tinea corporis, commonly known as “ringworm,” is a dermatophyte infection of nonhairy (glabrous) surfaces, not otherwise designated as to specific area. It is more prevalent in warm or moist climates.⁵¹ It may be caused by any of the dermatophytes making up the genera *Trichophyton*, *Microsporum*, and *Epidermophyton*.⁵² In children the most common cause is *T. tonsurans*.⁵³ Sites of predilection include the non-hairy areas of the face, trunk, and limbs with exclusion of scalp (tinea capitis), bearded areas (t. barbae), hands (t. manuum), nails (onychomycosis), groin (t. cruris), and feet (t. pedis).

Clinical Presentation

Tinea corporis presents as one or more red, scaly papules. These papules spread and eventually coalesce into plaques that become scaly. The center of these plaques tends to clear, producing annular configurations and occasionally concentric rings (Fig. 126–10). Mild erythema, edema, vesicles, or even bulla formation may occur. If extensive crusting develops, the resulting plaques can resemble psoriasis. Itching may be prominent with inflammatory infections. Pustules and inflammation are more common with *M. canis*. A marked perifollicular or follicular granulomatous inflammatory response may occur, especially in patients inadvertently treated with topical corticosteroids. This disorder is termed *Majocchi's granuloma*; it is caused by *T. rubrum* and often requires oral antifungals.⁵⁴ The use of topical corticosteroids may mask the diagnosis by distorting the lesion (tinea incognita).

The diagnosis is made by demonstrating septate branching hyphae on KOH examination or cultured in Sabouraud's agar. The differential diagnosis includes nummular eczema, granuloma annulare, candidiasis, urticaria, erythema annulare centrifugum, psoriasis, pityriasis rosea, secondary syphilis, sarcoidosis, leprosy, and discoid lupus.

FIGURE 126–10. Annular plaque seen in tinea corporis.

Management

Many cases of tinea corporis resolve spontaneously; however, contagion is still an issue that compels treatment.⁵⁵ Topical treatment alone is usually effective in those patients with limited disease (Table 126–7). Treatment that involves the lesion and surrounding borders should be continued for about 1 week after apparent clinical eradication. In persistent cases or widespread disease, oral antifungals are used (Table 126–8). High-potency corticosteroids are likely to worsen the infection and are associated with substantial adverse effects.⁵⁶

Imidazoles inhibit the enzyme lanosterol-14- α -demethylase, a cytochrome P-450–dependent enzyme that converts lanosterol to ergosterol. It results in unstable fungal cell wall and causes membrane leakage. Imidazoles include compounds such as econazole, miconazole, oxiconazole, and clotrimazole. All are broad-spectrum antifungal agents that have good activity against dermatophytes, *Candida*, and other yeasts. A second class of antifungals includes ciclopirox olamine, a pyridone ethanolamine salt that interferes with synthesis of cell membrane proteins. The allylamines are a

Table 126–7 Topical Drugs for Superficial Fungal Infections

Drugs	Strength	Formulations*	Application(s)/Day
Butenafine (Mentax, Lotrimin Ultra)	1%	C	1 or 2
Ciclopirox (Loprox)	0.77%	C	2
Clotrimazole (Lotrimin, Lotrimin AF, Mycelex)	1%	C, L, S	2
Econazole (Spectazole)	1%	C	1
Ketoconazole (Nizoral)	2%	C, Sh	2

Table 126–8 Oral Drugs for Fungal Infections

Drugs	Doses
Griseofulvin microsize	20–25 mg/kg/day qd or bid
Griseofulvin ultramicrosize	5–10 mg/kg/day qd or bid
Terbinafine	3–6 mg/kg/day qd
	<20 kg: 62.5 mg/day qd
	20–40 mg/kg: 125 mg/day qd
	>40 kg: 250 mg/day qd
Itraconazole	5 mg/kg/day qd or bid
Fluconazole	8 mg/kg/day qd

third class of agents, which includes naftifine and terbinafine. They interfere with ergosterol synthesis through inhibition of squalene oxidase and are fungicidal in vitro. In addition, naftifine has anti-inflammatory properties that may be useful in severe inflammatory disease.⁵⁷ The older antifungal compounds, undecylenic acid and tolnaftate, are of limited value and have no activity against *Candida*. Haloprogin is somewhat useful against *Candida* and dermatophytes but has been supplanted by newer agents. Miconazole, clotrimazole, and terbinafine are available over the counter in topical formulations and are acceptable first-line agents for most uncomplicated fungal infections. Follow-up should occur in 2 to 4 weeks to ensure complete resolution of the infection.

Pityriasis Versicolor

Pityriasis versicolor is a condition caused by proliferation of *Pityrosporum filamentous* yeast forms within the stratum corneum of human skin. It is characterized by hypopigmented and hyperpigmented macules and patches. The term *tinea* is inappropriate since this infection is caused by a yeast rather than a dermatophyte. It is most common in individuals 15 to 24 years of age.

Pityriasis versicolor is caused by *Malassezia furfur* (also known as *Pityrosporum orbiculare*, *Pityrosporum ovale*, and *Malassezia ovalis*), a dimorphic lipophilic yeast that can reside on skin as a normal skin flora. However, it can also be an opportunistic pathogen, and under appropriate conditions, the benign yeast (spore) form can transform into an invasive filamentous (hyphal) phase. Factors that lead to the conversion of the saprophytic yeast to the parasitic mycelial morphologic form include a genetic predisposition, warm

humid environments, immunosuppression, malnutrition, and Cushing's disease. Pityriasis is more common in areas of high heat and humidity because moisture promotes growth of the organism. The majority of cases occurs in adolescents and affect cutaneous areas where sebaceous glands are active. In children, up to one third have lesions on their faces.⁵⁸ It tends to be a chronic disease, and even with treatment, recurrences are common.⁵⁹

Clinical Presentation

The organism produces dicarboxylic acids, such as azaleic acid, that inhibit melanogenesis and cause direct damage to melanocytes, which may account for the prolonged hypopigmentation that occurs following infection. Patients usually present for cosmetic reasons, but may also complain of pruritus. Children frequently have facial lesions that involve the forehead and temple. Adolescents and adults commonly have lesions on the upper back, chest, and arms. Other less common sites include the neck, axilla, legs, popliteal fossa, forearms, and genitalia.

Lesions of the face consist of ovoid macules that are hypopigmented with a faint scale. Lesions at other sites, as the name “versicolor” implies, can vary in color. Hypopigmented, faint pink, red, or tan to darker brown lesions may be present^{59a} (Fig. 126–11). They consist of discrete and coalescent ovoid macules of varying size that have a fine, faint scale that is more noticeable upon scraping the area. They are often concentrated symmetrically over areas of high sebum content such as the upper chest and back. Papules and annular plaques are sometimes seen.

An inverse form of pityriasis versicolor exists in which the condition has an entirely different distribution, affecting the flexural regions, the face, or isolated areas of the extremities. It is usually seen in immunocompromised patients.

Microscopic examination of skin scrapings mounted in 10% KOH reveals both budding yeast and short, stubby hyphal forms (“spaghetti and meatballs”) (Fig. 126–12). Culture can be performed in a media enriched with C12- or C14-sized fatty acids. Wood's lamp examination shows a yellowish brown or copper-orange fluorescence.

The differential diagnosis for pityriasis versicolor includes vitiligo, pityriasis alba, pityriasis rosea, pityriasis rotunda, tinea corporis, seborrheic dermatitis, atopic dermatitis, candidiasis, guttate psoriasis, erythrasma, secondary syphilis, pinta, and leprosy.

FIGURE 126-11. Hypopigmented macules seen in pityriasis versicolor.

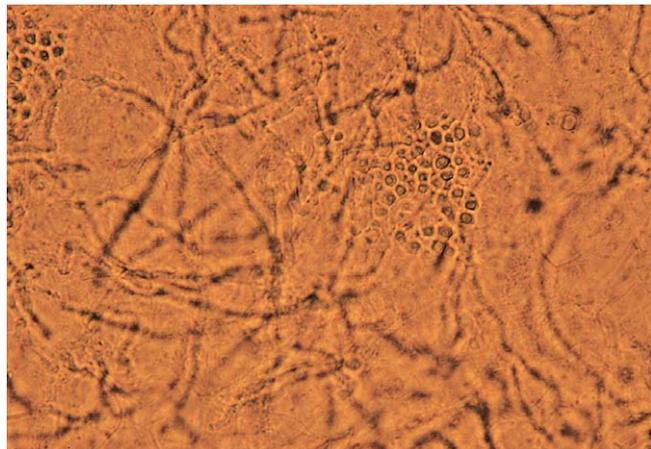

FIGURE 126-12. 10% KOH preparation showing the budding yeast and short, stubby hyphal form (“spaghetti and meatballs”) of pityriasis versicolor.

Management

A number of topical agents are effective in the treatment of pityriasis versicolor (Table 126-9). Topical agents should be applied to the trunk, neck, arms, legs, and scalp to minimize spore count and possibility of relapse. Although selenium sulfide lotion applied for 5 to 10 minutes for 7 days is commonly utilized, the cosmetic problem and prolonged therapy required with this agent have led to the increasing use of therapeutic alternatives. Systemic therapy is generally indicated for extensive lesions resistant to topical treatment, or those with frequent relapse; however, oral therapy is not approved by the Food and Drug Administration in children (Table 126-10).

Molluscum Contagiosum

Molluscum contagiosum is a viral infection characterized by umbilicated papules. It is caused by poxvirus, a DNA virus.⁶⁰

It can occur at any age, but infection is most common in young children, sexually active adults, and persons with impaired cellular immunity. Transmission is by person-to-person contact, contact with fomites, or autoinoculation. The incubation period ranges from 2 to 8 weeks, but has been noted to be as early as 1 week.⁶¹

Clinical Presentation

Children present because of the presence of visible bumps, pruritus, or soreness. The typical lesions are discrete, dome-shaped, umbilicated (central punctum) waxy papules⁶⁰ (Fig. 126-13). They may be skin colored, pink, or white. Lesions may appear to be vesicular because of a translucent quality. They also may appear as tiny, pinpoint papules simulating milia. Lesions vary in size from 1 to 5 mm, although they may be as large as 10 to 15 mm (giant molluscum). Secondary bacterial infection may occur producing crusting, redness, and pus formation.

Lesions may occur on any part of the body but, in young children, are most commonly on the axilla, side of the trunk, lower abdomen, thighs, and face. Lesions in the genital area that occur in adolescents or young adults are frequently sexually transmitted.⁶⁰ The presence of lesions in the genital area of young children is not usually a consequence of sexual abuse, but this possibility should be excluded. In this age group it is commonly a consequence of autoinoculation.

An eczematous eruption on the skin adjacent to molluscum (“molluscum dermatitis”) occurs in 10% of cases.⁶² Widespread cutaneous infection with hundreds of lesions has been reported in atopic dermatitis and in immunocompromised children.

Detection of the virus in skin lesions has been achieved using polymerase chain reaction.⁶³ Histologic examination by hematoxylin and eosin staining shows keratinocytes filled with intracytoplasmic inclusion bodies (Henderson-Paterson bodies), which are eosinophilic ovoid structures in the lower malpighian layer. These homogeneous molluscum inclusion bodies may also be demonstrated by smearing the cheesy

Table 126–9 Topical Agents Effective against Pityriasis Versicolor

Agents	Application
Ketoconazole 2% (Nizoral) shampoo, cream	Once or twice daily for 3–14 days
Selenium sulfide shampoo (Selsun Blue, Excel, Head & Shoulders)	Once daily for 7–14 days
Terbinafine (Lamisil AT) cream, spray, solution	Twice daily for 5–7 days
Econazole 1% (Spectazole) cream	Once daily
Ciclopirox 0.77% (Loprox) cream, lotion, gel, suspension	Twice daily for 2–4 wk
Sulconazole 1% (Exelderm) cream, solution	Daily or twice daily for 3 wk
Clotrimazole 1% (Lotrimin) cream, solution	Twice daily for 2–4 wk
Butenafine 1% (Mentax) cream	Daily 14 days
Miconazole 2% (Monistat Derm, Micatin, Lotrimin AF Spray) cream, shampoo	Twice daily for 2–4 wk

Table 126–10 Oral Agents Effective against Pityriasis Versicolor

Agents	Dose
Ketoconazole	200–400 mg 3–7 days, then once a month
Itraconazole	200 mg 5–7 days
Fluconazole	400 mg once

**FIGURE 126–13.** Dome-shaped, umbilicated waxy papule from molluscum contagiosum.

contents from a lesion onto a slide and staining with Gram, Giemsa, or Wright stain.⁶⁴ Electron microscopic examination shows the typical brick-shaped poxvirus particles.

The differential diagnosis includes verrucae, varicella, folliculitis, furunculosis, milia, juvenile xanthogranuloma, Spitz nevi, skin tags, and epidermal cysts.

Management

Molluscum infection, left untreated, nearly always resolves spontaneously, but resolution may take a few weeks to a few years. Therefore, treatment may not always be indicated.⁶⁵ In the case of bacterial superinfection, antistaphylococcal antibiotics should be administered. If treatment is considered, a large number of topical agents have been useful, such as tretinoin cream, benzoyl peroxide, podophyllum resin in tincture of benzoin, podoflox, salicylic acid, cantharidin, 10% KOH, and silver nitrate.^{66–68a} Topical 3% cidofovir has been used successfully in children with immunodeficiency,^{69,70} and oral cidofovir has been used in adults but is not approved in children.⁷¹ Oral cimetidine has been reported to be effective.⁷² In immunocompromised patients, ritonavir, cidofovir, saquinavir, lamivudine, and zidovudine have been used.^{73–75} In resistant cases, imiquimod cream or intralesional interferon alfa has been used.^{76,77} Cryotherapy (liquid nitrogen,

dry ice, or Frigiderm) applied to each lesion for a few seconds and repeated as needed in 2- to 3-week intervals has been effective.⁷⁸ For extensive lesions, ablative therapy may require general anesthesia with pulsed dye laser.⁷⁹

An easy method to remove the lesion is eviscerating the core with an instrument such as a no. 11 scalpel blade, a needle, the edge of a glass slide, or superficial curettage.⁸⁰ Application of a eutectic mixture of prilocaine and lidocaine cream (EMLA) for at least 1 hour prior to treatment may help diminish the discomfort.⁸¹ Scotch Tape applied one to three times daily on the lesion has also been successful.⁸⁰

Pityriasis Rosea

Pityriasis rosea is an acute, self-limited papulosquamous disorder. Most cases occur between 10 and 35 years of age, with both sexes equally involved.⁸² It is more prevalent in spring and autumn. The cause is unknown, but human herpesvirus 7 has been recovered from lesions of pityriasis rosea.⁸³

Clinical Presentation

Pityriasis rosea begins with a scaly erythematous patch or plaque known as the herald patch in 50% to 80% of cases, which precedes and heralds the onset of widespread papulosquamous eruption by several days to up to 3 months. In a small number of cases, appearance of the herald patch coincides with the onset of the widespread eruption. The herald patch begins as a nondescript, smooth, erythematous macule or papule, which expands over 1 to 2 weeks to form an oval-shaped patch or plaque. Central clearing gives rise to an annular lesion. It can occur on any body part, and 5% of patients have more than one herald patch. Desquamation eventually occurs, creating a surface scale that is attached at the periphery with the free edge directed toward the center of the lesion (“collarette of scale”). The widespread eruption evolves bilaterally and symmetrically over 1 to 3 weeks on the trunk, neck, face, and proximal limbs (Fig. 126–14). The eruption consists of oval-shaped, erythematous papules or macules that enlarge to a maximum size of 5 to 30 mm. The lesions are initially smooth but quickly develop the typical collarette of scale on the surface. On the back, the long axis of these lesions runs parallel to the ribs, giving rise to the highly characteristic “Christmas tree” or “fir tree” pattern. The eruption is typically pruritic. Resolution occurs in 4 to 12 weeks and may be associated with postinflammatory hypopigmentation or hyperpigmentation.

A number of clinical variants have been seen. The eruption can have vesicular, pustular, purpuric, or erythema multiforme-like lesions.^{84–87} The eruption can be localized to the

FIGURE 126–14. Oval-shaped, erythematous papules and macules with a collarette of scales seen in pityriasis rosea.

face and limbs with sparing of the trunk (inverse pityriasis rosea), localized to the axilla and groin as large plaques (pityriasis circinata et marginata of Vidal), or localized to one area of the body or one side of the body.^{87,88} Oral lesions may occur during the course of disease and may consist of punctate petechiae, ulcerations, erythematous macules, plaques, vesicles, or bullae.⁸⁹

On occasion a prodrome may occur consisting of headache, malaise, pharyngitis, and lymphadenopathy. The differential diagnosis for pityriasis rosea includes tinea corporis, guttate psoriasis, pityriasis lichenoides, lichen planus, drug eruptions, secondary syphilis, Lyme disease, human immunodeficiency virus seroconversion illness, and nummular eczema.

Management

In view of the self-limited nature of the eruption, treatment is only needed for patients with significant pruritus or cosmetic impairment. Treatment options for pruritus include antihistamines, topical emollients, calamine lotion, oatmeal bath, or colloidal starch. Others have used oral erythromycin, ultraviolet B (UVB) phototherapy, topical steroids, and oral steroids. Erythromycin has been shown to resolve lesions in 2 weeks in 73% of cases.⁹⁰ Daily erythemogenic doses of UVB phototherapy over 5 to 10 days can significantly improve the eruption, with variable degree in reduction of pruritus, but the course of the disease is not altered and this therapy may be associated with postinflammatory hyperpigmentation.⁹¹ Corticosteroids may temporarily reduce pruritus without altering the course of the disease and, due to the widespread nature of the disease, can be associated with significant adverse effects.

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome) (See Also Chapter 95)

Kawasaki disease (KD) is an acute febrile illness of unknown etiology with widespread vasculitis that affects children less than 5 years of age. It is a unique clinical symptom complex characterized by persistent high fever, bilateral nonexudative

conjunctival injection, oropharyngeal mucosal changes, cervical lymphadenopathy, erythematous rash, and changes in peripheral extremities.⁹² It is the most common cause of acquired heart disease in children in Japan and the United States.⁹³

KD has been reported on all continents and in all ethnic groups; however, most cases are described in Japan.⁹⁴ It peaks at 9 to 11 months of age, with 55% of patients under 2 years of age and 80% to 85% under 5 years of age.⁹⁵ Adult cases are extremely rare.⁹⁶ There is a slightly higher prevalence in males. The mortality with treatment is 0.1% to 2%. Blood vessel damage appears to result from an aberrant immune response leading to endothelial cell injury and vessel wall damage.

Clinical Presentation

Infants in particular are usually very irritable, much more than seen with a simple viral cause of fever. If five or six of the principal symptoms are present (Table 126–11), the diagnosis of KD can be established after other diseases with similar findings are excluded.^{96a} However, patients with only four or fewer of the six principal symptoms can be diagnosed as having KD when coronary artery aneurysm is recognized by two-dimensional echocardiography.

Other features of KD are less common, such as right upper quadrant pain, nausea, and vomiting caused by hydrops of the gallbladder, which can be confirmed by ultrasonography and resolves without surgical intervention. Other gastrointestinal manifestations include diarrhea, small bowel obstruction, ileus, hepatitis with hepatomegaly, and pancreatitis. Arthritis can occur in the first week in 30% of cases and is usually polyarticular, involving the knees, ankles, and hands and persisting for about 3 weeks. Sterile pyuria with monocytes is common. Dysuria may be associated with meatitis and cystitis. Evidence of aseptic meningitis may be seen in 50% of patients who undergo lumbar puncture. Rare findings include peripheral ischemia with resultant gangrene, pneumonitis, pleural effusion, testicular swelling, facial nerve palsy, and hemophagocytic syndrome.^{97–99}

Table 126–11 Clinical Symptoms of Kawasaki Disease (KD)

Symptoms	Characteristics
Fever (95%)	<ul style="list-style-type: none"> The illness starts and is suspected when fever of unknown etiology is present for more than 5 days. Typically high spiking and remitting with peak temperature greater than 39° C. Lasts 1–3 wk but subsides rapidly with intravenous immune globulin administration, and more so when aspirin is added.
Eye findings (87%–90%)	<ul style="list-style-type: none"> The longer the fever, the higher incidence of coronary aneurysm formation. Painless bulbar conjunctival injection with sparing of the limbus. Occurs within 2–4 days from onset of disease (Fig. 126–15). No purulent discharge (not "conjunctivitis"). If a slit-lamp examination is performed, evidence of anterior uveitis or acute iridocyclitis is commonly seen.¹³³ Usually subsides within 1 wk.
Oral changes (85%–95%)	<ul style="list-style-type: none"> Dryness, redness, fissuring, peeling, cracking, and bleeding of the lips. "Strawberry tongue" indistinguishable from streptococcal scarlet fever, with erythema and prominent papillae. Diffuse erythema of the oropharyngeal mucosa seen 3–5 days after the onset of disease (Fig. 126–16). Changes subside in 2 wk.
Lymph nodes (50%–70%)	<ul style="list-style-type: none"> Swelling of cervical lymph nodes seen 1 day before the onset or concomitant with the fever (Fig. 126–17). Child complains of pain and may have torticollis. Swelling ranges from 1.5 to 5 cm in diameter without fluctuance or overlying skin erythema. Seen in two thirds of children in Japan and only 50% in United States. Swelling usually disappears with defervescence. In children greater than 3 years old, cervical lymphadenopathy may be the most striking feature, and a misdiagnosis of adenitis may be made and antibiotic therapy given, which is ineffective.
Exanthem (85%–90%)	<ul style="list-style-type: none"> KD should be suspected in patients with cervical adenitis, especially if unresponsive to antibiotic therapy. From the first to fifth day after the onset of fever. Polymorphous exanthem appears on the body and/or extremities (Fig. 126–18). Morbilliform, maculopapular, scarlatiniform, urticarial with large erythematous plaques, or erythema multiforme–like with target or iris lesions. Individual lesions are 5–13 mm in diameter and spread over the body and extremities within several days. Each lesion becomes larger and may coalesce. Rash may disappear over the next few days and may be recurrent. Erythema and desquamation in the perianal region often occurs.
Peripheral extremity changes (90%–95%)	<ul style="list-style-type: none"> Reddening of palms and soles 2–5 days after onset of illness, at which time painful indurative edema occurs (Fig. 126–19). Swelling resolves as the fever disappears. At 10–15 days after onset, there is desquamation and fissuring between nails and tips of fingers, after which it spreads over palms and soles (Fig. 126–20). Fingertip desquamation is one of the most important features of KD. From 1½ to 2 months later, transverse furrows appear in the nails (Beau's lines).

FIGURE 126-17. Enlarged lymph node seen in Kawasaki disease.

FIGURE 126-18. Erythematous maculopapular plaques seen in Kawasaki disease.

The most important clinical complications affect the cardiovascular system, and may lead to myocardial ischemia and sudden death. Before the availability of IVIG, 15% to 25% of children developed coronary dilation or aneurysms; with therapy, this rate fell to 4%. Risk factors for developing coronary artery aneurysms include persistent fever, especially after IVIG therapy, low hemoglobin, low albumin, high white blood cell count, high band count, high C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR), serum sodium less than 135 mEq/L, male sex, and age less than 1 year.^{100,101} Children with giant coronary artery aneurysms (>8 mm in diameter) will have 50% stenosis and

FIGURE 126-19. Indurative edema seen in Kawasaki disease.

obstruction, and two thirds will have evidence of myocardial ischemia.¹⁰²

Other cardiac findings may include congestive heart failure, valvulitis (especially of the mitral valve), and pericardial effusion. The earliest cardiac changes occur within the first 10 days of onset and include endocarditis, myocarditis, and pericarditis. The formation of a coronary aneurysm may lead to turbulent flow and thrombus formation with coronary stenosis and subsequent myocardial ischemia, infarction, or sudden death.¹⁰³ Aneurysm may occur in other extraparenchymal muscular arteries such as the celiac, mesenteric, femoral, iliac, renal, axillary, and brachial arteries.¹⁰⁴

Laboratory findings are nonspecific: leukocytosis with left shift, eosinophilia, and elevated ESR, CRP, and α_1 -antitrypsin. Thrombocytosis, ranging from 500,000/mm³ to greater

FIGURE 126–20. Desquamation seen in Kawasaki disease.

than $1,000,000/\text{mm}^3$, occurs on the second week of illness, and serum immunoglobulins may increase. A normochromic, normocytic anemia is frequent, and elevated hepatic transaminases and bilirubin may be seen. Urinalysis reveals sterile pyuria in a third of the patients. Arthrocentesis during the arthritis yields purulent-appearing fluid with a mean white blood cell count of $125,000/\text{mm}^3$ to $300,000/\text{mm}^3$, normal glucose level, and negative Gram stain and bacterial culture.¹⁰⁵ Cerebrospinal fluid may show a mononuclear pleocytosis without hypoglycorrhachia or elevated protein.

Abnormalities in serum lipids can occur, with increased triglycerides and low-density lipoproteins and decreased high-density lipoproteins.¹⁰⁶ Elevation of serum cardiac troponin I has been reported.¹⁰⁷ Electrocardiographic changes may include prolongation of the PR interval or QT interval and ST-segment and T-wave changes. The diagnosis of coronary artery aneurysm is accomplished by two-dimensional echocardiography. It is noninvasive and has a high sensitivity and specificity for detection of abnormalities in the coronary arteries. Other modalities used to diagnose coronary artery aneurysms have included magnetic resonance imaging, magnetic resonance angiography, and coronary angiography.¹⁰⁸

The differential diagnosis for KD includes Stevens-Johnson syndrome, toxic shock syndrome, scarlet fever, measles, *Yersinia pseudotuberculosis* (Izumi fever), juvenile rheumatoid arthritis, drug eruption, serum sickness, Rocky Mountain spotted fever, infantile polyarteritis nodosa, acute adenovirus infection, measles, echovirus, leptospirosis, and mercury hypersensitivity reaction.¹⁰⁹

Management

Treatment of KD in the acute phase is directed at decreasing inflammation in the coronary artery wall and preventing coronary thrombosis, whereas long-term therapy in patients who develop coronary aneurysms is aimed at preventing myocardial ischemia or infarction.

It is now clear that IVIG and aspirin combined therapy results in a more rapid anti-inflammatory effect and reduces coronary artery abnormalities more than aspirin alone. In the United States, it is recommended to give a single 2-g/kg infusion of IVIG over 8 to 12 hours and aspirin (80 to 100 mg/kg four times a day) within the first 10 days of onset, with the aspirin dose reduced (3 to 5 mg/kg) after defervescence.^{112,111} In Japan, the initial aspirin dose is 30 to 50 mg/kg. Aspirin is discontinued if no coronary artery abnormalities

have been detected by 6 weeks after onset. Aspirin has been used to decrease inflammation and to inhibit platelet aggregation, although it has no effect on the development of coronary artery aneurysms.¹¹² Children who take salicylates while they are experiencing active infection with varicella or influenza are at risk of Reye's syndrome, and it has been reported in patients taking high-dose aspirin for a prolonged period after KD.¹¹³ It is unclear whether the low-dose treatment increases the risk of Reye's syndrome. Nevertheless, children who are taking salicylates long term should receive an annual influenza vaccine. Those who cannot take aspirin should be given dipyridamole or clopidogrel. About 10% to 15% of patients treated with aspirin and IVIG will have persistent fever and are at higher risk of developing coronary artery aneurysms.^{114,115} It is common practice to give a second dose of IVIG.^{103,116} If fever persists, other options used successfully include pulsed intravenous methylprednisolone (30 mg/kg once daily for 2 to 3 days), cyclophosphamide and prednisone, cyclosporine, plasmapheresis, and etanercept or infliximab (monoclonal antibodies to TNF- α).^{103,112,117,118} In Japan, other agents used include ulinastatin (human trypsin inhibitor) and abciximab (platelet glycoprotein IIb/IIIa receptor inhibitor).^{119–121} Despite earlier reports that corticosteroids may worsen outcomes, a recent report shows that adding methylprednisolone to IVIG and aspirin had a faster resolution of fever, more rapid improvement in markers of inflammation, and shorter length of hospitalization.¹¹⁸

About 20% of patients who develop coronary artery aneurysms during the acute disease will develop coronary stenosis and might need treatment for myocardial ischemia, including percutaneous transluminal balloon angioplasty, coronary artery stenting, percutaneous transluminal coronary rotational ablation, coronary artery bypass grafting, and even cardiac transplantation.^{122–124}

KD may be difficult to diagnosis when the classic features are not present. However, the diagnosis should be suspected in any child with fever greater than 5 days without a source. There should be follow-up with asymptomatic patients for repeat two-dimensional echocardiography in 2 weeks and at 6 to 8 weeks after onset of disease to detect dysrhythmias, heart failure, valvular insufficiency, or myocarditis.

Impetigo

Impetigo is a superficial vesiculopustular infection localized to the subcorneal epidermis and is the most common bacterial infection in children.¹²⁵ The peak incidence is between the ages of 2 and 6 years. The most common pathogen found on children's skin is *S. aureus* (70% to 80%), followed by *S. pyogenes*.^{125–127} Microscopic breaks in the epidermal barrier, such as trauma from scratching dermatitic skin, predispose to impetigo, as these organisms penetrate the skin and proliferate. A warm, humid climate favors the development of impetigo. Impetigo has a high attack rate, and its spread is enhanced by crowding, poor socioeconomic conditions, and poor personal hygiene.

Impetigo can be subdivided into nonbullous (70%) and bullous forms. Bullous impetigo results from invasion by phage group II *S. aureus* onto the skin. The epidermolytic toxin disrupts epidermal cell attachment. An ulcerative form called ecthyma is due to group A β -hemolytic streptococcus. Group B streptococci can cause impetigo in neonates. Recent

data from hospitalized patients demonstrate that *S. aureus*, Enterococcus species, coagulase-negative staphylococci, *Escherichia coli*, and *Pseudomonas aeruginosa* are the most prevalent pathogens in skin and soft tissue infections.¹²⁸

Clinical Presentation

Erosions covered by moist, honey-colored crusts are suggestive of impetigo.¹²⁹ Impetigo begins as small (1- to 2-mm) erythematous macules, which soon develop into vesicles or bullae with friable roofs surrounded by red borders that are quickly lost. The vesicles rupture easily, with release of a thin, cloudy, yellow fluid. The serous discharge subsequently dries, with formation of thick, soft, honey-colored crusts, the hallmark of impetigo (Fig. 126–21). They occur mostly on the face, nares, and extremities. The exudates spread easily by autoinoculation and produce satellite lesions adjacent to areas of impetigo or other parts of the body. Fever and regional lymphadenopathy may be present.

The term *bullous impetigo* has been used to describe lesions with a central moist crust and an outer zone of blister formation. The blister is translucent, with a flaccid roof that is easily shed, such that bullous impetigo may be seen as shallow erosions, like a “scalded skin,” with an outer rim of desquamation (Fig. 126–22).¹²⁶

The differential diagnosis is shown in Table 126–12.

Poststreptococcal glomerulonephritis may follow impetigo if nephritogenic strains of streptococci are involved. This most commonly occurs in children 3 to 7 years of age, and is seen 18 to 21 days after the onset of impetigo. Other complications include cellulitis, lymphangitis, suppurative lymphadenitis, SSSS, scarlet fever, rheumatic fever, osteomyelitis, septic arthritis, pneumonia, and sepsis.

Management

Antibiotics effective against *S. aureus* are indicated in cases of impetigo. Choices include cephalexin, dicloxacillin, and amoxicillin-calvunalate (Table 126–13). Topical mupirocin can be used for impetigo involving a small surface area and

is as effective as oral therapy.¹³⁰ For penicillin-allergic patients, choices of antibiotics include azithromycin, clarithromycin, and clindamycin. If *Haemophilus influenzae* is suspected, possible antibiotics include cefotaxime, ceftriaxone, and cefuroxime, and in those allergic to penicillin, clindamycin can be administered. Removal of the crust and scrubbing skin lesions with antibacterial soap has not been shown to be effective.¹²⁶ Use antibiotics effective against MRSA if there is a high prevalence of this organism in the community.

 Candidiasis
 Scabies

Table 126–13 Antibiotics Effective against Impetigo

Antimicrobials	Dose
Cephalexin	25–100 mg/kg/day divided q6h PO
Amoxicillin–calvulanic acid	25–45 mg/kg/day divided q12h PO
Dicloxacillin	12.5–25 mg/kg/day divided q6h PO
Azithromycin	5 mg/kg/day qd PO
Clarithromycin	15 mg/kg/day bid PO
Clindamycin	25–40 mg/kg/day divided q6–8h PO/IV
Cefotaxime	100–200 mg/kg/day divided q6–8h IV/IM
Ceftriaxone	50–75 mg/kg/day divided q24h or q12h IV/IM
Cefuroxime	75–150 mg/kg/day divided q8h IV/IM
Mupirocin	Apply qd-tid
Trimethoprim [TMP]/sulfamethoxazole	8–12 mg/kg/day of TMP divided bid

Abbreviations: IM, intramuscularly; IV, intravenously; PO, orally.

Hand washing with surgical soap and simple measures of good hygiene may reduce the likelihood of spread. A child with recurrent impetigo should be evaluated for carriage of *S. aureus*, especially in the nares, as this is the site of colonization three fourths of the time.¹³¹ Nasal carriage of both methicillin-susceptible and methicillin-resistant strains of *S. aureus* has been eliminated in more than 90% of patients within 2 to 4 days through use of topical mupirocin three times daily.¹³²

Sickle Cell Disease

Timothy G. Givens, MD

Key Points

Children with sickle cell disease are at risk for a variety of potentially life-threatening complications, due to vaso-occlusive phenomena, profound anemia, and infection.

Rapid identification of acute crises in sickle cell disease is essential to successful intervention and preservation of function.

Prompt reversal of hypoxemia, restoration of perfusion and oxygen-carrying capacity, and administration of antibiotics targeted toward encapsulated organisms remain the cornerstones of emergency department management.

Introduction and Background

Sickle cell disease refers to a group of disorders resulting from mutations in the hemoglobin gene that can lead to deformation of the red blood cell (RBC) into a crescent, or sickle, shape. Hemoglobin S is formed when valine replaces glutamine at the sixth amino acid position of the beta chain of hemoglobin. Patients who inherit hemoglobin S in a homozygous autosomal recessive fashion (Hb SS) have sickle cell anemia, while those who are heterozygous have sickle trait (Hb AS).¹

Sickle cell disease primarily affects persons of African, Mediterranean, Indian, and Middle Eastern descent. In the United States, African Americans are most affected, with approximately 0.15% having sickle cell anemia (Hb SS) and approximately 8% having sickle trait (Hb AS).^{1,2} There is also a high incidence of sickle cell disease in Hispanic Americans from the Caribbean, Central America, and South America.^{3,4} Children born in many hospitals in the United States are routinely screened in the neonatal period, and antenatal diagnosis is becoming more prevalent in at-risk populations. However, an index of suspicion is necessary when treating patients born outside U.S. hospitals or when results of the neonatal screen are unavailable.

Recognition and Approach

As the abnormal hemoglobin molecule is deoxygenated, it irreversibly forms a rigid polymer within the RBC, distorting its configuration. As a consequence, occlusion of small blood vessels, increased blood viscosity and concomitant stasis, and further tissue hypoxia follow. Sickle cell patients therefore develop symptoms related to impaired perfusion and ischemia, such as pain, impaired mental status, neurologic deficits, and tissue engorgement.

The rate and extent of sickling is related to three factors: the degree of cellular hypoxia, the hemoglobin concentration within the erythrocyte, and the presence (or absence) of fetal hemoglobin (Hb F).⁵ Therapy for sickle cell disease is often directed at these three variables.

Clinical Presentations and Important Clinical Features

Complications of sickle cell disease present in one of four general ways: vaso-occlusive crisis, acute splenic sequestration crisis, acute aplastic crisis, and infection/sepsis.

Vaso-occlusive Crisis

Vaso-occlusive phenomena can occur in any tissue or organ system, as the microvasculature becomes clogged with sickled erythrocytes. Most commonly, this results in pain. As occlusion of small vessels occurs, tissue hypoxemia results, leading to further sickling in a cascade effect. Interruption of this vicious cycle with hydration, oxygen, and analgesia is the goal of therapy for vaso-occlusive pain crisis.

Virtually all patients with sickle cell disease experience acute pain to some degree. Coping abilities vary between patients, yet epidemiologic studies indicate that patients who seek medical care for pain have lower levels of fetal hemoglobin (Hb F) and higher steady state hemoglobin levels.⁶ To expeditiously evaluate and manage a painful episode can be difficult. Painful crises may mimic a number of other disease states. A careful history and physical examination is key. The most frequently affected body regions are the lumbosacral spine, knee, shoulder, elbow, and femur. At times, pain episodes may be accompanied by localized tenderness, erythema, warmth, and swelling, raising a concern for osteomyelitis. Joint effusions are particularly common when the knees and elbows are involved. Often, however, there are no correlative physical findings, save for mild tachycardia

and hypertension. The clinician must exercise caution not to dismiss all pain in patients with sickle cell disease as a vaso-occlusive crisis, as in doing so, one may overlook serious underlying pathology. In light of the range of clinical findings of vaso-occlusive pain crises, it is best to proceed conservatively in the emergency setting, taking the patient's pain at face value and yet maintaining an attitude of critical discernment for underlying disease.

Hand-Foot Syndrome

Often the first episode of vaso-occlusive pain occurs in infants and toddlers as acute swelling of the hands and feet (dactylitis).¹ It may provide the first indication that a child has sickle cell disease in the event that he or she has escaped detection by neonatal screening.⁷ Hand-foot syndrome typically occurs symmetrically, involving the metacarpals and/or metatarsals. It may be unaccompanied by hematologic or radiographic abnormalities. When fever is present, osteomyelitis is difficult to exclude and may require a bone scan or MRI. Hand-foot syndrome should be treated as any other pain crisis, with regularly scheduled analgesia.

Acute Chest Syndrome

When the microcirculation of certain organ systems is compromised, life-threatening complications may result. One of these is acute chest syndrome, a leading cause of morbidity and mortality among patients with sickle cell disease. Pulmonary sequestration of erythrocytes and sickling leads to infarction of lung tissue and may progress to a full-blown acute respiratory distress syndrome picture. As with pain crises, the risk of developing acute chest syndrome is higher in sickle cell patients who are younger, have a lower concentration of Hb F, have a higher steady state hemoglobin concentration, or have a higher steady state leukocyte count.⁸ Clinically, acute chest syndrome is a common manifestation of a variety of pathologic processes, which may be difficult to differentiate in a patient with Hb SS disease. Findings may include fever, cough, chest pain, dyspnea, productive cough or hemoptysis, hypoxia, leukocytosis, and new pulmonary infiltrates on chest radiograph. Hence, admission diagnoses in those patients found ultimately to have acute chest syndrome include fever, anemia, infection, nonpulmonary vaso-occlusive events, abdominal pain, asthma, heart failure, and orthopedic conditions.^{9,10} In children, infection is somewhat more likely as a cause of acute chest syndrome than it is in adults, though often no etiologic agent is identified. When a pathogen is identified, the leading three organisms implicated are *Chlamydia*, *Mycoplasma*, and respiratory syncytial virus¹⁰ (Table 127–1). While there are other minor differences in the presentation of acute chest syndrome between adults and children, these do not appreciably impact its management.

Cerebrovascular Accident

Cerebrovascular accidents (CVAs) are another serious complication of vaso-occlusive sickling. Strokes are more common in children with homozygous (Hb SS) disease, occurring in about 11% of patients by the age of 20 years.^{11,12} Three quarters of CVAs are infarcts, and less than 10% are preceded by transient ischemic attacks. An association between recent and frequent episodes of acute chest syndrome and risk of CVA exists in children, perhaps because recurrent damage to the endothelium of the pulmonary vascular bed predicts

Table 127–1 Causes of Acute Chest Syndrome

Cause	0–9 years N = 329 patients (%)	10–19 years N = 188 patients (%)
Infarction without known precipitant	50 (15.9%)	43 (22.9%)
Viral	36 (10.9%)	5 (2.7%)
<i>Mycoplasma</i>	29 (8.8%)	7 (3.7%)
Fat embolism ± infection	24 (7.3%)	16 (8.5%)
<i>Chlamydia</i>	19 (5.8%)	15 (8%)
Mixed infections	16 (4.9%)	3 (1.6%)
Bacteria	13 (4%)	12 (6.4%)
<i>Mycobacterium (tuberculosis & avium complex)</i>	3 (0.9%)	0
Unknown*	129 (41.3%)	79 (42%)

*The cause of episodes for which some or all of the diagnostic data were incomplete and no etiologic agent was identified was considered to be unknown.

From Vichinsky EP, Neumayr LD, Earles AN, et al; National Acute Chest Syndrome Study Group: Causes and outcomes of the acute chest syndrome in sickle cell disease. *N Engl J Med* 342:1855–1865, 2000.

damage to cerebral vasculature.^{11,13} The diagnosis of stroke in patients with sickle cell disease can be challenging. Clinical signs are nonspecific and often subtle. Less than 10% of patients present with classic CVA symptoms, and headaches are common in sickle cell patients regardless of central nervous system involvement. Any sickle cell patient with focal neurologic signs, including seizure or hemiparesis, requires an intracranial imaging study and emergent intervention to limit ischemic injury (see Chapter 44, Central Nervous System Vascular Disorders).

Priapism

Males with sickle cell disease are susceptible to priapism, the presence of a persistent and often painful penile erection. Priapism may occur as a sustained episode lasting hours to weeks or as a series of repetitive, reversible erections with intervening detumescence (“stuttering”). Acute attacks of priapism sometimes follow sexual activity, but generally have no known precipitating event. In addition to the immediate effects of pain, cumulative ischemic damage with either a prolonged erection or recurrent priapism episodes over time puts the patient who suffers these episodes at risk of sexual dysfunction and impotence. Pediatric patients with priapism are more likely to respond to conservative measures such as analgesia and hydration, while management in adult patients usually requires a more aggressive approach, including surgery (see Chapter 89, Penile and Testicular Disorders).³

Acute Abdominal Pain

One of the most perplexing scenarios is the patient with sickle cell disease and acute abdominal pain. Intra-abdominal sickling and vaso-occlusion may occur and be difficult to distinguish from other myriad causes of intra-abdominal pathology. Analgesic therapy should not be withheld while pursuing a diagnosis in sickle cell patients with abdominal pain. Biliary colic and acute cholecystitis due to gallstones should always be considered. Sickled RBCs undergo chronic hemolysis, leading to hyperbilirubinemia and formation of bilirubin-containing gallstones. Patients

are often asymptomatic, but the gallstones may cause abdominal pain due to obstruction or inflammation. The resultant right upper quadrant pain may be indistinguishable from intrahepatic sickling or pain due to lower lobe pneumonia. If gallstones are present, however, abdominal pain coupled with fever, nausea, and vomiting point to cholecystitis, and should be managed appropriately (see Chapter 85, Gallbladder Disorders).

Acute Sequestration Crisis

Young children with Hb SS disease whose spleens have not yet experienced recurrent infarctions and resultant fibrosis, as well as those with other hemoglobin S syndromes with spleens that remain enlarged into adult life, may undergo obstruction of splenic sinusoids with sickled cells. This may lead to sudden trapping of large amounts of blood and a massively enlarged spleen. The patient rapidly develops a precipitous drop in hemoglobin level and signs of circulatory collapse, requiring prompt intervention to reverse hypovolemic shock. While a specific causative agent is often hard to identify, infection is a frequent precipitant. Acute sequestration usually occurs in patients with Hb SS after 6 months of age (due to the protective effects of Hb F prior to this) and is rare after the age of 2 years.^{3,7} It is a leading cause of morbidity and mortality among sickle cell patients in this age group.

Acute sequestration may also occur in the liver. Clinical signs include hepatomegaly and tenderness to palpation of the right upper quadrant, hyperbilirubinemia, anemia, and reticulocytosis. The liver is not as distensible as the spleen, however, so this presentation is seldom accompanied by cardiovascular collapse.

Acute Aplastic Crisis

The erythrocytes of patients with sickle cell disease have a shortened half-life (15 to 50 days) compared with normal erythrocytes (120 days). In the usual state, patients with Hb SS compensate for this by increasing marrow production of erythrocytes six- to eightfold.¹ However, any agent that can cause marrow suppression places the patient with sickle cell disease at risk of developing a profound anemia, as the hemoglobin concentration steadily falls by 10% to 15% per day without a compensatory reticulocytosis. Typically this phenomenon follows infection with parvovirus B19, although toxins, folate deficiency, and other viral and bacterial infections have been associated with erythropoietic suppression. While pallor and tachycardia are common features of an aplastic crisis, bone pain and hemodynamic instability are not. Patients may present with vague, nonspecific symptoms such as fever, headache, nausea and vomiting, fatigue, and dyspnea. The diagnosis is confirmed by noting the correlative laboratory values of anemia and absent reticulocyte production (i.e., reticulocyte count < 3%).

Infection/Sepsis

By far the most common cause of death in children with sickle hemoglobinopathies is infection. This is primarily related to splenic dysfunction. Both of the spleen's immunologic functions—removal of particulate matter from the intravascular space, and antibody synthesis—are impaired in sickle cell disease.¹ Additionally, the serum of patients with sickle cell disease is lacking in heat-labile opsonizing activity

related to an abnormality of the properidin pathway, which is specific for phagocytosis of pneumococci.^{14,15} Hence, Hb SS patients are at increased risk of sepsis from encapsulated organisms, particularly pneumococci. Outcomes for patients with sickle cell disease have been enhanced through the use of active immunization against *Streptococcus pneumoniae* and *Haemophilus influenzae* and through the use of prophylactic penicillin. Prophylactic penicillin is efficacious in reducing the incidence of pneumococcal sepsis and meningitis in children less than 5 years of age. After this age, this therapy shows no clinically beneficial effect and it is often discontinued.¹⁶ Prophylactic penicillin should be continued indefinitely in children with prior pneumococcal sepsis, as they are at much higher risk of recurrent sepsis.¹⁷ In spite of prophylactic penicillin use, the risk of sepsis is still great (see Chapter 13, Sepsis).

Management

Patients with sickle cell disease, like other emergency department patients, should first and foremost have their airway, breathing, and circulatory status addressed. Complications such as sequestration or sepsis can occur precipitously and become rapidly severe and even life-threatening. Frequent assessment of the patient is necessary to note subtle changes in physiologic status. Do not attribute tachycardia to baseline anemia in Hb SS patients and remember that, in the youngest patients, compensatory vasoconstriction can mask volume depletion and maintain blood pressure in the face of shock. In addition, ancillary tools for assessment of physiologic status may provide deceptive information. Pulse oximetry is not an accurate predictor of actual oxygen saturation in vaso-occlusive crisis, with true oxygen saturation averaging 5% higher than values measured by pulse oximetry.^{18,19}

Vaso-occlusive Crisis

A complete history will catalog the frequency and nature of prior pain crises, medications required to control pain crises in the past and current medication use, and baseline laboratory values. Physical examination must be thorough and target the identification of acute infection or other precipitants of a vaso-occlusive crisis. The development of new neurologic signs or symptoms is of particular concern and mandates appropriate imaging studies. Laboratory tests beyond a baseline hemoglobin determination add little to management in patients who present with typical sickle crisis symptoms.^{20,21} For patients with unusual presentations (e.g., worsening anemia, signs of joint or bone infection, fever, increased jaundice, or chest or abdominal pain) additional testing is generally required. Some clinicians routinely obtain a chest radiograph to screen for infection, though this practice in low-risk patients (i.e., those without fever, chills, or pulmonary signs or symptoms) is not supported by data.²²

The cornerstones of therapy for vaso-occlusive episodes are hydration and provision of analgesia. Initial intravenous fluid is usually isotonic saline, particularly in patients with evidence of impaired circulation. There are theoretical benefits to use of hypotonic fluids, in that hyponatremia is known to interfere with the polymerization of hemoglobin S. One study demonstrated that hyponatremia induced by using desmopressin (DDAVP) in combination with a low-sodium diet and a diuretic correlated with a decline in the

frequency and duration of painful crises.²³ However, there are no data to support the routine use of hypotonic fluids during acute vaso-occlusive crisis.

Analgesia is the other arm of mainstream therapy. Achieving adequate pain control while avoiding the complications of analgesic agents, such as opioids, is a clinical challenge. This is particularly true in pediatric patients who may not have developed tolerance to such agents. Oral analgesics are adequate for most patients with mild to moderate pain. Ibuprofen or acetaminophen with or without codeine is often adequate to control pain in children who are not yet of school age. Massage and local heat may also provide ancillary relief. Parenteral medications are generally reserved for those who cannot tolerate oral therapy or who are in severe pain. Ultimately, this is the majority of patients who seek emergency care. The experience of pain is multifactorial and difficult to objectively measure. By the teen years, many patients with Hb SS disease have experienced numerous pain crises, developed a level of opioid tolerance, and require high doses of opioid agents to relieve their acute pain. Medical personnel are often concerned about the chance of furthering drug dependence in these individuals with repeated provision of higher doses of medication. Unfortunately, there is little beyond subjective self-report by patients to inform the clinician about the level of their pain. In an effort to control the patient's pain adequately, analgesia must be titrated to patient need and not to artificially derived limits, while monitoring the patient appropriately for side effects. A fixed administration schedule, with an interval that maintains adequate analgesia, will foster a steady state drug level, improved pain control, and decreased patient anxiety.³

When using parenteral narcotics, morphine is preferred to meperidine (Demerol), which has a metabolite (normeperidine) that is epileptogenic and poorly metabolized in patients with sickle cell disease.²⁴ Also, morphine may be administered subcutaneously if venous access is problematic. A synergistic therapy is intravenous ketorolac (Toradol), which has a narcotic-sparing effect when administered for acute pain of various origins, including sickle cell disease.^{25,26} Patient-controlled analgesia (PCA) is an effective method for administering narcotics to older children and adolescents. In addition to enabling titration of medication to pain severity, PCA provides patients with a sense of control and involvement in their own care (see Chapter 158, Approach to Pain Management).

Acute Chest Syndrome

Any patient with vaso-occlusive disease and demonstrated hypoxemia should receive supplemental oxygen therapy. While oxygen has been shown to reverse sickling in vitro, clinically it has not been shown to affect the incidence or course of vaso-occlusive episodes.^{27,28} Paradoxically, oxygen can suppress erythropoietin levels and reticulocytosis, interfering with a compensatory response and increasing the mass of sickled cells. Also, empirical oxygen therapy in the child who is not hypoxic can mask the evolution of acute chest syndrome and delay its diagnosis.¹ At present, there are no conclusive data either supporting or contradicting the use of oxygen in this clinical setting, though it is traditionally provided to Hb SS patients in some centers.

Splinting due to pain and resultant atelectasis can exacerbate or even cause acute chest syndrome. Pain control is

therefore an important facet of chest pain management in Hb SS patients. Nonetheless, judicious care must be exercised with opioids due to the attendant risks of pulmonary edema and respiratory depression. Incentive spirometry has been shown to be of use in limiting progression of acute chest syndrome.²⁹ These patients are also easily fluid overloaded and, once rehydrated, should receive fluid only at maintenance rates. Patients who have or are at risk of developing this complication often deteriorate quickly and require close monitoring, often in a pediatric intensive care unit. Hypoxemia is common and should be treated with supplemental oxygen. Because this disorder is difficult to distinguish from pneumonia, and because infection is a concomitant or antecedent factor in acute chest syndrome, empirical antibiotics are routinely given. Typically, a broad-spectrum cephalosporin such as cefuroxime and a macrolide to cover for atypical organisms are the recommended antimicrobial agents. Patients usually have hemoglobin levels 1 to 2 g/dl below their baseline and often respond well to simple transfusion of packed RBCs. In more severe cases, partial exchange transfusion should be considered. Guidelines for partial exchange transfusion include multilobar disease, rapidly progressive disease, marked respiratory distress, partial pressure of oxygen (Po₂) less than 70 mm Hg in a child, or a fall of 25% in baseline Po₂.³⁰ This is best accomplished in the intensive care setting.

Cerebrovascular Accident

Cerebrovascular events are managed with expeditious exchange transfusion. The goal in treatment of acute stroke is to limit further sickling by acutely decreasing the proportion of hemoglobin S to less than 30%. While doing so, it is advisable to avoid hyperviscosity by keeping the hematocrit in the 35% range. Seizures should be controlled with anti-convulsants. Intensive care monitoring is usually necessary, as some patients develop increased intracranial pressure requiring assisted ventilation and pharmacologic therapy. Because the recurrence rate for stroke is high (greater than two thirds of patients who are not chronically transfused), regular transfusions of packed erythrocytes at monthly intervals are employed to keep the hemoglobin S level below 30%. This approach has been shown to be effective in limiting further strokes.^{11,12}

Priapism

Treatment of priapism is aimed at relieving pain, emptying the distended corpora cavernosa, and preventing impotence. The initial physical examination should include prostatic massage, which may cause detumescence. Minor repetitive episodes of priapism are often managed at home, with warm baths, exercise, and frequent bladder emptying. However, extremes of temperature should be avoided, as cold increases sickling and heat increases blood flow, compounding pain. If an individual episode persists for greater than 3 hours, patients should be encouraged to seek medical attention. Therapy of a more prolonged episode includes pain management with parenteral opioids, intravenous fluids, and, if needed, placement of a Foley catheter. As in stroke, reduction of the hemoglobin S level to less than 30% is the next immediate goal, via exchange transfusion. Complete detumescence may take weeks, but a response to exchange transfusion should see the onset of detumescence within a day or two.

If a response is not realized within that time frame, surgical intervention may be required, and a urologic consultation should be sought. Surgical techniques are seldom necessary in prepubertal boys, who usually respond to simpler maneuvers. The usual surgical procedure is the Winter procedure or one of its modifications, which may be performed under local anesthesia.³¹ The Winter procedure is a corporospongiosum shunt performed by inserting a needle or scalpel through the glans into one of the corpora cavernosa and draining the viscous blood. The instrument is removed, the skin closed, and an ongoing drainage of cavernous blood into the systemic circulation occurs. Intermittently applied compression limits refilling of the corpora cavernosa. The shunt usually closes spontaneously after several weeks, permitting normal subsequent erectile function. Without intervention, severe priapism results in impotence in greater than 80% of cases, while with transfusions and surgery the incidence falls to between 25% and 50%.³

Acute Abdominal Pain

Management of patients with acute abdominal pain in sickle cell disease is like that of other patients with acute abdominal pain. Early involvement of a surgical consult is critical in the appropriate at-risk population, based upon history, physical examination, and laboratory and radiographic studies. If an Hb SS patient requires surgery, a simple or exchange transfusion should be performed prior to the operation if possible. Abdominal ultrasonography is an excellent imaging choice when considering gallstone disease in the differential diagnosis, as up to 50% of bilirubin stones are not radiopaque on plain radiographs. The clinician should be aware that the mere existence of gallstones in the presence of right upper quadrant pain and fever may not be indicative of acute cholecystitis. Often patients who have undergone cholecystectomy have been surprised to have their “cholecystitis” symptoms return.

Acute Sequestration Crisis

In the emergency setting, therapy for sequestration is directed at restoration of both intravascular volume and oxygen-carrying capacity via immediate transfusion of packed RBCs. Once normal hemodynamics are restored, patients improve quickly. If there is a delay in obtaining blood for transfusion, a bolus of isotonic saline may temporize and possibly mobilize some red cells from the spleen. However, in this situation, transfusion is life saving. Other general supportive measures are appropriate.

Splenic sequestration may recur, usually within a few months of the initial episode. On this basis, some hematologists have advocated elective splenectomy after the first instance of sequestration. Because asplenic patients have increased susceptibility to invasive disease from encapsulated organisms (e.g., *S. pneumoniae*), which primarily affect children under 2 years of age, splenectomy is ideally delayed until after the patient's second birthday.

Acute Aplastic Crisis

Most aplastic episodes are short lived and require no specific therapy beyond supportive measures. Transfusion of packed RBCs is primarily based on symptoms, though some recommend elective transfusion in patients whose hematocrit falls 20% to 25% below baseline values, or below an arbitrary

Table 127–2 Criteria for Outpatient Treatment of Fever in Sickle Cell Disease (6 mo–12 yr of Age)

Normal mental status Normal blood pressure/capillary refill Temperature $\leq 40^{\circ}$ C (104° F) No prior pneumococcal sepsis Mild pain only No evidence of pneumonia WBC count 5000–30,000 cells/mm ³ Hemoglobin ≥ 5 gm/dl Platelets $> 100,000$ /mm ³ Able to administer ceftriaxone 50 mg/kg IV/IM (no allergy) Reliable 24-hr follow-up
--

Abbreviations: IM, intramuscularly; IV, intravenously; WBC, white blood cell.

From Wilimas JA, Flynn PM, Harris SC, et al: A randomized study of outpatient treatment with ceftriaxone for selected febrile children with sickle cell disease. *N Engl J Med* 329:472–476, 1993.

value such as 18%. During the aplastic episode, the patient with sickle cell disease is contagious and should be isolated from vulnerable groups such as pregnant women and the immunocompromised.

Infection/Sepsis

Because of the heightened risk of serious infection in sickle cell patients, the diagnostic approach to a young child who has fever without apparent source is fairly dogmatic. A thorough history and physical examination notwithstanding, a complete blood count, urinalysis, chest radiograph, and cultures of the blood, urine, and throat are generally obtained on febrile patients. Children who appear toxic or who have signs of meningitis should additionally have a lumbar puncture performed. All children who appear ill and all infants ≤ 6 months old require empirical parenteral antibiotics (e.g., ceftriaxone), even before the return of laboratory results, and admission to the hospital.³ Well-appearing infants and children ≥ 6 months old who meet specific criteria (Table 127–2) may be treated as outpatients with closely coordinated follow-up.^{32–35} It is prudent to confer with the patient's hematologist in making disposition decisions for sickle cell patients with fever.

All patients with a new infiltrate on chest radiograph, even if nontoxic appearing and with normal laboratory indices, require hospital admission due to the possibility of developing acute chest syndrome. Empirical antibiotics should be administered as previously described—a cephalosporin and a macrolide. Those with clinical findings suggestive of osteomyelitis require needle aspiration and culture of the offending lesion, and administration of empirical antibiotics directed against likely organisms (i.e., *Staphylococcus aureus*, *S. pneumoniae*, and *Salmonella*). Patients with urinary tract infections and pyelonephritis often develop papillary necrosis coincident with the infection, due to sickling in the renal papillae. The sloughing of the papillae may present clinically as hematuria. Urine cultures should guide antibiotic selection, and urologic consultation is recommended. Hydration should accompany intravenous antibiotic therapy in these instances, to ensure adequacy of renal perfusion.

Future Directions

Research continues into ways to cure sickle cell disease or prevent its complications. Some of these investigations are noted here. Hydroxyurea, an oral metabolite that promotes the synthesis of Hb F, has shown promise as a prophylactic agent to reduce the incidence of vaso-occlusive crises, acute chest syndrome, and stroke in pediatric patients with severe sickle cell disease.³⁶ Recent data have shown it to be safe, effective, and well tolerated by children over prolonged periods.³⁷ Bone marrow transplantation has been attempted and been curative in some cases of sickle cell disease. It is not without complications, however, and is expensive and not widely available. A substantial barrier to widespread use is the lack of human lymphocyte antigen–matched sibling donors.³⁸ Stem cell transplantation using cells harvested from cord blood may avoid the problems encountered by bone marrow transplantation, and this is being actively investigated.³⁹ Use of gene therapy is being explored as well. Angles of attack include attempts to inactivate the sickle gene, ways to increase expression of the Hb F gene, and introduction of genes whose protein products will block hemoglobin S polymerization.⁴⁰

Summary

Infants and children with sickle cell disease are at risk for a variety of potentially life-threatening complications due to vaso-occlusive phenomena, profound anemia, or infection. Evaluation to exclude these and other complications is mandatory. Rapid identification of acute crises in sickle cell disease is essential to successful intervention and preservation of function. Prompt reversal of hypoxemia, restoration of perfusion and oxygen-carrying capacity, and administration of antibiotics targeted toward encapsulated organisms remain the cornerstones of emergency department management.

Cancer and Cancer-Related Complications in Children

Peter D. Sadowitz, MD and Abdul-Kader Souid, MD, PhD

Key Points

Cancer remains a leading cause of death in children, accounting for approximately 10% of fatalities.

Febrile-neutropenic events are common in children receiving chemotherapy. Often the first sign of sepsis is fever ($>38.0^{\circ}\text{C}$). The standard care for these patients includes *immediate* triage and clinical assessment, appropriate central venous line and peripheral blood cultures, administration of broad-spectrum antibiotics, and hospitalization.

Tumor lysis syndrome may produce hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcaemia, and renal failure. Patients with these complications require vigorous hydration, diuretics, and allopurinol or rasburicase. Potassium-containing solutions should be avoided.

Tumors compressing the airway, superior vena cava, or spinal cord require *immediate* assessment and urgent interventions.

Complications of chemotherapy
Febrile neutropenia
Acute tumor lysis syndrome
Tumor-induced compression

Discussion of Individual Diagnoses

Acute Leukemias and Lymphomas

Acute leukemias and lymphomas account for approximately one third of childhood cancers. Children with immune deficiency (e.g., hypogammaglobulinemia, immunosuppressive therapy, human immunodeficiency virus infection) or constitutional chromosomal anomalies (e.g., trisomy 21) are particularly susceptible.

Acute lymphoblastic leukemia (ALL) accounts for approximately 85% of childhood leukemias. The disease peaks in early childhood. Malignant lymphoblasts originate from immature B cells in 80% of cases (B-cell precursor ALL), mature B cells in 5% of cases (B-cell or Burkitt's leukemia/lymphoma) and immature T cells in 15% of cases (T-cell leukemia/lymphoma). The term *lymphoma* is used when lymphoblasts arise primarily within lymph nodes, and the percentage of malignant cells in the bone marrow is less than 25%. Certain chromosomal abnormalities in lymphoblasts produce poor outcome, such as t(9;22)(q34;q11) or Philadelphia chromosome.¹

Acute myelogenous leukemia (AML) accounts for approximately 15% of childhood leukemias. Its incidence is steady from birth to 18 years of age. Myeloblasts may originate from myeloid (M1 through M4), monocytic (M4 and M5), erythroid (M6), or megakaryocytic (M7) precursors.

Clinical Presentation

Patients may be asymptomatic, with leukemia detected on routine examination of blood smear or complete blood counts (CBCs). Symptoms and signs of leukemia (Table 128–1) occur when blasts proliferate in the bone marrow cavity (producing anemia, neutropenia, and/or thrombocytopenia) and other organs (producing lymphadenopathy, hepatomegaly, and splenomegaly). Clinical manifestations may also include fever (due to infection or leukemia itself), pallor, fatigue (due to anemia), bacterial infections (due to neutropenia), petechiae, and bruises (due to thrombocytopenia).

Selected Diagnoses

- Acute leukemias and lymphomas
- Abdominal tumors
 - Neuroblastoma
 - Wilms' tumor
 - Hepatoblastoma
- Bone and tissue sarcomas
 - Osteosarcoma
 - Ewing's sarcoma (primitive neuroectodermal tumor)
 - Rhabdomyosarcoma
- Other tumors
 - Hodgkin's lymphoma
 - Retinoblastoma
 - Germ cell tumors

Table 128–1 Emergency Department Recognition, Workup and Management of Acute Lymphoblastic Leukemia (ALL) and Lymphoma**B-Cell Precursor (Common) ALL****Presentation**

- Fever ($1/2$ of patients)
- Petechiae/bruises ($1/2$ of patients)
- Bone/joint pain ($1/3$ of patients), limp, refusal to walk
- Lymphadenopathy ($2/3$ of patients)
- Hepatomegaly ($2/3$ of patients)
- Splenomegaly ($2/3$ of patients)
- Pallor ($1/2$ of patients)

Workup

- CBC, type and screen, blood culture
- Serum electrolytes, BUN, creatinine, calcium, phosphate, uric acid, LDH, PT, PTT, TT, fibrinogen, AST, ALT, bilirubin
- Chest radiograph
- Urinalysis

Laboratory Findings

- Anemia, thrombocytopenia, neutropenia, and circulating blasts are common.
- White blood cell counts are $\leq 10 \times 10^3/\text{mm}^3$ in $1/2$ of the patients, $10\text{--}50 \times 10^3/\text{mm}^3$ in $1/4$ of the patients, and $> 50 \times 10^3/\text{mm}^3$ in $1/4$ of the patients.
- Hemoglobin concentrations are ≤ 7.5 g/dl in $1/2$ of the patients, $7.5\text{--}10$ g/dl in $1/4$ of the patients, and > 10 g/dl in $1/4$ of the patients.
- Platelet counts are $< 20 \times 10^3/\text{mm}^3$ in $1/4$ of the patients, $20\text{--}100 \times 10^3/\text{mm}^3$ in $1/2$ of the patients, and $> 100 \times 10^3/\text{mm}^3$ in $1/4$ of the patients.
- LDH and uric acid are frequently elevated.

Management

- IVF (5% dextrose, 0.45% NaCl or 5% dextrose, 0.2% NaCl + 30 mEq/L NaHCO_3) at twice the maintenance rate
- IV antibiotics for febrile neutropenia (see Table 128–3)
- PRBC transfusion for hemoglobin concentration < 8.0 g/dl (see Chapter 132)
- Platelet transfusion for platelet count $< 20 \times 10^3/\text{mm}^3$ (see Chapter 132)
- Allopurinol (10 mg/kg/day in three divided doses) or rasburicase (single IV dose of 0.15–0.2 mg/kg/day, mixed in 50 ml of 0.9% NaCl, over 30 min)

T-Cell ALL/Lymphoma**Presentation**

- Cough, wheezing, stridor
- Massive cervical or mediastinal lymphadenopathy

Workup

- Same as for B-cell precursor ALL
- CT scans of the neck and chest

Laboratory Findings

- Leukocytosis and circulating blasts are common. Hemoglobin concentration and platelet count are frequently normal.
- LDH and uric acid are markedly elevated.

Management

- Consultations with pediatric oncology, intensive care, and anesthesia services
- Careful airway management (e.g., may require steroid therapy and/or mediastinal radiation after pediatric oncology consultation to prevent life-threatening airway compromise)
- Frequent monitoring of vital signs and urine output, preferably in a pediatric intensive care unit (since intubation to secure the airway may be necessary)
- IVF and allopurinol or rasburicase as for B-cell precursor ALL

Burkitt's (B-Cell) Lymphoma**Presentation**

- Abdominal involvement is common as the lymphoma cells infiltrate the various abdominal organs (e.g., abdominal mass, ascites, ileocecal intussusception, small bowel obstruction, mesenteric/retroperitoneal lymphadenopathy, renal infiltration and hepatosplenomegaly).
- Other sites of the disease include bone marrow and lymph nodes (including the tonsils).
- Spinal cord compression by a tumor occurs in $\sim 10\%$ of patients, producing paresis, neurogenic bladder, and lower extremity motor and sensory defects.

Workup

- Same as for B-precursor and T-cell leukemias
- Abdominal CT scan and spinal MRI (if neurologic findings are present)
- Peritoneal fluid (ascites) aspiration may be needed to obtain cells for diagnosis.

Laboratory Findings

- CBC could be normal if there is no bone marrow involvement.
- LDH and uric acid are markedly elevated.

Management

- Emergent consultations with pediatric oncology and surgery services are necessary.
- IVF and allopurinol or rasburicase as for B-cell precursor ALL

Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; IV, intravenous(l); IVF, intravenous fluids; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PRBC, packed red blood cells; PT, prothrombin time; PTT, partial thromboplastin time; TT, thrombin time.

Bone pain (due to expanding leukemic clumps in the marrow cavity and infiltration into the subperiosteal space) is common, producing limp, refusal to walk, swollen joints, and arthralgias (mimicking juvenile rheumatoid arthritis).

Respiratory compromise with cough, wheezing, and stridor may result from airway compression by massive cervical, thoracic, and/or mediastinal lymphadenopathy (see Table 128–1). Superior vena cava compression produces venous congestion, swelling, and cyanosis in the upper chest, neck, and face. Eye examination is necessary to evaluate orbital masses (more common in AML) and retinal infiltration. Leukemic involvement of the testes should be carefully documented. Abdominal masses, ascites, and small bowel obstruction (e.g., ileocecal intussusception) can be seen in Burkitt's (B-cell) lymphoma (see Table 128–1).

The initial workup includes a CBC and examination of a blood smear (for blasts). Anemia, neutropenia, and thrombocytopenia are present in the majority of patients with B-cell precursor (common) ALL (see Table 128–1). The remaining workup includes a chest radiograph (a large thymus and mediastinal lymphadenopathy are common in T-cell leukemia/lymphoma); blood typing (for possible need of packed red blood cell and/or platelet transfusions); blood culture (in the presence of fever); prothrombin time, activated partial thromboplastin time, and thrombin time (all are prolonged in AML-induced disseminated intravascular coagulopathy [DIC]); fibrinogen (low in AML-induced DIC); serum electrolytes, creatinine, calcium, and phosphate (the initial value is often low due to phosphate uptake by the leukemia clone); lactate dehydrogenase and uric acid (both are usually elevated); and hepatic transaminases, bilirubin, and urinalysis.

All patients with suspected leukemia/lymphoma require admission for definitive evaluation, which includes a spinal tap to evaluate central nervous system (CNS) infiltration and a bone marrow examination to evaluate leukemic cell morphology, immunophenotyping, and cytogenetics. These procedures should be done after thrombocytopenia and coagulopathy are corrected. Cerebrospinal fluid (CSF) should be evaluated for cytology, cell count, protein, and glucose. CNS disease (present in approximately 5% of cases) is associated with an increased CSF white cell count ($>5/\text{mm}^3$) and leukemic blasts on a cytospin slide prepared shortly after CSF collection.

The differential diagnosis of acute leukemia includes juvenile rheumatoid arthritis, Epstein-Barr virus or cytomegalovirus infection, aplastic anemia, and bone marrow infiltration by metabolic cells (e.g., Gaucher's disease) or other neoplasms (blood smear frequently shows nucleated red blood cells and left shift).

Management

Intravenous antibiotics should be given for bacterial infections or febrile neutropenia. Packed red blood cell and platelet transfusions (using leukoreduced and irradiated products) may be necessary. The goals are to raise the hemoglobin concentration to greater than 8.0 g/dl and the platelet count to greater than $50 \times 10^3/\text{mm}^3$, especially prior to invasive procedures (e.g., spinal tap, central venous catheter placement). Patients with wheezing, cough, and/or respiratory distress due to a massive mediastinal or cervical lymphadenopathy may require emergent airway control. These patients

should be admitted to the intensive care unit for observation. Immediate interventions (e.g., steroid therapy, mediastinal radiation) may be necessary. Other complications include tumor lysis syndrome (see "Complications of Chemotherapy" section),^{2,3} renal failure (due to leukemic infiltrations and/or uric acid nephropathy), seizures (due to CNS leukemia, intracranial bleeding, or metabolic derangements), pleural effusion (due to leukemic infiltration), and DIC (seen in AML) (see Chapter 40, Seizures; Chapter 42, Conditions Causing Increased Intracranial Pressure; and Chapter 88, Renal Disorders).

Abdominal Tumors

Neuroblastoma

Neuroblastomas arise in the adrenal glands (~40% of cases) and abdominal (~25% of cases) or thoracic (~20% of cases) sympathetic ganglia. These tumors occur in children less than 5 years of age. Over 90% of tumors produce catecholamines (e.g., homovanillic acid [HVA], vanillylmandelic acid [VMA]).⁸ These biochemical markers aid in establishing the diagnosis and in documenting a response to therapy. Patients may present with a large abdominal mass (potentially causing respiratory distress) or metastatic lesions to the orbits, bones, bone marrow, or lymph nodes. Tumors in the posterior mediastinum may be asymptomatic (discovered on a chest radiograph) or result in airway obstruction. Dumbbell-shaped tumors involving the intervertebral foramina may compress the spinal cord, causing paraplegia. Tumors involving the cervical sympathetic chain may produce Horner's syndrome (miosis, ptosis, enophthalmos, and anhidrosis). About 5% of the tumors produce cerebellar dysfunction, causing opsoclonus-polymyoclonus syndrome (ataxia and dancing eyes). Periorbital metastases produce "raccoon eyes." Hypertension due to excess catecholamines may require anti-hypertensives. The workup includes a CBC; urine HVA/VMA; CT scans of the chest, abdomen, and pelvis; bone marrow examination; and technetium-99m (^{99m}Tc) bone scan. Spine MRI should be obtained if paraspinal tumors are suspected. Spinal cord compression requires immediate neurosurgical evaluation, radiation therapy, dexamethasone, or chemotherapy.

Wilms' Tumor

Wilms' tumors account for approximately 5% of the childhood cancer. Most children are less than 8 years old. Aniridia, hemihypertrophy, and Beckwith-Wiedemann syndrome (neonatal hypoglycemia, omphalocele, macroglossia, and visceromegaly) are highly associated with Wilms' tumors. Patients with any of these anomalies require regular abdominal ultrasounds for the first several years of life to detect tumor at an early stage. Urinary tract malformations (e.g., hypospadias, cryptorchidism, horseshoe kidney, ureteral duplication, polycystic kidney) are also associated with Wilms' tumors. Patients may present with a large abdominal mass, acute abdominal pain (due to tumor necrosis or hemorrhage), constipation, hypertension, microscopic hematuria, anemia, and rarely polycythemia. The workup includes abdominal and chest CT scans to evaluate the renal vein, inferior vena cava, right atrium (for tumor thrombus), regional lymph nodes (iliac, periaortic, and celiac), liver, opposite kidney, and lungs (lung metastasis occurs in

approximately 15% of the cases). Nephrectomy is necessary for all tumors. More than 90% of children are cured with surgery plus chemotherapy (with or without radiation).⁹

Hepatoblastoma

Hepatoblastomas affect children in the first 2 years of life. They may occur in association with Beckwith-Wiedemann syndrome, hemihypertrophy, or extreme prematurity. Familial forms also occur in association with CNS anomalies, glycogen storage disease, and familial adenomatous polyposis.¹⁰ Children usually present with a large abdominal mass. Lungs are a common metastatic site. Most tumors produce α -fetoprotein, which confirms the diagnosis and guides the treatment. The workup includes CBC, blood type (for possible need of packed red blood cell transfusion), serum α -fetoprotein and β -human chorionic gonadotropin (β hCG), abdominal CT scan (shows large hepatic tumor), chest radiograph, and chest CT scan. The diagnosis is confirmed by tumor biopsy. The risk of tumor bleeding is high due to extensive tumor vascularity. As a consequence, tumor rupture can be produced by overzealous abdominal examination. The differential diagnosis includes hepatocellular carcinoma and hemangioma. The majority of patients are cured with chemotherapy followed by tumor resection.

Bone and Tissue Sarcomas

Osteosarcoma

Osteosarcoma (spindle cell tumor of the metaphysis) is the most common bone cancer.¹¹ The disease peaks between approximately 10 and 18 years of age (coinciding with the growth spurt). More than 80% of these tumors occur in the knee region (lower femur or upper tibia) and approximately 15% in the humerus. Lungs and bones are the most common metastatic sites. Typical presentations include localized pain with or without physical findings (e.g., firm, tender mass fixed to underlying bone) and pathologic fractures. A plain radiograph of involved bone shows poorly defined tumor margins, bone destruction, periosteal reaction, and calcification (reflecting new bone formation). In approximately 10% of cases, the lesion is purely osteolytic. In contrast, benign tumors are round, smooth, and well circumscribed, without cortical destruction or periosteal reaction. The workup includes MRI of the entire extremity (to detect skip lesions), ^{99m}Tc bone scan (to detect bone metastasis), chest radiography, and chest CT scan (to detect lung metastasis). The diagnosis is confirmed by open biopsy. The treatment involves preoperative chemotherapy followed by surgery (e.g., “en bloc” tumor resection with endprosthesis).¹²

Ewing's Sarcoma (Primitive Neuroectodermal Tumor)

Ewing's sarcomas are small round cell tumors of neuronal origin. The tumor arises in the diaphyses of long or flat bones and in soft tissues. Pelvic and femoral tumors account for approximately 50% of cases. Undifferentiated tumors are termed *Ewing's sarcoma*, and tumors exhibiting primitive neural characteristics are termed *peripheral primitive neuroectodermal tumors* (PNET). Ewing's sarcoma typically occurs after 10 years of age, with lungs, lymph nodes, bones, and bone marrow being the most common metastatic sites. The clinical presentation is similar to osteosarcoma. The tumors

share common abnormalities involving chromosome 22 [t(11:22)(q24;q12) or t(21:22)(q 22;q 12)]. Successful treatment requires surgery and chemotherapy (with or without radiation).¹³

Rhabdomyosarcoma

Rhabdomyosarcomas arise from mesenchymal cells that normally differentiate to striated muscles. This tumor is the most common soft tissue sarcoma in children, accounting for approximately 50% of all sarcomas.¹⁴ The disease may occur at any age. Tumors originate in the head and neck region (e.g., orbit, nasopharynx, sinuses, middle ear) in 40% of cases, genitourinary area (e.g., bladder, prostate, paratesticular, perineal, vaginal) in 20% of cases, extremities and trunk in 20% of cases, and retroperitoneum in 10% of cases. Parameningeal tumors may invade the CNS, causing cranial nerve palsies, increased intracranial pressure, and meningeal involvement. Lungs, lymph nodes, bones, bone marrow, and liver are common metastatic sites. The workup includes CBC, CT scan of involved sites, bone marrow examination, and ^{99m}Tc bone scan. Parameningeal tumors require brain or spine MRI and CSF cytology. The standard treatment involves chemotherapy, surgery, and radiation.

Other Tumors

Hodgkin's Lymphoma

Hodgkin's lymphoma is a neoplasm arising in the lymphatic system. Despite their undetermined origin, Reed-Sternberg cells are responsible for the disease.^{15,16} Tumors spread from one nodal area to an adjacent nodal region. Extranodal spread (bone marrow, lungs, and bones) is rare. The disease is more common in adolescents. A typical presentation includes painless cervical, supraclavicular, or mediastinal lymphadenopathy, which progresses over several months. Symptoms such as fatigue, anorexia, weight loss, and night sweats may be present. The workup includes chest radiograph; CT scans of neck, chest, abdomen, and pelvis; and ^{99m}Tc and gallium bone scans. Lymph node biopsy is necessary to confirm the diagnosis. Treatment involves chemotherapy with or without radiation.¹⁷ The cure rate is over 80%.

Retinoblastoma

Retinoblastomas are the most common primary eye tumor.¹⁸ They arise from the outer layer of the retina. The mean age at diagnosis is approximately 17 months, with few cases occurring after 5 years of age. The most common presentations are leukocoria (white reflex within the eye), strabismus, and poor vision. The workup includes orbit MRI/CT scan, CSF cytology, bone marrow examination, and bone scan. Photocoagulation or cryotherapy is used for tumors less than 4 disk diameters in size, while larger tumors are treated with surgery or radiation. Chemotherapy is used for extensive local disease or distant metastasis. Enucleation is reserved for advanced unilateral disease. The current approach cures greater than 90% of patients. Children with a known family history of the disease need retinal examinations at regular intervals. Patients with the inherited form of retinoblastoma have increased risk of developing second malignancy (e.g., osteosarcoma).

Germ Cell Tumors

Germ cell tumors (germinoma, dysgerminoma, teratoma, endodermal sinus or yolk sac tumor, embryonal carcinoma, and choriocarcinoma) involve the gonads (testes and ovaries) and extragonadal regions (pineal gland, suprasellar area, anterior mediastinum, and sacrococcygeum).^{19,20} Serum α -fetoprotein and β hCG are usually elevated, which confirms the diagnosis and guides the treatment. Clinical presentations vary depending on tumor location. Pineal/suprasellar tumors produce headache, upward paralysis, and poor coordination. Anterior mediastinal lesions produce cough and wheezing. Sacrococcygeal tumors occur in infants, who may present with constipation and a mass in the buttock or presacral region. Ovarian tumors occur in young girls and present with an abdominal or pelvic mass. Testicular tumors produce painless testicular swelling or torsion of the testis. Optimal therapy includes chemotherapy and, in some cases, radiation.

Complications of Chemotherapy

Febrile Neutropenia

Fever and neutropenia (febrile neutropenia) are common in children receiving chemotherapy (Table 128–2). In this setting, neutropenia is defined as an absolute neutrophil count (ANC) of less than $500/\text{mm}^3$, and determined as the total white blood cell count multiplied by the percentage of neutrophils plus bands. Fever is defined as temperature greater than 38.0°C (100.4°F). The risk of bacterial infection correlates with the severity of neutropenia and its duration. For example, life-threatening sepsis is more common when the ANC is less than $200/\text{mm}^3$ for more than 7 days. Other predictive parameters for invasive bacterial infections include

high-dose chemotherapy (e.g., myeloablative therapy), young age, delayed capillary filling time (>3 seconds), tachycardia, hypotension, high temperature ($>39^\circ\text{C}$), pneumonia (cough, short of breath, decreased hemoglobin-oxygen saturation, or abnormal chest radiograph), and compromised physical barriers due to oral mucositis or enterocolitis.^{21–24}

Fever may be the first and only sign of a life-threatening infection. Other clinical presentations may include headache, fatigue, chills, gastrointestinal symptoms (abdominal pain, nausea, vomiting, diarrhea, and perianal or perirectal cellulitis), mucositis or pain at central venous catheter or rectal region. All patients with fever and neutropenia require *immediate* clinical evaluation, appropriate cultures (blood cultures from central and peripheral venous catheter, and cultures of infected mucosal or skin lesions), prompt administration of broad-spectrum intravenous antibiotics, and hospitalization. The choice of empirical antibiotics (which should be administered as soon as intravenous access and cultures are obtained) is based on commonly isolated pathogens.²⁵ Gram-positive organisms include the low-virulence coagulase-negative *Staphylococcus* species and viridans streptococci (common contaminants of central venous catheters), and high-virulence α -hemolytic streptococci, enterococci, and *Streptococcus pneumoniae* (producing disseminated infections, such as meningitis). These organisms respond to vancomycin (15 mg/kg per dose intravenously every 8 hours). Common gram-negative organisms include *Escherichia coli*, *Pseudomonas* species, and *Klebsiella* species. These organisms respond to antipseudomonal cephalosporins (ceftazidime, cefoperazone, or cefepime) or aminoglycosides (e.g., amikacin, 5 mg/kg per dose every 8 hours) (see Table 128–2).

Table 128–2 Febrile Neutropenia

Definitions

- Neutropenia is defined as an absolute neutrophil count of $< 500/\text{mm}^3$.
- Fever is defined as a temperature of $\geq 38.0^\circ\text{C}$ (100.4°F).

Presentation

- Fever may be the only sign of a life-threatening infection.
- Other symptoms may include headache, lethargy, abdominal pain, nausea, vomiting, diarrhea, oral mucositis, perianal pain, and pain at central venous catheter site.

Workup

- CBC, type and screen, and blood cultures from the central venous catheter
- Peripheral blood cultures
- Cultures from infected mucosal or skin lesions

Monitoring

- All patients require *immediate* clinical evaluation, including frequent vital signs. Tachycardia and hypotension may reflect sepsis.
- Physical examination includes careful assessment of the cardiopulmonary-neurologic status, tissue perfusion, perianal region, oral mucosa, and central line site.
- Continuous patient monitoring is necessary for several hours following antibiotic administration, since endotoxin release may produce septic shock.

Management

- All patients with febrile neutropenia should be admitted and receive parenteral antibiotics.
- Hemodynamically unstable patients should be admitted to a pediatric intensive care unit.
- Vancomycin (15 mg/kg IV q8h) *plus* antipseudomonal cephalosporins (ceftazidime, cefoperazone or cefepime) or aminoglycosides (e.g., amikacin, 5 mg/kg q8h)
- Tachycardia, hypotension, and poor tissue perfusion require emergent fluid resuscitation (e.g., 0.9% NaCl or Ringer's lactate at 20–60 ml/kg). Dopamine may be required if fluid resuscitation does not improve perfusion and blood pressure.
- Packed red blood cell (if hemoglobin concentration < 8.0 g/dl) and platelet (if platelet count $< 20 \times 10^3/\text{mm}^3$) transfusions are necessary. The products should be leukoreduced and irradiated (see Chapter 132).

Abbreviations: CBC, complete blood count; IV, intravenously.

Antifungal treatment is given for prolonged fever and neutropenia while on broad-spectrum antibiotics. *Aspergillus* species respond to voriconazole and *Candida* species respond to fluconazole.²⁶ All patients require admission. Hemodynamically unstable patients (tachycardia, hypotension, and poor tissue perfusion) require emergent intravenous fluid resuscitation (with 20 to 60 ml/kg of 0.9% NaCl or Ringer's lactate); vasoactive pressors (e.g., dopamine) may also be necessary. Stress-dose steroids may be required, especially in patients on steroid therapy. Careful physical evaluation, including overall appearance, vital signs (tachycardia and hypotension reflect sepsis), tissue perfusion, and perirectal, oral, and central catheter sites, is essential. Digital rectal examination and rectal temperatures should be avoided. Tachycardia and hypotension may reflect sepsis. Continuous monitoring is necessary, since septic shock may follow antibiotic administration. Packed red blood cell transfusion (~15 ml/kg over ~2 hours) improves tissue perfusion and may help correct tachycardia and hypotension in anemic patients. Platelet transfusion (1 apheresis unit, or ~15 ml/kg for infants, over 1 hour) may also be necessary in thrombocytopenic patients. Blood products should be leukoreduced and irradiated (see Chapter 132, Utilizing Blood Bank Resources/Transfusion Reactions and Complications). Patients with a history of a prior transfusion reaction (e.g., urticaria, chills, and fever) require premedication with acetaminophen (15 mg/kg orally), diphenhydramine (0.5 mg/kg orally or intravenously), methylprednisolone (1 mg/kg intravenously), and/or cimetidine (1 mg/kg; 25 mg maximum, intravenously) to decrease transfusion reactions. Granulocyte colony-stimulating factor decreases the incidence of febrile neutropenia and may be useful in severely neutropenic patients when documented bacterial infections cannot be controlled.²⁷

Acute Tumor Lysis Syndrome

Acute tumor lysis syndrome may complicate the course of induction chemotherapy² (Table 128–3). The metabolic derangements include hyperuricemia (due to increased purine metabolism), hyperkalemia, and hyperphosphatemia.

Hyperphosphatemia can produce hypocalcemia (cramps, tetany, and seizures). Phosphate and uric acid may precipitate in renal tubules, producing renal failure. Vigorous hydration to ensure production of dilute urine (specific gravity < 1.010) and adequate elimination of cellular debris (e.g., 5% dextrose + 0.45% NaCl [D₅^{1/2}NS] or 5% dextrose + 0.2% NaCl [D₅^{1/4}NS] plus 30 mEq/L NaHCO₃ at twice the maintenance rate) is necessary. If urine output is inadequate, diuretics (furosemide, 0.5 to 1.0 mg/kg) can be used. Potassium-containing solutions must absolutely be avoided. Urine alkalization (with intravenous NaHCO₃ or acetazolamide) is necessary in the presence of marked hyperuricemia. Allopurinol (300 mg/m²/day or 10 mg/kg/day in three divided doses orally) or rasburicase³ (a single dose of 0.15 to 0.2 mg/kg/day, mixed in 50 ml of 0.9% NaCl and infused intravenously over 30 minutes) should be administered to prevent uric acid formation. Rasburicase, a recombinant uricolytic agent (urate oxidase) derived from *Aspergillus*, converts uric acid to allantoin, which is easily excreted in the urine. By preventing uric acid nephropathy, phosphate and potassium excretion are also improved.³ Hyperkalemia and symptomatic hypocalcemia require urgent corrections; patients with these complications require continuous cardiac monitoring. Dialysis is required for severe hyperkalemia and renal failure (see Chapter 114, Hyperkalemia; and Chapter 115, Hypocalcemia).

Tumor-Induced Compression

Tumor-induced *airway compression* produces cough, wheezing, stridor, dyspnea, and cyanosis. *Superior vena cava compression* produces face and neck swelling, dyspnea, cyanosis, and prominent chest wall veins. All patients will require admission, imaging (chest radiograph and CT), and a tissue diagnosis for confirmation. Management includes administration of oxygen, elevating the head of the bed, and observing the patient for airway compromise. Clinicians should be aware that sedation may further compromise the airway. Thus early involvement of pediatric intensive care, pediatric oncology, and anesthesia teams should be considered. Emer-

Table 128–3 Acute Tumor Lysis Syndrome

Definition

- The metabolic derangements (hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia) that occur during induction chemotherapy from the destruction of tumor cells.

Complications

- Phosphate and uric acid may precipitate in renal tubules and can produce renal insufficiency or failure.
- Hyperphosphatemia may produce hypocalcemia, which may become symptomatic.

Management

- Hydration with 5% dextrose + 0.45% NaCl (D₅^{1/2}NS) or 5% dextrose + 0.2% NaCl (D₅^{1/4}NS) plus 30 mEq/L of NaHCO₃ at twice the maintenance rate. Intravenous boluses with 0.9% NaCl (20 ml/kg each) may be necessary in severely dehydrated patients. Potassium-containing solutions must be avoided.
- If urine output remains low (e.g., < 2 ml/kg/hr) after ~8 hr of adequate hydration, furosemide IV at 1 mg/kg IV should be administered.
- Allopurinol (300 mg/m²/day or 10 mg/kg/day orally in three divided doses) or rasburicase (single IV dose of 0.15–0.2 mg/kg/day, mixed in 50 ml of 0.9% NaCl, given over 30 min)
- Dialysis is required for severe hyperkalemia and renal failure.

Monitoring

- Close monitoring of urine output and urine parameters is essential.
- Serum electrolytes, BUN, creatinine, phosphate, calcium, and uric acid should be repeated every 4–24 hr depending on the severity of tumor lysis.

Abbreviations: BUN, blood urea nitrogen; D, dextrose; IV, intravenously; NS, normal saline.

gent use of steroids or radiation may be necessary (although these modalities may obscure the diagnosis).

Spinal cord compression is most frequently caused by tumor extension through the neural foramina and may occur at any level of the cervical, thoracic, or lumbar spine. Most of these tumors distribute evenly throughout the cervical, thoracic, and lumbar spine. The mass can be intramedullary (e.g., astrocytoma, ependymoma, lipoma), intradural extramedullary (e.g., dermoid, neuroblastoma, neurofibroma, schwannoma, meningoma, PNET, hemangioepithelioma), or epidural (e.g., Ewing's sarcoma, neuroblastoma, ganglioneuroma, rhabdomyosarcoma, osteosarcoma, germ cell tumor, teratoma, lymphoma). Signs and symptoms of spinal cord compression include back pain, weakness, reflex changes, sensory deficit, atrophy, extremity pain, and incontinence. MRI (with and without gadolinium) of the involved region should be obtained. Consultations with neurosurgery, radiation therapy, and pediatric oncology are necessary. Dexamethasone (1 to 2 mg/kg intravenously) may decrease localized edema and swelling. In the absence of severe spinal cord compression, most tumors can be treated with chemotherapy or radiation. However, sarcomas usually require *immediate* surgical decompression.

Acute Childhood Immune Thrombocytopenic Purpura and Related Platelet Disorders

Peter D. Sadowitz, MD and Abdul-Kader Souid, MD, PhD

Key Points

Acute childhood immune thrombocytopenic purpura is a common pediatric disease.

Children with profound thrombocytopenia (platelet counts $< 20 \times 10^3/\text{mm}^3$) and severe mucosal or cutaneous bleeding have significant risk of developing a life-threatening hemorrhage (intracranial, pulmonary, or upper airway). Patients with these findings should be admitted, and promptly treated with high-dose corticosteroids and anti-D antibody or immunoglobulin concentrates.

Aspirin and nonsteroidal anti-inflammatory drugs are *absolutely* contraindicated in children with thrombocytopenia.

Introduction and Background

Acute childhood immune thrombocytopenic purpura (ITP) is characterized by the sudden onset of profound thrombocytopenia in an otherwise healthy child.¹ The disease results from production of antiplatelet antibodies, which promote Fc/ γ receptor-mediated platelet destruction in the spleen. Anti-D antibodies and immunoglobulins block these receptors.²⁻⁴

Recognition and Approach

Bruising and mild bleeding from minor trauma is common in active, healthy children and must be differentiated from serious or life-threatening disorders. To accurately diagnose ITP, clinicians must consider its diagnosis in all children with mucocutaneous bleeding that is either prolonged, profuse, in an unusual location, or inconsistent with the level of trauma.

In children with significant bleeding, the history, physical examination, and radiologic and laboratory screening are focused on discriminating between trauma (nonaccidental or accidental), blood vessel disorders, and hematologic disorders. Accidental trauma occurs in typical exposed areas with a history that is consistent with findings on physical examination. Children with nonaccidental trauma have bleeding or bruising that is inconsistent with the history given, while typical bony and soft tissues injuries are usually present (see Chapter 119, Physical Abuse and Child Neglect). Defects in coagulation are often associated with muscle, joint, or intracranial bleeding (see Chapter 130, Disorders of Coagulation). In contrast, platelet and vessel diseases (vasculitis) typically cause mucosal bleeding (e.g., epistaxis; gastrointestinal, gynecologic, or genitourinary) or purpura or petechiae. Importantly, other signs of systemic illness are often present in other serious causes of bleeding, while children with ITP are usually well appearing unless intracranial bleeding or significant blood loss is present.

In contrast to adults with ITP, males and females are affected with equal frequency. The median age of childhood ITP is 3 to 5 years, with most cases less than 10 years old. Childhood ITP is more likely to resolve spontaneously and to respond to treatment compared to adult cases.

Clinical Presentation

The typical clinical presentation of acute childhood ITP includes the sudden onset of bruises and petechiae in an otherwise healthy child. Often there is an antecedent viral illness. In a few patients, the thrombocytopenia follows infection with varicella virus, mumps, Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus (HIV), viral hepatitis (A, B, or C), or vaccination (usually approximately 2 to 3 weeks following attenuated live virus immunization). The physical examination reveals a healthy-appearing child (unless there is significant blood loss or intracranial bleeding) with widespread bruises, petechiae, and purpuric lesions involving the skin (especially dependent areas). Mucous membrane bleeding (e.g., gingival or gastrointesti-

nal bleed, epistaxis, menorrhagia) is also common with ITP. Intracranial bleeding, the most feared complication, occurs in less than 1% of cases. Lymphadenopathy, hepatomegaly, splenomegaly, bone or joint pain, fever, neutropenia, and anemia are characteristically absent; their presence suggests bone marrow infiltration by leukemia or solid tumor.

The complete blood count (including peripheral blood smear examination) demonstrates an isolated thrombocytopenia. The diagnosis of ITP should be considered if the platelet count is less than $150 \times 10^3/\text{mm}^3$; most patients have a platelet count of less than $20 \times 10^3/\text{mm}^3$. The platelets are typically large, reflecting production of fresh platelets. The hemoglobin concentration, white blood cell count, and differential are normal. Neutropenia, anemia, or circulating nucleated red blood cells, promyelocytes, metamyelocytes, or blasts are not found in ITP.

Bone marrow examination shows normal trilineage hematopoietic cells with increased megakaryocytes. This procedure (usually performed by a pediatric hematologist) is sometimes necessary to confirm the diagnosis of ITP (e.g., to exclude acute leukemia, which can be partially treated with corticosteroids).

The majority of children recover without recurrence. The platelet count usually becomes normal in 1 to 6 months. Recurrent thrombocytopenia occurs in approximately 10% of patients. Chronic ITP occurs in approximately 10% of children, and is defined as thrombocytopenia that persists more than 6 months. Patients with common variable immunodeficiency frequently develop ITP (alone or in combination with autoimmune hemolytic anemia, or Evans' syndrome). Thus it is recommended to measure immunoglobulin levels in patients with chronic ITP.⁵ In some patients, eradicating *Helicobacter pylori* infection cures chronic ITP.^{6,7} Thus it is also recommended to search for and treat *H. pylori* in patients with chronic ITP. Chronic ITP is more common in adolescents.⁸ In these patients, other autoantibodies (e.g., antinuclear and anti-DNA antibodies) or autoimmune diseases (e.g., systemic lupus erythematosus) may be present or develop in the future.⁸

Important Clinical Features and Considerations

ITP should be distinguished from other causes of thrombocytopenia (Tables 129–1 and 129–2).⁹ The most common entities are discussed in this section.

Acute leukemia often produces bone or joint pain, pallor, fever, and fatigue (in addition to bruising and petechiae). The physical examination usually reveals lymphadenopathy and hepatosplenomegaly. The blood smear may show circulating blasts. The complete blood count often shows abnormalities involving the leukocyte and erythroid lineages in addition to thrombocytopenia (e.g., anemia, reticulocytopenia, neutropenia, abnormal leukocyte differential) (see Chapter 128, Cancer and Cancer-Related Complications in Children).

Vasculitis (endothelial cell injury) produces microangiopathic intravascular hemolytic anemia (thrombocytopenia, circulating red blood cell fragments, hemoglobinemia, and hemoglobinuria). This process occurs in hemolytic-uremic syndrome (see Chapter 131, Hemolytic-Uremic Syndrome), thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, and autoimmune vasculitis.

Table 129–1 Causes of Thrombocytopenia

Increased Platelet Destruction

Immune Mediated

- Immune thrombocytopenic purpura (ITP)
- Collagen vascular diseases (e.g., systemic lupus erythematosus)
- Post-viral infections (e.g., human immunodeficiency virus)
- Drug-induced thrombocytopenia
- Neonatal alloimmune thrombocytopenia (due to incompatibility between fetus and mother)¹⁹
- Neonatal thrombocytopenia due to maternal chronic ITP¹⁹

Non-Immune Mediated

- Hemolytic-uremic syndrome
- Thrombotic thrombocytopenic purpura
- Disseminated intravascular coagulation
- Prosthetic heart valve

Platelet Sequestration

- Hemangiomas (e.g., Kasabach-Merritt syndrome)
- Venous malformation
- Splenomegaly with hypersplenism

Decreased Platelet Production

Congenital

- Fanconi's aplastic anemia
- Thrombocytopenia and absent radii
- Amegakaryocytic thrombocytopenia
- Wiskott-Aldrich syndrome (X-linked, characterized by thrombocytopenia, severe eczema, and recurrent bacterial infections)
- Paroxysmal nocturnal hemoglobinuria

Acquired

- Bone marrow infiltration (e.g., leukemia, metastatic tumors, metabolic disorders)
- Drug induced
- Acquired aplastic anemia

Bruises with Normal Platelet Counts

- Child abuse
- Henoch-Schönlein purpura
- Increased vascular leak

Pseudothrombocytopenia

Bone marrow failure is associated with various severities of neutropenia, anemia, and thrombocytopenia (with small-size platelets) and a reduced number of megakaryocytes in the bone marrow.

Many *medications* (e.g., heparin, penicillin, cephalothin, sulfisoxazole, rifampin, phenytoin, valproic acid) produce destructive thrombocytopenia or decreased platelet production.

On rare occasions, platelets can be trapped and destroyed in capillary *hemangiomas*, producing thrombocytopenia (Kasabach-Merritt syndrome).

HIV infection is often associated with immune-mediated thrombocytopenia. The clinical presentation can be similar to that of acute ITP. Thus, HIV infection should be considered in high-risk patients (see Chapter 69, Human Immunodeficiency Virus Infection and Other Immunosuppressive Conditions).

Thrombocytopenia is common in infants with *congenital viral infections*. These infants usually have microcephaly, low birth weight, hepatosplenomegaly, and intracranial calcifications.

Henoch-Schönlein purpura is a systemic vasculitis associated with the development of painful symmetric, palpable purpura involving proximal regions of the extremities, particularly the legs and buttocks. There may be renal involvement with associated hematuria and proteinuria. Vasculitis

Table 129–2 Discriminating Features of Patients with Thrombocytopenia

Disorder	Clinical Findings	Laboratory Findings
ITP	Well-appearing child Generalized bruises and petechiae Absence of lymphadenopathy and hepatosplenomegaly	Isolated thrombocytopenia
Acute leukemia	Often appears ill Bone and/or joint pain, fever, etc. Lymphadenopathy and hepatosplenomegaly	Anemia Thrombocytopenia Neutropenia Circulating blasts
Bone marrow failure	Pallor, bruising, and fever Absence of hepatomegaly and lymphadenopathy	Pancytopenia of varying severity
Hemolytic-uremic syndrome	Pallor Petechiae and bruising Diarrhea Oliguria and hematuria	Thrombocytopenia Microangiopathic anemia Hemoglobinuria Elevated creatinine
DIC	Ill-appearing child Pallor with petechiae and purpura	Thrombocytopenia Microangiopathic anemia Prolonged PT, PTT, and TT Hypofibrinogenemia
Child abuse	Bruises of earlobes, back, buttocks, genitalia, etc.	Normal CBC, PT, PTT, and TT
Henoch-Schönlein purpura	Painful purpura involving the buttocks and lower extremities	Normal CBC Occasionally hematuria and proteinuria
Hypersplenism	Splenomegaly	Pancytopenia (cells are trapped in the spleen)

Abbreviations: CBC, complete blood count; DIC, disseminated intravascular coagulation; ITP, immune thrombocytopenic purpura; PT, prothrombin time; PTT, partial thromboplastin time; TT, thrombin time.

involving the intestinal tract can lead to intussusception. The platelet count is normal (see Chapter 122, Henoch-Schönlein Purpura).

Petechiae can result from increased *vascular leak/pressure* due to vomiting, coughing, or application of a tourniquet. The resulting petechiae mostly involve the upper chest and extremities. The platelet count is normal.

Child abuse should be considered in the presence of petechiae and bruises in certain locations (e.g., earlobes, back, buttocks) if the platelet count and coagulation studies are normal. The bruises are typically limited to contact sites (see Chapter 119, Physical Abuse and Child Neglect).

Rarely, platelets may agglutinate in blood tubes containing ethylenediaminetetraacetate (the anticoagulant used for blood counts), producing *pseudothrombocytopenia*. This possibility should be considered if the patient has no signs of thrombocytopenia. An estimation of the platelet count can be obtained by placing the patient's blood directly on a slide. Alternatively, the blood sample can be collected in a citrate-containing blood tube.

Management

Corticosteroids remain the best treatment option (Table 129–3).¹⁰ Steroids increase vascular stability, decrease anti-platelet antibody production, and reduce clearance of the antibody-platelet complexes. Clinical improvement (e.g., decreased tendency to bruise) usually occurs before a rise in the platelet count. Conventional treatment is prednisone at 2 mg/kg/day (in three divided doses) for 14 days, followed by tapering and discontinuation by day 21. The efficacy of high-dose corticosteroids for 1 to 4 days (e.g., intravenous methylprednisolone at 6 mg/kg per dose over 30 minutes every 8 hours for approximately 2 days; pulsed dexamethasone

Table 129–3 Management of Childhood Acute ITP

Corticosteroids

Conventional Dose Options

- Prednisone, 2 mg/kg/day (in three divided doses) for 14 days, followed by tapering and discontinuation by day 21
- Prednisone, 4 mg/kg/day (in three divided doses) for 14 days, followed by tapering and discontinuation by day 21
- Prednisolone, 60 mg/m² (in three divided doses) for 14 days, followed by tapering and discontinuation by day 21

High-Dose Options

- (Active bleeding—platelet count < 20 × 10³/mm³)
- Pulsed methylprednisolone, 30 mg/kg (maximum dose, 1 g) IV over 30 min q24h for two or three doses²⁰
- Methylprednisolone, 6 mg/kg IV over 30 min q8h for 2–4 days
- Pulsed dexamethasone, 40 mg/day (maximum dose) orally for 4 days¹¹

Immunoglobulins

Intravenous Anti-D Antibody (for patients who are Rh+):

- Rh₀(D) immune globulin, 50–75 mcg/kg IV over 5 min (one dose) (see text for appropriate precautions)

Intravenous IgG Concentrate Options (for patients who are Rh–):

- Conventional schedule: 0.4 g/kg/day IV over ~4 hr for 5 consecutive days
- Two-day schedule: 0.8–1 g/kg/day IV over ~4 hr for 2 consecutive days
- One-day schedule: 1 g/kg/day IV over ~4 hr for one dose (the most commonly used regimen)

Combined Corticosteroids and Immunoglobulins (for Severe ITP)

Conventional or high-dose steroid plus IV anti-D antibody or IgG concentrate

Abbreviations: IgG, immunoglobulin G; ITP, immune thrombocytopenic purpura; IV, intravenous(ly).

at 40 mg/day [maximum dose] orally for 4 days¹¹; or dexamethasone 0.25 mg/kg every 6 hours orally for approximately 2 days) in severe acute ITP is well documented. This approach increases the platelet count to greater than $20 \times 10^3/\text{mm}^3$ by approximately 48 hours in the majority of patients.

Intravenous anti-D antibody, or human Rh₀(D) immune globulin, is an effective treatment for patients who are Rh positive.¹² The dose is 50 to 75 mcg/kg intravenously over 5 minutes. In most patients, the platelet count rises to greater than $20 \times 10^3/\text{mm}^3$ within approximately 48 hours. Anti-D antibodies bind to red cells, promoting their destruction in the spleen. This process temporarily spares platelet destruction. Intravenous anti-D antibody is contraindicated in immunoglobulin A (IgA) deficiency and in patients with hemoglobin concentrations less than 8 g/dl. The immediate side effects include headache, chills (due to hemolysis of Rh₀(D) antigen-positive red cells), nausea, vomiting, fever, hemolysis, and reduction in hemoglobin concentration. The hemoglobin concentration typically drops by 1 to 3 g/dl in approximately 24 hours. Marked drops in hemoglobin (requiring blood transfusion) and renal insufficiency (due to hemolysis) have been reported; however, their occurrence is very rare. Administration of methylprednisolone (1 mg/kg), acetaminophen, and ondansetron prior to anti-D antibody treatment may prevent fever, nausea, vomiting, and headache.

Intravenous polyvalent immunoglobulin G (IgG) concentrates (e.g., 1 g/kg intravenously over approximately 4 hours daily twice) represent an alternative treatment to anti-D antibody for patients who are Rh negative. IgG molecules block splenic Fc γ receptors on macrophages (sites of platelet destruction). Disadvantages of IgG infusion include high cost and inconvenience (given over 4 hours). Adverse effects include headache (migraine like, lasting for 1 to 2 days), positive Coombs' tests, hemolytic anemia (due to high isoagglutinins), anaphylaxis (occurs in patients with IgA deficiency; IgA-depleted preparations are available), and viral transmission (e.g., hepatitis C).

Life-threatening hemorrhage (intracranial, pulmonary, and upper airway) may occur in children with platelet counts less than $20 \times 10^3/\text{mm}^3$.^{13,14} The presence of severe mucosal, retinal, and cutaneous bleeding identifies patients at greatest risk for serious bleeding. These patients should be admitted and promptly treated with high-dose corticosteroids and anti-D antibody or immunoglobulin concentrates (see Table 129–3).

Danazol, mycophenolate mofetil, and rituximab (recombinant antibodies to the lymphocyte membrane antigen CD20) are used in refractory ITP.^{15–17} Emergency splenectomy is considered for life-threatening, refractory bleeding. Platelets should be administered in active, life-threatening bleeding. Platelet survival is improved if they are transfused soon after immunoglobulin infusion.

Aspirin, aspirin-containing compounds, nonsteroidal anti-inflammatory drugs, and anticoagulants are *absolutely* contraindicated. Intramuscular injections should be avoided. For venous access, the dorsa of the hands and feet are the most suitable sites. Antecubital fossa, jugular, and femoral veins should be avoided to prevent neurovascular compromise if excessive bleeding occurs. After a venipuncture, pressure should be applied to the site for 5 to 10 minutes. Arterial punctures are *absolutely* contraindicated.

The risk for significant bleeding should be carefully assessed. Patients with potential complications related to thrombocytopenia require prompt treatment (see Table 129–3) and admission for observation. For example, patients with significant head injury require combined therapy (see Table 129–3) and hospitalization (even if a head computed tomography scan is normal). Similarly, patients with significant trauma (e.g., blunt trauma from a car accident) should also receive combined therapy and be admitted for observation. In patients with suspected meningitis, antibiotics should be administered and the spinal tap deferred until the platelet count is approximately $50 \times 10^3/\text{mm}^3$. Major trauma with the need for emergent surgery (e.g., chest, abdominal, central nervous system, orthopedic) requires aggressive combined therapy (see Table 129–3) and immediate consultations with a hematologist and surgeon. A hematology consultation should be considered for assistance in confirming the diagnosis or, in the patient with known stable ITP, arranging disposition and follow-up care, if appropriate.

Children should be kept away from sports and playground activities until the platelet count is approximately $50 \times 10^3/\text{mm}^3$. Protective equipment should be used during activities to prevent trauma, especially head injury (e.g., wearing a helmet).

Summary

Acute childhood ITP is a self-limited disease in the majority of children. The diagnosis requires a careful medical history, a thorough physical examination, and complete blood counts (including a careful review of the blood smear) to exclude other etiologies of thrombocytopenia. Physicians outside tertiary care centers can diagnose and treat children with acute ITP based on clinical and laboratory evaluations. Consultation and referral to a tertiary care center are necessary for children who deviate from the “typical” features of this entity.¹⁸

Disorders of Coagulation

Abdul-Kader Souid, MD, PhD

Key Points

Regarding the need for a product replacement, the clinician should remember: when in doubt, infuse.

The product of choice for patients with factor VIII deficiency is recombinant factor VIII, and for patients with factor IX deficiency, recombinant factor IX.

For factor VIII deficiency, 20 to 30 units/kg are infused for mild to moderate bleeding, and 50 to 75 units/kg for moderate to severe bleeding. Follow-up infusions may be necessary.

For factor IX deficiency, 40 to 60 units/kg are infused for mild to moderate bleeding, and 80 to 100 units/kg for moderate to severe bleeding.

Inherited thrombophilia underlies a large percentage of venous thromboembolic events in children. Other risk factors include estrogen therapy, central venous catheters, congenital heart disease, and nephrotic syndrome.

Selected Diagnoses

- Factor VIII deficiency (hemophilia A or classic hemophilia)
- Factor IX deficiency (hemophilia B or Christmas disease)
- Factors VIII and IX inhibitors
- von Willebrand's disease
- Venous thromboembolism

Discussion of Individual Diagnoses

Factor VIII Deficiency (Hemophilia A or Classic Hemophilia)

Factor VIII deficiency is the most common inherited (X-linked recessive) disorder involving secondary hemostasis (affecting approximately 1 in 5000 to 10,000 males). Normal plasma levels of factor VIII are 50 to 150 units/dl. Male patients and female carriers who have factor VIII levels greater than 30 units/dl generally have normal hemostasis. Patients with levels less than 1 unit/dl have severe disease (60% of

total patients), those with levels of 1 to 5 units/dl have moderate disease, and those with levels greater than 5 units/dl have mild disease (mild and moderate disease comprise 40% of all patients). Patients with severe disease have frequent bleeding episodes (spontaneously or following trauma), particularly into the joints and muscles. Patients with moderate disease experience bleeding after minor trauma. Patients with mild disease experience bleeding after significant trauma or surgery. Some female carriers have factor levels less than 30 units/dl, and may exhibit symptoms of mild hemophilia (symptomatic carriers).

The half-life of endogenous factor VIII is approximately 8 to 12 hours. The half-life of infused factor VIII should be measured in each patient at the time of starting a new product. For repetitive infusions, factor VIII is usually given every 8 to 12 hours. Some patients receive prophylactic infusions (e.g., two to three times per week). Most patients, however, receive on-demand treatment (e.g., following trauma or symptoms related to bleeding). The average cost of factor VIII concentrates is about \$1.00 per unit. Most patients with moderate and severe disease have a supply of factor at home. Young children with severe hemophilia usually have an intravenous access device to facilitate infusions (see Chapter 170, Access of Ports and Catheters and Management of Obstruction). Self-infusion education usually begins after about 10 years of age.

Clinical Presentation

Patients with hemophilia A are typically males. Their symptoms may begin at the time of crawling and walking. Almost all severely affected patients are diagnosed by about 1 year of age. It should be noted that normal screening coagulation tests—prothrombin time (PT), activated partial thromboplastin time (aPTT), and thrombin time (TT)—exclude a clinically significant coagulation factor deficiency (including hemophilias).

The diagnosis of hemophilia A should be suspected in children with a family history of the disease or a bleeding event (e.g., prolonged bleeding from circumcision, medical procedure, surgery, dental extraction, hemarthrosis, or hematoma) associated with a prolonged PTT. A positive family history for the disease is present in only two thirds of patients; the remaining cases have de novo mutations. Infants with hemophilia may tolerate circumcision without excessive bleeding. Thus a history of uneventful circumcision does not exclude the presence of a severe bleeding disorder.

The hallmarks of factor VIII deficiency are joint and muscle hemorrhages.¹ The initial symptoms of hemarthrosis are warmth and a tingling sensation (these complaints require immediate factor infusion). As blood fills the joint space, swelling, pain, and limitation of movement occur. Bleeding into a target joint (a joint that the patient bleeds into repetitively due to synovitis; defined as 4 bleeding episodes in 6 months, 8 bleeding episodes in 12 months or 20 total bleeding episodes) produces progressive synovitis, hemophilic arthropathy, and chronic arthritis. The latter complication is progressive and irreversible. Thus joint bleeding should be treated at the onset of the earliest symptoms and prior to the development of physical findings. The joint should be immobilized with no weight bearing by using crutches for weight-bearing joints or splinting for joint support. Management includes elevating the limb, applying ice packs, and wrapping the joint.¹ Joint bleeding is common in severe and less common in mild hemophilia. Thus some patients with severe hemophilia receive prophylactic factor infusion to prevent chronic arthritis.

Patients with hematomas present with pain and limited mobility. Iliopsoas bleeding causes pain in the right lower quadrant, resembling appendicitis or hip disease. Muscle bleeding at this site (after heavy weight lifting or strenuous exercise) causes leg flexion, pain in the anterior surface of the thigh due to femoral nerve compression, and inability to extend the leg. Abdominal cavity bleeding (into the liver, spleen, pancreas, or retroperitoneum) produces falling hemoglobin and abdominal or back pain. Buttock, thigh, deltoid, and forearm bleeding may produce neurovascular compression and compartment syndrome. Neck or oral hematoma may cause dyspnea and dysphagia and compromise the airway. Gastrointestinal (GI) bleeding causes melena and bloody vomiting. Each of these scenarios requires immediate (major-dose) factor infusion, rest, close observation, and consultation with a hematologist.

Bleeding in the gum, tooth, frenulum, tongue, throat, or pharynx may last a few days. It responds to factor infusions, antifibrinolytic therapy (aminocaproic acid), and diet instructions (using soft/cool diet, such as jello, soft drinks, baby foods, and spaghetti; avoiding hard foods, such as chips, popcorn, and tacos).

Painless hematuria is treated by increased fluid intake and bed rest for several days. Factor infusions (for 2 to 4 days) are necessary for persistent painless hematuria. Painless hematuria should be distinguished from hematuria with flank pain. Painful hematuria (e.g., abdominal or flank pain) requires renal ultrasound to assess renal parenchymal bleed and to rule out clots obstructing the ureter, bed rest, and factor infusions for a few days, depending on severity of the bleeding. Antifibrinolytic agents should be avoided due to their ability to cause clots that may obstruct the ureter.

Intracranial bleeding is the leading cause of death. Central nervous system (CNS) bleeding may be spontaneous. Head trauma or any signs or symptoms of intracranial hemorrhage (e.g., headache, irritability, vomiting, seizure, ocular or visual problems, focal deficits, stiff neck, change of consciousness) require *immediate* treatment with a major-dose factor infusion prior to any diagnostic imaging or lengthy clinical evaluation. The onset of neurologic signs or symptoms following head trauma may be delayed due to the slowly oozing nature of hemophilic bleeding.

Hemophilia A is diagnosed by prolonged aPTT and low factor VIII activity (<50 units/dl). PT and TT are normal. There is no need to repeat these tests in the emergency department (ED) in patients with known hemophilia. A postinfusion factor VIII level is necessary in severe bleeding or if inhibitors to factor VIII are suspected. This test assures adequate factor dosing and confirms that factor VIII is at the desired level. A postinfusion aPTT level is not sensitive for assessing adequate replacement, since the aPTT is normal with factor VIII levels greater than 30 units/dl.

Management

Hemophilia A treatment involves infusing recombinant factor VIII (produced by cell lines transfected with human factor VIII gene).²⁻⁴ The dose, frequency, and duration of infusions vary depending on the site and severity of bleeding. The required in vivo level of factor VIII for mild to moderate bleeding (e.g., early joint, muscle, lip, or dental bleed; laceration; persistent hematuria) is 40 to 60 units/dl, and that for moderate to severe bleeding (e.g., surgery; major trauma; intracranial, retroperitoneal, advanced joint, pharyngeal, neck, or GI bleed) is 100 to 150 units/dl. In theory, each unit per kilogram of factor VIII results in an approximately 2-units/dl rise in plasma level (e.g., a 20-kg patient with bleeding requiring a factor VIII level of approximately 60 units/dl needs: $20 \text{ kg} \times 60 \text{ units/dl} \div 2 \text{ units/dl} = 600 \text{ units}$). Thus 20 to 30 units/kg should be infused for mild to moderate bleeding and 50 to 75 units/kg for moderate to severe bleeding (Table 130-1). The infusion is repeated as necessary. Instructions on factor reconstitution are found on the drug insert. The lot number(s), expiration date, trade name, and total number of units infused should be documented (empty boxes should be given to the patient). Most patients bring unmixed factor to the ED to minimize treatment delay and cost. Mixed products are stable for approximately 3 hours. The contents of all reconstituted vials for an infusion should be used (reconstituted factor should not be wasted). Further evaluation is necessary if the patient experiences increasing joint pain and swelling within 24 hours after multiple (e.g., greater than two) adequate factor infusions. If this occurs, the clinician should assess the patient for inhibitors, obtain radiographs looking for a fracture, and consider tapping the joint if infection is highly suspected.

Aminocaproic acid (Amicar), an antifibrinolytic agent, is administered for oral, gingival, or dental bleeding (see Table 130-1). The dose is 25 to 100 mg/kg every 6 to 8 hours for approximately 7 days.⁵ The intravenous and oral preparations contain 250 mg/ml. The tablets are 500 mg or 1000 mg each. Aminocaproic acid should be avoided in patients with hematuria.

In patients with mild factor VIII deficiency and minor bleeding, desmopressin acetate (1-deamino-8-D-arginine vasopressin, or DDAVP) is the treatment of choice.⁶⁻⁸ Desmopressin increases factor VIII (and von Willebrand factor) levels by three- to fivefold within 30 to 60 minutes.⁵ A test dose is recommended. DDAVP is not likely to achieve adequate hemostasis if baseline factor VIII levels are less than 10%. Desmopressin (DDAVP Injection) is given intravenously at 0.3 mcg/kg in 50 ml normal saline over 30 minutes. Intravenous administration is preferred in acute bleeding and prior to surgery. Desmopressin (DDAVP Injection) can also be given subcutaneously at 0.3 mcg/kg. Intranasal des-

Table 130–1 Treatment of Hemophilias and von Willebrand Disease

Deficiency	Treatment	Preparation	Dosing
Factor VIII	Factor VIII concentrates	Recombinant factor VIII	Mild to moderate bleeding: 20–30 units/kg* Moderate to severe bleeding: 50–75 units/kg*
	Desmopressin	DDAVP Injection Stimate Nasal Spray	0.3 mcg/kg IV or subQ (single daily dose) [†] One or two sprays (single daily dose) [†]
Factor IX	Aminocaproic acid	Amicar	25–100 mg/kg q6–8h for ~7 days
	Factor IX concentrates	Recombinant factor IX	Mild to moderate bleeding: 50–70 units/kg [‡] Moderate to severe bleeding: 100–120 units/kg [‡]
von Willebrand factor	Aminocaproic acid	Amicar	25–100 mg/kg q6–8h for ~7 days
	Desmopressin	DDAVP Injection Stimate Nasal Spray	0.3 mcg/kg IV or subQ (single daily dose) ² One or two sprays (single daily dose) ²
	Aminocaproic acid Intermediate-purity factor VIII concentrates	Amicar Humate-P	25–100 mg/kg q6–8h for ~7 days ~50 vWF:RCof units/kg IV q8–12h

*For repetitive infusions, factor VIII is commonly given every 8 to 12 hours.

[†]The same dose can be repeated once a day for 3 to 5 days if necessary.

[‡]For repetitive infusions, factor IX is commonly given every 12 to 24 hours.

Abbreviations: IV, intravenously; subQ, subcutaneously; vWF:RCof, von Willebrand factor: Ristocetin Cofactor.

mopressin (Stimate Nasal Spray), one spray (150 mcg) if the patient's weight is less than 110 lb or two sprays (300 mcg) if weight is greater than 110 lb, is also effective.⁸

If factor VIII concentrates are unavailable and bleeding is unresponsive to desmopressin, or for those patients with severe disease who are not candidates for desmopressin, fresh frozen plasma (20 ml/kg) or cryoprecipitate (1 to 4 units/10 kg, 8 to 12 bags for adults) can be administered. If appropriate replacement is unavailable, transfer the patient to a center that has factor VIII concentrates. It should be noted that fresh frozen plasma and cryoprecipitate do not undergo virus inactivation (see Chapter 132, Utilizing Blood Bank Resources/Transfusion Reactions and Complications).

Intramuscular injections, aspirin, and aspirin-containing compounds (e.g., Pepto-Bismol, Exedrin, Percodan) are contraindicated. Aspiration of the joint should be avoided. Acetaminophen can be used for mild pain, while narcotics may be required for severe acute pain.

A hematologist should be consulted prior to surgery or invasive procedures (e.g., spinal tap). The surgeon should be familiar with hemophilia. The pharmacy should have adequate recombinant factor VIII. Prior to a major surgery, 50 units/kg should be infused at least every 8 hours; plasma levels greater than 50 units/dl should be maintained for 7 to 10 days after surgery. Prior to spinal tap, 50 units/kg should be infused every 8 to 12 hours for at least 24 hours.

For venous access, the limb with the joint or muscle bleeding should be avoided. As a rule, proximal, deep, and non-compressible venous access sites (e.g., jugular, femoral, and subclavian veins) should also be avoided, as bleeding at these sites can lead to a neurovascular compromise. The dorsa of the hands and feet are the most suitable sites. After needle stick, pressure and a bandage are applied for a few minutes. Arterial punctures are contraindicated.

Patients with severe bleeding require hospital admission and close observation for progression of symptoms. Those with significant head trauma or neurologic findings require admission for continuation of factor infusion and observation. Depending on the clinical situation, patients with moderate bleeding may require admission or close follow-up with a hematologist. Most patients with mild bleeding are

discharged with instructions and a follow-up appointment. For patients who are discharged, caregivers should be instructed to observe for clinical deterioration, continued bleeding, or progressive symptoms. For patients with mild head injury who are discharged, caregivers should be instructed to observe for signs of CNS bleeding for at least 2 weeks since late signs and symptoms may develop. For patients with joint bleeding, the discharge instructions should include rest, compression (Ace wraps), elevation of an affected limb, and use of splinting for joint support for at least 24 hours. In all patients who are discharged, consultation with a hematologist is necessary for possible need for follow-up factor infusions. When a patient or the family is traveling, regional hemophilia treatment centers can be located on the National Center on Birth Defects and Developmental Disabilities website at www.cdc.gov/ncbddd/hbd/care_model.htm.

Risks of acquisition of hepatitis B or C virus, human immunodeficiency virus, parvovirus B19, and human T-lymphotropic virus type I are eliminated with the use of recombinant factors. Recombinant factor products that are completely free of all human and animal proteins (e.g., Advate) are available.⁴ The risk of viral transmission via cryoprecipitate is the same as that for other blood components (see Chapter 132, Utilizing Blood Bank Resources/Transfusion Reactions and Complications).

Early application of factor infusions (prophylaxis or intense-on-demand) prevents joint destruction and the need for repetitive infusions.¹ The majority of hospitalizations are for joint and soft tissue bleeding, especially in patients with inhibitors.⁹ Psychological and economic problems remain major issues.

Factor IX Deficiency (Hemophilia B or Christmas Disease)

Factor IX deficiency is a heterogeneous X-linked recessive disorder involving secondary hemostasis (affecting approximately 1 in 60,000 males). Normal plasma levels of factor IX are 50 to 150 units/dl. Patients with levels less than 1 unit/dl have severe disease, those with levels of 1 to 5 units/dl moderate disease, and those with levels greater than 5 units/dl mild

disease. The half-life of factor IX is approximately 18 to 24 hours. For repetitive infusions, factor IX is commonly given every 12 to 24 hours. About one third of patients have *de novo* mutations.

The clinical presentation is indistinguishable from that of hemophilia A. Patients with hemophilia B are also males. Their initial symptoms frequently begin at the time of crawling and walking. The diagnosis of hemophilia B should be suspected in children with positive family history for the disease (in two thirds of patients) or a bleeding event associated with prolonged aPTT.

The diagnostic tests show prolonged aPTT and low factor IX activity (<50 units/dl). PT and TT are normal. There is no need to routinely repeat these tests in the ED. In severe or refractory bleeding or in patients with known or suspected factor IX inhibitors, the factor IX level should be measured immediately following the infusion (see discussion for hemophilia A). A postinfusion aPTT level is not sensitive for assessing adequate replacement, since the aPTT is normal with factor IX levels greater than 35 units/dl.

Treatment involves infusing recombinant factor IX. The dose, frequency, and duration of infusion vary depending on the site and severity of bleeding. The required plasma level of factor IX for mild to moderate bleeding (e.g., early joint or muscle bleed, persistent hematuria) is 40 to 60 units/dl, and that for moderate to severe bleeding (e.g., surgery; major trauma; intracranial, retroperitoneal, advanced joint, pharyngeal, neck, or GI bleeding) is 80 to 100 units/dl. In theory, each unit per kilogram of factor IX (e.g., recombinant factor IX, or Benefix) results in an approximately 0.8-units/dl rise in plasma level (e.g., a 20-kg patient with bleeding requiring a factor IX level of approximately 60 units/dl needs: $20 \text{ kg} \times 60 \text{ units/dl} \div 0.8 = 1500 \text{ units}$). Thus 50 to 70 units/kg of recombinant factor IX should be infused for mild to moderate bleeding and 100 to 120 units/kg for moderate to severe bleeding (see Table 130–1). The infusion should be repeated as necessary. When repeated factor IX infusions are administered for serious bleeding, plasma levels should be measured immediately after the infusion (peak) and just before the next infusion (trough). Peak levels should be kept at approximately 100 units/dl and trough levels at greater than 50 units/dl.

Prior to surgery, the patient's factor IX level should be increased to 100 units/dl and maintained by infusions every 12 to 24 hours for 7 to 10 days, depending on the type of surgery. In addition to factor IX infusions, aminocaproic acid can be administered for oral, gingival, or dental bleed (see Table 130–1 and section on factor VIII deficiency). Desmopressin is ineffective in hemophilia B.

If factor IX concentrates are unavailable, fresh frozen plasma (20 ml/kg) can be considered (see Chapter 132, Utilizing Blood Bank Resources/Transfusion Reactions and Complications). The patient should then be transferred to a center that has factor IX concentrates. It should be noted that fresh frozen plasma does not undergo virus inactivation.

Factors VIII and IX Inhibitors

Inhibitors to factors VIII and IX are more common in severely affected patients.¹⁰ These antibodies neutralize the activity of infused factors. The presence of inhibitors should be suspected if the bleeding does not stop after two adequate infusions. The patient, family, and treating hematologist should

inform the ED staff if inhibitors have been present in the past.

Inhibitors are quantified by measurements of factor VIII or IX activity in mixes of serial dilutions of patients' plasma with normal plasma. Levels of the inhibitor are expressed in Bethesda inhibitor units (BIU). One BIU causes 50% reduction in the factor activity. Patients with low-titer (low-responding) inhibitors (<10 BIU) can be treated with increased factor VIII or IX dosing (e.g., using two to three times the recommended dose). In patients with high-titer (high-responding) inhibitors (>10 BIU), a factor infusion stimulates further rise in BIU. For these patients, management requires infusion of products that bypass the missing factor in the clotting cascade. These preparations include recombinant factor VIIa (90 mcg/kg of NonoSeven) or activated prothrombin complex concentrate (APCC) (75 to 100 units/kg of FEIBA).^{11,12} The patient's hematologist should be consulted prior to using these preparations. FEIBA should not be used in patients with factor IX deficiency who have inhibitors associated with known history of anaphylaxis. Moreover, APCC can produce thrombosis and disseminated intravascular coagulation. The response to NonoSeven and FEIBA is evaluated clinically (no laboratory tests are necessary).

von Willebrand's Disease

Von Willebrand's disease (vWD) is the most common inherited hemorrhagic disorder (prevalence is ~1%). Its inheritance is mostly autosomal dominant. The disease is heterogeneous, produced by a deficiency (types 1 and 3) or dysfunction (type 2) of Willebrand factor (vWF). vWF is an adhesive, multimeric glycoprotein produced by platelets and endothelial cells. It is present in plasma and subendothelial surfaces. It mediates platelet adhesion to exposed subendothelial collagen and platelet-platelet spreading and aggregation. vWF carries factor VIII, preventing its premature activation by factor IX and proteolysis by protein C. Acquired vWD due to accelerated vWF consumption (e.g., autoimmune diseases, cancer, aortic stenosis) occurs rarely; the treatment is the same as discussed here in addition to correcting the underlying cause.

The diagnosis and treatment of vWD can improve the lifestyle of patients and allow their surgeries to be safer. The clinical history is the most sensitive screen for vWD. Diversity exists in the clinical and laboratory findings within each family whose affected members have the same genetic defect. Repeated laboratory testing may be necessary to confirm the diagnosis.

Clinical Presentation

The clinical presentation is usually mild. Patients characteristically bleed from the mucous membranes (most notably, epistaxis and menorrhagia). Recurrent epistaxis occurs in more than two thirds of the patients. However, most children presenting to the ED with epistaxis have normal hemostasis. Among patients referred for hematology evaluation for recurrent epistaxis, 20% have vWD, 10% have another coagulopathy, and 70% have normal hemostasis.¹³ Impaired primary or secondary hemostasis is present in 10% to 30% of adolescents with menorrhagia.^{5,14–17} Thus hemostatic evaluation (Table 130–2) is indicated in patients with recurrent epistaxis or menorrhagia. Other presentations include bleeding following

Table 130–2 Treatment of von Willebrand Disease Based on Bleeding Site

Bleeding Site	Treatment
Easy bruising Prolonged nose bleeding	Requires no treatment. 1. Stimate Nasal Spray on the side that is not bleeding. 2. If no response within 1 hour, administer IV DDAVP Injection. 3. If no response, request ENT consult and consider Humate-P.
Oral bleeding Dental extraction	Stimate Nasal Spray and aminocaproic acid are the treatment of choice. Aminocaproic acid (starting the evening before the procedure) plus desmopressin (Stimate Nasal Spray or DDAVP Injection) just before the procedure.
Menorrhagia	DDAVP Injection. Discharge the patient on aminocaproic acid and Stimate Nasal Spray (one spray in each nostril every day for ~5 days). If refractory, request gynecologic consultation and consider contraceptives pills.
Bleeding after surgery	Mild bleeding: DDAVP Injection and aminocaproic acid. Severe bleeding: Humate-P (~50 vWF:RCof units/kg IV q8–12h).
Minor surgery or procedure Major surgery or procedure	DDAVP Injection and aminocaproic acid. Humate-P (~50 vWF:RCof units/kg IV every 8–12 hr) for 7–10 days.

Abbreviations: ENT, otorhinolaryngology; IV, intravenously; vWF:RCof, von Willebrand factor: Ristocetin Cofactor.

surgery (most notably, tonsillectomy), dental extraction (greater than half of the patients diagnosed with vWD), mild trauma, spontaneous ecchymoses (more common in females), and GI bleeding (more common in adults). Hemarthroses and muscular bleeding do not occur with vWD.

For patients with known vWD disease, no specific tests are necessary in the ED. Bleeding time has limited clinical use and should be avoided. For patients with bleeding disorders who are undiagnosed, complete blood counts, PT, aPTT, and TT are usually performed in the ED. The aPTT is abnormal in severe vWD (type 3). The platelet function analyzer (PFA) is available acutely at many hospitals and has replaced the bleeding time. This test generally takes less than 15 minutes to perform. Pediatric studies have found the PFA to be sensitive and specific for detecting impaired primary hemostasis due to vWD or qualitative platelet abnormalities.¹⁸ Inpatient studies that confirm the diagnosis of vWD include a vWF multimer assay, low-dose ristocetin-induced platelet aggregation, and cryoprecipitate-induced platelet aggregation.

Management

Treatment of vWD depends on severity and site of bleeding (see Table 130–2). Desmopressin acetate stimulates the release of stored vWF, increasing its plasma level approximately threefold within about 30 minutes. Desmopressin increases vWF secretion from Weibel-Palade bodies in endothelial cells through the cyclic AMP signaling pathway. It is the drug of choice for most patients with vWD (see Tables 130–1 and 130–2).^{5–8} Patients with type 2 vWD may have a suboptimal response to desmopressin.⁵

The DDAVP Injection preparation (4 mg/ml) is given intravenously (0.3 mcg/kg in 50 ml normal saline over 30 minutes) or subcutaneously (0.3 mcg/kg). The intravenous route is more effective.⁵ The intranasal preparation (Stimate Nasal Spray, 1.5 mg/ml) is given as one spray (150 mcg) if the patient weighs less than 110 lb or one spray per nostril (300 mcg) if the patient weighs greater than 110 lb. Testing the response to DDAVP is important. DDAVP Nasal Spray (0.1 mg/ml) is a different preparation given for nocturnal enuresis, and is ineffective in vWD. Adverse effects of desmopressin are water retention, facial flushing, nausea, headache, tachycardia, hypertension, angioedema, and tachyphylaxis (due to depletion of vWF stores). Desmopressin is

contraindicated in heart failure, unstable coronary artery disease, polydipsia, and pregnancy (the drug crosses the placenta). Rarely, hyponatremic seizures occur due to water intoxication (e.g., in patients receiving large volumes of hypotonic fluids during anesthesia), especially in infants with repetitive intravenous fluid administration.⁵ Fluid restriction is recommended during and immediately following DDAVP treatment.

Aminocaproic acid (Amicar) inhibits plasminogen activators and plasmin activity. This agent is used for dental and nasal bleeding. The dose is 25 to 100 mg/kg every 6 to 8 hours for 7 to 10 days (see Tables 130–1 and 130–2). The intravenous and oral preparations contain 250 mg/ml. The tablets are 500 mg or 1000 mg each.

Humate-P, an intermediate-purity factor VIII concentrate (pasteurized, i.e., heated at 60° C for 10 hours to inactivate blood-borne viruses), is rich in vWf (containing two- to threefold more vWf than factor VIII).⁵ This product contains approximately 2 to 3 units of von Willebrand factor: Ristocetin Cofactor (vWF:RCof) per unit of factor VIII, and retains high-molecular-weight vWF multimers. It is widely used for serious or refractory bleeding. It is indicated for all types of vWD if desmopressin and aminocaproic acid are inadequate or inappropriate. The dose is approximately 50 vWF:RCof units/kg intravenously every 8 to 12 hours, as necessary (see Tables 130–1 and 130–2). Each unit of vWF:RCof per kilogram raises plasma level by 1.5 units/dl (or 1.5%). For minor bleeding, one to two doses are sufficient. Significant bleeding (e.g., CNS trauma, refractory bleeding) requires infusions for 3 to 10 days. In these situations, trough vWF:RCof levels greater than 50% should be maintained.

Humate-P is labeled as a “triple safety net” product (donor self-referral, rigorous testing, and virucidal treatment). If Humate-P is unavailable and the patient has active bleeding despite intravenous desmopressin and aminocaproic acid, fresh frozen plasma (20 to 25 ml/kg) or cryoprecipitate (1 to 4 units/10 kg, 8 to 12 bags for adults) can be considered.⁵ The patient should then be transferred to a center that has Humate-P. It should be noted that fresh frozen plasma and cryoprecipitate do not undergo virus inactivation (see Chapter 130, Utilizing Blood Bank Resources/Transfusion Reactions and Complications).

Severe patients (type 3 vWD) may experience muscle or joint bleeding and should be treated like those with hemophilia A.⁵ Nonsteroidal anti-inflammatory drugs are contraindicated. Criteria for admission include postoperative (e.g., tonsillectomy, adenoidectomy) bleeding (these patients must receive aminocaproic acid and desmopressin), uncontrolled bleeding, head trauma, and neurovascular compromise.

Most patients with vWD present to the ED with epistaxis, menorrhagia, or excessive postoperative bleeding (e.g., following tonsillectomy or dental extraction). The treatment of choice includes desmopressin and aminocaproic acid. Humate-P is mostly used for patients with vWF:RCof levels less than 10 units/dl or with refractory or serious bleeding. If a diagnostic procedure is necessary, it should be performed after treatment. Routine laboratory tests are not indicated. Successful treatment depends on consultative dialogues among the ED physician, hematologist, and patient/family. Follow-up with the treating hematologist within 24 hours is necessary.

Venous Thromboembolism

Inherited thrombophilia underlies a large percentage of the venous thromboembolic events in children. Common entities include factor V Leiden, prothrombin mutation, antithrombin deficiency, proteins C and S deficiencies, hyperhomocystinemia, and elevated lipoprotein (a). Other less common inherited disorders of thrombosis include elevated factor VIII, dysfibrinogemias, plasminogen deficiency, and paroxysmal nocturnal hemoglobinuria. The genes for factors V and antithrombin are located on the long arm of chromosome 1, which allows for co-inheritance of both mutations. The risk of thrombosis markedly increases in compound heterozygous states, emphasizing that venous thrombosis is a multigenic disorder.¹⁹⁻²⁸

Acquired causes of thrombosis include estrogen therapy, pregnancy, diabetes mellitus, hyperlipidemia, congestive heart failure, nephrotic syndrome (due to urinary losses of antithrombin and free protein S), immobilization (e.g., postoperative period), vertebral artery dissection (due to neck trauma), central venous catheter, and antiphospholipid syndrome (causes prolonged aPTT). These acquired conditions (Table 130–3) markedly increase the risk of thrombosis in the presence of an inherited disorder (e.g., factor V Leiden and birth control pills).²¹ Thus estrogen therapy is contraindicated in the presence of inherited thrombophilia.¹⁹⁻²⁸

Clinical Presentation

The medical history should include precipitating factors, recurrent episodes, involved sites, patient ethnicity, sickle cell disease, metabolic disorders, and familial thromboembolic diseases (including early stroke or heart attack). Upper venous system thrombosis is relatively common in children with central venous catheters.²⁵ One study found that the majority of infected central venous devices contained clots.²⁹ Presenting features of deep venous thrombosis (DVT) in the lower extremity include progressive pain, swelling, erythema, and limping. Importantly, DVT may not be noticed until pulmonary embolism (PE) occurs.^{22,23} Shortness of breath, chest pain, tachycardia, tachypnea, and unexplained syncope are prominent features of PE in adults, and can be expected to be present in children.³⁰ In one pediatric study, up to 50% of patients who died from PE had no symptoms attributable

Table 130–3 Risk Factors in Children with Deep Venous Thrombosis or Pulmonary Embolism

Risk Factor	Percent*

*Numbers add up to > 100% as many patients have more than one risk factor.

Data from Andrew M, David M, Adams M, et al: Venous thromboembolic (VTE) complications in children: first analysis of the Canadian Registry of VTE. *Blood* 83:1251–1257, 1994.

to PE, and the diagnosis was suspected in only 15%.³¹ In another study, hypoxia (Po₂ 35 to 80 mm Hg) was present in all 17 children with PE.³² In adults with PE, nonspecific complaints such as fever (present in 14%), cough (37%), and wheezing (13%) may lead to an erroneous diagnosis.³³

Children with renal vein thrombosis may present with flank (or abdominal) pain, flank mass, hematuria, proteinuria, and hypertension. With inferior vena cava thrombosis, the legs are often cold, cyanotic, and edematous; a chronic obstruction also causes development of collateral veins in the abdomen and thighs.³⁴ Predisposing conditions include severe dehydration, polycythemia, cyanotic congenital heart disease, septicemia, nephrotic syndrome, and systemic lupus erythematosus.³⁰

A detailed neurologic examination is necessary to detect thrombi involving the CNS.³⁵ Important historical features include head and neck trauma, hypertension, migraine, dehydration, polycythemia, drug abuse, oral contraceptive use, and prior radiation therapy or chemotherapy. Other risk factors include sickle cell anemia and metabolic (e.g., hyperhomocystinemia, hyperlipidemia, mitochondrial diseases, Fabry's disease, urea cycle defects), infectious (e.g., varicella, meningitis, cat-scratch fever), and autoimmune (e.g., vasculitis, antiphospholipid antibody syndrome, systemic lupus erythematosus) diseases. Sinus vein thrombosis produces headache, blurred or double vision (with or without cranial nerve palsy), and increased intracranial pressure. Cerebral venous or arterial thrombosis can produce an acute headache, slurred speech, facial drooping, blurred or double vision, cranial nerve palsies, ataxia, head tilt, hemiparesis, altered mental status, and increased intracranial pressure (see Chapter 44, Central Nervous System Vascular Disorders).

Purpura fulminans (disseminated thrombi) occurs in neonates with homozygous protein C or S deficiency. In these patients, ecchymoses occur on the head, trunk, and extremities, often accompanied by cerebral thrombosis.³⁵ In older children, purpura fulminans occurs with sepsis or high-dose warfarin (due to rapid depletion of protein C and S).

EVALUATION

A complete blood count, PT, aPTT, TT, and type and screen are required for patients receiving heparin or warfarin. Anti-factor Xa is required for those patients on low-molecular-weight heparin, and fibrinogen and fibrin split products for those on thrombolytics. Further inpatient testing will be directed by the admitting physician or consultant and may include factor II (prothrombin), factor VIII, fibrinogen, immunogenic and functional assays for protein C, immunologic and functional assays for protein S (total and free), antithrombin immunologic and functional assays, plasminogen, lipoprotein (a), cholesterol, triglyceride, serum creatinine, albumin, urinalysis, fasting plasma homocysteine, antiphospholipid antibodies (lupus-like anticoagulants), anticardiolipin antibodies, and genetic testing for factor V Leiden (Q506R) and antithrombin (G to A at 20210 locus) mutations. Patients with factor V Leiden show resistance to activated protein C (APC) in an aPTT-based assay (APC resistance). D-dimer assay is elevated in more than 60% of children with arterial or venous thrombosis; however, this test has limited specificity.^{30,36} Some of the tests mentioned here need to be requested in the ED prior to starting anticoagulant therapy. Otherwise, genetic testing is most appropriately ordered by the admitting physician.

RADIOLOGIC IMAGING

Diagnostic imaging is required to confirm the presence and extent of thrombi.³³ Doppler ultrasound detects almost all DVTs of the lower extremities and axillary and internal jugular veins.³⁷ However, proximal upper extremity clots (e.g., subclavian vein, innominate vein, superior vena cava) can be missed by ultrasound and require contrast venography or computed tomography (CT).²² Multidetector helical CT (CT angiography) identifies most subclavian, superior vena cava and internal jugular venous clots.³⁸ Renal vein thrombi are detected by doppler ultrasound, CT angiography, and magnetic resonance (MR) venography.^{28,39,39a} Echocardiography identifies clots in the right atrium.

In cerebral vein and venous sinus thrombi, CT during the acute phase may show hyperdense blood at the site of thrombosis.⁴⁰ A linear hyperdense area may be seen with a cerebral vein thrombosis or an abnormally shaped hyperdense area with a venous sinus thrombosis (e.g., dense triangle sign consistent with thrombosis of the posterior aspect of the superior sagittal sinus). Beyond 2 weeks, this area may appear isodense and is easily missed. Acutely, magnetic resonance imaging (MRI) may show hypointense areas on T2-weighted images with venous sinus thrombi. Subacutely (after 3 to 5 days), MRI may show hyperintense areas on T1- and T2-weighted images.⁴⁰ MR venography will show abnormal flow signal of the sinus and changes within the brain's parenchyma.²⁵⁻²⁸

In one study, plain chest radiographs were normal in 88% of children with PE, while 12% had small infiltrates.³² The frequency of other radiologic findings of PE in pediatric patients (e.g., atelectasis, pleural effusion, wedge-shaped defect, consolidation) is still unknown. Pulmonary angiography, once considered the procedure of choice, has a high interobserver disagreement for diagnosing subsegmental PE.⁴¹ CT angiography, in contrast, is equally accurate. With increased acquisition speed, the entire chest can be imaged

with thinner (0.6-mm or 1.25-mm) collimation, which improves the resolution and quality of images. The use of thin section widths (1 to 1.25 mm) results in a greater interobserver agreement and improvement in identifying peripheral pulmonary arterial clots.^{41,42} While CT angiography has become the standard diagnostic test for PE in adults, no pediatric series have compared its accuracy to that of pulmonary angiography or ventilation/perfusion (V/Q) scanning. If V/Q scanning is employed, clinicians should realize that this test is often nonspecific and its accuracy in children is extrapolated from that in adults. In adults, a normal V/Q scan signifies that the patient has a less than 5% chance of PE, an abnormal but nondiagnostic scan signifies the patient has at least a 15% chance of PE, and a diagnostic scan signifies the patient has at least an 85% chance of PE.⁴³

Management

The guidelines published by the American College of Chest Physicians give specific recommendations for neonates and children with thrombosis.⁴⁴ National referral services (1-800-NO CLOTS) are available for phone consultation. Whenever possible, a pediatric hematologist should be consulted. Patients with newly diagnosed DVT require continuous cardiac and oxygen saturation monitoring. Supplemental oxygen is required for patients with hypoxia or respiratory difficulties. The underlying thrombotic defect predicts the risk of recurrent events and determines the length of anticoagulant therapy.²⁷ Patients with two or more thrombotic episodes or one life-threatening thromboembolic event should receive anticoagulant therapy for life (warfarin or low-molecular-weight heparin).

HEPARIN INFUSION

Infants require higher heparin dosing than older children and adults. Heparin therapy typically involves an intravenous bolus dose followed by continuous infusion (Table 130–4). An aPTT should be checked 4 hours after the loading dose, and the infusion rate should be adjusted to keep the aPTT between 60 and 85 seconds (the rate is increased or decreased by 10% to 15% to achieve this goal) (see Table 130–4). A heparin level (measured by an anti-factor Xa assay) of 0.35 to 0.7 units/ml assures that the aPTT reflects heparin concentration. The heparin infusion is continued for at least 5 days. Intramuscular injections, arterial punctures, acetylsalicylic acid, and nonsteroidal anti-inflammatory drugs should be avoided. Maintenance warfarin or low-molecular-weight heparin can begin on day 2 or 3 of heparin therapy.

The half-life of heparin is approximately 60 minutes. Thus, if the drug needs to be stopped for bleeding or other clinical needs, discontinuation of the infusion is usually sufficient. If an immediate antidote is necessary, intravenous protamine sulfate will neutralize heparin within 5 minutes (see Table 130–4). The side effects of protamine include hypersensitivity reaction and hypotension (associated with rapid infusions). Contraindications to heparin include active bleeding, severe hypertension, recent CNS neoplasm, recent trauma or surgery, prior heparin-induced thrombocytopenia, recent GI bleeding, and hemorrhagic stroke.

LOW-MOLECULAR-WEIGHT HEPARIN THERAPY

Enoxaparin (Lovenox) contains 110 anti-factor X units/mg and is the most commonly used product.³⁴ The drug is

Table 130–4 Dosing for Local and Systemic Anticoagulation in Children***Heparin**

Loading dose: 75 units/kg IV over 10 min

Maintenance dose:

- Infant < 1 yr old: 28 units/kg/hr
- Child ≥ 1 yr old: 20 units/kg/hr

Adjustment: adjust heparin to maintain aPTT at 60–85 sec, assuming that this is equivalent to anti-factor Xa level of 0.35–0.7

Check initial aPTT 4 hr after loading dose:

- aPTT < 50 sec, rebolus with 50 units/kg IV over 10 min and ↑ rate 10%
- aPTT 50–59 sec, ↑ rate 10%
- aPTT 60–85 sec, do not alter rate
- aPTT 86–95 sec, ↓ rate 10%
- aPTT 96–120 sec, hold maintenance for 30 min, then ↓ rate 10%
- aPTT > 120 sec, hold maintenance for 30 min, then ↓ rate 15%

Protamine (reversal for heparin, partial reversal for LMWH†)

If time since last heparin dose is

- <30 min: administer 1 mg protamine IV for every 100 units heparin received
- 30–60 min: administer 0.5–0.75 mg protamine IV for every 100 units heparin received
- 60–120 min: administer 0.375–0.5 mg protamine IV for every 100 units heparin received

Maximum dose: 50 mg

Infusion rate 10 mg/ml; solution should not exceed 5 mg/min

For LMWH: a dose of 1 mg protamine per 100 units LMWH can be used if protamine is given within 3–4 hours of LMWH.

Reviparin (LMWH)

Weight < 5 kg

- Treatment dose: 150 units/kg q12h
- Prophylactic dose: 50 units/kg q12h

Weight ≥ 5 kg

- Treatment dose: 100 units/kg q12h
- Prophylactic dose: 30 units/kg q12h

Enoxaparin (LMWH)

Age < 2 mo

- Treatment dose: 1.5 mg/kg q12h
- Prophylactic dose: 0.75 mg/kg q12h

Age ≥ 2 mo

- Treatment dose: 1 mg/kg q12h
- Prophylactic dose: 0.5 mg/kg q12h

Alteplase‡ (t-PA)

Local instillation for CVL:

- If < 10 kg: Dilute 0.5 mg in 0.9% NaCl to the volume required to fill the line.
- If ≥ 10 kg: Mix 1 mg in 1 ml 0.9% NaCl. Instill the amount required to fill the volume of the line to a maximum of 2 ml (= 2 mg).
- Use the same amount above for each lumen if a double-lumen CVL is present.

Local instillation for subcutaneous port:

- If < 10 kg: Dilute 0.5 mg with 0.9% NaCl to 3 ml
- If ≥ 10 kg: Dilute 2 mg with 0.9% NaCl to 3 ml

Systemic dosing: 0.1–0.6 mg/kg/hr for 6 hr. Monitor fibrinogen, thrombin clotting time, prothrombin time, and activated partial thromboplastin time.

Urokinase

Load 4400 units/kg, then infuse 4400 units/kg/hr for 6–12 hr. Monitor fibrinogen, thrombin clotting time, prothrombin time, and activated partial thromboplastin time.

Streptokinase

Load 2000 units/kg, then infuse 2000 units/kg/hr for 6–12 hr. Monitor fibrinogen, thrombin clotting time, prothrombin time, and activated partial thromboplastin time.

*Based on the 7th ACCP Conference on Antithrombotic and Thrombolytic Therapy.^{34,45}

†Administered subcutaneously.

‡Consider concurrent administration of heparin (10 units/kg/hr) and administration of fresh frozen plasma (10 units/kg) prior to systemic t-PA administration.

Abbreviations: aPTT, activated partial thromboplastin time; CVL, central venous line; IV, intravenously; LMWH, low-molecular-weight heparin; t-PA, tissue-type plasminogen activator.

From Rothrock SG (ed): Tarascon Pediatric Emergency Pocketbook, 5th ed. Lompoc, CA: Tarascon Publishing, 2006.

administered subcutaneously every 12 hours (see Table 130–4). For therapeutic treatment, the goal is to maintain an anti-factor Xa level between 0.5 and 1.0 units/ml in a sample taken 4 to 6 hours following subcutaneous injection. For prophylactic treatment, the goal is to maintain an anti-factor Xa level between 0.2 and 0.4 units/ml in a sample taken 4 to

6 hours following subcutaneous injection. Osteoporosis is a potential long-term side effect. Protamine sulfate does not completely reverse enoxaparin. Nevertheless, if it is necessary to reverse an enoxaparin dose that is given within the prior 3 to 4 hours, 1 mg protamine sulfate per milligram enoxaparin can be given intravenously over 10 minutes.

WARFARIN THERAPY

The administration of the oral anticoagulant warfarin (Coumadin) typically begins 2 to 3 days after starting heparin infusion, and continues for at least 3 months. Patients with liver dysfunction or direct hyperbilirubinemia require less dosing. Thus baseline liver functions and direct bilirubin should be checked prior to initiating warfarin treatment. To decrease toxicity, the diet should contain $\leq 1 \mu\text{g}/\text{kg}/\text{day}$ of vitamin K. Warfarin should be avoided in neonates. Infants on exclusively breast milk need at least 4 oz of formula (usually contains $30 \mu\text{g}/\text{L}$ vitamin K) as a steady supplement of low-dose vitamin K. The PT and international normalized ratio (INR) are elevated by warfarin. The starting dose of warfarin is usually 0.1 to 0.2 mg/kg (maximum initial dose should not exceed 10 mg), and subsequent doses should be based on the INR. The INR should be maintained between 2 and 3. Warfarin antidotes include vitamin K (subcutaneous injection of 0.5 to 5 mg, depending on patient's size and clinical history), fresh frozen plasma (20 ml/kg), or factor IX concentrate (50 units/kg). Rapid intravenous infusion of vitamin K can produce anaphylactic shock. Warfarin should be withheld for at least 72 hours prior to invasive procedures.

SYSTEMIC THROMBOLYTIC THERAPY

Thrombolytic agents (tissue-type plasminogen activator [t-PA], urokinase, and streptokinase) convert plasminogen to plasmin, the major protease that degrades fibrin. The use of t-PA (Alteplase) is preferred. The decision to use t-PA is made after careful consultation with an experienced pediatric hematologist. Indications for systemic t-PA include massive PE, arterial occlusion, and extensive DVT (e.g., acute superior vena cava syndrome, extensive DVT with a possibility of limb gangrene, bilateral renal vein thrombi with renal insufficiency). Contraindications to t-PA include active bleeding, surgery within the prior 10 days, neurosurgery within the prior 3 weeks, thrombocytopenia, and prematurity. Complications include bleeding (e.g., intracranial hemorrhage), especially in preterm infants. One protocol administers t-PA at 0.5 mg/kg/hr for 6 hours plus heparin infusion at 10 units/kg/hr during t-PA infusion plus fresh frozen plasma (ensures adequate plasminogen and fibrinogen levels) at 10 ml/kg over 30 minutes given 30 minutes prior to t-PA (see Table 130-4). In cases of severe bleeding, t-PA infusion should be stopped, and cryoprecipitate (1 unit/5 kg for fibrinogen levels $< 100 \text{ mg}/\text{dl}$), protamine sulfate, or aminocaproic acid (100 mg/kg intravenous bolus dose) may be necessary.

SURGICAL INTERVENTIONS

Surgical thrombectomy and the use of temporary venous interruption devices (e.g., inferior vena cava filters) have not been fully investigated in children.

BLOCKED VENOUS ACCESS DEVICES

Depending on the clinical situation, blocked central venous catheters, manifested by a failure to infuse or draw back, require investigation by linogram or venogram. A linogram or contrast study through the catheter may identify a clot at the tip of the line, a leakage due to tear, or retrograde flow due to large vessel occlusion. However, venograms remain the procedure of choice to identify large vessel occlusion. An

abnormal venogram requires removal of the line and initiation of anticoagulant therapy. For local thrombi confined to the line, t-PA (Alteplase, 1 mg/ml) can be administered (see Table 130-4). To avoid systemic leakage, the dose of Alteplase (in milliliters) should be equivalent to estimated intraluminal volume (usually approximately 1 to 2 ml) (see Table 130-4). The dose is instilled for 30 to 120 minutes, followed by aspiration (see Chapter 170, Access of Ports and Catheters and Management of Obstruction).

Hemolytic-Uremic Syndrome

Boura'a Bou Aram, MD and Abdul-Kader Souid, MD, PhD

Key Points

Hemolytic-uremic syndrome is characterized by the acute onset of nonimmune microangiopathic hemolytic anemia (circulating red cell fragments, hemoglobinemia, and hemoglobinuria), consumptive thrombocytopenia, and renal insufficiency or failure.

Although the disease usually follows infectious enteritis (e.g., *Escherichia coli* serotype O157:H7), up to 10% of cases occur without a diarrheal prodrome.

Severity of acute symptoms (anuria, hypertension, and seizure) is the main predictor of a complicated course.

Management includes observation and supportive care (e.g., plasmapheresis, dialysis, packed red blood cell transfusion).

Introduction and Background

Hemolytic-uremic syndrome (HUS) is a leading cause of acute renal failure in children under 5 years of age. Its hallmarks are the acute onset of nonimmune microangiopathic (thrombotic microangiopathy) hemolytic anemia (circulating red cell fragments, hemoglobinemia, and hemoglobinuria), consumptive thrombocytopenia, and renal insufficiency or failure. The disease is sporadic, peaking in the summer and early fall. It usually follows acute infectious hemorrhagic colitis (vomiting, bloody diarrhea, and abdominal pain). This stage lasts 2 to 14 days before the onset of HUS. Bacterial contamination may occur from water supplies, undercooked meat, yogurt, unpasteurized milk, apple cider made from unwashed apples, and vegetables grown in a garden fertilized with cow manure. Bacteria can also be transmitted by person-to-person contact.^{1,2} Outbreaks and multiple relapses are well known.

Recognition and Approach

Diarrhea-associated (typical or epidemic) HUS accounts for approximately 90% of cases. The disease mainly affects chil-

dren between 7 months and 5 years of age. It is best described as a thrombotic microangiopathy that is produced by a 71-kDa protein termed *verotoxin* or *Shiga toxin* (produced by *Shigella dysenteriae*). Verotoxin binds to high-affinity glycosphingolipid surface (GB₃) receptors on endothelial cells, causing vasculitis. The toxin is frequently produced by the enterohemorrhagic strains of *Escherichia coli* (especially serotype O157:H7). Other responsible organisms include *S. dysenteriae*, *Campylobacter jejunae*, *Salmonella*, *Streptococcus pneumoniae*, and viruses. The incidence of HUS in children with enteritis caused by *E. coli* O157:H7 ranges from 6% to 15%. Complete recovery occurs in 1 to 2 weeks in greater than 95% of cases.

Non-diarrhea-associated (atypical, hereditary, or familial) HUS accounts for approximately 10% of cases. This form of the disease occurs in all ages, any time of the year, and without a diarrheal prodrome. It has a higher incidence of relapses. It is also more likely to produce end-stage renal disease, proteinuria, and hypertension.

Rare forms occur in association with systemic disease (e.g., systemic lupus erythematosus, transplant rejection, pregnancy) or medications (e.g., cyclosporin A, tacrolimus).

Pathogenesis

The development of thrombotic microangiopathy is preceded by verotoxin-induced endothelial cell injury (vasculitis), platelet aggregation, augmented thrombin generation, and impaired fibrinolysis.³⁻⁷ Acquired or congenital deficiency of a specific von Willebrand factor–cleaving metalloproteinase (factor H, or ADAMTS13) produces persistent, extremely large von Willebrand factor multimers, which induce platelet aggregation at sites with high levels of intravascular shear stress.^{7,8} Verotoxin also directly activates platelets.^{9,10} These prothrombotic disturbances (intravascular platelet aggregation and fibrin clot formation) involve multiple organs, but are more prominent in the kidneys and central nervous system. Intravascular red blood cell destruction occurs as blood passes through involved organs (mechanical stress).

Clinical Presentation

The diagnosis of HUS is based on clinical features (simultaneous acute anemia with circulating red cell fragments, hemoglobinemia, hemoglobinuria, thrombocytopenia, and increased serum creatinine). The clinical presentation usually begins ~2-14 days after the onset of diarrhea. Other

prodromes include upper respiratory tract infection, abdominal pain, bloody diarrhea or heme-positive stools.

Acute symptoms of HUS are related to renal failure, hypertension, volume overload (due to anuria/oliguria), dehydration (due to diarrhea, decreased intake, and renal disease), profound anemia (due to intravascular hemolysis), congestive heart failure (due to anemia, hypertension, and volume overload), bleeding (due to thrombocytopenia), central nervous system thrombosis (seizures, strokes, alterations of consciousness, abnormal muscle tone, and cerebral edema, all due to thrombosis), hyperkalemia (due to acute renal failure), and acidosis (due to HCO_3^- loss in the diarrhea and decreased H^+ excretion due to renal failure). Rare complications include bowel perforation and/or necrosis, rectal prolapse (due to colitis), hepatitis, pancreatitis, and diabetes mellitus.¹ Chronic complications include end-stage renal disease, hypertension, and long-term central nervous system insults (due to thrombosis or bleeding).

The natural history of HUS varies markedly. More than 95% of affected children recover from the acute illness in 1 to 2 weeks. In mild forms, urine output may remain normal, and renal insufficiency resolves spontaneously without intervention. In more severe cases, plasmapheresis, dialysis, packed red blood cell transfusion, and long-term supportive care are necessary.

Recovery is reflected by improvements in urine output, renal function, platelet count, and hemoglobin concentration. Patients with severe disease develop chronic hypertension, renal failure, and persistent proteinuria. Poor outcome is associated with older age at onset of the disease, marked leukocytosis ($>20 \times 10^3/\text{mm}^3$), central nervous system involvement (e.g., stroke, seizure), and prolonged anuria (>7 days) or oliguria (>14 days). Relapses lead to hypertension and end-stage renal disease.

Laboratory Evaluation

A complete blood count often shows normocytic anemia and thrombocytopenia (Table 131–1). The plasma is pink-red, reflecting hemoglobinemia. The blood smear shows red cell fragments and thrombocytopenia. Blood typing is necessary because of a potential need for packed red blood cell transfusion. Serum electrolytes, blood urea nitrogen (BUN), creatinine, phosphate, and uric acid levels may show disturbances produced by diarrhea (hyperchloremic metabolic acidosis with normal anion gap) or acute renal failure (increase serum

creatinine, hyperkalemia, hyperphosphatemia, elevated uric acid, and metabolic acidosis). Lactate dehydrogenase is markedly elevated due to red cell hemolysis and microangiopathy. Indirect bilirubin is mildly elevated due to the hemolysis. Urinalysis shows hemoglobinuria (without red blood cells) and, sometimes, granular casts. A centrifuged urine sample remains pink-red, containing free hemoglobin molecules. In contrast, hematuria due to the presence of red blood cells produces clear urine supernatant.

Normal tests in HUS include direct and indirect antiglobulin (Coombs') tests, partial thromboplastin time, prothrombin time, thrombin time, and fibrinogen. Antinuclear antibodies, anti-DNA antibodies, and C3 and C4 are negative (as evidence against the presence of systemic lupus erythematosus and membranoproliferative glomerulonephritis). Other frequently abnormal but nonspecific laboratory tests include serum albumin, amylase, lipase, glucose, triglyceride, and liver transaminases.

Stool culture may identify the infectious agent (important for reporting outbreaks). However, routine stool cultures may not identify *E. coli*. A rapid screening test for *E. coli* (based on failure to ferment on sorbitol) has been developed; a positive reaction should be confirmed by commercially available agglutination tests. Positive results are more common within 7 days of the onset of diarrhea. Verotoxin can be identified in stool samples by polymerase chain reaction or other readily available laboratory techniques.

Differential Diagnosis

Thrombotic thrombocytopenic purpura (TTP) has a presentation similar to HUS (Table 131–2). TTP usually develops in adolescents and adults. It produces more prominent neurologic deterioration than renal involvement. Prompt recognition is essential, since this entity requires immediate plasmapheresis.

Autoimmune hemolytic anemia may produce intravascular hemolysis (more commonly seen in cold agglutinin disease and paroxysmal cold hemoglobinuria). In these entities, platelet count and renal function are normal. In cold agglutinin disease, immunoglobulin M-coated red blood cells activate the hemolytic complement cascade, causing intravascular hemolysis (red blood cell fragments, hemoglobinemia, and hemoglobinuria). Acrocyanosis and hemolysis follow exposure to cold. A direct antiglobulin test is positive with the reagent containing anticomplement antibodies. Par-

Table 131–1 Interpretation of Laboratory Results in Hemolytic-Uremic Syndrome

Laboratory Tests	Interpretation/Purpose
CBC	Anemia and thrombocytopenia.
Peripheral blood smear	Red blood cell fragments.
Urinalysis	Hemoglobinuria.
Serum electrolytes, BUN, creatinine, phosphate, and uric acid	Metabolic derangements (e.g., hyperkalemia, metabolic acidosis) are common.
Lactate dehydrogenase and bilirubin	Elevated levels reflect hemolysis.
Stool culture and other stool studies	Used to detect <i>E. coli</i> , verotoxin, or other causative pathogens.
Antiglobulin (Coombs') tests	Normal, positive results suggest autoimmune hemolytic anemia and not HUS as cause of symptoms.
aPTT, PT, TT, and fibrinogen	Normal, prolonged results suggest DIC and not HUS as cause of symptoms.
Antinuclear antibodies, anti-DNA antibodies, C3 and C4	Normal, positive results suggest systemic lupus erythematosus or membranoproliferative glomerulonephritis and not HUS as cause of symptoms.

Abbreviations: aPTT, activated partial thromboplastin time; BUN, blood urea nitrogen; CBC, complete blood count; DIC, disseminated intravascular coagulation; HUS, hemolytic-uremic syndrome; PT, prothrombin time; TT, thrombin time.

Table 131–2 Differential Diagnosis of Hemolytic-Uremic Syndrome

Disorder	Clinical Features
HUS	Prodrome manifestations include diarrhea, abdominal pain, and bloody or heme-positive stools. Simultaneous occurrence of acute anemia with circulating red cell fragments, hemoglobinemia, hemoglobinuria, thrombocytopenia, and increased serum creatinine.
TTP	Clinical presentation similar to HUS. More prominent neurologic deterioration than renal involvement. Immediate plasmapheresis is necessary.
ITP	Normal renal function; absence of hematuria; normal hemoglobin (see Chapter 129).
Autoimmune hemolytic anemia	Acute hemolytic anemia with positive Coombs' tests. Platelet count and renal function are normal.
Renal disease	Normal platelet count and absence of microangiopathic hemolytic anemia.
DIC	Prolonged PT, aPTT, and TT; hypofibrinogenemia.
Henoch-Schönlein purpura	Painful symmetric, palpable purpura involving proximal regions of the extremities, particularly legs and buttocks. Petechiae/purpura with normal platelet count.

Abbreviations: aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; HUS, hemolytic-uremic syndrome; ITP, immune thrombocytopenic purpura; PT, prothrombin time; TT, thrombin time; TTP, thrombotic thrombocytopenic purpura.

oxysmal cold hemoglobinuria is produced by immunoglobulin G antibodies (Donath-Landsteiner cold autoantibodies), having biphasic thermal activities. These antibodies fix to red blood cell membranes in the cold (4° C) and activate the hemolytic complement cascade at 37° C.

Thrombocytopenia (see Chapter 129, Acute Childhood Immune Thrombocytopenic Purpura and Related Platelet Disorders) may occur as a result of immune-mediated destruction (acute childhood immune thrombocytopenic purpura), after a viral infection (human immunodeficiency virus, chicken pox, and postimmunization), drugs, vasculitis (systemic lupus erythematosus), intravascular destruction (disseminated intravascular coagulation and prosthetic heart valve), platelet trapping (venous malformation, hemangiomas, and hypersplenism), and decreased platelet production (aplastic anemia, thrombocytopenia-absent radius syndrome, amegakaryocytic thrombocytopenia, and Wiscott-Aldrich syndrome).

In *disseminated intravascular coagulation*, fibrinogen is low. Renal parenchymal disease is usually associated with a normal platelet count and absence of microangiopathic hemolytic anemia.

Important Clinical Features and Considerations

Clinicians should be aware that HUS might reoccur. While debate exists as to causation or worsening of disease with antibiotic administration,^{11,12} clinicians should avoid their use unless absolutely necessary (e.g., proven bacterial infection, bowel perforation). Renal manifestations including hematuria, oliguria, and hypertension many herald the onset of renal failure. Neurologic findings include altered mental status, seizures, and coma. The skin features include pallor (due to anemia), petechiae, and purpura.

Management

All patients require hospitalization for observation and appropriate interventions. Treatment is mainly supportive² (Table 131–3). Dehydration due to diarrhea and decreased intake must be corrected while avoiding volume overload. Acute hypertension is treated with short-acting oral agents if asymptomatic or intravenous agents for encephalopathy or other hypertensive emergencies (see Chapter 65, Hyper-

Table 131–3 Management of Hemolytic-Uremic Syndrome

1. Correct dehydration due to diarrhea while avoiding fluid overload
2. Adequately treat hypertension using intravenous agents (e.g., nicardipine, sodium nitroprusside) for hypertensive emergencies.
3. Avoid platelet transfusions.
4. Use antibiotics only for proven infections or suspected bowel perforation.
5. Dialysis is indicated if patient develops anuria, severe oliguria, hyperkalemia unresponsive to conventional therapy, severe azotemia (e.g., encephalopathy), fluid overload, or pulmonary edema.
6. Administer packed red blood cells to keep hemoglobin ~8.0 g/dl.
7. Plasma infusion (10 ml/kg over 2–4 hr) or plasmapheresis is indicated in patients with central nervous system involvement or severe renal disease.
8. Patients with seizures require emergent imaging to exclude intracranial pressure or bleeding. Promptly treat seizures with standard agents (e.g., lorazepam followed by fosphenytoin).
9. Early consultations with nephrology, hematology, and plasmapheresis teams to assist with clinical care and to expedite interventions (e.g., dialysis, plasmapheresis).
10. Admit patients to a floor that can adequately monitor vital signs and fluid intake/output, and observe for acute deterioration (e.g., seizures).

tensive Emergencies). Packed red blood cells should be administered to maintain hemoglobin concentrations above approximately 8.0 g/dl. Seizures should be investigated with computed tomography or magnetic resonance imaging of the brain and treated appropriately (see Chapter 40, Seizures).

Platelet transfusion should be avoided and antibiotics reserved for suspected bowel perforation or documented bacterial infection. Dialysis is indicated in the presence of anuria (>24 hours), severe oliguria, uncontrollable hyperkalemia, severe azotemia (e.g., encephalopathy, BUN >100 mg/dl), or fluid overload with pulmonary edema. Once fluid deficit is corrected, total fluid intake should be limited to replacing insensible water loss (pure water at ~50% of estimated maintenance fluid therapy), measured urine output, and measured ongoing fluid loss from the diarrhea.

Plasma infusion or plasmapheresis is indicated in patients with central nervous system involvement or severe renal disease (e.g., oliguria, hypertension, hyperkalemia, hypervolemia, pulmonary edema). Treatment frequency varies

from daily to twice weekly.² Consultations include those to nephrology, hematology, and plasmapheresis teams. Controversial therapies include tissue-type plasminogen activator (Alteplase) and aspirin (platelet inhibitor).

Summary

Children with mild to moderate HUS can be treated with supportive care only. Children with moderate to severe HUS are more likely to need plasmapheresis and dialysis (especially if neurologic and severe renal involvements are present). TTP has a presentation similar to HUS; it occurs in adolescents and requires aggressive treatment, particularly with plasmapheresis. Antibiotics may increase the release of verotoxin and should be avoided unless they are absolutely indicated. Platelet transfusion may lead to thrombosis, and should be avoided in the absence of a life-threatening hemorrhage.

Utilizing Blood Bank Resources/ Transfusion Reactions and Complications

Abdul-Kader Souid, MD, PhD, Lazaro G. Rosales, MD,
and Boura'a Bou Aram, MD

Key Points

A transfusion should be recommended only after the risks and benefits are carefully considered.

Most transfusion fatalities occur as a result of ABO incompatibility due to an error in identifying the patient or a unit of blood.

Leukocyte-depleted blood components are recommended for patients requiring chronic transfusion.

Irradiated blood components are recommended for immune-compromised patients.

Permission with informed consent to transfuse should be obtained for each patient.

Blood Bank Resources

Collecting Donated Blood and Testing Blood Components Prior to Use

Blood products obtained for medical use are donated by healthy volunteers under federal and state regulations.^{1,2} Donated blood is tested for infectious disease markers, such as syphilis, hepatitis B surface and human immunodeficiency virus type 1 (HIV-1) p24 antigens, and hepatitis B core, human T-cell lymphotropic virus types I and II (HTLV-I and HTLV-II), hepatitis C, HIV-1, and HIV type 2 (HIV-2) antibodies. Polymerase chain reaction is performed for HIV and hepatitis C virus. Risk of missing the detection of infectious agents occurs in the “window period” between exposure and positive testing. A high risk especially involves hepatitis B

virus due to its long window period; vaccination for hepatitis B virus reduces this risk. Other rare viruses and diseases include West Nile virus, herpesviruses, parvovirus B19, variant Creutzfeldt-Jakob disease, and severe acute respiratory syndrome. Current standard testing does not detect these infections; nevertheless, viral transmission via blood components is very rare.^{3,4}

The blood groups routinely tested for donors and recipients are the ABO and Rh systems. The ABO blood group is determined because anti-A and/or anti-B immunoglobulin M (IgM) alloantibodies in the recipient's serum produce rapid hemolysis of donor red cells. Commercially available anti-A and anti-B antibodies are used to determine ABO blood type. These IgM molecules bind to A group and B group red cell antigens, respectively, producing direct (macroscopic) agglutination. Moreover, incubating the recipient's serum with commercially available group A and group B red cells demonstrates the presence of specific alloantibodies, confirming the ABO blood type. For example, blood type A shows the recipient's red cell agglutination with commercial anti-A antibodies and commercial group A red cell agglutination with the recipient's serum. Commercially available (modified) anti-Rh immunoglobulin G (IgG) can directly agglutinate (macroscopically visible) D-positive (or Rh₀) red blood cells.

The Rh blood group is determined because D antigen, the major determinant of the Rh system, is a strong immunogen, producing anti-D antibodies in Rh-negative recipients. An Rh-negative woman who is immunized to D antigen by transfusion or pregnancy is at risk of delivering a newborn with severe hemolysis. Thus individuals who are Rh-negative, especially females of childbearing age, require Rh-negative blood and platelets to prevent Rh sensitization.

For Rh-negative recipients, the decision to stay with Rh-negative blood versus switching to Rh-positive components is based on the anticipated need for future red blood cell (RBC) transfusion, availability of Rh-negative components, and urgency of transfusing other Rh-negative patients. As soon as it becomes apparent that the Rh-negative patient will

receive massive transfusion (more than the patient's blood volume in 24 hours; blood volume is estimated as 100 ml/kg for preterm neonates, 85 ml/kg for term neonates, and 75 ml/kg for children >1 month of age) that will exceed the Rh-negative blood inventory, the patient should be switched to Rh-positive components. The problem with giving O-positive red cells immediately without antibody screening in an emergency is the potential for developing hemolytic transfusion in patients who have anti-D antibodies.

Detecting blood group antibodies (isoagglutinins) directed against non-ABO blood group antigens is also performed prior to blood transfusion. This antibody screening test is performed using recipient serum against a panel of "group O" RBCs of known antigenic composition. The term *antibody screening test* is sometimes used synonymously with the term *indirect antiglobulin (Coombs) test (IAT)*. If the test is positive (hemolysis or agglutination), further tests to determine specific antibodies will be performed.

The IAT is performed by incubating the recipient's serum (at 37° C) with commercially available red blood cells of known antigen type. Unbound antibodies are removed by washing RBCs with 0.9% NaCl. An antiglobulin reagent (rabbit anti-human IgG or IgG plus complement) is then added. A positive test shows red cell agglutination, reflecting the presence of allo- or autoantibodies. Allo- versus autoantibodies are determined by a commercially available panel of red cells, varying with antigen phenotype. Agglutination of all red cell panels indicates autoantibodies (e.g., patients with autoimmune hemolytic anemia). By contrast, specific reactivity indicates alloantibodies (e.g., patients with alloimmunization). The direct antiglobulin (Coombs') test detects antibodies or complement on the surface of red cells. Washed recipient's red cells are incubated with antiglobulin reagent (rabbit anti-human IgG or IgG plus complement) as in the IAT. Agglutination is observed if antibodies or complement are present on the surface of red cells. A crossmatch with an ABO- and Rh-compatible unit of blood determines whether the recipient's serum contains unexpected antibodies to the donor's red cell antigens.

Whenever red cell products are requested, ABO and Rh typing, antibody screening, and a full crossmatch are routinely performed. If the antibody screen is negative, the patient may be transfused the appropriate ABO/Rh type. An immediate spin crossmatch (mixing the patient's serum with RBCs from a unit selected for transfusion and observing for hemolysis or agglutination) provides added safety. If the antibody screen is positive, the specificity of the antibody is identified; if clinically significant, only red cells negative for the relevant antigen will be transfused. A full crossmatch is also performed. Additional time is required to identify the antibodies, find antigen-negative red cells, and perform full crossmatch tests. This may take hours or days if multiple antibodies are present (Table 132-1).

In an emergency situation, blood may need to be transfused before standard testing is completed. In these circumstances, physicians are asked to sign an "emergency release form" to document the reason for the urgent need and to acknowledge that the blood is not fully crossmatched at the time of transfusion. O-negative red cells are available for immediate transfusion to any patient, but should be used only when the patient's blood type is not known and there is no time to determine it. This situation sometimes occurs in

Table 132-1 Estimated Times for Blood Bank to Release Units of Red Blood Cells

Test/Product	Time to Completion
O ⁻	Immediate
ABO and Rh typing	10 min
Type and screen	15 min
Type and crossmatch	45 min
Leukocyte-reduced PRBCs	Typically performed at the time of blood collection or at the bedside using a filter
Irradiated PRBCs	10 min

Abbreviation: PRBCs, packed red blood cells.

the setting of trauma and should apply to the first few units transfused.

Packed Red Blood Cell (Red Cell Concentrate) Transfusion

Packed red blood cell (PRBCs) transfusions are used to improve blood oxygen-carrying capacity and restore blood volume. Units are prepared from whole blood by removing most of the plasma (producing an average hematocrit value of 70%). This procedure reduces the transfusion volume and the isoagglutinin load. Each unit usually contains approximately 200 ml of RBCs, 70 ml of plasma, and 100 ml of additive nutrient solution (e.g., citrate [as an anticoagulant], phosphate, dextrose, and ATP). Clinical citrate toxicity (hypocalcemia due to calcium chelation) is rare, occurring only with massive transfusions (e.g., exchange transfusion), and responds to calcium supplements. Prolonged storage produces a leakage of potassium into the plasma, which is usually clinically insignificant. Blood should be infused through a filter (170 to 260 μm) to remove debris caused by storage.^{1,2}

Transfusion is usually given if the symptoms of anemia or blood loss are severe and further delay might result in significant disability or death. Selected indications for transfusion include acute bleeding, high-dose chemotherapy, severe prematurity, sickle cell disease (e.g., splenic sequestration, severe acute chest syndrome), thalassemia major, aplastic anemia, pure red cell aplasia, and severe autoimmune hemolytic anemia (using the most compatible unit).² Transfusing 10 to 15 ml/kg of PRBCs in a child raises the hemoglobin concentration by 2 to 3 g/dl and the hematocrit by 6% to 9% (Table 132-2).^{1,5} Transfusion is usually given at 15 ml/kg over 2 to 4 hours. Faster transfusion may be necessary to replace acute blood loss. If the intention is to transfuse small amounts (e.g., in infants), a unit can be divided into several aliquots.

Leukocyte-reduced PRBCs are prepared by passing the unit through a filter that removes 85% to 90% of the white blood cells; the procedure is frequently performed at the time of blood collection. This type of product produces fewer non-hemolytic febrile reactions, which are mediated by antibodies against the donor's white cell antigens as well as by cytokines produced during component storage. This product also produces less alloimmunization and viral (e.g., cytomegalovirus) transmission. It is indicated for patients who need chronic transfusion (e.g., children on chemotherapy or with hemoglobinopathy) or who have prior exposure to blood antigens (e.g., multiparous females).¹

Table 132–2 Blood Component Transfusion*

Product	Indication	Crossmatch	Dose	Expected Rise
PRBCs Leukocyte-reduced PRBCs Irradiated PRBCs Washed PRBCs	Improving blood oxygen-carrying capacity and restoring blood volume Chronic PRBC transfusions Immune-compromised patients Persistent allergic reactions	Complete	10–15 ml/kg	Hemoglobin concentration increases by 2–3 g/dl [†]
Platelets (whole blood derived)	Thrombocytopenia	ABO	1 unit/10 kg; 4–6 units for adults [‡]	Platelet count increases by 25–50 × 10 ³ /mm ³
Platelets (apheresis)	Chronic platelet transfusions	ABO	10 ml/kg; 1 unit for adults [§]	
FFP	Acquired coagulopathy, reversal of warfarin, clotting factor (II, X, XI and XIII) deficiency, TTP and HUS	ABO	10–25 ml/kg	Each coagulation factor increases by 10%–20% [¶]
Cryoprecipitate	Rich in fibrinogen, von Willebrand's factor, and factor VIII	ABO	1–4 units/10 kg; 8–12 units for adults ^{**}	Plasma fibrinogen increases by 60–100 mg/dl

*Modified from Pisciotto P (ed): Pediatric Hemotherapy Data Card. Bethesda, MD: American Association of Blood Banks, 2002.

[†]Increments depend on anticoagulant-preservative solution.

[‡]Each unit contains 5.5×10^{10} platelets in 50 ml of plasma.

[§]Each unit contains 3.0×10^{11} platelets in 250 ml of plasma.

[¶]Different recovery for each factor (depending on circulatory half-lives).

**Each unit contains approximately 250 mg of fibrinogen.

Abbreviations: FFP, fresh frozen plasma; HUS, hemolytic-uremic syndrome; PRBC(s), packed red blood cell(s); TTP, thrombotic thrombocytopenic purpura.

Irradiated PRBCs are prepared by exposing the unit to 2500 cGy of radiation. This treatment inactivates the donor's T cells, which reduces the risk of a graft-versus-host reaction in the recipient. This type of product is recommended for immune-compromised patients (e.g., children on chemotherapy).¹

Washed PRBCs are prepared by washing red cells with 0.9% NaCl, which removes most of the plasma. This type of product is used for patients who have severe allergic reactions (e.g., cough, wheezing, swollen lips, and urticaria) to transfusion despite antihistamine administration. Immunoglobulin E antibodies against the donor's plasma proteins mediate this adverse reaction. This product is also used for patients with immunoglobulin A (IgA) deficiency who have developed IgA antibodies.²

Platelet Transfusion

Platelets are the principal mediator of hemostasis and are constantly required to support endothelial functions. Bleeding (e.g., petechiae, epistaxis, melena, hematemesis, menorrhagia, hematuria) is common when the platelet count is 10,000/mm³ or less. Moreover, life-threatening hemorrhage (e.g., into the airway, lungs, central nervous system, and gastrointestinal tract) becomes more likely when the platelet count is 5000/mm³ or less. Thus profound thrombocytopenia (defined as a platelet count < 20,000/mm³) due to decreased production (e.g., patients on chemotherapy or with aplastic anemia) should be promptly treated with platelet transfusion. A prophylactic transfusion is recommended when the platelet count is less than 20,000/mm³. A therapeutic transfusion, in contrast, is given to treat any significant bleeding even if the platelet count is greater than 20,000/mm³.²

Platelet concentrates are prepared from routinely donated whole blood by centrifugation, producing platelet-rich plasma that, on further centrifugation and separation of

the supernatant plasma, yields a platelet concentrate (unit) of 50 ml. A single unit (prepared from 1 unit of whole blood) should contain greater than 5.5×10^{10} platelets, which raises the platelet count by 6 to 10×10^3 /mm³ in adults. Transfusing 4 to 6 pooled random-donor units of platelets for adults and children greater than 20 kg (1 unit/10 kg for children < 20 kg) raises the platelet count by 25 to 50×10^3 /mm³ (see Table 132–2), which is usually adequate for supporting hemostasis (see Table 132–2).⁵ Platelets are also prepared from blood from a single donor with the use of blood cell separator machines, yielding a platelet product (apheresis) equivalent to that of 5 random units. For adults and children greater than 20 kg, a platelet transfusion requires 1 single-donor apheresis unit (10 ml/kg for children < 20 kg) (see Table 132–2).^{1,5} This type of product (apheresis unit of platelets) aims to minimize donor exposure and is recommended for patients requiring chronic transfusion.⁵ If the intention is to transfuse a small volume (e.g., in infants), an apheresis unit of platelets can be divided into two aliquots.

Platelet survival (normal, 9.6 ± 0.6 days) is shorter in patients with profound thrombocytopenia (platelets are normally consumed in the spleen and blood vessels), alloimmunization, fever, infection, and splenomegaly. ABO-compatible, single-donor apheresis, leukocyte-depleted and irradiated platelets are less likely to produce alloimmunization, and are therefore recommended for patients requiring chronic transfusion. Other indications for leukocyte-depleted and irradiated products are as discussed for PRBC transfusion. Platelet transfusion is not recommended in patients with hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura, heparin-induced thrombocytopenia, and idiopathic thrombocytopenic purpura. Any medication that could inhibit platelet function (e.g., salicylates and nonsteroidal anti-inflammatory drugs) should be avoided in thrombocytopenic patients.

Fresh Frozen Plasma and Cryoprecipitate Transfusion

Fresh frozen plasma (FFP) is prepared from whole blood; it should be frozen at less than 18° C within 6 hours of collection. This procedure preserves the activities of labile proteins, such as factors V and VII. It is a nonconcentrated source of clotting factors and is used for acquired coagulopathy (e.g., liver disease and disseminated intravascular coagulation), rapid reversal of warfarin, congenital coagulation factor deficiency (e.g., factors II, X, XI, XIII), thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome (see Chapter 129, Acute Childhood Immune Thrombocytopenic Purpura and Related Platelet Disorders; and Chapter 131, Hemolytic-Uremic Syndrome). The dose ranges from 10 to 25 ml/kg, repeated as necessary (see Table 132–2).⁵ The product should be ABO compatible. Potential complications include viral transmission (e.g., HIV, hepatitis), anaphylactic reaction, urticaria, and alloimmunization. Because of the risk of viral transmission, FFP should be used only if absolutely necessary.

Cryoprecipitate is prepared from FFP by thawing at 4° C. The precipitate is then suspended in 15 ml plasma and refrozen at less than 18° C. It is rich in fibrinogen (each unit contains approximately 250 mg), factor VIII, and von Willebrand's factor. It is used to treat bleeding due to fibrinogen deficiency, such as severe liver disease, disseminated intravascular coagulation, and afibrinogenemia (rare). The recommended dose is 1 to 4 units (bags) per 10 kg (8 to 12 units for adults), which raises plasma fibrinogen to by 60 to 100 mg/dl (see Table 132–2).⁵ Due to the risk of viral transmission and availability of safer products, cryoprecipitate should not be used to treat patients with hemophilia A or von Willebrand's disease.

Transfusion Reactions

Hemolytic Transfusion Reactions

ABO incompatibility produces severe immune-mediated hemolytic reactions. The anti-A and/or anti-B IgM alloantibodies in the recipient's plasma produce intravascular hemolysis (circulating RBC fragments, hemoglobinemia, and hemoglobinuria) of the donor's RBCs. The symptoms include rigors, headache, fever, chest tightness, flank pain, red/black urine, hypotension, nausea, and vomiting. Serious progression may be fatal due to shock and organ failure. Management includes immediately stopping the transfusion and administering isotonic fluid (0.9% NaCl) and mannitol (0.25 g/kg intravenously) to induce diuresis. Careful monitoring (respiratory and circulatory status, urine output, and urine color), supportive care (intravenous fluid, diuretics, and oxygen) and appropriate consultations (blood bank, nephrology, and hematology) are necessary. The blood bag and blood sample from the recipient should be returned to the blood bank for retyping.

Nonimmune hemolytic reaction occurs when RBCs are damaged prior to transfusion (e.g., exposed to improper temperature during shipping or storage, mishandling during transfusion). Hemoglobinemia and hemoglobinuria are present in the recipient without symptoms. This complication requires no treatment.

Nonhemolytic Transfusion Reactions

Febrile reactions are caused by cytokines (produced by the donor's leukocytes) accumulated in stored blood. These molecules produce fever, rigors, tachycardia, and dyspnea. Management consists of stopping the transfusion and excluding a hemolytic transfusion reaction (repeat crossmatching of the unit of blood and performing Coombs' tests). The symptoms usually subside within 30 minutes of stopping the transfusion. Premedication with acetaminophen is usually helpful.

Allergic symptoms (rash and urticaria, pruritus, flushing, and, rarely, angioedema) follow the recipient's exposure to the donor's plasma proteins or other substances (e.g., medications taken by the donor). This reaction can be ameliorated by premedicating with diphenhydramine (0.5 to 1 mg/kg) and methylprednisolone (0.5 to 1 mg/kg). A severe form of allergic reaction (anaphylactic) can occur in recipients who are IgA deficient. Management of urticaria consists of discontinuing the transfusion and administering diphenhydramine and methylprednisolone. Anaphylaxis requires intravenous fluids, steroids, and subcutaneous or intravenous epinephrine administration depending upon the severity.

Transfusion-related acute lung injury is a noncardiogenic pulmonary edema associated with passive transfusion of donor granulocyte antibodies. The reaction occurs when the donor's antileukocyte antibodies (e.g., in multiparous or previously transfused donors) react with the recipient's leukocytes, which are then aggregated and activated in the lung microvasculature, producing altered vascular permeability and pulmonary capillary leak syndrome, resembling acute respiratory distress syndrome (ARDS). It should be managed similarly to ARDS.

Circulatory overload (cough, precordial pain, tachycardia, tachypnea, dyspnea, and hypoxia) may follow rapid transfusion. This complication is more common in patients with cardiac or renal disease, hypertension, or profound anemia (hemoglobin concentration < 5.0 g/dl). Treatment includes stopping the transfusion, oxygen supplementation, and administration of furosemide (0.5 to 1 mg/kg intravenously). Volume overload can be avoided by transfusing half of the desired transfusion over 4 hours, followed by administration of intravenous furosemide (0.5 to 1 mg/kg), followed by the second half of the transfusion over 4 hours.

Rare acute complications include bacterial contamination (most notably from platelet transfusion), citrate-induced hypocalcemia, and hyperkalemia (due to ruptured red cells).

Delayed Transfusion Reactions

Viral contamination with cytomegalovirus, HIV, and hepatitis A, B, and C virus remains a serious complication. Posttransfusion hepatitis is of particular concern because donors are usually asymptomatic. The risk of HIV transmission is almost negligible (probably 1 in 8 million transfusions).

Alloimmunization (developing alloantibodies against red cell, platelet, and leukocyte antigens) results from multiple exposures to donor antigens. Every transfusion has the potential to induce alloimmunization.

Posttransfusion graft-versus-host reaction occurs in patients on chemotherapy or with immunodeficiency. It also occurs

in newborns and young infants who receive transfusion from blood relatives. Donor T cells attack recipient tissues, producing skin rash, increased transaminases, and diarrhea. Gamma irradiation of blood components eliminates this risk.

Iron overload results from repeated PRBC transfusions. Long-term complications of hemochromatosis include cirrhosis, fibrosis of the pancreas, and cardiomyopathy. Chelation therapy with deferoxamine mesylate (Desferol) is necessary for patients receiving long-term transfusions.

Summary

Viral transmission through transfusion occurs very rarely, and the risk of developing acquired immunodeficiency syndrome from a blood transfusion is almost negligible. Nevertheless, the risk of not receiving a transfusion should always outweigh the potential adverse effects. Serious transfusion reactions can be avoided by verifying each patient's identification and the blood groups of recipients and donors. Blood

components should be transfused slowly in the first 15 minutes, with the patient being closely monitored. Diphenhydramine (0.5 to 1 mg/kg), methylprednisolone (1 mg/kg), and acetaminophen can be given for minor allergic and/or febrile reactions. These medications also can be used as prophylaxis for patients with prior adverse reactions to transfusion. Leukocyte-reduced and irradiated blood components produce less adverse reactions.

Chapter 133

Common Pediatric Overdoses

Deborah J. Mann, MD and Richard M. Cantor, MD

Key Points

Specific medications are harmful to children, even in small amounts.

Cyanosis unresponsive to supplemental oxygen may be a sign of methemoglobinemia.

Exposure to long-acting oral hypoglycemics often necessitates overnight admission for glucose monitoring.

Serum acetaminophen and aspirin levels are mandatory in all intentional overdose cases.

Acetaminophen levels drawn before 4 hours postingestion do not reflect or predict potential toxicity or the need for *N*-acetylcysteine therapy.

tion. Enhanced skin permeability of children is a factor in absorption as well.

The average 2-year-old places nonfood items in his or her mouth at a rate that approximates three events per hour; however, most pediatric ingestions are benign in nature. A small percentage of pediatric patients (12%) will develop signs and symptoms following ingestion.^{3,4} Current annual estimates suggest that 2000 patients less than 6 years of age will develop life-threatening events as a result of intoxication. Approximately 20 fatal cases are reported from toxic exposure each year.¹⁻⁴

Ingestion involves a complex interplay of variables that include the child, the substance, and the environment. The typical child is unable to discriminate safe from unsafe, and is observant of the ritual of self-medication in other family members. The child often mistakes the substance for an edible ingredient, when in fact it is a medication (as in “look-a-like medications”) (Table 133–3). The environment may be unsafe for children, with poor storage techniques of toxicants within the household (Table 133–4). A common pitfall is storage of a harmful substance within a recognizable container (i.e., kerosene or gasoline in a soda bottle). Many poisonings are a result of poor parental supervision.

The Individual Encounter

An ingestion should be suspected when a preverbal child is found with an open container, when a classic toxidrome is present, or in cases of unexplained multiorgan system abnormality.

Liquids or pelleted materials are more likely to be ingested in larger amounts than aerosols or powders. Flavoring or irritant additives have little to do with determining whether the product was actually ingested. The volume of the swallow is a function of body mass. The volume of a swallow is 0.27 ml/kg, or roughly 1 teaspoon, for a 2-year-old, 1 tablespoon for an adult female, and 1 to 2 tablespoons for an adult male.

The situation of an unwitnessed disappearance of the contents of a container of a toxic substance often presents poison centers with difficult management decisions. When the amount of toxicant ingested is difficult to estimate, the physician must default to the assumption that the child may have consumed the full container of the toxicant involved. When two children are involved in an ingestion, it must be assumed that each took the entire amount. The classic concept of sharing may not apply.

Introduction and Background**Epidemiology of Pediatric Poisonings**

Exposure to toxins represents a large subset of pediatric emergencies, both within the home and in emergency departments. Poisoning is ranked as the third leading cause of mortality following motor vehicle accidents and farm injuries. Poisoning was the underlying cause of death for 18,549 people in the United States in 1998.^{1,2}

Analysis of Poison Control Center national data reveals that 75% of exposures occur within the home. In the pediatric subgroup, 85% to 90% of exposures are unintentional. There is a peak age under 5 years with parallel rises at ages 12, 13 to 19, the 20s, and the 30s. As children enter adolescence, accidental exposures become rare and intentional exposures more common. Seventy-five percent of exposures are ingestions, followed by dermal, inhalation, and ocular exposures. Commonly involved agents and reported fatalities are listed in Tables 133–1 and 133–2.^{3,4}

Parents often underestimate the motor skills of children. Children are curious about their environment. They explore using hand-to-mouth behavior. Children’s higher respiratory rates impart greater susceptibility to toxic gases and aspira-

Discussion of Individual Pediatric Overdoses

Nonsteroidal Anti-Inflammatory Drugs

The nonsteroidal anti-inflammatory drugs (NSAIDs) are a group of medications that have antipyretic, anti-inflammatory, and analgesic properties. With their widespread availability and increasing use in the United States, NSAIDs represent some of the most common medications involved in the overdose setting. Fortunately, most NSAID exposures cause minimal morbidity and mortality. The most prevalent complications are therapeutic side effects, specifically gastrointestinal (GI) bleeding.

NSAIDs exert their pharmacologic effect by inhibiting cyclooxygenases, which are involved in prostaglandin synthesis.^{5,6} NSAIDs are rapidly and almost completely absorbed. They are weak acids, highly protein bound, and metabolized by the cytochrome P-450 system. More than half of the drug is excreted unchanged in the urine.

NSAIDs seldom cause serious toxicity, even in large doses. At this time, there are inadequate data defining the minimum toxic or lethal dose.⁷ Following acute overdose, most children are asymptomatic or develop only mild GI symptoms. Specific signs and symptoms are summarized in Table 133–6. Generally, full recovery can be expected within 6 to 24 hours. In contrast, phenylbutazone and its active metabolite oxypenbutazone can cause coma, seizures, shock, respiratory alkalosis, and metabolic acidosis. Within 24 hours, hepatic necrosis may develop. Urine discoloration due to a metabolite may result in a red hue.

The emergency department evaluation consists of standard supportive care and GI decontamination. Gastrointestinal bleeding should be treated by standard measures for hemodynamic support. Activated charcoal remains the preferred method of GI decontamination.⁷

Oral Hypoglycemics

Diabetes mellitus is the most common endocrine disorder in our country today and is frequently managed with oral agents. Oral medications including sulfonylureas, meglitinides, biguanides, and thiazolidinediones. Of all these drug classes, only the sulfonylureas and meglitinides are truly hypoglycemic agents (Table 133–7).

Most poisonings from oral hypoglycemic agents involve sulfonylureas, with most of the fatalities involving biguanides.^{8–10} Their primary mechanism of action is the release of endogenous insulin. Glyburide has the highest incidence of hypoglycemia and is the most widely utilized of these agents. Most hospitalizations are due to overdose of long-acting agents. In the overdose setting, hypoglycemia typically occurs within the first several hours after ingestion. Delayed hypoglycemia has also been reported in some cases. In a retrospective pediatric study, 96% of children exposed to oral

hypoglycemics had a drop in their blood sugar within 8 hours.¹¹

The biguanide class includes metformin and phenformin. Phenformin was removed from U.S. distribution as a result of fatal lactic acidosis. Metformin is the only biguanide in common use today. It increases insulin sensitivity, decreases hepatic gluconeogenesis, and diminishes intestinal glucose absorption. Insulin secretion remains unaffected. Therefore, metformin will correct hypoglycemia in diabetics but will

Table 133–5 Medicinal Preparations Fatal to a 10-kg Toddler

Drug	Minimal Potential Fatal Dose (per kg weight)	Maximal Unit Dose Available	Amount Causing Fatality

Organ System	Sign/Symptom
GI	Nausea, vomiting, anorexia, abdominal pain, gastritis, GI bleeding, cholestasis
Neurologic	Dizziness, nystagmus, diplopia, blurred vision, headache, tinnitus, lethargy, ataxia, confusion, seizures
Respiratory	Hyperventilation, respiratory depression, apnea
Cardiovascular	Hypotension, bradycardia
Renal	Sodium retention and edema, proteinuria, hematuria, renal failure
Hematologic	Decreased platelet aggregation, elevated PTT and PT
Other	Metabolic acidosis

Abbreviations: GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; PT, prothrombin time; PTT, partial thromboplastin time.

not induce hypoglycemia in nondiabetics. Lactic acidosis is the most serious side effect associated with metformin.¹²

Hypoglycemia affects many organ systems. Autonomic symptoms are prominent and result from excessive adrenergic tone. Symptoms and signs include anxiety, diaphoresis, palpitations, irritability, and tremor. Neurologic symptoms include dizziness, tingling, and faintness. Simultaneous therapy with β -blockers may mask the autonomic symptoms. Hypoglycemia may also cause focal neurologic deficits.

Emergency department management involves standard gastrointestinal decontamination techniques. Intravenous (IV) dextrose remains the first line of therapy for hypoglycemia. Children should receive 2 to 4 ml/kg of 25% dextrose. Euglycemia maintenance may require an infusion of 5% to 10% dextrose. Infusions of higher concentrations of dextrose may require the use of a large-bore or central venous catheter. All children who are symptomatic or potentially ingested long-acting agents require admission and prolonged observation for hypoglycemia.

Refractory hypoglycemia may be treated with either diazoxide or octreotide. Diazoxide inhibits pancreatic insulin release. The dose is 1 to 3 mg/kg IV in children (to a maximum of 150 mg). Octreotide inhibits pancreatic insulin secretion and has a well established place in the management of sulfonyleurea-induced refractory hypoglycemia. Clinical trials

have clearly demonstrated its effectiveness.¹³ The suggested dose is 4 to 5 mcg/kg/day divided every 6 hours in children (maximum dose should not exceed 1500 mcg/24 hr).

Agents Causing Methemoglobinemia

Methemoglobinemia is caused by the conversion of iron molecules in hemoglobin from the ferrous to ferric state. Under normal conditions, methemoglobin levels are less than 1% to 2% of a child's total hemoglobin. Oxyhemoglobin is red and methemoglobin is dark brown, creating its characteristic chocolate brown color. At least 5 g of hemoglobin per deciliter of blood must be oxidized to methemoglobin to cause clinical cyanosis. Methemoglobin is incapable of transporting oxygen. This induces a leftward shift in the oxyhemoglobin dissociation curve. The final result is a global decrease in tissue oxygenation accompanied by metabolic acidosis.

Mammalian red blood cells contain enzymes that are capable of reducing methemoglobin back to oxyhemoglobin. The vast majority of this reduction is carried out by the transfer of electrons from NADH (NADH-dependent methemoglobin reductase). In the normal resting state, the

enzymatic reduction of methemoglobin keeps up with its spontaneous formation. In the neonate, any oxygen stress may cause methemoglobinemia due to decreased reducing ability.^{14,15}

Many agents have been known to result in acquired methemoglobinemia (Table 133–8). The mechanisms for their causation are varied, either involving direct oxidant stress or a secondary effect of their metabolites. The most commonly reported substances associated with methemoglobinemia are local anesthetics such as benzocaine. These may be delivered parenterally or topically (as in teething gels). Other prescribed medications implicated in methemoglobinemia include metoclopramide, phenazopyridine, and diaminodiphenylsulfone. Environmental factors include aniline dyes and exposure to either nitrates or nitrites. Well water is a common source of nitrites. Recreational use of inhaled nitrites has also been associated with cases of methemoglobinemia. Finally, acute diarrheal conditions in infants have also been associated with methemoglobinemia.¹⁶

As methemoglobin levels exceed 10%, patients present with unexplained cyanosis and often no other symptoms. At levels from 15% to 35%, headache, shortness of breath, tachypnea, and tachycardia may occur. As levels rise further, central nervous system (CNS) signs and symptoms include confusion, coma, seizures, and apnea. Death occurs with levels over 70%.^{14,15}

Patients with methemoglobinemia remain cyanotic even with administration of supplemental oxygen. Arterial oxygen levels are normal or elevated. Bedside pulse oximetry¹⁵ is unreliable in most cases. Venous blood will turn brown when exposed to room air.

All patients with suspected methemoglobinemia should be placed on supplemental oxygen. This will ensure oxygen delivery to the fraction of hemoglobin that is functional. Most patients with levels less than 30% will not require any

additional treatment. Methylene blue should be administered to symptomatic patients, those with levels above 30%, those with electrocardiogram changes, or those with metabolic acidosis. The recommended dose is 2 mg/kg given IV over 3 to 5 minutes. Most patients resolve their cyanosis within 15 minutes. In refractory cases, repeat doses may be given. The total dose of methylene blue during the first 2 to 3 hours should not exceed 5 to 7 mg/kg. Methylene blue is contraindicated in patients with known glucose-6-phosphate dehydrogenase (G6PD) deficiency since hemolysis may occur. There is an increased incidence of G6PD deficiency in individuals of African and Mediterranean descent.

Treatment with hyperbaric oxygen or exchange transfusion may be effective for patients with G6PD deficiency or those who are resistant to methylene blue. All patients with methemoglobinemia should be admitted to a monitored setting for observation. A toxicologist or poison control center should be consulted in difficult-to-manage cases.

Iron Poisoning

Iron poisoning is the leading cause of accidental death from pharmaceutical agents in young children. There are over 30,000 iron ingestions annually.¹² Iron is readily available in the home, with many preparations resembling chewable candy. Toxicity is dependent on the amount of elemental iron ingested. Ingestion of greater than 20 mg/kg will often produce GI upset. Exposures above 50 mg/kg are potentially fatal. Exposure to children's chewable vitamins rarely causes severe iron poisoning.

Free unbound iron is toxic to tissues. The body protects itself by binding iron to ferritin. Iron is transported globally bound to transferrin. The total iron-binding capacity (TIBC) represents the amount of iron that transferrin can bind. Normally, the TIBC far exceeds the serum iron concentration, resulting in no circulating unbound iron.

Iron is a corrosive with the potential to cause hemorrhage, hypovolemia, and GI perforation. Systemic effects occur if enough iron is absorbed. Iron disrupts oxidative phosphorylation and promotes the formation of free radicals, contributing to cell death. Iron is also a vasodilator. The net effect is shock and metabolic acidosis.

Traditionally, clinicians have attempted to characterize iron poisoning by clinical stages according to symptoms. However, the emergency physician must be aware of overlapping presentations.¹⁷ The first stage of iron poisoning occurs within the first few hours and is characterized by abdominal pain, vomiting, and diarrhea. Significant GI bleeding may occur. The second stage involves resolution of GI symptoms, with silent absorption of toxic amounts of iron. This may last up to 36 hours after exposure, giving a false sense of clinical improvement. Clinically evident systemic iron poisoning heralds the third stage. Shock and metabolic acidosis will occur because of shifts of fluid out of the vasculature. Liver failure may result. Scarring of the gastric outlet or small bowel represents the fourth stage. This may occur several weeks after the acute event.

Serum iron concentrations usually peak 2 to 6 hours after exposure. A normal serum iron level drawn very early or late after ingestion does not exclude toxicity. Previous management favored the use of white blood cell or serum glucose levels to predict severity. This has been proven to be unreliable.¹⁷ Plain radiographs of the abdomen may demonstrate

opacities in severe poisoning and confirm the suspicion of iron poisoning.

Most symptomatic patients, or those with a history of ingesting more than 20 mg/kg, are referred to emergency departments by poison control centers. Activated charcoal does not bind iron and is of no use in a pure ingestion. Gastric lavage is ineffective as well. There are no data supporting the use of bicarbonate or phosphate solutions to prevent absorption. Whole bowel irrigation (WBI) has been shown to be effective in reducing toxicity and is especially effective if tablets are seen on plain radiography. Patients undergoing WBI must be awake and alert without evidence of GI dysfunction (e.g., intractable vomiting, ileus, significant bleeding, obstruction, or perforation). Elevate the head of the bed to 45 degrees. Administer 25–40 ml/kg per hour of polyethylene glycol by nasogastric tube until effluent clear and radiography no longer shows any iron tablets.

Patients who are asymptomatic after 6 hours with normal serum iron levels (50–150 mcg/dl) may be discharged. Patients who develop emesis or diarrhea, or have evidence of hypovolemia, tablets seen on plain radiography, serum iron levels > 350 mcg/dl, or serum iron levels > TIBC should receive fluids and chelation with deferoxamine mesylate. Chelation should not be delayed while waiting for serum iron levels in ill patients. Administration of 20 to 40 ml/kg of crystalloid or more may be necessary. The dose of deferoxamine is 15 mg/kg/hr, administered IV until all symptoms and signs of toxicity have resolved, serum iron is <100 mcg/dl plus 24 hours after vin rose urine disappears. Rapid administration can be associated with histamine release and hypotension. If this occurs, administer IV fluids, lower the rate of administration and administer antihistamines for histamine symptoms.

Acetaminophen

Acetaminophen is one of the most popular medications used to treat pain and fever in children and comes in many forms, including tablets, elixirs, and rectal suppositories. With its popularity and ready availability in homes, acetaminophen overdoses, both intentional and unintentional, are common. Over 60,000 acetaminophen-only exposures and approximately 150 acetaminophen-induced deaths were reported by the American Association of Poison Control Centers in 2003. More than 40,000 of these exposures occurred in patients less than 19 years old. Fortunately, most acute one-time accidental ingestions in small children are associated with lower risks of toxicity than in adults due to difference in metabolism.¹⁸ However, significant morbidity and mortality may occur after repeated supratherapeutic dosing.¹⁹

Acetaminophen is metabolized by the liver primarily through glucuronidation and sulfation. A small percentage of acetaminophen is metabolized by the cytochrome P-450 mixed function oxidase pathway into a toxic intermediate compound, *N*-acetyl-*p*-benzoquinoneimine (NAPQI). At recommended doses of acetaminophen, NAPQI is conjugated with glutathione, making it nontoxic and allowing its excretion in the urine and bile. With overdoses and repeated supratherapeutic doses of acetaminophen, glutathione stores are depleted. The toxic metabolite, NAPQI, then accumulates and binds to hepatocytes, causing centrilobular necrosis.

Patients taking medications that induce cytochrome P-450 activity (e.g., anticonvulsants) may be at increased risk of hepatotoxicity following an acetaminophen overdose, as are

those with depleted glutathione stores (e.g., alcoholics and acquired immunodeficiency syndrome patients).²⁰⁻²² The clinical presentation of acetaminophen toxicity can be divided into four stages. Symptoms of stage I are vague and may include anorexia, nausea, vomiting, and pallor. These symptoms, if present, typically resolve in the first 12 to 24 hours. Stage II occurs at 24 to 48 hours postingestion, and clinical signs of hepatotoxicity may be present, such as right upper quadrant abdominal pain and elevation of liver transaminases and bilirubin. Even without treatment, most of these patients will recover without sequelae. By days 3 to 4 postingestion, some patients will progress to stage III with signs of fulminant hepatic failure, including metabolic acidosis, coagulopathy, jaundice, renal failure, encephalopathy, and recurrent GI symptoms. Stage IV occurs 4 to 14 days postingestion, and patients either make a full recovery or die from complete liver failure or its complications.⁶

Clinical Presentation

Early recognition of patients with acetaminophen poisoning and treatment with *N*-acetylcysteine (NAC) limit morbidity and mortality. This is challenging since patients are often asymptomatic at the time of presentation. All patients with suspected overdose should be screened for acetaminophen.²³ Important historical factors to determine are the time of acute ingestion, repeated supratherapeutic dosing, formulation (immediate release versus extended release), amount of acetaminophen ingested, and co-ingestants. Dose history is not always reliable, especially in situations in which the ingestion is not witnessed, there is suspected drug abuse, or the patient's intent is self-harm.

During initial evaluation, the patient should be placed in one of the following categories for acetaminophen exposure: acute acetaminophen ingestion within 24 hours; acute ingestion for which the time is unknown or greater than 24 hours; ingestion of extended-release acetaminophen; ingestion of repeated supratherapeutic doses; and signs or symptoms of hepatic injury (Fig. 133–1).

When used properly, the acetaminophen nomogram is an excellent screening tool for assessing potential acetaminophen toxicity (Fig. 133–2). The acetaminophen nomogram applies only to acetaminophen levels obtained between 4 and 24 hours postingestion. It is important to precisely define the time at which the ingestion occurred; if this is not possible, the earliest possible time of ingestion should be used. If the level falls below the treatment line on the nomogram, then no NAC therapy is needed.

ACUTE ACETAMINOPHEN INGESTION WITHIN 24 HOURS

An acute acetaminophen overdose is defined as a single ingestion of at least 7.5 g in an adult or 150 mg/kg in a child and should be considered possible in any patient who presents with a history of another overdose or altered mental status.²³⁻²⁵ In these patients, a serum acetaminophen level should be acquired 4 hours postingestion or as soon thereafter and plotted on the acetaminophen nomogram (see Fig. 133–2). If the serum acetaminophen level falls above the treatment line on the nomogram, therapy with NAC is started. If the acetaminophen level will not be available within 8 hours of ingestion, NAC should be started and then discontinued if the acetaminophen level falls below the treatment line when plotted on the nomogram.

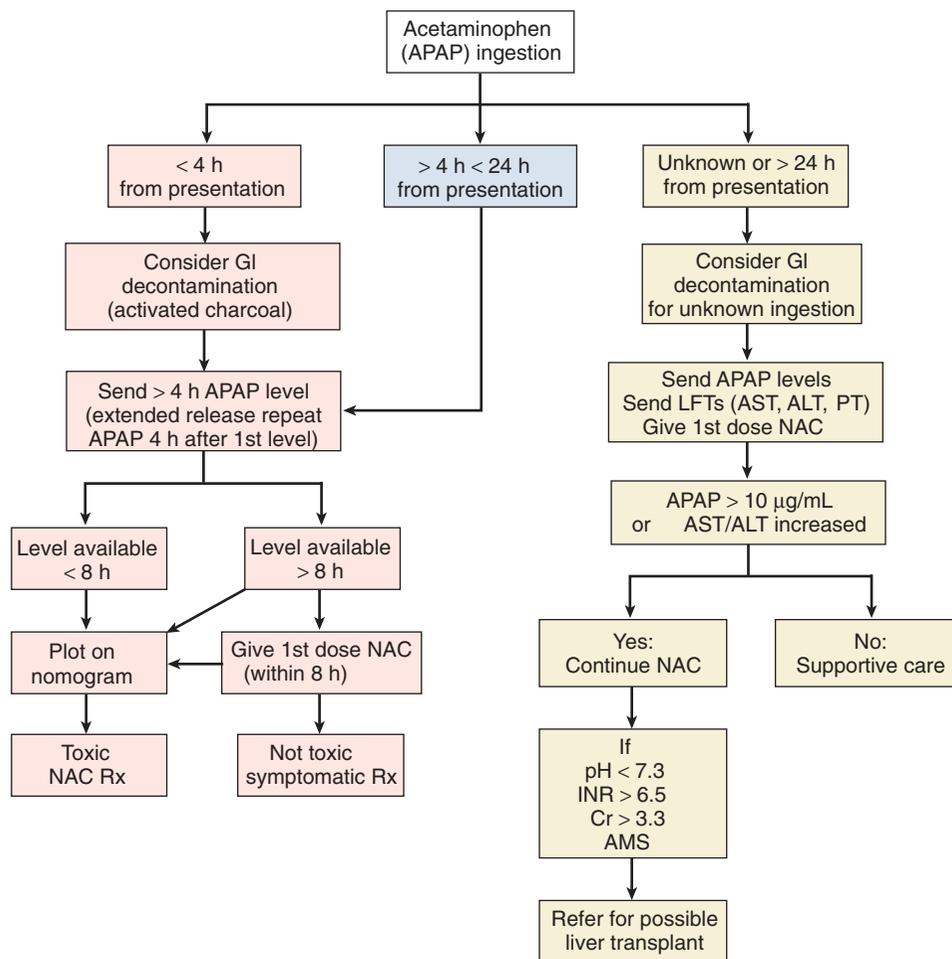

FIGURE 133–1. Treatment guidelines for acetaminophen ingestion. All times noted are postingestion. Abbreviations: ALT, alanine aminotransferase; AMS, altered mental status; APAP, acetaminophen; AST, aspartate aminotransferase; Cr, creatinine; GI, gastrointestinal; INR, international normalized ratio; LFTs, liver function tests; NAC, *N*-acetylcysteine; PT, prothrombin time; Rx, treatment.

If the patient presents within 4 hours of the acetaminophen ingestion or there is a history of a co-ingestant, oral activated charcoal can be given. There is no evidence that administering activated charcoal will interfere with oral NAC therapy.²⁶ In patients who present greater than 8 hours postingestion with serum acetaminophen levels that plot above the treatment line, liver function tests (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]) should be ordered before and after NAC therapy²⁷ (see Fig. 133–1).

ACUTE ACETAMINOPHEN INGESTION WITH UNKNOWN TIME OR GREATER THAN 24 HOURS POSTINGESTION

It may be challenging to obtain the exact time of acetaminophen ingestion, but with a careful history obtained from the patient, family, and others, a time window can often be established. If the time of ingestion cannot be determined or it has been greater than 24 hours, a serum acetaminophen level and liver function tests (AST and ALT) should be drawn immediately. The acetaminophen nomogram cannot be used. Potential toxicity must be assumed and NAC therapy started (see Fig. 133–1).

EXTENDED RELEASE ACETAMINOPHEN INGESTION

For patients presenting after an overdose of an extended-release acetaminophen, a serum acetaminophen level is drawn 4 hours postingestion and repeated again in 4 hours.

The acetaminophen levels are plotted on the acetaminophen nomogram.^{24,28} If either of the acetaminophen levels drawn falls above the treatment line, NAC therapy is started (see Fig. 133–1).

REPEATED SUPRATHERAPEUTIC ACETAMINOPHEN DOSING

Although death has rarely been reported in children less than 6 years old with a single overdose of acetaminophen, there have been multiple reports of hepatotoxicity and death associated with repeated supratherapeutic doses of acetaminophen in children.²⁹ Many studies have investigated what factors may put children at increased risk of hepatotoxicity with repeated supratherapeutic dosing, such as febrile illness, starvation states, total dose given, duration of acetaminophen therapy, and use of P-450–inducing medications. Although there have been more cases of hepatotoxicity and death in children with febrile illness who received supratherapeutic doses of acetaminophen than in nonfebrile children, it is not clear what role fever plays. Prevention of future overdoses may be accomplished with adequate therapy instructions or education during well-child visits. All recommendations for acetaminophen therapy should include the dose, frequency, duration of therapy, and specific strength and formulation for the individual child.

Chronic acetaminophen toxicity should be considered in any child with a history of acetaminophen doses of

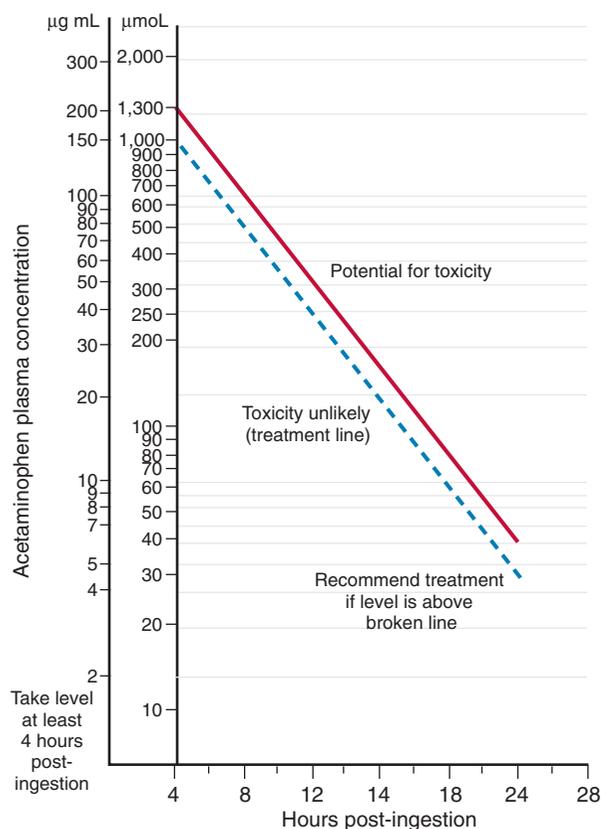

FIGURE 133-2. Acetaminophen nomogram: serum acetaminophen concentration versus time after ingestion. (From Management of Acetaminophen Overdose. Raritan, NJ: McNeil Consumer Products, 1986.)

150 mg/kg/day for more than 2 days or in an adult with a history of acetaminophen doses of 4 g/day for more than 2 days, as well as in a patient who presents with signs of hepatic dysfunction.

In patients with signs or symptoms of hepatic injury, acetaminophen levels should be drawn immediately. Additional laboratory workup should include liver function tests (AST and ALT), international normalized ratio (INR) for prothrombin time, bilirubin, glucose, blood urea nitrogen, creatinine, lactate, phosphate, electrolytes, and arterial blood gases. With repeated doses, the physician should assume the ingestion to begin from the time of the first dose, and use this to plot the level on the acetaminophen nomogram. Laboratory tests should be repeated every 12 to 24 hours.³⁰ NAC therapy should be started if the acetaminophen level is greater than 10 µg/ml or if the acetaminophen level is not detectable but the liver function test results are elevated (see Fig. 133-1).

Treatment of Acetaminophen Toxicity

The treatment of acetaminophen toxicity consists of GI decontamination with activated charcoal, supportive care, and the timely administration of the antidote, NAC.³¹ Activated charcoal may be given orally or by nasogastric tube (1 g/kg) if the patient presents within 4 hours or if co-ingestants are suspected. More aggressive GI decontamination, with orogastric lavage and whole bowel irrigation, is not recommended for isolated acetaminophen toxicity because of acetaminophen's rapid absorption and the effectiveness of NAC as an antidote. Aggressive forms of GI decontamination

should be reserved for potentially life-threatening polydrug overdoses.

NAC is the mainstay of therapy for acetaminophen toxicity, although its mechanisms of action are not fully understood. One of several ways that NAC prevents hepatotoxicity is through its conversion to cysteine, which repletes glutathione stores. Secondly, NAC binds directly to NAPQI, creating a nontoxic metabolite. Thirdly, it provides a substrate for sulfonation and thus promotes nontoxic metabolism of acetaminophen. These mechanisms of action promote the early administration of NAC (within 24 hours of acetaminophen overdose) to prevent hepatotoxicity, but there is evidence that IV NAC is also effective in late acetaminophen overdose (>24 hours postingestion) and in fulminant hepatic failure.³² Proposed mechanisms for this benefit in late toxicity include an antioxidant effect, decreased neutrophil accumulation, improved oxygen delivery to tissues, and improved microcirculatory changes in the liver.

Both the oral and IV treatment protocols are nearly 100% effective in preventing hepatotoxicity when given within 8 hours of ingestion, and lessen the risk of hepatotoxicity when given within the first 24 hours. The 72-hour oral NAC regimen had been the standard of care for acetaminophen toxicity in the United States, but the Food and Drug Administration approved IV NAC in January of 2004.

The standard 72-hour oral NAC regimen is a loading dose of 140 mg/kg followed by maintenance doses of 70 mg/kg every 4 hours for 17 additional doses. Few side effects are associated with oral NAC except for nausea and vomiting, which are aggravated by oral NAC's foul rotten egg odor. In order to mask its unpleasant odor, the standard 10% to 20% NAC solution may be diluted to a 5% concentration in a chilled beverage, and served from a covered cup with a straw. Beverages that may mask the odor are soft drinks and fruit juice. If this is not enough to prevent nausea and vomiting, then an antiemetic such as metaclopramide or ondansetron can be given. In cases in which the nausea and vomiting cannot be controlled or oral NAC is contraindicated because of a caustic ingestion, IV NAC should be considered. The IV solution is well tolerated by most patients and considered safe when administered properly. The most common complication of IV NAC is an anaphylactoid reaction producing flushing, urticaria, angioedema, and bronchospasm. Most of these reactions are mild and related to the infusion rate. Symptoms can be controlled by slowing down the rate of infusion, or by treatment with an antihistamine or epinephrine if needed.³³ There is the potential for severe hyponatremia in small children when following the manufacturer's guidelines, since the amount of NAC received is weight based but the amount of fluid is constant for all patients: 1700 ml of free water over 20 hours. When using the 20-hour IV NAC protocol, a concentration of 40 mg/ml should be used in children less than 40 kg in order to avoid hyponatremia³⁴ (Table 133-9).

Fulminant Hepatic Failure

Unfortunately, a small percentage of acetaminophen overdose patients do develop fulminant hepatic failure. The mortality rate without NAC therapy is greater than 50%. NAC increases a patient's chances for survival even in the setting of fulminant hepatic failure. Predictors of poor outcome, including death and the need for a liver transplant, are as follows: serum pH less than 7.3 after fluid resuscitation, INR

Table 133–9 Intravenous NAC (Acetadote)
Pediatric Dosing (weight < 40 kg)/
Fluid Restrictions

Prepare 4% Concentration in D5W

- Mix 50 ml of NAC (20% solution) with 200 ml of D5W (remove 50 ml from a 250-ml bag of D5W) to obtain 40 mg/ml (4% concentration)

Loading Dose

- 150 mg/kg infused over NOT LESS THAN 15 min
- Infuse 3.75 ml/kg over NOT LESS THAN 15 min

First Maintenance Infusion

- 50 mg/kg infused over 4 hr
- Infuse 1.25 ml/kg over 4 hr (0.31 ml/kg/hr)

Second Maintenance Infusion

- 100 mg/kg infused over 16 hr
- Infuse 2.5 ml/kg over 16 hr (0.16 ml/kg/hr)

Abbreviations: D5W, dextrose 5% in water; NAC, N-acetylcysteine.

Adapted from package insert for Acetadote (2004) and Sung et al.³⁴

greater than 6.5, grade III or IV encephalopathy; creatinine greater than 3.3 mg/dL (275 micromol/L), lactate greater than 25 mg/dl (3.0 mmol/L) after fluid resuscitation, and phosphorus greater than 3.8 mg/dl (1.2 mmol/L) after fluid resuscitation.³⁰

Patients with acetaminophen-induced fulminant hepatic failure should receive early referral to a liver transplant center. The treatment of patients with fulminant hepatic failure includes correction of metabolic acidosis, correction of coagulopathy, and close monitoring and aggressive treatment of cerebral edema. In addition, IV NAC therapy is preferable to oral NAC therapy and should be continued until the patient improves, receives a liver transplant, or dies.

Aspirin (Salicylate)

The use of childproof containers, aspirin alternatives such as acetaminophen, and education to avoid the use of aspirin in children because of Reye's syndrome have reduced the incidence of unintentional salicylate poisoning in the United States. The American Association of Poison Control Centers' Toxic Exposure Surveillance System reported approximately 20,000 salicylate exposures and 60 salicylate-related deaths in the United States in 2003. Approximately half of these exposures occurred in people less than 19 years old.

Serious intoxications continue to occur because people are often unaware that over-the-counter medications such as Pepto-Bismol contain salicylate (1 ml contains 8.77 mg of aspirin), or that topical ointments or liniments used in hot vaporizers contain methyl salicylate (oil of wintergreen). Topical ointments may cause toxicity with extensive application. Even more dangerous is the consumption of oil of wintergreen. It contains 1440 mg/ml of salicylate, and even a small ingestion of 1 to 2 ml may be fatal for a young child.³⁵ Aspirin continues to be readily available, and serious salicylate toxicity may result from suicide attempts in adolescents and adults.

Clinical Presentation

The toxic effect of salicylates is complex. Salicylates stimulate the respiratory center of the brainstem, causing early hyper-

ventilation and respiratory alkalosis. In children, the initial respiratory alkalosis may be missed at the time of presentation, whereas metabolic acidosis may be quite pronounced.³⁶ Salicylates uncouple oxidative phosphorylation, leading to increased heat production, heavy sweating, and dehydration. In addition, salicylates interfere with glucose metabolism and may cause hypoglycemia or hyperglycemia. In acute large ingestions, salicylates may produce nausea and vomiting resulting from gastric irritation and direct stimulation of chemoreceptor zones. Vomiting, if severe, may result in dehydration, which impairs renal salicylate elimination and contributes to acid-base and electrolyte disturbances. These physiologic abnormalities are progressive and more severe with larger ingestions and at extremes of age.

ACUTE ASPIRIN OVERDOSE

Potential aspirin toxicity occurs at doses of 150 mg/kg and should be suspected with any ingestion of methyl salicylate. The symptoms vary with the amount ingested, but usually begin 3 to 8 hours postingestion and may progress more rapidly in children. The earliest signs and symptoms of salicylate poisoning include nausea, vomiting, diaphoresis, and tinnitus. As the CNS salicylate levels rise, tinnitus may progress to deafness. Other CNS effects include tachypnea, disorientation, agitation, delirium, convulsions, and lethargy. Coma is rare and usually occurs with massive or mixed overdoses.

Children usually present with an unintentional ingestion, and symptoms occur within a few hours of ingestion. Children less than 4 years of age typically present with metabolic acidosis, whereas older children and adults typically present with a mixed disturbance of respiratory alkalosis and increased anion gap metabolic acidosis. Sweating, dehydration, tachypnea, and fever are often attributed to the underlying illness for which the patient is taking aspirin or aspirin-containing products, and not correctly attributed to salicylate toxicity. The clinical presentation of salicylate toxicity may be indistinguishable from septic shock with multiple organ failure, encephalopathy, and acute respiratory distress syndrome.

Adult and adolescent salicylate toxicity typically occurs after an intentional overdose and often mixed with substances such as CNS depressants, which impair hyperpneic response. This produces a respiratory acidosis rather than the expected respiratory alkalosis. Salicylate and acetaminophen levels must be obtained for all intentional overdoses.

CHRONIC ASPIRIN TOXICITY

Chronic toxicity occurs most commonly in the elderly, with symptoms that overlap with those of acute ingestion. However, symptoms of chronic toxicity are typically milder at the time of presentation and have a more gradual onset. These patients are more difficult to diagnose and often have a worse prognosis.³⁷

Diagnosis and Treatment of Salicylate Toxicity

The differential diagnosis of salicylate toxicity in all age groups includes infection, sepsis, diabetic ketoacidosis, and other causes of increased anion gap metabolic acidosis.

If potential salicylate toxicity is suspected in an asymptomatic patient, a urine ferric chloride test should be obtained. Do not rely on a serum salicylate level unless it is obtained

at least 6 hours post-ingestion. Chronic toxicity and sustained release tablets may cause problems in interpreting serum levels. The salicylate level is repeated in 1 hour to obtain a trend, and at intervals of every 2 to 4 hours based on the patient's clinical condition until the serum salicylate level is ≤ 15 mg/dL.

If the patient is symptomatic, vital signs and mental status should be monitored and the following laboratory studies obtained: serum salicylate level, electrolytes, and arterial blood gases. The serum salicylate level should be repeated in 1 hour and every 2 to 4 hours thereafter as clinically indicated. If the patient requires intubation, the same degree of hyperventilation needed prior to intubation should be maintained, since failure to do so may cause rapid deterioration of the patient.³⁸ Failure to hyperventilate the patient causes respiratory acidosis and the rapid shift of salicylate into the CNS.

Supportive care includes hydration at 1.5 to 2 times maintenance to compensate for dehydration and fluid losses brought on by salicylates. Glucose must be monitored closely and should be administered in all cases of altered mental status, even if there is peripheral euglycemia. CNS hypoglycemia can occur despite peripheral euglycemia.³⁹ Gastric decontamination with multiple doses of activated charcoal should be used to prevent further salicylate absorption in doses of 1 to 2 g/kg without sorbitol. Although there is no true antidote for salicylate toxicity, alkalization therapy is crucial. Alkalinizing the blood and urine traps salicylate (a weak acid) in the blood, preventing CNS toxicity. Alkalinization also increases urinary excretion of the salicylate ion. The recommended dosage of NaHCO_3 is 1 to 2 mEq/kg as an IV bolus followed by an infusion of 3 ampules of NaHCO_3 (containing 44 mEq NaHCO_3 each) in 1 L of dextrose 5% in water at 1.5 to 2 times maintenance. (The bolus of NaHCO_3 can be omitted if blood pH is > 7.45 .) This fluid may replace the hydration fluid discussed previously. Alkalinization is successful when the blood pH is 7.45 to 7.55 and the urine pH is greater than 7. Potassium should be monitored and supplemented prophylactically since the increasing pH causes intracellular shifting of potassium and may cause hypokalemia, which will limit urinary alkalization.^{36,40} Acetazolamide and other carbonic anhydrase inhibitors are dangerous and should not be used since they achieve urinary alkalization at the expense of blood acidification, which promotes salicylate movement into the CNS.^{41,42} Hemodialysis is indicated in acute overdoses when the salicylate level is 100 mg/dl or rapidly approaching such levels. It is also indicated if acidosis is refractory to alkalization, CNS symptoms are already present, there is progressive deterioration despite appropriate treatment, there are signs of pulmonary edema, or the patient has severe cardiac disease or renal failure. In chronic overdoses, hemodialysis should be considered if the salicylate level is greater than 30 mg/dl and the patient is symptomatic.

Selected Comments on Other Pharmaceuticals

Chloroquine and *quinine* are antimalarial medications. Toxic symptoms include immediate epigastric discomfort, nausea, vomiting, and diarrhea followed by CNS stimulation or seizures.

Imidazoline products are sympathetic amines present in ocular drops and nasal sprays. Toxicity occurs rapidly with

CNS stimulation and/or depression and either hypertension and tachycardia or hypotension and bradycardia. Naloxone is indicated for altered sensorium, atropine or isoproterenol for bradycardia, and dopamine for hypotension refractory to fluid administration.

Theophylline, once a mainstay of asthma therapy, is a xanthine producing GI manifestations, generalized major motor seizures, tachydysrhythmias, hypotension, hypokalemia, hyperglycemia, and acidosis. Whole bowel irrigation alone or whole bowel irrigation combined with activated charcoal will greatly enhance elimination. Seizures may occur and should be managed with standard protocols.

Acetonitrile is an artificial nail removing compound that causes cyanide toxicity. Gastrointestinal manifestations herald the onset of CNS alterations and the cardiac manifestations of cyanide. Utilization of the cyanide antidote kit is indicated.

Camphor is contained in over-the-counter liniments. Patients present with GI disturbances followed by CNS excitation and seizures.

Hydrocarbons are common ingredients in household cleaning products, solvents, and gasoline. Emesis and lavage are contraindicated. Patients may present with transient CNS or GI disturbances followed by bronchospasm, seizures, or dysrhythmias.

Summary

The details of individual toxic ingestions can vary considerably, and the guidelines and therapies may change over time. Therefore, calling a regional Poison Control Center (1-800-222-1222) for consultation should always be considered.

Toxic Alcohols

Kevin C. Osterhoudt, MD, MSCE

Key Points

Ethanol intoxication may cause hypoglycemia in young children.

Isopropyl alcohol poisoning does not typically cause acidosis, but may cause profound central nervous system depression.

Methanol poisoning causes metabolic acidosis and may lead to blindness, encephalopathy, and/or multisystem organ failure.

Ethylene glycol poisoning causes metabolic acidosis and may lead to renal failure and/or multisystem organ failure.

Ethanol or fomepizole, both of which inhibit alcohol dehydrogenase, are important emergency antidotes for methanol or ethylene glycol poisoning.

Selected Diagnoses

- Ethanol intoxication
- Isopropanol poisoning
- Methanol poisoning
- Ethylene glycol poisoning

Discussion of Individual Diagnoses

Ethanol Intoxication

Ethanol is nearly ubiquitous in American homes as a constituent of beverages, mouthwashes, and cleaning products. In 2003, over 19,000 pediatric ethanol exposure cases were reported to the American Association of Poison Control Centers (AAPCC).¹ Of note, these statistics do not represent the formidable health hazards associated with driving while intoxicated, or other risk behaviors associated with inebriation and impaired decision making.

An ethanol dose of 0.7 g/kg produces a blood alcohol concentration of approximately 0.1 g/dl (100 mg/dl). This equates to ingestion of 17.5 ml (slightly more than one tablespoon) of 80-proof vodka by a 10-kg toddler. Ethanol is a central

nervous system (CNS) depressant. Intoxication initially manifests through loss of inhibition, incoordination, slurred speech, and stupor. The examiner may note flushing of the face, dysarthria, and/or nystagmus. As blood ethanol levels approach 0.3 g/dl, coma, inhibition of airway-protective reflexes, and respiratory depression ensue. Aspiration pneumonia is a frequent complication, as is gastritis.

Hepatic alcohol dehydrogenase is the primary metabolic pathway for ethanol; dependent upon differences in individual enzyme phenotypes and ethanol tolerance, ethanol may be metabolized at a rate of 10 to 30 mg/dl/hr.² The enzymatic activity of alcohol dehydrogenase requires the cofactor nicotinamide adenine dinucleotide, oxidized (NAD⁺), and the consumption of this cofactor inhibits gluconeogenesis. As a result, young children, with reduced glycogen stores, are at risk for profound hypoglycemia.³ This most often presents with CNS depression in the morning hours after the overnight fast.

Ethanol intoxication may be suspected based upon clinical history, physical examination findings, hypoglycemia, or an elevated osmolal gap (Table 134–1). It can be confirmed by measurement of the blood alcohol concentration.

Careful attention to the patient's airway, breathing, and circulation will be sufficient treatment for most cases of ethanol intoxication. There is no evidence to support a correlation between the Glasgow Coma Scale score and a need for endotracheal intubation after alcohol poisoning, so individual risks and benefits should be considered. Rapid bedside blood glucose concentration should be performed on any obtunded patient, and hypoglycemia should be treated as indicated (see Chapter 106, Hypoglycemia). Due to the diuretic nature of ethanol, hypovolemia may warrant intravenous fluid administration. Hemodialysis effectively eliminates ethanol from the bloodstream, and may be considered in severe cases of ethanol-induced coma and respiratory depression, but is rarely indicated. The possibility of concomitant traumatic injury, or co-ingestion, should be considered in any intoxicated adolescent. Alcohol withdrawal seizures and delirium tremens are rare among pediatric patients, but may complicate hospitalization of chronic high-level alcohol-abusing teens. A pattern of chronic alcohol abuse would warrant activation of social services.

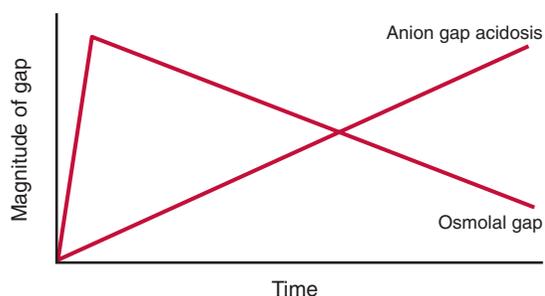

Isopropanol Poisoning

Isopropyl alcohol, also known as “rubbing alcohol,” is a widely used solvent and is commonly found within the home

Table 134–1 Estimation of Alcohol and Glycol Levels from the Osmolal Gap*

Toxic Alcohol	Conversion Factor
Methanol	3.2
Ethanol	4.6
Isopropanol	6.0
Ethylene glycol	6.2

*[Osmolal gap (mOsm/L) × conversion factor] estimates alcohol concentration (mg/dl).
 Osmolal gap = measured – calculated osmolality.
 Calculated osmolality = 2[Na (mEq/L)] + [glucose (mg/dl)]/18 + [BUN (mg/dl)]/2.8.

**FIGURE 134–1.** Relationship of osmolal gap to anion gap acidosis.

as the cooling ingredient among topical liniments. Over 12,000 isopropanol exposures among children up to 19 years of age were reported to the AAPCC in 2003.¹ Isopropyl alcohol toxicity may occur via the dermal and inhalation routes, such as may result during misguided sponge baths for fever.

Isopropanol is twice as potent as ethanol in terms of CNS depression. Altered mental status, when it occurs, typically manifests within 2 hours of ingestion.⁴ Hypotension may occur due to diuresis, peripheral vasodilation, and myocardial depression. In addition to an osmolal gap (see Table 134–1), ketonemia or ketonuria may occur. Isopropyl alcohol is metabolized to acetone by alcohol dehydrogenase without the production of significant metabolic acidosis but may lead to hypoglycemia in young children, as was described for ethanol. Gastritis is common after ingestion. Patient care is supportive. The risks and benefits of hemodialysis may be considered for comatose patients with blood isopropanol levels exceeding 500 mg/dl.

Methanol Poisoning

Methanol poisoning may result from the ingestion of windshield washer fluid, gasoline additives, duplicating fluids, canned cooking fuels, and a variety of other products found in the home and workplace. Over 1000 pediatric exposures were reported to the AAPCC in 2003.¹

Ingestion of greater than 100 mg/kg of methanol should be deemed potentially toxic. Therefore, even a single swallow of windshield washer fluid, with 40% methanol, is to be considered dangerous. Methanol is less inebriating than ethanol or ethylene glycol, so patients may appear well shortly after ingestion. As methanol is osmotically active, an increased osmolal gap is sometimes evident on initial laboratory testing (see Table 134–1), but disappears as methanol is

Table 134–2 Antidotal Therapy for Methanol Poisoning

Alcohol Dehydrogenase Inhibition

Ethanol (10% ethanol in D5W IV or 40% ethanol by NG)

- 100 mg/kg/hr infusion*

Or

Fomepizole

- 15 mg/kg IV load, then
- 10 mg/kg IV q12h × 4 doses, then 15 mg/kg q12h[†]

Folate

- 1 mg/kg (max: 50mg) IV q4h

*Titrate ethanol infusion to achieve blood ethanol concentration of 100 mg/dl. During hemodialysis, the infusion rate may need to be doubled (or ethanol may be added to dialysate).

[†]During hemodialysis, fomepizole should be dosed every 4 hours. Abbreviations: D5W, dextrose 5% in water; IV, intravenously; NG, nasogastric tube.

metabolized (Fig. 134–1). The presence of an increased osmolal gap has good positive predictive value, but the absence of an osmolal gap is not sensitive enough to screen for methanol poisoning.⁵ Blood methanol levels greater than 50 mg/dl, obtained soon after ingestion, should be regarded with concern.⁶ Unfortunately, blood methanol levels are not available on an immediate basis in many emergency departments, mandating that clinical decisions be based on a combination of history, examination, and laboratory factors.

Gastritis and/or pancreatitis sometimes occur after acute ingestion of methanol. Methanol is slowly metabolized by alcohol dehydrogenase into formaldehyde, which is further metabolized to formic acid. Hypoglycemia may occur as was described for ethanol. After several hours, profound metabolic acidosis, with a wide anion gap (see Chapter 111, Metabolic Acidosis), is common. Clinical evidence of toxicity may be further delayed if ethanol has also been ingested. Formic acid is directly toxic to the retina, and may lead to blindness.⁷ Patients may describe the initial visual disturbance as being akin to “standing in a snowfield.” Fundoscopic examination may reveal a hyperemic optic disc and venous engorgement. Severe poisoning may progress to seizures, coma, and possibly persistent encephalopathy.

Emergency management of methanol poisoning should first focus upon support of airway patency, breathing, circulation, and glycemic control. Endotracheal intubation, if performed, should be accompanied by mechanical ventilation to match the patient’s physiologic hyperventilation to prevent worsening acidemia. Intravenous fluids should be administered to reverse hypovolemia, and sodium bicarbonate is a useful adjunct in the face of metabolic acidosis⁶ (and may reduce the penetration of formic acid through the blood-brain barrier). Specific antidotal therapies for methanol poisoning are summarized in Table 134–2. Fomepizole, as an alcohol dehydrogenase inhibitor, may be easier to use than ethanol therapy as it is not inebriating, does not cause hypoglycemia, and does not require a continuous infusion.⁸ However, fomepizole is more expensive than ethanol, and its use in pediatrics is off-label. Alcohol dehydrogenase inhibition should be continued until all metabolic acidosis is corrected and the blood methanol level falls below 20 mg/dl. The

Table 134–3 Relative Indications for Hemodialysis after Methanol or Ethylene Glycol Poisoning

Methanol or ethylene glycol level >50 mg/dl PLUS one or more of the following:

- Visual disturbance or renal failure
- Acidemia not corrected with bicarbonate therapy
- Coma
- Difficulty maintaining adequate alcohol dehydrogenase inhibition
- Long elimination half-life, which portends prolonged, intensive hospitalization

relative indications for hemodialysis are listed in Table 134–3.

Ethylene Glycol Poisoning

Ethylene glycol is a sweet-tasting common constituent of automobile antifreeze, and the similarly toxic diethylene glycol is commonly used as a glycerin substitute in commercial products. Sporadic epidemics of diethylene glycol–tainted medications and beverages still occur. Over 1400 pediatric ethylene glycol exposures were reported to poison control centers in 2003.¹

Ethylene glycol is inebriating, and ingestion may first manifest with vomiting, somnolence, nystagmus, and/or incoordination. As described for methanol, ethylene glycol in the bloodstream may produce an osmolal gap (see Table 134–1), but metabolism to glycolic and oxalic acids by alcohol dehydrogenase leads to metabolic acidosis as the osmolal gap recedes (see Fig. 134–1). Calcium oxalate crystals in the urine and urine fluorescence under Wood’s lamp illumination (due to fluorescein added to some commercial antifreezes) have been advocated as screens for ethylene glycol poisoning; but neither is sensitive or specific enough to be recommended clinically.^{9,10} Hypocalcemia may be noted after severe poisoning due to calcium and oxalic acid complex formation. Hypoglycemia, dehydration, and pancreatitis are common complications. However, metabolic acidosis, encephalopathy, and especially renal failure are complications of ethylene glycol poisoning. Blood ethylene glycol levels greater than 50 mg/dl should warrant concern.

The principles of management of ethylene glycol poisoning are similar to those presented for methanol. Appropriate ventilation must be maintained to compensate for metabolic acidosis, intravenous fluid hydration is commonly warranted,

Table 134–4 Antidotal Therapy for Ethylene Glycol Poisoning

- As described in Table 134–2 for methanol

Thiamine

- 50 mg IV/IM q6h

Pyridoxine

- 50 mg IV/IM q6h

Abbreviations: IM, intramuscularly; IV, intravenously.

and blood glucose, renal function, and clinical manifestations of hypocalcemia must be closely monitored. Sodium bicarbonate can be useful to alleviate metabolic acidosis. Specific antidotal therapy for ethylene glycol poisoning is presented in Table 134–4, and alcohol dehydrogenase inhibition should be continued until the blood ethylene glycol concentration is below 20 mg/dl and acidosis is resolved. The indications for hemodialysis are presented in Table 134–3.

Chapter 135

Drugs of Abuse

John A. Tilelli, MD

Key Points

One should always treat the patient, not the poison. Supportive care is the first priority in the setting of drug abuse.

Drug abuse histories are unreliable and laboratory testing is only minimally helpful.

Polydrug ingestion is common in the setting of drug abuse.

Drug diluents and vehicles may be more toxic than the ingested drug.

Introduction and General Principles

Patterns of Abuse

Drug abuse is largely a phenomenon of the young. Drug experimentation and use achieves significant proportions by adolescence and peaks in the early 20s.¹ By age 30, the rate of use of and addiction to all substances of abuse declines, and continues to do so throughout adulthood.

It is clear that specific socioeconomic status correlates exist among all drugs of abuse, and that certain drugs are more prevalent in one age population as opposed to another.² Inhalant abuse, for example, begins to appear at age 10, peaks by age 14, and declines thereafter. Tobacco use appears at age 10 and increases throughout adolescence. Alcohol, marijuana, amphetamine, cocaine, and hallucinogen use follow a similar pattern. Age-related incidences of each class of drug may reflect drug availability, perception of safety, financial independence, peer interactions, or parental control of children and permissiveness.

General Approach to the Intoxicated Patient

The intoxicated patient generally presents with acute symptoms that may at first suggest an illness unrelated to intoxication. The agitated, hyperthermic patient might be considered to have encephalitis or meningitis. Focal neurologic symptoms secondary to stroke might be suggestive of a clotting disorder or embolic event. Similarly, seizures, loss of consciousness, ataxia, peripheral neuropathy, tremor, weakness,

acute psychosis, chest pain, palpitations, and respiratory distress have extensive differential diagnoses of diseases unrelated to poisoning. Similarly, many common complaints have toxic diagnoses. A brief, and by no means comprehensive, list of drugs of abuse associated with common complaints is provided in Table 135–1.

Finally, the patient experiencing withdrawal from a substance of abuse may present with a confusing array of symptoms that may mimic another intoxication. Withdrawal toxidromes are discussed later.

Detection of Drugs of Abuse

All laboratory tests have intrinsic sensitivity and specificity, as well as timeliness and cost-effectiveness constraints. Testing for drugs of abuse is no exception. Compared to the number of potential intoxicants comprising the drugs of abuse, few analytic techniques of value are available. Definitive assays are often time consuming and unavailable on an emergency basis. Screening techniques are often insensitive to intoxicants at clinically significant concentrations, and may be masked by or detected as a cross-reacting substance present in the sample.

Commonly tested substrates for substances of abuse include blood, urine, and gastric aspirate. The latter should be inspected, as gastric contents may contain pill fragments suggestive of a particular intoxicant. Although medical management issues should take priority, it should be recalled that a crime might have been committed. Specimen collection should be done, if appropriate, in a manner that will make the laboratory assays useful in subsequent legal proceedings, by preservation of the chain of custody, retention of the specimen, and processing. Frequently, forensic specimens, when obtained, are separated from those destined for clinical use, and are handled by law enforcement officers present. The emergency department should have policies in place for the collection of specimens compliant with the National Institute on Drug Abuse Guidelines.^{3,4}

The commonly available drug assays rely upon either immunologic or chromatographic techniques to determine the presence of a drug or its metabolite. Other techniques rely upon specific physical-chemical properties of the compound, such as atomic absorption spectra. The sensitivity and specificity of both techniques are method specific.⁵

Serum testing is available for barbiturates and ethanol, but most of the commonly tested substances are assayed in urine. Table 135–2 summarizes the tests commonly provided by

hospital laboratory services on site. Notably absent from this list, or missed by assay techniques, are lysergic acid diethylamide (LSD) and the other hallucinogens, methylenedioxymethamphetamine (MDMA) and other substituted amphetamines, toxic inhalants, nitrates and nitrites, γ -hydroxybutyrate (GHB), anabolic steroids, and the botanical agents (except Ma Huang).

Laboratory techniques, then, can be incorrect, misleading, or irrelevant. Not uncommonly, the intoxicated patient may have another substance present more toxic than the compound detected in testing. The caveat is, therefore, that one should *always treat the patient, not the poison*. A positive laboratory test should not deter the clinician from considering an alternative etiology to the substance detected in screening, nor persuade the clinician that another cannot be present. In the emergency setting, managing the patient in accordance with the symptoms is less fraught with risk than an approach reliant upon analytic techniques.

Withdrawal

Many of the drugs of abuse are associated with some form of tolerance and dependence. Irrespective of the agent, *tolerance* is caused by pharmacologic or pharmacodynamic alterations

necessitating increasing the dose of a drug to achieve an equivalent desired effect. *Withdrawal* is a constellation of symptoms that appear after a period of drug abstinence and represent a displacement of homeostasis that occurs when a drug is administered. The two processes are linked, and, generally speaking, one occurs in the context of the other.

Both stimulant and depressant drugs are associated with symptomatic withdrawal. Like drugs tend to produce similar symptoms in abstinence. Withdrawal from both narcotics and sedative-hypnotic drugs is associated with restlessness, hypertension, and tachycardia (see Table 135–3 for their similarities and differences).

Considerable overlap exists between the two presentations, but the presence of seizures, hyperpyrexia, and agitated delirium strongly suggest sedative withdrawal. Sedative-hypnotic withdrawal and alcohol withdrawal seem to be similarly mediated, by down-regulation of the central nervous system inhibitory transmitter γ -aminobutyric acid (GABA). Alcohol withdrawal presents also with tremor, diaphoresis, irritability, restlessness, nausea, vomiting, hallucinations, insomnia, and agitation, but hyperpyrexia and hypertension are uncommon.⁶ Hallucinations associated with alcohol withdrawal may be the consequence of depleted thiamine stores.⁷ Symptoms of alcohol withdrawal seem to be related to the intensity of drinking and duration, and the age of onset of problem drinking behavior. Alcoholics who began drinking before age 20 were more likely to experience symptomatic withdrawal upon cessation than older drinkers, notwithstanding a substantial difference in duration of the behavior.⁸ Delirium tremens has been reported in a child who was 10 years old and had a history of alcohol consumption for 3 years.⁹ There is a strong similarity between the alcohol abstinence syndrome and that of benzodiazepines, barbiturates, hydrocarbon inhalants, and GABA. It is strongly suggested that therapeutic effects as well as symptoms of withdrawal are mediated by GABA.¹⁰ A strategy for therapy, then, would include, in addition to basic stabilization measures, augmentation of GABA with either a benzodiazepine or barbiturate. There are no studies comparing one approach to the other; both have been reported effective.¹¹ A recent double-blind, controlled study comparing the use of the benzodiazepine antagonist flumazenil to oxazepam in the treatment of symptomatic withdrawal found that flumazenil does not precipitate withdrawal in tolerant subjects, and is effective at modulating symptoms.¹²

Table 135–1 Drugs of Abuse Associated with Common Complaints

If the Patient Demonstrates	Consider
Depressed LOC, somnolence	Narcotics, sedative-hypnotics, toxic inhalants, GHB, ketamine, nitrous oxide, amphetamine withdrawal
Delirium, agitation	Phencyclidine, amphetamines, MDMA, cocaine
Hypertension, stroke, chest pain	Cocaine, phencyclidine, amphetamine, MDMA
Hyperpyrexia	Cocaine, phencyclidine, amphetamine, LSD, anticholinergics, narcotic and sedative withdrawal
Hallucinations	LSD, MDMA, other organic hallucinogens
Cyanosis/priapism	Nitrates

Abbreviations: GHB, γ -hydroxybutyrate; LOC, level of consciousness; LSD, lysergic acid diethylamide; MDMA, methylenedioxymethamphetamine.

Table 135–2 Commonly Used Screening Tests for Drugs of Abuse

Drug or Class	Sensitivity	Cross-Reacting Substance	Misses
Cannabinoids	Good	None	
Opioids	Fair	Dextromethorphan*	Dextromethorphan,* all synthetic narcotics, notably fentanyl
Phencyclidine	Fair	Dextromethorphan	PCP congeners
Cocaine	Good	None	
Benzodiazepines	Fair	None	Many congeners unrelated to oxazepam [†] (especially flunitrazepam)
Barbiturates	Good	None	None
Amphetamine	Poor	Pseudoephedrine, ephedrine [‡]	MDMA and congeners

*Dextromethorphan may (when detected) be from a cough suppressant and confused for an abused drug. On the other hand, many assays are of insufficient sensitivity to detect dextromethorphan, which also may confound PCP assays.

[†]Benzodiazepines detected by urinary screens include chlordiazepoxide, oxazepam, diazepam, temazepam.

[‡]Over-the-counter decongestants are most commonly confused with abused amphetamines.

Abbreviations: MDMA, methylenedioxymethamphetamine; PCP, phencyclidine.

Table 135–3 Manifestations of Narcotic versus Sedative-Hypnotic Withdrawal

	Narcotics	Sedative-Hypnotics
Blood pressure	Hypertension	Hypertension
Pulse	Tachycardia	Tachycardia
Respiratory rate	Elevated	Elevated
Temperature	NORMAL	ELEVATED
Mental status	Normal (or restless)	Restless, irritable, DISORIENTED
Miscellaneous	Piloerection Nausea Diarrhea Myalgias	Tremor SEIZURES

Adapted from Hamilton RJ: Substance withdrawal. In Goldfrank LR, Flomenbaum NE, Lewin NA, et al (ed): Goldfrank's Toxicologic Emergencies, 7th ed. New York: McGraw-Hill, 2002, pp 1059–1074.

Opiate withdrawal differs from sedative-hypnotic withdrawal, as it is not commonly associated with seizures or hyperpyrexia, and psychosis is rarely seen. Opiate effects and withdrawal symptoms are mediated by specific receptor proteins in the brain and spinal cord that are down-regulated with the administration of an agonist drug. These receptors are closely linked central α_2 receptors that may be stimulated by the centrally acting agent clonidine. Symptoms of withdrawal, while uncomfortable, are rarely life threatening. A strategy of symptomatic relief from opiate withdrawal would consist of basic stabilization and the administration of a pure narcotic agonist or clonidine to modulate symptoms.^{13–15} Rapid opiate withdrawal techniques use general anesthesia to subdue symptoms and accelerate the course of withdrawal.¹⁶ It has been used successfully in a child.¹⁷ Experience is too limited to make a general recommendation on the utility of this technique.

A syndrome of excessive somnolence, craving, depression, and lethargy has been identified with the discontinuation of amphetamines and hallucinogens. It has been identified in children after discontinuation of stimulant medications and in neonates exposed to amphetamines in utero.^{18,19} While symptoms are not life threatening, drug craving may precipitate a relapse or exploration of the use of another drug. Recently bupropion has been used successfully to modulate the symptoms of amphetamine withdrawal.²⁰

Selected Drugs of Abuse

- Marijuana
- Opioids
- Sedative-hypnotics
 - Barbiturates
 - Benzodiazepines
- Cocaine
- Amphetamines
- Lysergic acid diethylamide
- “Club drugs”
 - Ketamine and phencyclidine
 - Flunitrazepam
 - γ -Hydroxybutyrate
- Inhalants
 - Volatile nitrogen oxides

- Miscellaneous agents
 - Over-the-counter drugs
 - Botanicals and natural products
 - Anabolic steroids

Discussion of Individual Agents

Marijuana

Marijuana is the most commonly encountered drug of abuse among children and adolescents after tobacco and alcohol. As many as 20 million Americans may use this drug on a regular basis.

Marijuana is the popular term for the substances obtained from the plant *Cannabis sativa* that grows wild and is cultivated, both domestically and abroad, for recreational purposes. The principles of *Cannabis* horticulture are easily available on the Internet. As a consequence, availability is widespread and difficult to eradicate. All parts of the plant, including leaves and flowers, contain the active alkaloids known as cannabinoids. The most important of these is Δ^9 -tetrahydrocannabinol (THC), which is present in its highest concentration in the buds. The leaves are dried and ground into a mass resembling oregano or tobacco. The buds may be compressed into a fine powder or resin (“hashish” or “hash”), prized for its potency. Marijuana is conventionally smoked, but is effective orally. Hashish is smoked in small pipes resembling those used for crack cocaine abuse, while marijuana is rolled into cigarettes (Fig. 135–1). Occasionally, its use may be ritualized, inhaling the drug through an elaborate water pipe or “bong.”

The subjective sense attendant to marijuana use is dose dependent, but also varies among individuals. The widespread belief is that naive users do not appreciate its effect as much as those who have prior extensive drug experience. The user generally describes a state of dreamy intoxication, in which sensory perception, especially to color and sound, seems enhanced. Increased appetite is commonly expressed. Conjunctival injection is commonly present. Judgment, especially that which is required for complex or subtle activities such as driving, is significantly impaired, a finding that may persist as long as 24 hours after use.²¹ The concurrent use of ethanol with marijuana appears to impair judgment

more than either drug alone. Acute psychosis and panic attacks are infrequent, but have been described. Pneumomediastinum and pneumothorax may occur as a consequence of the widespread practice of taking the drug by deep inhalation and retaining the breath to encourage absorption of the drug.

Chronic effects of marijuana include chronic lung disease and gynecomastia, caused by diminished testosterone levels associated with its use.²² It may appear after relatively brief use.²³ There is debate over a relationship to psychiatric disease, cognitive impairment, or a chronic amotivational state attributed to its use, but unequivocal data are lacking.²⁴ Neuropsychiatric effects attributed to the chronic use of marijuana may be attendant to preexistent psychopathology. Marijuana is advocated for a variety of medical indications, including cachexia, glaucoma, and chemotherapy-induced nausea, none of which has been rigorously investigated.²⁵⁻²⁹ Its legalization in various states has been the subject of great public debate.³⁰ The precise clinical role, if any, for marijuana in the medical center has not yet been well defined. Some analgesic potential for marijuana may exist, but its role in pain management is uncertain.

Severe intoxication due to marijuana use is rare. The patient who presents to the emergency department with complaints directly related to its use can be often managed by removal to a nonthreatening environment and emotional support. Occasionally an especially anxious or agitated patient may benefit from the administration of a benzodiazepine. Marijuana is frequently adulterated with other compounds of greater potency. The user may be unaware of the presence of excipients, added to alter or increase the effect of the drug. Among these are phencyclidine, LSD, amphetamines, anticholinergics, narcotics, and benzodiazepines. The presence of severe hypertension and tachycardia, mydriasis, miosis, frank hallucinations, hyperthermia, depressed level of consciousness, or respiratory depression should alert the caregiver to the possibility of an occult co-intoxicant.

Opioids

In the simplest terms, opioids (narcotics) are a class of drugs characterized by the production of analgesia, miosis, sedation, and respiratory depression; in overdose they are treated with supportive care. The term *narcotic*, however, is misleading, as these drugs produce analgesia better than sleep. The generic term *narcotic* is used to connote a group of drugs that alter the perception of pain, notwithstanding that many of these drugs bear no structural similarity. The drugs most commonly identified with the narcotics are the natural and semisynthetic alkaloids of the poppy that have been used throughout the ages for recreational and religious purposes. The natural poppy alkaloids are morphine, thebaine, and papaverine. Alteration of the chemical structure was undertaken in an attempt to modulate the undesirable properties of the drug without altering analgesic strength. Heroin (diacetyl morphine) was the first such semisynthetic derivative. Codeine, dihydromorphine (Dilaudid), and oxycodone (OxyContin) are the three other semisynthetic derivatives of poppy alkaloids, the latter being a thujone derivative. Other commonly used narcotic analgesics, such as dextromethorphan, pentazocine, meperidine, fentanyl, methadone, and propoxyphene, are synthetic.

Opioids are absorbed by the oral, parenteral, and inhalational routes. Intravenous abuse of narcotics in the 1950s has given way to abuse by smoking or intranasal insufflation. Effects are noted shortly after administration, and peak 10 minutes after an intravenous dose and 30 minutes after administration by another route. Some addicts may introduce the drug by the subclavian vessels (a so-called “pocket shot”) to increase the effect, a technique associated with air embolism, subclavian vessel thrombosis, and pulmonary thromboembolism.³¹ Generally, however, an intravenous abuser will self-administer the drug until a subjective effect is perceived (the “flash”), and then stop. This practice may lead to fatal overdose if the drug is of unanticipated potency.^{32,33}

Abused opioids are inevitably adulterated with extraneous substances, some of which have pharmacologic activity. Heroin is often diluted with quinine, manitol, lactose, talc, bicarbonate, acetaminophen, lidocaine, phenobarbital, methaqualone, caffeine, antihistamines, or phencyclidine.³⁴ The specific pattern of adulterants may be of forensic value in determining the source of the drug.³⁵ As a consequence, the original bag of drug, and any paraphernalia with the patient, should be saved with the protection of the chain of custody for later use by law enforcement. As these are nonsterile, they are often contaminated by biologic agents, including *Clostridium* species, *Bacillus*, and others.³⁶ Intravenous users typically prepare heroin for consumption by dissolving the drug in a spoon and heating it with a flame. It is then aspirated through a cotton ball into a syringe. The cotton is subsequently reused, causing “cotton fever,”³⁷ the etiology of which is obscure. Inhalation of heroin fumes is called “chasing the dragon.”

Tolerance develops to all effects of narcotics except miosis. The central nervous system effects include tolerance to pain, suppression of anxiety, sedation, suppression of the cough reflex, and euphoria. The therapeutic index of narcotic agonists varies considerably depending on the relative potency of the drug and the experience of the user. Cross-tolerance is the rule, and resistance to one narcotic generally implies resistance to all others. In overdose, therapeutic symptoms are exaggerated. Pupils may become dilated in the presence of hypoxia or with overdose of meperidine, pentazocine, diphenoxylylate/atropine (Lomotil), propoxyphene or non-narcotic coingestants. Respiratory depression and hypoxia are generally the mechanism for death. Orthostatic hypotension and syncope may occur as a consequence of histamine release observed uniquely with morphine. Noncardiogenic pulmonary edema may occur, although rarely at therapeutic doses. Seizures rarely occur except uniquely after the abuse of pentazocine or propoxyphene. Similarly, meperidine has an active metabolite that is capable of causing seizures. The naturally occurring and semisynthetic opioids may be detected in the urine by a commonly available and rapid urinary immunofluorescent assay. Morphine, heroin, oxycodone, and codeine are all detected, but many assays are not of sufficient sensitivity to detect agents such as dextromethorphan, and drugs with unrelated structures, such as meperidine and fentanyl, are not detected at all.³⁸ Definitive drug testing and confirmation of positive drug screens may be accomplished by chromatographic techniques such as gas chromatography–mass spectrometry.

Basic stabilization is the mainstay of therapy. The presence of an adequate airway should be assured in all patients with

a depressed level of consciousness and/or lack of airway-protective reflexes. Noncardiogenic pulmonary edema should be managed by the administration of oxygen and positive airway pressure. The use of narcotic antagonists is controversial, as they may precipitate withdrawal symptoms. They may have a role in the diagnostic assessment of the patient. Partial response may indicate the presence of another drug, such as a sedative-hypnotic, or hypoxia.

Naloxone, a pure opioid antagonist, reverses all effects of opiates, including analgesia, miosis, respiratory depression, and sedation. It is unknown if it protects against seizures encountered with some opiates such as propoxyphene, but appears to do so in animal models. It does not appear to reverse pulmonary edema. It has a half-life of 20 to 30 minutes. The initial dose is 0.01 mg/kg IV or SQ. Give a subsequent dose of 0.1 mg/kg if there is an inadequate response. Higher doses may be required for the reversal of some drugs such as propoxyphene and dextromethorphan. If the use of naloxone is undertaken, it should be remembered that the half-life of the abused substance may exceed that of the antagonist, and that continued observation of the patient, and possibly repeated or continuous administration, is indicated. Recently, a shortage of naloxone has been reported, mitigating against its prolonged use except in unusual circumstances. Nalmefene, a newer agent, has a half-life of 10.3 to 12.9 hours, and appears to be safe and potent.

Bowel decontamination of ingested drugs may be occasionally indicated. Polyethylene glycol catharsis may be useful for the removal of packets of drugs from body packers or body stuffers when bowel obstruction is not present. Gastrointestinal hypomotility may prolong the gastric retention of the ingested substance.

Some of the acute and chronic complications of narcotic abuse are listed in Table 135–4. Infectious complications are especially common among intravenous drug abusers. Infective endocarditis, hepatitis, human immunodeficiency virus (HIV) infection, and abscess formation are commonplace among them.^{36–38} Patients may present with a complication attendant to their habit and symptoms only peripherally suggestive of an acute complication of narcotic abuse, with chronic illness acquired as the result of a high-risk behavior, or both. Malnutrition and accessory diseases unrelated to the intoxication, but related to the lifestyle of a drug-addicted individual (e.g., tuberculosis, sexually transmitted disease) are also common.

The general belief is that some tolerance occurs after both the therapeutic and nontherapeutic use of all narcotic agonists, usually after the administration of successively higher doses over several weeks. However, some tolerance begins after the first dose, especially with the more potent drugs, such as fentanyl. The course is similar for all opiates, with the time course compressed for the more potent and shorter acting drugs. The initial stage of withdrawal begins with drug craving and anxiety. Later, yawning, mydriasis, lacrimation, rhinorrhea, piloerection (from which is derived the term “cold turkey”), twitching, nausea, vomiting, diarrhea, and abdominal pain are observed. Dehydration, fever, hyperglycemia, and spontaneous erections may occur. Symptom intensity seems to correlate with the duration and dose of the abused drug. The administration of opioid agonists is effective in modulating the symptoms of withdrawal, and may be required in significant doses. Fear of enhancing the patient’s

addiction to a narcotic should not prevent the clinician from administering them to the individual with symptomatic withdrawal. Recently, centrally acting α_2 agonist drugs such as clonidine have been reported effective as well. The effects of clonidine and opiates, including respiratory depression and sedation, are additive. Sedative agents, such as the benzodiazepines, may assist in relieving the agitation and anxiety that accompany narcotic withdrawal, but do not reverse the autonomic effects.¹⁴

Sedative-Hypnotics

The first of the sedative-hypnotic drugs, the barbiturates, appeared in the early 20th century. The barbiturates, and associated drugs such as the benzodiazepines, whose principal manifestations are anxiolysis and sedation, have been widely used in medicine and as targets for illicit abuse. Between 1950 and 1970, they were the most common cause of drug-induced death. The replacement of barbiturates with drugs of wider therapeutic index, and a general trend of decline in illicit drug use of sedative-hypnotics, have significantly reduced mortality associated with these agents. Numerous agents unrelated to the barbiturates and benzodiazepines are used for their sedative properties. The clinical

effects and unique toxicities of some of these agents are summarized here.

The barbiturates and benzodiazepines are used, often in combination with other drugs, to treat anxiety, pain, and sleep disorders. They also have important use in the acute and chronic treatment of seizure disorders, and are used as anesthetic agents.³⁹ Barbiturates all share a common nucleus, the modification of which alters its pharmacologic properties but not its effects, which are common to all drugs of this class. All barbiturates are absorbed well by the intestine. The rate of elimination among them varies considerably. The half-life of these agents depends on their lipophilicity, and thus volume of distribution. More lipophilic agents, such as thiopental, are classified as ultra-short acting, while longer acting drugs such as phenobarbital are more water soluble. Shorter acting agents are eliminated by hepatic metabolism. Only the longer acting barbiturates have substantial renal clearance. Toxic doses are generally seen at five times the therapeutic dose, and toxicity is an extension of the therapeutic effects.

Benzodiazepines are among the most commonly prescribed drugs. Over 3000 have been synthesized and over 50 are marketed worldwide. As a group, they account for the majority of toxic exposures to sedative-hypnotic agents. Like barbiturates, all drugs of this class share a common chemical nucleus, but unlike the barbiturates, each varies slightly in effects. Some, such as flunitrazepam and midazolam, are more commonly associated with amnesia and hallucinations than other benzodiazepines. They are metabolized in the liver. Many have active metabolites, the notable exception being lorazepam, which is metabolized to solely inactive compounds.

Both the barbiturates and benzodiazepines have sedative, hypnotic, amnesic, anxiolytic, and anticonvulsant properties.⁴⁰ Additionally, the benzodiazepines are muscle relaxants, and are often prescribed for that purpose. Although specific benzodiazepine and barbiturate receptors probably exist, both appear to exert their sedative and anticonvulsant effects by exerting an effect on the inhibitory neurotransmitter GABA.

The effects of sedative-hypnotic drugs are related to dose and prior drug experience. The onset and duration of symptoms depend on the type and amount of drug ingested.³⁹ While short-acting agents have an onset of symptoms 15 to 20 minutes after ingestion, the effects of longer acting agents may be delayed as much as 18 hours. The early stage of intoxication may resemble the effects of alcohol, a substance commonly co-ingested with sedative agents. Patients with mild intoxication may appear stuporous but responsive. More impaired patients become unresponsive, and eventually anemic, areflexic, and hypotensive. Pupils generally demonstrate miosis in early coma, but are dilated later. Respiratory depression is common in symptomatic ingestion. Hypoglycemia and hypothermia are occasionally observed. Cardiovascular instability with hypotension and shock is more characteristic of barbiturate than benzodiazepine overdose, but the effects of both drugs are similar in type if not degree.⁴¹

Tolerance and dependence on sedative-hypnotics are well recognized.⁴² An abstinence syndrome of restlessness, insomnia, irritability, agitation, seizures, tremors, tachycardia, and hypertension may be seen, its intensity and duration being dependent on the type and amount of the substance

abused. Hyperpyrexia, uncommon in narcotic withdrawal, is observed in the sedative-hypnotic abstinence syndrome.⁴³

The treatment of sedative-hypnotic overdose relies heavily on supportive measures. Protection of the airway and the support of respiration with adequate oxygenation is the cornerstone of management of the seriously intoxicated patient. Hypotension is mediated by vasodilation, and may be managed with the administration of volume expansion and vasopressor drugs such as dopamine and norepinephrine. Pure inotropic agents such as dobutamine and milrinone are rarely necessary except in the most severe circumstances, as many sedatives do not lend themselves to enhanced elimination. Phenobarbital, which has a smaller volume of distribution than many of the other agents, is the exception, and has been reported as being successfully treated with dialysis.⁴⁴ The effects of the benzodiazepines may be reversed by the specific antagonist flumazenil. It may provoke seizures and withdrawal symptoms in the patient who chronically uses a benzodiazepine either therapeutically or as a recreational drug,⁴⁵ or in the patient who has an underlying seizure diathesis.⁴⁶ A recent study concluded that flumazenil was not cost effective compared to supportive therapy, nor did it improve outcome.⁴⁷ It does not reverse the sedative effects of other drugs with similar manifestations such as the barbiturates. Its use in the acutely intoxicated patient may be of diagnostic benefit. Failure to respond may imply the presence of another substance, hypoxic encephalopathy, or the postictal state. Its half-life is shorter than that of many benzodiazepines, and repeated administration may be necessary. Flumazenil should not be considered a replacement for supportive therapy.

Barbiturates

Massive oral overdose of barbiturates is associated with bezoar formation, which may be observable on plain film or demonstrable by endoscopy. Drug removal may be hastened by lavage or endoscopic removal. The detection of barbiturates may be accomplished by either serum or urine screens. The presence of a therapeutically administered drug such as phenobarbital may obfuscate the presence of another barbiturate. The management of barbiturate overdose may necessitate prolonged mechanical ventilation for a long-acting drug. Drug elimination may be hastened by the administration of multiple doses of activated charcoal.⁴⁸ Barbiturate intoxication may precipitate noncardiogenic pulmonary edema, necessitating the administration of positive pressure ventilation.⁴⁹ The unique manifestation of cutaneous bulla formation is occasionally seen with massive barbiturate poisoning.⁵⁰

Benzodiazepines

Generally speaking, the manifestations of benzodiazepine intoxication are less severe than barbiturate overdose. Death after the sole oral ingestion of a benzodiazepine is rare. Benzodiazepines are, however, additive to the effects of other depressant medications, such as narcotics and alcohol.⁵¹ Death is more commonly the result of a multiple drug ingestion. The exception may be flunitrazepam. A series of deaths were reported over a 2-year period in which flunitrazepam appeared to be the sole or principal precipitating agent.⁵² The most commonly abused agents at the time of this writing are diazepam and lorazepam. Both of these drugs are easily

obtainable from offshore sources, and are frequently sought from legitimate sources in drug-seeking behavior. Most benzodiazepines are detectable by urinary screening assay, but some, such as flunitrazepam, may be present in a sufficiently small quantity to render screening techniques ineffective. This latter drug deserves special mention as it has achieved a reputation for producing amnesia, sexual arousal, and euphoria, making it a target drug for date rape (see the “Club Drugs” section later). The treatment of patients intoxicated with a benzodiazepine is supportive, as outlined previously. The usefulness of the benzodiazepine antagonist flumazenil in the management of benzodiazepine intoxication is at best limited. Recovery without sequelae is the rule in the absence of hypoxic encephalopathy acquired antecedent to the initiation of supportive management.

Cocaine

Cocaine is the alkaloid of the *Erythroxylon coca*, which grows wild in many South American countries. It has been advocated as an aid to psychotherapy, an analeptic, and an anesthetic agent. It has been considered a controlled substance in the United States since the passage of the Harrison Narcotic Act of 1914.

Legal cocaine manufacture is strictly controlled. Illicit use in the United States, after a long period of relative quiescence, has increased dramatically over the past 20 years. As many as 11% of Americans over 11 years of age report having used cocaine at least once in their lifetime; 0.7% of children 12 to 17 years of age admitted using it at least twice per week.⁵³ Cocaine intended for abuse is smuggled into the country by a variety of routes, the most important of which medically is the practice of “body packing,” in which condoms filled with drug are ingested orally with the intention of later passage through the gastrointestinal tract⁵⁴ (Fig. 135–2).

Children have been used as “mules” to assist in the illicit transport of cocaine. One such child was reported to have ingested 53 packets of cocaine, recovering after rupture of a packet.⁵⁵ Bowel obstruction of ingested packets may occur, and accidental rupture of a packet may prove fatal. Oral polyethylene glycol administration has been advocated as a relatively safe method to expedite the passage of ingested packets. Bowel obstruction may necessitate surgical removal.⁵⁶

Cocaine is absorbed by all routes—by ingestion, inhalation, intranasal absorption, or the intravenous route. Orally, its potency is about one tenth that of the intranasal route. A high vaporization temperature renders the hydrochloride salt unacceptable for smoking.⁵⁷ The typical intranasal dose is between 30 and 45 mg. Cocaine is frequently adulterated with lidocaine, ephedrine, and caffeine,⁵⁸ which are included to mimic the anticipated effects and suggest a higher potency drug to the user. The diagnosis of cocaine intoxication may be suggested in the appropriate clinical context by the finding of drug paraphernalia at the scene or a white residue on the nose.

“Freebase” and “crack,” extractions of free cocaine from the hydrochloride salt, have a lower temperature of vaporization and are therefore better suited for smoking. The latter acquires its name from the popping sound when smoked. It is supplied as brown crystalline pebble wrapped in tin foil, which is ignited over a screen placed in the bottom of a pipe.

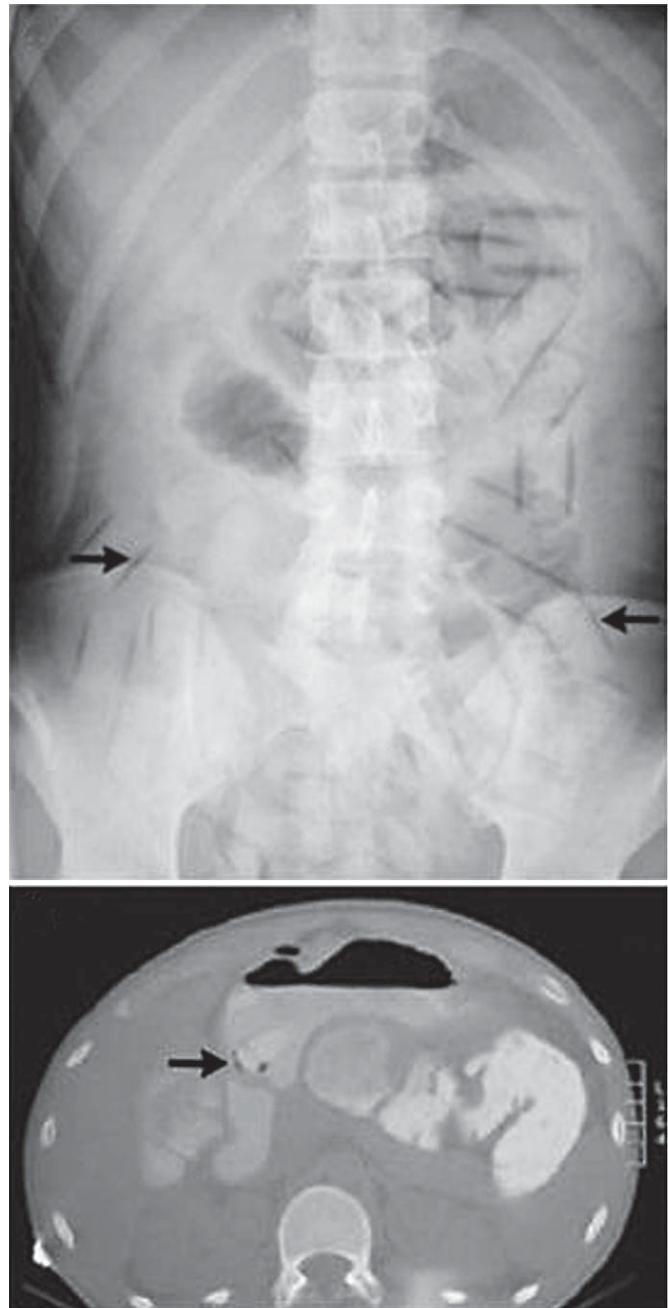

FIGURE 135–2. Computed tomographic scan of a body packer. Arrows indicate air trapped within, and outlining packets. (From Traub SJ, Hoffman RS, Nelson LS: Body packing—the internal concealment of illicit drugs. *N Engl J Med* 349:2519, 2003.)

The usual dose is 5 to 10 mg. Inhalation of the smoked vapors provides a more direct route for the drug to the circulation compared to the intranasal route, thereby amplifying its effect; both provide levels approximately two-thirds that of intravenously administered drug.⁵⁹ Accidental fatal ingestion of crack cocaine by a child has been reported.⁶⁰

Cocaine is the benzoic acid ester of ecgonine, with anesthetic and central stimulatory properties. Conventional detection techniques utilize enzyme-amplified immunofluo-

Table 135–5 Symptoms of Cocaine Intoxication**Phase I: Early**

- Euphoria, elation, garrulousness, emotional lability, pseudohallucinations, sense of impending doom
- Tics

rescent techniques to detect one or another metabolite in urine.

Cocaine is a potent central nervous system stimulant and anesthetic. It exerts its principal effects by blocking the reuptake of norepinephrine, serotonin, and other neurotransmitters at nerve endings. Administration is accompanied shortly by a sense of euphoria, elation, garrulousness, and restlessness. Intranasal use is attended by local anesthesia, termed “*the freeze*”. The pulse is usually elevated, but may be transiently depressed by reflex vagal effects. The blood pressure is usually elevated. Mydriasis and myoclonic twitching can be noted. The patient can experience auditory or visual hallucinations, or tactile hallucinations known as “*cocaine bugs*.” Toxic psychosis may occur. In more advanced intoxication, the patient becomes unresponsive and hyperreflexic. Seizures may occur. Hypertension or hypotension may be present, and arrhythmias, especially atrial and ventricular tachycardia, could occur. Irregular respirations may give way to apnea. Greater toxicity is accompanied by flaccid paralysis, coma, fixed pupils, ventricular fibrillation, and death. Symptoms are summarized in Table 135–5.⁵⁷

Cardiac complications of cocaine use include myocardial ischemia, infarction, accelerated atherosclerosis, and cardiomyopathy.^{61,62} Rhabdomyolysis and renal failure may occur as a consequence of hyperpyrexia.⁶³ Cocaine-associated chest pain may mimic a myocardial infarction and merits monitored observation.⁶⁴ Neurologic complications include central nervous system hemorrhage, ischemic infarction, and seizures. Headache in the patient who presents after cocaine exposure may be the result of sympathetic stimulation, migraine, impending stroke, or hemorrhage, and may occur during cocaine withdrawal. Concern for cerebrovascular injury

should strongly suggest appropriate neuroimaging studies for all patients with altered mental status, focal neurologic signs, or severe headache. Smoking crack cocaine has been associated with pneumothorax.⁶⁵ Chronic use has been associated with renal insufficiency and hypertension,⁶⁶ chronic cognitive defects,⁶⁷ nasal septal perforation, sinusitis, and a necrotizing vasculitis.^{68,69} Cocaine is likely a teratogen, with cardiac, urogenital, central nervous system, and gastrointestinal anomalies in 7% to 26% of exposed infants.⁷⁰ Cocaine metabolites may be detected in meconium and infants’ hair.

Treatment of cocaine intoxication is largely supportive. Elimination techniques are generally of no benefit, although activated charcoal absorbs cocaine and may have some role in the management of the body packer. There is no antidote of proven value. Airway control should be undertaken in patients with compromised mental status. Hyperthermia should be aggressively treated (see Chapter 139, Hyperthermia). The risk of rhabdomyolysis probably contraindicates the use of depolarizing muscle relaxants in rapid sequence intubation.⁷¹ Sedation with benzodiazepines has been demonstrated beneficial for the management of fever, seizures, hypertension, and agitation.⁷² Butyrophenones and other major tranquilizers may be associated with worse outcome.⁷³ Rhabdomyolysis should be managed by the administration of intravenous fluids, and maintaining urine flow at 3 ml/kg/hr. Hypertension is usually responsive to the administration of sedatives. Occasionally, antihypertensive agents are indicated. Nitroprusside, nitroglycerine, or other vasodilators are effective.⁷⁴ Beta-blocking agents such as labetalol may worsen hypertension by failing to reverse α -mediated vasoconstriction, and do not reverse coronary vasoconstriction.^{75,76} They should be avoided in the management of cocaine intoxication. Anticoagulation for cocaine-induced arrhythmias is not well studied. Most cocaine-associated arrhythmias respond to sedation. Ventricular tachycardia occurring shortly after exposure may result from the local anesthetic property of cocaine and should be managed similarly to intoxication with class IA or IC agents, with the administration of bicarbonate.⁷⁷ Lidocaine in this circumstance may exacerbate seizures and arrhythmias and therefore is contraindicated.^{72,73} Conversely, ventricular arrhythmias occurring several hours after exposure are likely the result of ischemia, and may be managed safely with lidocaine.⁷⁸ Pulmonary edema may be of cardiac or noncardiogenic origin and is managed with positive pressure ventilation. There is no consensus for the management of cocaine-associated congestive heart failure. Postmortem examination suggests a direct toxic effect of cocaine on the heart,⁷⁹ correlating clinically with the development of a dilated cardiomyopathy.⁸⁰ Management of the low cardiac output state would be directed at inotropic support and afterload reduction.

Amphetamines

The amphetamines are a group of substituted noncatecholamine phenylamines with diverse central nervous system stimulant and hallucinatory properties (Fig. 135–3). They were first synthesized in the late 19th century and were quickly recognized for their biologic effects. Amphetamines are still used in the management of attention deficit/hyperactivity disorder and narcolepsy and in weight control, and for these indications they are widely prescribed. Use migrated to the recreational market in the 1960s, when “speed freaks”

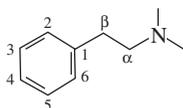

FIGURE 135-3. Amphetamine ring.

would engage in serial use, often consuming thousands of milligrams over days (“the rush”), to be terminated by a period of lethargy and somnolence during withdrawal (“the crash”). The introduction of substituted amphetamines as drugs of abuse began in 1968 with MDMA, known first as “Adam” and later as “Ecstasy,” which was, for a brief time, legally sold without prescription. What followed was a series of drugs, each replacing the one before, as the sale of prior agents was restricted or discredited by the community of users. The substituted amphetamines, then, became the first “designer” drugs. This process was interrupted in 1986 with the passage of the Controlled Substances Act.⁸¹ Notwithstanding their proscription, their popularity has not waned and they remain popular in the club culture as one of the so-called rave drugs (see later). It has been estimated that as many as 6.8 million individuals have used Ecstasy.⁸²

Amphetamine is often abused orally, but may be used intravenously. In this form it may be used with heroin, known as a “speedball.” Tolerance develops to the drug, and users may take hundreds of milligrams at a time. The hydrochloride salt of amphetamine is smokable, and is known as “ice.” It is occasionally mixed with lidocaine to mimic the “freeze” of cocaine, and sold as that drug. Amphetamine is well absorbed orally and by inhalation, and has a large volume of distribution. It undergoes some hepatic metabolism, but substantial amounts are excreted in the urine. The half-life of amphetamine is dependent on urine pH, and is between 12 and 34 hours, an alkaline urine prolonging its retention.⁸³

The clinical effects of amphetamine are caused by the release of norepinephrine, dopamine, and serotonin at nerve endings. A wide variety of signs and symptoms may be present.⁸⁴ The intoxicated patient appears restless, hypervigilant, and agitated. Anxiety, paranoia, and delusions are common. Hallucinations, frequently visual, are also common. The seriously intoxicated patient may exhibit toxic psychosis, suicidal ideation, or aggressive behavior. Mydriasis may be present. Seizures, cerebral edema, intraventricular hemorrhage, and cerebral infarction occur. The patient may experience tightness in the chest, or chest pain, and a sense of impending doom. Hypertension is common and may be severe. A dilated cardiomyopathy may be present, to which sudden death in amphetamine abuse has been attributed.⁸⁵ Renal failure, hyperpyrexia, rhabdomyolysis, and vasculitis are also reported. The intravenous user is subject to all the complications of the abuse of drugs by that route, including HIV and hepatitis. Additionally, pulmonary granulomas may occur as a consequence of the intravenous administration of dissolved pills containing talc.^{86,87}

MDMA (Ecstasy) use has increased more rapidly than any other drug.⁸⁸ It has acquired a place among the “club drugs,” used to enhance social experiences, along with flunitrazepam, ketamine, and GHB. Increasing use has been reported among 8th, 10th, and 12th graders.⁸⁹ It has a reputation as a harmless drug and is easily synthesized in clandestine laboratories. Tablets typically contain 50 to 150 mg of the drug,

and are often imprinted in different colors with a popular icon. Common adulterants include aspirin, other amphetamines, ketamine, LSD, and dextromethorphan.⁹⁰ Drug paraphernalia includes a pacifier, used to control bruxism common with MDMA use, and Vicks Vapo-Rub, inhaled through a surgical mask, which has a reputation for enhancing the effect of the drug. MDMA has both stimulant and hallucinogenic properties. Effects begin 30 minutes after ingestion, and include euphoria, increased libido, altered visual perception, and a distorted sense of time. Tachycardia is observed, and peaks 1 to 2 hours after administration.⁹¹ Ecstasy did not reliably increase the body temperature of volunteers,⁹² but life-threatening hyperpyrexia has been reported.⁹³ Elevations in body temperature may be attendant to activities undertaken during its use that produce dehydration, but a relationship to the serotonin syndrome has also been proposed.⁹⁴ Persistent cognitive defects have been reported after prolonged use.⁹⁵

Side effects of Ecstasy are similar to those of other amphetamines. MDMA decreases thirst, and concurrent activity may cause dehydration. Hyponatremic dehydration has been reported.⁹⁶ Cerebral infarction⁹⁷ and myocardial infarction⁹⁸ have been reported as a cause of death. In a recently reported series of Ecstasy-related deaths with a review of the literature, two thirds were attributable to aortic dissection, disseminated intravascular coagulation, rhabdomyolysis, myocardial infarction, hyperpyrexia, or sudden collapse, presumably due to arrhythmia.⁹⁹ One third of deaths were due to blunt trauma or gunshot wounds. A relationship between inhibition of hepatic cytochromes by antiretroviral drugs and sudden death attendant to simultaneous use of Ecstasy has been proposed.¹⁰⁰

Detection of the amphetamine-intoxicated patient is based on history and symptoms. Immunofluorescent screening of the urine may be of assistance. False-positive screens may be caused by ephedrine-containing over-the-counter medications. MDMA is detected by high-sensitivity urinary assays.^{101,102} Evaluation of the patient should include a search for commonly present co-intoxicants, such as fentanyl, GHB, and flunitrazepam. A diagnostic survey for occult injury should be performed. Diagnostic tests may include serum electrolytes, an electrocardiogram, and cardiac enzymes. Management of the patient who is intoxicated with an amphetamine congener is largely supportive. As symptoms usually are noted more than 1 hour after ingestion, there is little role for the use of activated charcoal or gastric lavage. The comatose patient should be intubated. Neuroimaging should be performed on patients with altered mental status or severe headache. There is no antidote, but most symptoms can be controlled with the aggressive administration of benzodiazepines. Dehydration and electrolyte abnormalities, especially hyponatremia, should be corrected. Hyperthermia should be aggressively controlled, and neuromuscular blockade may be required to control shivering that may contribute to heat production. Dantrolene may be helpful.¹⁰³ A relationship between MDMA and the serotonin syndrome has been proposed, prompting the suggestion that cyproheptidine may also be of use.^{94,104} No clinical trials of either therapy have been conducted. Rhabdomyolysis with myoglobinuria mandates alkaline diuresis, to maintain a urine flow greater than 3 ml/kg/hr.⁸⁸ Concern over prolongation of the excretion time of MDMA should not deter one from urinary

alkalinization. Hypertension may be severe, but is frequently controlled with satisfactory sedation. A vasodilator, such as nitroprusside, should be considered in those patients with refractory hypertensive urgency. Seizures are also usually responsive to benzodiazepines, but may be caused by hyponatremia, which, once again, should be corrected.¹⁰⁵

Lysergic Acid Diethylamide

LSD is one of a class of drugs abused for their perception-altering qualities. It is an indole derivative and was first synthesized by Hoffman in 1946 from a rye fungus (ergot). Several other compounds share the neuropsychiatric characteristics of LSD and are similarly abused, or misrepresented as LSD. Among them are psilocybin, dimethyltryptamine, and dimethoxy methylamphetamine (known as DOM or STP). The latter is a hallucinogenic amphetamine congener (see previous section). The piperidine derivatives ketamine and phencyclidine are also hallucinogens. Use of LSD peaked in the 1960s and then waned, with reemergence in the 1990s among high school students.¹⁰⁶ It is sold in thin gelatin squares, on colored paper, or as tablets that may be crushed.

LSD is commonly taken orally. Symptoms begin 30 to 90 minutes after ingestion, and persist for 2 to 4 hours. There is no clinically useful laboratory test for detection. There is a wide variation in clinical effect, but the most common experience is altered visual perception, including the unusual description of crossed sensory experience, or synesthesia, in which the subject believes he or she can smell a color or see a sound.¹⁰⁷ Sympathomimetic effects such as mydriasis, flushing, tremor, hyperthermia, tachycardia, hypertension, and piloerection are seen, and a syndrome resembling neuroleptic malignant syndrome has been described.¹⁰⁸ Depression, mood swings, and altered body perception may occur. Persistent or recurrent perceptual alterations, or “flashbacks,” are reported, and LSD may exacerbate preexisting psychosis.¹⁰⁹ Panic attacks or “bad trips” are the most common reason for presentation to the emergency department.

Most patients who present after LSD ingestion may be managed conservatively. There is no antidote, and elimination techniques are not of assistance. Vital signs should be monitored and the presence of other intoxicants ruled out. Patients with psychotic reactions frequently may be managed by removal to quiet surroundings and verbal reassurance. Benzodiazepines may occasionally be of use, but phenothiazines may potentiate seizures and has been associated with cardiovascular collapse.^{110,111} Clonazepam may be of assistance in the management of persistent hallucinations.¹¹²

“Club Drugs”

A group of drugs has become popular at all-night dance parties called “raves.” The so-called club drugs are used recreationally in social settings, frequently among young people.¹¹³ Among them are MDMA (see earlier), phencyclidine, ketamine, GHB, and flunitrazepam. They are considered safe by the population of individuals who use them, and consumption, especially of Ecstasy, is increasing among adolescents, as reported by the Drug Awareness Warning Network and the Monitoring the Future studies.¹¹⁴

Ketamine and Phencyclidine

Phencyclidine and ketamine are related piperidine derivatives with analgesic, amnestic, and dissociative properties.

Both have been used as anesthetic agents, and ketamine is still widely used for procedural sedation. They are termed *dissociative*, in that the patient may remain semiconscious but indifferent to surroundings.¹¹⁵ Phencyclidine was first synthesized in the 1950s and appeared as a substance of abuse in the 1970s. It is commonly sold as a powder or pill that is ingested, or laced in marijuana and smoked. Impurities such as benzocaine, ephedrine, caffeine, and other piperidine derivatives are common.¹¹⁶ Ketamine may be smoked or taken orally or intravenously. It is formulated for legal use as an intravenous drug, and entry to the illicit market is by diversion from legitimate sources. Pediatric intoxication after accidental ingestion has been reported.¹¹⁷ Phencyclidine and ketamine may be detected by a urinary immunofluorescent assay that is both sensitive and relatively specific.

Phencyclidine and ketamine are agonists of *N*-methyl-D-aspartate, an excitatory neurotransmitter. A typical dose of phencyclidine is 0.01 mg/kg, which causes distorted body image and a sense of depersonalization; 10 mg causes total disorientation and catatonic stupor. Ketamine is given in doses typically of 1 mg/kg, which causes stupor and depersonalization. Higher doses are associated with progressive unconsciousness and respiratory arrest. Patients present with a combination of central nervous system stimulation and depression, as well as cholinergic and anticholinergic effects. Nystagmus, often rotatory, and hypertension are the most commonly noted findings.¹¹⁸ Miosis, an unusual finding in association with an excitatory drug, may be observed. Patients present with confusion, disorientation, agitation, or violence and behavior indistinguishable from acute schizophrenia.^{119,120} The level of consciousness may vary from alert to comatose. Hypertension, hyperthermia, and rigidity with opisthotonus may occur but are rarely severe. Rhabdomyolysis may attend violent behavior in both ketamine and phencyclidine abuse.^{121,122} Death in phencyclidine intoxication is commonly due to behavioral mishap, such as violent trauma, suicide, or bizarre behavior.¹²³ Asphyxial death attendant to the restraint of a violent or uncooperative patient has been reported.¹²⁴ A prior history of psychiatric disease is common among fatal cases.¹¹³

The management of phencyclidine and ketamine intoxication is supportive. There is no antidote, and elimination techniques are of little value. Accidental therapeutic administration of ketamine in as much as 100 times the intended dose has been associated with a favorable outcome.¹²⁵ Comatose patients, or those with depressed respirations, should undergo intubation. The avoidance of depolarizing muscle relaxants that may transiently raise vagal tone or exacerbate hyperthermia seems prudent. Physical restraint of the severely agitated or combative patient should be avoided; a nonthreatening environment and chemical restraint would be better utilized, a benzodiazepine being the drug of choice. Rhabdomyolysis should be managed with intravenous fluids and attention to electrolyte balance. Patients should be observed for several hours until the return of normal mental status. Rhabdomyolysis, seizures, persistent psychosis, or injuries are indications for hospitalization. In a series of 20 patients presenting to the emergency department after ketamine abuse, 18 were discharged from the emergency department without admission.¹²²

Flunitrazepam

Flunitrazepam, marketed as Rohypnol, is a potent benzodiazepine that is marketed legally in South America, although its sale in the United States and Canada has been restricted. It is 10 times as potent as diazepam, and shares amnesic properties with other benzodiazepines.¹²⁶ Its potency and ability to produce amnesia has led to its misuse in facilitating sexual assault, giving it the reputation of being a “date rape drug.”^{127,128} It is available under a variety of street names including “rookie,” “circle,” “rope,” and “forget-me,” as a 1- or 2-mg scored pill that may be colored to obscure its identity. The pills are inexpensive, and thus thought of as a “cheap high.” They are imported illegally through the mail, and are acquired over the Internet from offshore sources. Although benzodiazepines may be detected by urine screen, flunitrazepam is generally taken at a dose below the detection limits of most assays.¹²⁹

At low doses, flunitrazepam is an anxiolytic, muscle relaxant, and sedative-hypnotic. At higher doses, behavioral inhibition, amnesia, and unconsciousness occur, as may respiratory depression. Its effects are potentiated by the concurrent use of alcohol. Disinhibition may lead to motor vehicle accidents, other trauma, violent behavior, or sexual assault,¹³⁰ and flunitrazepam has been implicated in the occurrence of violent crime.¹³¹ Fatal intoxication has been reported with the concurrent use of alcohol; rarely, death associated solely with the ingestion of flunitrazepam may occur.⁵²

Management of flunitrazepam intoxication is largely supportive. Neurologic impairment, amnesia, and respiratory depression, which may begin as early as 30 minutes after ingestion, generally last for 8 to 12 hours and are dose related.¹³² Support of the patient with a jeopardized airway is indicated. Gastric lavage and activated charcoal are likely to be of little benefit, unless the patient presents shortly after the ingestion. The benzodiazepine antagonist flumazenil may reverse respiratory depression, but should be used with caution as it may precipitate benzodiazepine withdrawal, manifested as tremor, irritability, and seizures.¹³³ Supportive care with airway protection and mechanical ventilation until the patient is fully awake is the safest approach.

γ -Hydroxybutyrate

GHB was introduced to the mass market as a dietary supplement that could enhance muscle growth. Reports of intoxication and death appeared soon thereafter.^{134,135} Sale as a dietary supplement was restricted, but reports began appearing in 1997 of its use as a rave drug. Of 72 patients in a reported cohort, 20 were admitted to intensive care with coma or apnea; there was one death.¹³⁶ Its reputation for increasing libido and producing amnesia increased its popularity. The prior restriction of its sale resulted in the appearance of two congeners, γ -butyrolactone (GBL) and 1,4-butanediol (1,4-BD) with similar properties. It is easily manufactured, and instructions for production can be obtained on the Internet.¹³⁷ In addition to increasing reports of acute toxicity, it has been recognized, along with flunitrazepam, as a date or acquaintance rape drug.¹²⁸

GHB is a naturally occurring analogue of GABA, an inhibitory neurotransmitter. It is supplied as a white powder that has a soapy taste when dissolved. It is rapidly absorbed after

oral administration, and effects are observed within 15 to 30 minutes. There is no clinically useful laboratory assay detection or confirmation of the poisoning. Central nervous system effects include euphoria, headache, dizziness, ataxia, miosis, and hallucinations. The effect is dose dependent, and at higher doses euphoria gives way to somnolence and coma. Apnea is rare, but vomiting and salivation are common.¹³⁸ Seizures have occasionally been noted. A withdrawal syndrome consisting of toxic psychosis, severe agitation, and seizures has been reported¹³⁹ after compulsive repeated use.¹⁴⁰

There is no antidote for GHB intoxication. Most patients may be treated supportively. Induced emesis is contraindicated because of the possibility of rapidly occurring loss of consciousness or seizures. There are no data on the use of activated charcoal or gastric lavage, but neither is likely to be effective in a symptomatic intoxication. Comatose patients should have their airway protected. Evacuation of the stomach by nasogastric suction may offer some protection against aspiration. Seizures may be treated with benzodiazepines. Most patients recover within 8 hours. There is no consensus on the treatment of GHB withdrawal syndrome, but high-dose benzodiazepines and barbiturates have been advocated.

Inhalants

The abuse of volatile substances is appealing to the drug-seeking adolescent. Inhalation is associated with rapid onset and predictable euphoria, quickly dissipating, which allows the child to engage in the practice while unobserved. They are often legally obtained, readily available, and inexpensive. A national annual survey of drug abuse trends among schoolchildren has reported that the lifetime prevalence of inhalant abuse among 8th graders is 20%. The only more commonly abused substances are nicotine and alcohol.¹⁴¹ A wide variety of inhalant substances and sources are reported (Table 135–6).

Table 135–6 Commonly Abused Volatile Substances

Family	Substance	Source
Aliphatic hydrocarbons	Propane	Bottled fuel
	Butane	Cigarette lighter fluid
	Gasoline	Automotive fuel
	n-Hexane	Model glue, rubber cement
Alkyl halides	1,1,1-Trichloroethane	Correction fluid, degreaser
	Trichloroethylene	Dry cleaning fluid
	Trichlorofluoromethane	Freon refrigerant
	Dichloromethane	Paint stripper
Aromatic hydrocarbons	Benzene	Resins, varnishes
	Toluene	Spray paint, glues
	Xylene	Paint thinner, glue
	Naphthalene	Mothballs
Ethers	Diethyl ether	Solvent
Ketones	Actone	Nail polish remover
	Butanone	Adhesives
	Methyl n-butyl ketone	Paint
	Methyl isobutyl ketone	Spray paint
Nitrogen oxides	Butyl/isobutyl nitrite	Room air freshener
	Amyl nitrate	Coronary vasodilator
	Nitrous oxide	Whipped cream

Inhalants are often abused by a group, but may be engaged in as a solitary activity. Typically, the agent is sprayed into a bag, which is placed over the face and inhaled (so-called “bagging”), or sprayed into a rag, which is then placed over the face (“huffing”). Some agents are supplied in characteristic dispensers such as whippets or glass beads (see below). Intoxicated individuals frequently present with altered mental status, rendering history difficult, but the identification of an offending substance may be facilitated by inquiring among others present, or an inspection of the surroundings. Emergency medical services personnel should be instructed to retrieve items such as paint cans, rags, or other paraphernalia. These items, along with the patient’s clothing, should be brought in an airtight container along with the patient. Examination of the patient may be of assistance: the child may have a suggestive odor, or the presence of residue such as paint or correction fluid on the face. Mucous membrane irritation, especially perioral (termed a “*huffer’s rash*”), and swelling may be present. Cyanosis unresponsive to oxygen therapy suggests methemoglobinemia secondary to nitrite abuse.

Inhalant abuse is a hazardous activity. Death, although uncommon, may result from cardiac arrhythmia or asphyxia.¹⁴² Severe burns have been reported after ignition of a volatile substance concurrent with cigarette smoking.¹⁴³ Sudden death is associated with the abuse of butane, propane, and halogenated hydrocarbons. It has been attributed to the sensitization of myocardium to circulating catecholamines,¹⁴⁴ and is suggested by the history of cardiac arrest following vigorous physical activity after inhalant abuse. Most recently, it has been described with the abuse of typewriter correction fluid, which contains 1,1,1-trichloroethylene, and spray containers using Freon propellants.^{145,146}

Solvent inhalation generally produces central nervous system depression, which may impair ventilation and airway reflexes. Subjective effects and symptoms are dose dependent and are subject to considerable individual variation. Patients may be lethargic, disinhibited, ataxic, dysarthric, or comatose.¹⁴⁷ Hallucinations may occur. Seizures have been reported.¹⁴⁸ The duration of symptoms is dependent on the individual agent. Most solvents produce euphoria after 15 to 20 inhalations. Rebreathing the substance by bagging may produce hypoxia that enhances its effects.¹⁴⁹ Duration of symptoms depends on the lipid solubility of the substance. Gasoline sniffing will produce sedation for as long as 8 hours. Patients may wake with headache, dizziness, palpitations, vomiting, and weakness. These symptoms, although unpleasant, are rarely life threatening. Tolerance to the acute effects of hydrocarbon inhalants, especially with toluene and 1,1,1-trichloroethylene abuse, has been described after as little as 3 months’ regular use.¹⁵⁰⁻¹⁵² An acute withdrawal syndrome characterized by tremor, agitation, insomnia, and delirium tremens has also been described.¹⁵³ Acute methylene chloride exposure may produce the unique problem of carboxyhemoglobinemia, developing hours after exposure, as a consequence of carbon monoxide generated in its metabolism.¹⁵⁴

Chronic solvent inhalant abuse produces a wide range of organ system injuries, summarized in Table 135–7. The most common neurologic sequelae are polyneuropathy and dementia.¹⁵⁵⁻¹⁵⁸ Gasoline sniffing presents unique problems. The chronic multifocal polyneuropathy associated with its chronic abuse may worsen after cessation of the practice.¹⁵⁹

Table 135–7 Chronic Effects of Inhalant Abuse

Organ System	Manifestation	Associated with:
Neurologic	Cerebellar ataxia	Toluene
	Electroencephalographic slowing	n-Hexane
	Peripheral neuropathy	n-Hexane
	Trigeminal neuralgia	1,1,1-Trichloroethylene
Psychiatric	Parkinsonism	Gasoline additive
	Dementia, memory loss	Multiple
Renal	Renal tubular acidosis	Toluene
Cardiovascular	Myocarditis	Gasoline
Pulmonary	Chemical pneumonitis	Multiple
	Emphysema	Gasoline
Hepatotoxicity	Chemical hepatitis	Chlorinated hydrocarbons
Hematologic	Carboxyhemoglobinemia	Methylene chloride
	Leukemia, aplastic anemia	Benzene

Adapted from Brouette T, Anton R: Clinical review of inhalants. *Am J Addict* 10:79–94, 2001.

Additionally, acute and chronic lead encephalopathy has been reported.¹⁶⁰

Volatile Nitrogen Oxides

Nitrous oxide, still used as an anesthetic gas, has been increasingly reported as a drug of abuse. As many as 10% of adolescent youths in some populations may use nitrous oxide regularly; one third of adolescents surveyed at a correctional institution reported use, beginning at a median age of 13 years.¹⁶¹ It is readily available in health care facilities and restaurants, but in the pediatric population it has been obtained in the form of “whippets,” which are sold for the production of whipped cream. They can be obtained at grocery stores and at specialty shops specializing in drug paraphernalia, often sold with a device to puncture and evacuate the canister. The gas is expended into a balloon, which may be passed around in a group setting. Many first-time users experience nausea, chest tightness, or no effect; however, some report a sense of dreamlike anesthesia shortly after inhalation.

Nitrous oxide, like other inhaled drugs of abuse, readily crosses the alveolus to the bloodstream and thereafter penetrates the blood-brain barrier. After termination of exposure, nitrous oxide in the bloodstream is rapidly excreted by the lungs. Its lifetime in the central nervous system is longer than its circulatory half-life. It has the reputation of being a clean and safe drug, but deaths, principally in the workplace, have been reported,¹⁶² attendant to asphyxia during the inhalation of high concentrations. Death has not been reported with the use of nitrous oxide whippets; however, impaired driving skills were observed after brief recreational exposure.¹⁶³ Chronic intermittent inhalation has been associated with a diffuse polyneuropathy, commonly more sensory than motor, which is caused by inactivation of vitamin B₁₂. Ataxia and lower extremity weakness are often noted.^{164,165} Megaloblastic anemia, leukopenia, and thrombocytopenia are also occasionally observed.¹⁶⁶

Organic nitrites have been abused by inhalation since the 1970s, when they acquired the reputation of being a sexual stimulant, particularly among homosexuals. Popularity

waned with their unproven association with the acquisition of acquired immunodeficiency syndrome. Similarly, an alleged association of nitrite abuse with Kaposi's sarcoma is unproven, and is more likely the result of promiscuous unprotected sex.¹⁶⁷ Abuse of amyl nitrate and butyl nitrite, although less common than in the past, continues to be occasionally seen.

Amyl, butyl, and isobutyl nitrite are potent vasodilators and have narcotic effects similar to nitrous oxide. Alkyl nitrites are also found as the propellant in a variety of cleaning products and sold as a "locker room deodorant," to be bagged or huffed. Amyl nitrite is distributed in glass beads called "poppers," which are broken and the contents inhaled. Inhalation is accompanied by sexual arousal and a dreamy, euphoric state. Onset is within seconds, but the effect last only minutes. The pattern of abuse is repeated inhalation, often dozens of times.

Patients may present with flushing reactions that can be attributed to nitrite-induced vasodilation or allergy. The principal severe toxicities associated with volatile nitrite abuse, however, are consequent to oxidative stress, as nitrite-induced methemoglobin formation may overwhelm NADH- and NADPH-dependent reduction pathways. Hemolytic anemia, often associated with congenital glucose-6-phosphate dehydrogenase (G6PD) deficiency, has been reported.¹⁶⁸ Methemoglobinemia is rare but may be life threatening. The diagnosis is suggested by the presentation of cyanosis unresponsive to 100% oxygen, and is confirmed by co-oximetry. Pulse oximeters do not detect methemoglobin and may falsely report satisfactory oxygen saturation in the presence of severe disease. Manifestations are those of acute anemia. Symptomatic tachycardia develops with a methemoglobin level over 30%. Neurologic symptoms, including headache, lethargy, and coma, are noted at a level over 55%. Arrhythmias and cardiovascular collapse occur at this level, and a concentration over 70% is frequently fatal. Symptomatic patients should be treated with methylene blue, 1 to 2 g of 1% solution.¹⁶⁹ Unresponsiveness to therapy may indicate G6PD deficiency. Occasionally, exchange transfusion may be required.

Miscellaneous Agents

Over-the-Counter Drugs

Over-the-counter medications are frequently abused by children and adolescents. A recent report from the Utah poison control system identified 2214 contacts over a 10-year period, asserting the inappropriate use of medications by children 6 to 19 years old.¹⁷⁰ Most common among them were the anticholinergic decongestants, caffeine, dextromethorphan, and stimulants.³⁸ Two thirds of the children were brought to a health care facility. There were no deaths.

Caffeine is a methylxanthine, chemically related to theophylline and a ubiquitous substance in the Western diet. Caffeine is a stimulant that elevates blood pressure, pulse, and respiratory rate. It is used clinically in the management of neonatal apnea. At doses near therapeutic, it may produce palpitations, sweating, and a sense of anxiety. In overdose, tremors, fasciculations, and seizures are observed. Fatal caffeine poisoning has been reported.¹⁷¹ Caffeine dependence in childhood has been described, and a withdrawal syndrome consisting of somnolence and a decline in motor perfor-

mance 24 hours after the discontinuation of caffeinated beverages has been recognized.¹⁷² The acutely poisoned patient should be observed for the abrupt onset of seizures. Peritoneal dialysis was reported to be effective in accelerating the removal of caffeine from one seriously poisoned child.¹⁷³

Ephedrine and pseudoephedrine are noncatecholamine stimulants chemically related to amphetamines, with biologic effects similar to that group of compounds. Ephedrine is a naturally occurring alkaloid and has been sold in herbal form (see later). It was sold as an over-the-counter stimulant, anorectic, and bronchodilator. Its sale was prohibited in 2004 after a series of deaths were reported,¹⁷⁴ but it is still available by mail order from offshore sources. Pseudoephedrine is present in many decongestants, frequently with diphenhydramine or dextromethorphan, and is still widely sold. Both are abused by adolescents for their stimulant properties and as anorectic agents. Like caffeine, they are sold under the misrepresentation of being other illicit substances. At therapeutic doses, both ephedrine and pseudoephedrine produce tachycardia, hypertension, increased respirations, sweating, salivation, mydriasis, nausea, and palpitations. Tolerance develops rapidly, and increasing doses are required for the user to achieve the desired effect. The urine drug screen for amphetamines may be positive, rendering the distinction from methamphetamine or MDMA intoxication difficult. In acute overdose, arrhythmias, myocardial infarction, hypertension, hyperpyrexia, seizures, and death have been reported.¹⁷⁵ A chronic dilated cardiomyopathy has been reported in adolescents using ephedrine as an anorectic.¹⁷⁶⁻¹⁷⁸ An acute toxic psychosis has been reported in children ingesting the combination of pseudoephedrine and dextromethorphan.^{179,180} An abstinence syndrome consisting of excessive somnolence and lethargy has been recognized.¹⁸¹

Dextromethorphan is a semisynthetic opioid with poor analgesic properties used commonly as a cough suppressant (e.g., Coricidin Cough and Cold whose street name is triple C's). It is commonly sold in combination with acetaminophen, diphenhydramine, or pseudoephedrine. Sedation and relaxation are noted at recommended doses, but increasing amounts are associated with hallucinations and psychosis.¹⁸² The serotonin syndrome, consisting of confusion, ataxia, hyperthermia, and rigidity, has been associated with the use of dextromethorphan.¹⁸³ The abuse potential of dextromethorphan has been long recognized.¹⁸⁴ Dependence and death have been also associated with abuse.¹⁸⁵ Recently, reports have appeared suggesting the increased abuse of Coricidin HBP, apparently because of its high dextromethorphan content.¹⁸⁶ In 92 reported patients, the most common symptoms were tachycardia, hypertension, lethargy, mydriasis, agitation, ataxia, and dizziness. Most patients were treated in the emergency department and released. All patients recovered.

Diphenhydramine, an antihistamine, is a common constituent of cough and cold remedies and is also sold as a sleep aid. Literally hundreds of over-the-counter formulations exist. Much of its therapeutic potential is obtained from its anticholinergic potential. Dry mouth, tachycardia, sedation, and mydriasis are observed. Its abuse potential has been long recognized,^{185,187} and unintentional intoxication in the therapeutic setting has been reported.¹⁸⁸ Diphenhydramine has been used in intentional poisoning of children.¹⁸⁹ A syndrome of diphenhydramine dependence has been recently recognized,¹⁹⁰ and chronic abuse may manifest as adolescent

depression.⁶⁸ Diphenhydramine is commonly taken orally, but it may occasionally be used intravenously or smoked with marijuana.¹⁹¹ In overdose, diphenhydramine produces symptoms of acute anticholinergic poisoning: fever, seizures, coma, agitation, toxic psychosis, and tachyarrhythmias. A wide-complex tachycardia resembling torsades de pointes may be observed.¹⁹² There is no clinically useful laboratory assay, and the diagnosis must be made by history and physical examination with a high index of suspicion. Most patients recover with conservative management. Benzodiazepines may be used for agitation and seizures. Bicarbonate has been reported to be therapeutic in the treatment of wide-complex tachycardia. The use of physostigmine as an antidote for anticholinergic poisoning is controversial but has been reported effective.^{193,194} Its use is contraindicated if tricyclic antidepressant poisoning is considered in the differential diagnosis of the intoxicated child.

Botanicals and Natural Products

A wide variety of naturally occurring products are used as alternative medical therapies and substances of abuse. Many herbal remedies are available as dietary aids at health food stores and sold as stimulants, appetite suppressants, antidepressants, and dietary aids. They are subject to limited regulation, and neither purity nor safety nor consistent formulation can be assured. Common contaminants of herbal products include pesticides, metals, orthodox drugs such as phenylbutazone or salicylate, and microbial substances and toxins.¹⁹⁵ Some substances of abuse are harvested as wild or locally grown plants. It is beyond the scope of this chapter to comprehensively review the botanical substances of abuse, but those of importance to the pediatric emergency physician are presented herein.

Ephedrine, a precursor of methamphetamine, is the active alkaloid of the plant *Ephedra vulgaris*, which has been used in China for centuries as the herb Ma Huang. Ma Huang was extensively marketed as a stimulant and weight loss product, and is popular among adolescents. In this formulation, it was subject to the variations in purity and potency of other herbal products. Its sale, and that of other ephedrine-containing products, has recently been restricted by the Food and Drug Administration after the appearance of reports of adverse cardiovascular events, including stroke, myocardial infarction, and sudden death.^{175,196} The acute toxicity of ephedrine-containing compounds is similar to that of other stimulants. Patients are restless, agitated, diaphoretic, tachycardic, and often hypertensive. Mydriasis is common. Seizures and unresponsiveness have been reported.¹⁹⁷ A toxic psychosis has been reported.¹⁹⁸ Chronic effects including vasculitis, myocarditis, hepatotoxicity, and a fixed drug eruption have been reported with the use of Ma Huang, possibly the result of unidentified additives to the preparation.¹⁹⁹⁻²⁰¹

Ginseng is prepared from the root of *Panax quinquefolium*, and is advocated as a stimulant and general aid to well-being (Fig. 135-4). The active ingredients are poorly characterized saponins. It is widely popular and supplied as herbal tea, chewing gum, and dietary supplements. Few medical problems have been described specifically; however, a syndrome of hypertension, restlessness, and diarrhea has been attributed to heavy use.²⁰²

Many decorative and wild plants are sought as drugs of abuse. Two such common agents are angel's trumpet and

FIGURE 135-4. Wild ginseng.

FIGURE 135-5. Angel's trumpet.

Jimsonweed. They are related *Datura* species, and both are cultivated as a decorative plant and grow as weeds. Synonyms are "devil's weed," and "thorn apple," and they contain solanine alkaloids that are potent anticholinergic substances. They appear as graceful, trumpet-shaped yellow or white flowers becoming thorny seedpods in the autumn (Figs. 135-5 and 135-6). All parts of the plant are toxic. It is commonly harvested, dried, and either smoked or ingested as a soup or tea. Intoxicated patients present with agitation, delirium, hyperthermia, dry mouth, tachycardia, and mydriasis.²⁰³ In a reported series of 35 patients, all had mydriasis, 88% had delirium, and 33% had tachycardia. Symptoms were prolonged (18 to 29 hours). No patient had seizures or arrhythmias, and none died.²⁰⁴ Conservative management, with sedation and occasionally airway protection, is indicated. In

FIGURE 135-6. Jimsonweed.

FIGURE 135-7. Morning glory.

one reported case of severe anticholinergic syndrome secondary to angel's trumpet abuse, physostigmine was of benefit.²⁰⁵

Several botanical agents are used for their hallucinogenic properties. Among these are the morning glory, mimosa, and peyote cactus. The seeds of the morning glory, of the *Convolvulaceae* family, produce an alkaloid similar to LSD that causes altered perception and hallucinations when ingested (Fig. 135-7). The seeds are first obtained from the mature plant or in garden supply stores. They are ground, soaked, and filtered before consumption. Synesthesia, visual hallucinations, and mydriasis are common signs and symptoms. The effect lasts about 60 minutes.²⁰⁶ Medical complications are rare, and death has not been reported.²⁰⁷ Dimethyltryptamine is a serotonin agonist contained in snuff manufactured from the seeds and bark of *Justia pectoralis*, *Mimosa hostilis*, and other plants. They are collected wild and are available by mail order. Abuse is by inhalation of the ground powder or by smoking. Intoxication closely resembles LSD. The treatment is supportive. Pharmacologic management of agitation may be undertaken with benzodiazepines. A powder ground from the seeds of the spice nutmeg is used as a hal-

A

B

FIGURE 135-8. A and B, *Psilocybe* mushrooms.

lucinogen similar to LSD. Myristicin, the active alkaloid, is present in a concentration of 0.2 mg/g of spice. Ingestion of 5 g of ground nutmeg induces hallucinations and arousal.²⁰⁸ Symptoms are said to resemble acute anticholinergic poisoning, with mydriasis, tachycardia, palpitations, and a feeling of impending doom.²⁰⁹ Uncomplicated recovery with supportive care is the rule, but death, presumably secondary to tachyarrhythmia, has been reported.²¹⁰

The use of mushrooms and cactus as hallucinogenic agents dates back to antiquity. *Psilocybe cubensis* is found in moist southeastern climates and produces the alkaloids psilocybin and psilocin, which closely resemble dimethyl tryptamine, a serotonin analogue (Fig. 135-8). The active agent is stable and retains potency when boiled. It is foraged by amateur mushroom hunters and is sold as a street drug frequently misrepresented as LSD. It is commonly ingested as a soup or tea, but occasionally has been abused intravenously.²¹¹ Ingestion is accompanied by symptoms closely resembling those of other hallucinogens, with hallucinations, altered color perception, tachycardia, hypertension, and mydriasis. Patients may present with an agitated delirium or paranoid delusions. Symptoms begins shortly after ingestion and last

3 to 4 hours. Medical complications are rare, but convulsions and myocardial infarction have been reported.^{212,213} A principal danger is the misidentification of a more toxic species, such as *Amanita* species.²¹⁴ Treatment is supportive. An attempt should be made to formally identify the mushroom if it is available. Peyote is the common name of the cactus *Lophophora williamsii*, from which the active alkaloid, mescaline, is extracted. It grows wild in the Southwest and is still used legally in religious ceremonies. As a drug of abuse, it is produced from buttons of the dried cactus, which are consumed as a tea. It is often misrepresented as LSD or phencyclidine. Effects begin 30 minutes after ingestion. A gastrointestinal phase is accompanied by nausea, vomiting, diaphoresis, and mydriasis, to be followed by a psychoactive phase closely resembling that of LSD. Prolonged psychosis and fatal intoxication have been reported.^{215,216} Treatment is once again supportive. Pharmacologic management of agitation is better accomplished with benzodiazepines rather than phenothiazines, which may contribute to hyperpyrexia.²¹⁷

Anabolic Steroids

Not all drugs are abused for their mind-altering properties. Androgenic steroids are frequently used by athletes to increase muscle mass and improve performance. They are structurally related to testosterone, and, in addition to masculinization, increase muscle mass (anabolism). Their use has increased among adolescents seeking to improve athletic performance. Two recent surveys of high-school children reported prevalence of anabolic steroid use in all students as 2.8% and 5.8%. One third of those who admitted use indicated that they abused these drugs parenterally.²¹⁸ The use of anabolic agents, along with stimulants, hormones such as erythropoietin and growth hormone, and blood doping, is officially proscribed. In 1990, Congress enacted the Anabolic Steroid Control Act, which placed them on Schedule III of controlled substances, but acquisition is easily accomplished through illicit sources. Surreptitious use is accomplished by taking them in cycles to avoid detection. Athletes tend to use more than one agent and cycle their use to modulate drug tolerance. Numerous complications of anabolic steroid use have been reported and include toxic hepatitis, overuse injuries, gynecomastia, cerebral hemorrhage, and pulmonary embolism.²¹⁹⁻²²³ Anabolic steroids lower high-density lipoprotein and increase platelet adhesiveness. Cardiac effects include myocardial infarction and sudden death.²²⁴ Athletes who parenterally abuse anabolic steroids are subject to the infectious and noninfectious complications of nonsterile administration, including hepatitis, HIV, and abscesses, but at a rate that may be lower than that of intravenous drug users.²²⁵

Chapter 136

Adverse Effects of Anticonvulsants and Psychotropic Agents

Paul Kolecki, MD and Richard D. Shih, MD

Key Points

The side effects of anticonvulsant medications are categorized as acute or long-term adverse effects.

The treatment of anticonvulsant adverse events is mainly supportive.

Phenothiazine's mechanism of action is through central and peripheral dopaminergic blockade.

The management of antipsychotic adverse effects is mainly supportive.

Introduction and Background

Seizures and status epilepticus (SE) are common pediatric emergencies. Approximately 60,000 patients suffer from SE annually.¹ Prompt pharmacologic treatment of pediatric seizures and SE is necessary to terminate the seizures and avoid permanent and potentially fatal neurologic damage.

Antipsychotics are medications used to reduce and potentially terminate hallucinations, delusions, and other mental and behavioral disturbances. Many child and adolescent psychiatrists prescribe antipsychotics on both an inpatient and outpatient basis.² In addition, many antipsychotics may cause significant adverse effects, including death.

Typical pediatric anticonvulsant agents (Table 136–1) and typical pediatric antipsychotic agents (Table 136–2) are discussed.

Selected Pediatric Overdoses

- Anticonvulsant agents
- Antipsychotic agents
 - Phenothiazines
 - Butyrophenones
 - Atypical antipsychotics

Discussion of Individual Overdoses

Anticonvulsant Agents

Phenytoin (*Dilantin*)

Phenytoin is a first-line anticonvulsant used for most seizure disorders, except for absence seizures. Phenytoin's anticonvulsant activity stems from its ability to block neural sodium channels. Unlike the benzodiazepines and other anticonvulsants, phenytoin does not cause sedation in therapeutic doses. Phenytoin can be given orally and intravenously. Therapeutic levels are 10 to 20 mg/L.

Adverse effects associated with phenytoin use can be subdivided based on acute use versus chronic use. Idiosyncratic adverse effects can also occur.

Adverse effects associated with acute use include nystagmus, ataxia, dizziness, diplopia, and dyskinesia-like movements. Rapid intravenous (IV) phenytoin administration can cause significant hypotension, bradycardia, atrioventricular conduction delays, ventricular tachycardia, ventricular fibrillation, and asystole. Extravasation of IV phenytoin can produce local skin irritation, skin and soft tissue necrosis, compartment syndrome, gangrene, and amputation. A delayed bluish discoloration of the effected extremity (purple glove syndrome) followed by erythema, edema, vesicles, bullae, and local tissue ischemia, can also occur. These cardiovascular and soft tissue side effects from IV administration occur secondary to phenytoin's diluent (propylene glycol).

Adverse effects associated with long-term phenytoin use include gingival hyperplasia, facial coarsening, peripheral neuropathy, collagen disturbances, bone diseases, hypovitaminosis D, and megaloblastic anemia (secondary to folic acid deficiency). Idiosyncratic reactions include leukopenia, thrombocytopenia, aplastic anemia, agranulocytosis, and a hypersensitivity syndrome.³

The treatment of the adverse effects with both acute and chronic phenytoin use is mainly supportive. No specific antidote exists for phenytoin poisoning. Serial phenytoin levels are necessary when treating overdose patients. Activated charcoal binds phenytoin well, and multiple doses of activated charcoal should be considered for patients with rising phenytoin levels. Oral overdoses of phenytoin rarely produce

Table 136–1 Pediatric Anticonvulsant Agents

Benzodiazepines (Ativan, Valium)
Carbamazepine (Tegretol)
Clonazepam (Klonopin)
Ethosuximide (Zarontin)
Felbamate (Felbatol)
Fosphenytoin (Cerebix)
Gabapentin (Neurontin)
Lamotrigine (Lamictal)
Levetiracetam (Keppra)
Oxcarbazepine (Trileptal)
Phenobarbital (Luminal)
Phenytoin (Dilantin)
Primidone (Mysoline)
Tiagabine (Gabitril)
Topiramate (Topamax)
Valproate (Depakote)
Vigabatrin (Sabril)
Zonisamide (Zonegran)

Table 136–2 Pediatric Anticonvulsant Agents**Phenothiazines**

Aripiprazole (Abilify)
Chlorpromazine (Thorazine)
Fluphenazine (Prolixin)
Loxapine (Loxitane)
Mesoridazine (Serentil)
Molindone (Moban)
Perphenazine (Trilafon)
Pimozide (Orap)
Thioridazine (Mellaril)
Thiothixene (Navane)
Trifluoperazine (Stelazine)

Butyrophenones

Droperidol (Inapsine)
Haloperidol (Haldol)

Atypicals

Clozapine (Clozaril)
Olanzapine (Zyprexa)
Quetiapine (Seroquel)
Risperidone (Risperdal)
Ziprasidone (Geodon)

cardiovascular complications, thus cardiac monitoring is not routinely recommended. Admission should be considered for patients suffering severe ataxia or dizziness. Patients with mild and moderate symptoms can be discharged and observed closely by responsible individuals. Discharged patients need timely follow-up with their primary care physician and/or neurologist. Intravenous phenytoin-induced hypotension is best avoided with slow infusions (<15 to 20 mg/kg over 20 minutes) and continuous cardiac and blood pressure monitoring. Treatment includes the discontinuation of the infusion and the administration of IV boluses of normal saline solution. Skin and soft tissue toxicity secondary to phenytoin extravasation is best avoided with close observation of the extremity during IV infusion.

Fosphenytoin (Cerebix)

Fosphenytoin is a water-soluble derivative of phenytoin that can be given intramuscularly (IM) and IV. Fosphenytoin's anticonvulsant activity stems from its ability to block neural sodium channels.

The adverse effects and their respective treatments associated with fosphenytoin are very similar to those of phenytoin.⁴ However, skin and soft tissue toxicity is rarely seen with fosphenytoin use.

Carbamazepine (Tegretol)

Carbamazepine, an oral agent, is a potent anticonvulsant used to treat many seizure disorders, except absence seizures. Carbamazepine blocks neural sodium channels. In addition, carbamazepine has strong anticholinergic activity.⁵ Therapeutic levels are 4 to 12 mg/L.

Acute carbamazepine toxicity can produce neurologic and cardiovascular adverse effects. The neurologic effects include nystagmus, ataxia, dysarthria, lethargy, seizures (including SE), and fluctuating coma.⁵ The cardiovascular effects include tachycardia, hypotension, QRS widening, prolonged QTc interval, and conduction abnormalities. Interestingly, pediatric toxicity compared to adult toxicity is more commonly associated with dystonic reactions, choreoathetosis, seizures, and a lower serum concentration.^{3,5} Acute carbamazepine overdoses can form gastric concretions with a resultant delay in levels or signs and symptoms. In addition, the formation of an active metabolite also contributes to delayed toxicity.⁵

Chronic carbamazepine toxicity can produce headaches, diplopia, ataxia, and hyponatremia (secondary to increased vasopressin stimulation).⁵⁻⁷

Neuropsychiatric adverse effects include irritability, impaired concentration, and memory impairment. Idiosyncratic reactions include rashes, hepatitis, drug-induced systemic lupus erythematosus, leukopenia, and aplastic anemia.³

The treatment of adverse effects with both acute and chronic carbamazepine use is mainly supportive. No specific antidote exists for carbamazepine poisoning. Serial carbamazepine levels are necessary when treating overdose patients. Activated charcoal binds carbamazepine well, and multiple doses of activated charcoal should be considered for patients with rising carbamazepine levels or concretions. Cardiac monitoring is recommended, and IV sodium bicarbonate should be considered for QRS widening of greater than 100 msec. Carbamazepine-induced seizures respond well to benzodiazepines.⁸ Serum electrolytes should be followed, especially in severe overdoses. Admission to an intensive care unit is recommended for poisoned patients with severe neurologic and/or cardiovascular toxicity. Admission should also be considered for patients suffering severe ataxia or dizziness. Patients with mild and moderate symptoms can be discharged and observed closely by responsible individuals. Discharged patients need timely follow-up with their primary care physician and/or neurologist.

Valproate (Depakote)

Valproate is an oral and IV anticonvulsant agent used to treat a wide range of seizure disorders. Valproate also blocks neural sodium channels. In addition, it prevents the metabolism of the inhibitory neurotransmitter γ -aminobutyric acid (GABA). Therapeutic levels typically are in the 50- to 100-mg/L range.

There are many adverse hepatic effects associated with valproate use. Hepatotoxicity can present as transient reversible aminotransferase elevation, reversible hyperammonemia, toxic hepatitis, Reye's-like syndrome, and fulminant hepatitis. Gastrointestinal symptoms, anorexia, and seizures may precede liver failure. Age less than 2 years is a risk factor for

valproate-induced liver failure. Other adverse effects include pancreatitis, hypoglycemia, metabolic acidosis, alopecia, respiratory depression, and coma.³ Leukopenia, thrombocytopenia, and anemia may occur, all of which typically are reversible.

The treatment of valproate toxicity is mainly supportive. Serial valproate levels are necessary when treating overdose patients. Activated charcoal binds valproate well, and multiple doses of activated charcoal should be considered for patients with rising valproate levels. Naloxone (Narcan) has been reported to reverse valproate-induced central nervous system (CNS) depression. Admission to an intensive care unit is recommended for poisoned patients with severe neurologic, hepatic, and/or metabolic toxicity. Carnitine has been recommended as an antidote for patients with valproate-induced hepatic dysfunction or hyperammonemia. Supplemental carnitine has also been recommended for pediatric patients less than 2 who are receiving valproate. Hemodialysis and hemoperfusion have been successfully used for patients with severe valproate toxicity (levels > 1000 mg/L). Patients with mild and moderate symptoms can be discharged and observed closely by responsible individuals. Discharged patients need timely follow-up with their primary care physician and/or neurologist.

Gabapentin (Neurontin)

Gabapentin is a derivative of the inhibitory neurotransmitter GABA and is used mainly for the treatment of partial seizures. Gabapentin levels are not readily available in most hospital laboratories. The recommended therapeutic level for seizure control is 2 to 15 mg/L.

Sedation, ataxia, and slurred speech can occur after an overdose of gabapentin. Adverse effects associated with gabapentin use include somnolence, dizziness, ataxia, fatigue, nystagmus, weight gain, headache, and rhinitis.⁹ Compare to many other anticonvulsants, the adverse effects associated with gabapentin use are relatively benign. The treatment of gabapentin overdose is mainly supportive. No specific antidote exists.

Felbamate (Felbatol)

Felbamate is a sodium channel–blocking anticonvulsant. Felbamate levels are not readily available in most hospital laboratories. Overdoses may cause mild CNS depression and mild gastrointestinal irritation, and treatment is supportive. Chronic felbamate use is associated with significant hepatic toxicity and aplastic anemia.⁴

Lamotrigine (Lamictal)

Lamotrigine is an anticonvulsant used for the treatment of partial seizures. Lamotrigine is also a sodium channel–blocking anticonvulsant. Lamotrigine levels are not readily available in most hospital laboratories. Acute poisoning with lamotrigine may cause lethargy, ataxia, nystagmus, slurred speech, and QRS prolongation. Acute pediatric lamotrigine poisoning may cause seizures.¹⁰ Chronic lamotrigine use can cause rashes, Stevens-Johnson syndrome, elevations in the hepatic aminotransferases, and elevations in creatine phosphokinase.⁴

The treatment of lamotrigine poisoning is supportive. Cardiac monitoring is recommended, and sodium bicarbonate may resolve QRS durations greater than 100 msec. Sei-

zures secondary to lamotrigine poisoning can be treated with benzodiazepines. Admission to a monitored unit is recommended for poisoned patients with moderate or severe neurologic and/or cardiovascular toxicity. Patients with mild symptoms can be discharged and observed closely by responsible individuals. Discharged patients need timely follow-up with their primary care physician and/or neurologist.

Topiramate (Topamax)

Topiramate is an anticonvulsant used mainly for adults with partial seizures. Topiramate's precise mechanism of action is unclear. Topiramate levels are not readily available in most hospital laboratories. Large overdoses are presumed to cause neurologic impairment, cardiac conduction abnormalities, metabolic acidosis, electrolyte disturbances, ataxia, slurred speech, hallucinations, and possibly seizures.^{11,12} Adverse effects associated with the chronic use of topiramate include lethargy, confusion, somnolence, dizziness, ataxia, diplopia, paresthesias, weight loss, and the formation of kidney stones.^{4,9}

The treatment of a topiramate overdose is mainly supportive. Cardiac and electrolyte monitoring are recommended. Admission to a monitored unit is recommended for poisoned patients with moderate or severe neurologic, metabolic, and/or cardiovascular toxicity. Patients with mild symptoms can be discharged and observed closely by responsible individuals. Discharged patients need timely follow-up with their primary care physician and/or neurologist.

Tiagabine (Gabitril)

Tiagabine, a new anticonvulsant, blocks the uptake of GABA. Tiagabine levels are not readily available in most hospital laboratories. Large tiagabine ingestions may cause seizures.¹³ Other adverse effects include dizziness, tremor, and difficulty concentrating.⁴ Admission is recommended for poisoned patients with moderate or severe neurologic toxicity. Discharged patients need timely follow-up with their primary care physician and/or neurologist.

Levetiracetam (Keppra)

Levetiracetam, a new anticonvulsant, is generally well tolerated. The mechanism of action is unknown. Levetiracetam levels are not readily available in most hospital laboratories. Reported adverse effects include dizziness, asthenia, flulike syndrome, headache, rhinitis, and somnolence.^{4,9,15} Treatment of overdose is supportive care.

Oxcarbazepine (Trileptal)

Oxcarbazepine, a sodium channel–blocking anticonvulsant, is structurally related to carbamazepine.¹⁵ Oxcarbazepine levels are not readily available in most hospital laboratories. Reported adverse effects include vomiting, somnolence, fatigue, dizziness, nausea, rash (Stevens-Johnson syndrome), and hyponatremia.^{4,9,16} Treatment of overdose is supportive care.

Zonisamide (Zonegran)

Zonisamide, a sodium channel– and calcium channel–blocking anticonvulsant, is a sulfonamide derivative. Zonisamide levels are not readily available in most hospital laboratories. Reported adverse effects include ataxia, somnolence, agitation, anorexia, psychosis, nephrolithiasis, oligohydrosis, rash (Stevens-Johnson syndrome), and hyperthermia.^{4,17-19}

Treatment of overdose is supportive care. Zonisamide is contraindicated in patients allergic to sulfonamides.⁹

Vigabatrin (Sabril)

Vigabatrin is a new anticonvulsant that decreases the metabolism of the neurotransmitter GABA. Vigabatrin levels are not readily available in most hospital laboratories. The major adverse effects are depression, psychosis, and visual field deficits.⁴

Antipsychotic Agents

Phenothiazines

Phenothiazines are used to treat a variety of psychiatric conditions. The mechanism of action is central and peripheral dopaminergic blockade. Many of the phenothiazines have anticholinergic, α receptor–blocking, sodium channel–blocking, and potassium channel–blocking properties. These properties cause the clinical manifestations listed in the following paragraph. Phenothiazine levels are not readily available in most hospital laboratories. These medications are given orally, IM, or IV.

Numerous adverse effects are associated with phenothiazine use. The first is orthostatic hypotension. QRS and QT interval prolongation can occur along with tachycardia, conduction abnormalities, and anticholinergic toxicity.^{20,21} Movement disorders (acute dystonia, parkinsonism, akathisia, and tardive dyskinesia) frequently are seen with phenothiazine use. Acute dystonic reactions (oculogyric crisis, torticollis, retrocollis, and opisthotonos) typically occur within 24 to 72 hours of phenothiazine use. Akathisia, the sensation of restlessness and the inability to sit still, also occurs rapidly. Phenothiazine-induced parkinsonism and tardive dyskinesia are delayed, typically 1 month to years after initiating therapy.

The treatment for phenothiazine toxicity is predominantly supportive. Activated charcoal and/or gastric lavage should be considered for an acute symptomatic overdose, as long as the airway is protected. No specific antidote exists for phenothiazine poisoning. Hypotensive patients should receive IV fluids and vasopressors if necessary. Cardiac monitoring is recommended, and IV sodium bicarbonate should be considered for QRS widening of greater than 100 msec. Admission to an intensive care unit is recommended for poisoned patients with severe neurologic and/or cardiovascular toxicity. Discharged patients need timely follow-up with their primary care physician and/or psychiatrist.

Acute dystonic reactions rapidly resolve with anticholinergic agents (diphenhydramine 1 mg/kg IM or IV; benztropine 1 to 2 mg IV or IM) and typically do not require hospital admission. To prevent a recurrence of the dystonic reactions, all treated patients should receive several days of anticholinergic therapy. Akathisia also resolves with anticholinergic therapy. Phenothiazine-induced parkinsonism and tardive dyskinesia are more difficult to treat, often necessitating a reduction in phenothiazine dosage.

Butyrophenones

Butyrophenones, like the phenothiazines, block central and peripheral dopaminergic receptors. These medications typically are given orally, IM, or IV. Butyrophenone levels are not readily available in most hospital laboratories.

Severe cardiac toxicity may occur with high-dose butyrophenone use, mainly cardiac dysrhythmias including prolonged QT-associated torsades de pointes.^{20,21} Dystonic reactions can also occur following butyrophenone use.

The treatment for butyrophenone overdose is mainly supportive. Activated charcoal and/or gastric lavage should be considered for an acute symptomatic overdose, as long as the airway is protected. No specific antidote exists for butyrophenone poisoning. Cardiac monitoring is recommended. Treatment options for torsades de pointes include magnesium (25 to 50 mg/kg IV or IM), isoproterenol (0.05 to 2 mcg/kg/min IV), and overdrive pacing. Admission to an intensive care unit is recommended for poisoned patients with cardiovascular toxicity. Discharged patients need timely follow-up with their primary care physician and/or psychiatrist.

Dystonic reactions rapidly resolve with anticholinergic agents (diphenhydramine or benztropine) and typically do not require hospital admission. To prevent a recurrence of the dystonic reactions, all treated patients should receive several days of anticholinergic therapy.

Atypical Antipsychotics

The atypical antipsychotics have effects mainly at the dopaminergic and serotonergic receptors. Clozapine and olanzapine have strong anticholinergic properties. All of these agents can be given orally, IM, or IV.

Several adverse acute effects are associated with the atypical antipsychotics. Clozapine and olanzapine, when taken as an overdose, can cause CNS depression and seizures mainly from their anticholinergic properties. Interestingly, olanzapine poisoning has been reported to cause miosis and not mydriasis.²² Acute risperidone, quetiapine, and ziprasidone poisoning may cause obtundation, respiratory depression, and cardiac conduction abnormalities. Acute dystonic reactions may also occur.^{23,24} Chronic clozapine use has been reported to cause agranulocytosis.

The treatment for an atypical antipsychotic adverse effect is mainly supportive. Airway and cardiac monitoring are recommended.

Cardiovascular Agents

John A. Tilelli, MD

Key Points

Most antihypertensive and antiarrhythmic poisoning is treated with supportive measures (i.e., fluid replacement, correction of electrolyte abnormalities, and inotropic support).

Intoxicated patients may present with an array of symptoms not related to the heart, such as vomiting, lethargy, ataxia, weakness, tinnitus, and visual disturbance.

Digoxin Fab antidote is indicated for unstable arrhythmias and hyperkalemia. It may be given for acute and chronic intoxications.

Specific therapies, when available, should not substitute for stabilization with supportive care.

Children may present with either intoxication with their own medication, or, more commonly from ingestion of a caregiver's pills. Ingestion of medications, such as quinidine and digoxin, can have a high morbidity and mortality even with a single pill.

Introduction and Background

The emergency physician frequently encounters children with toxicity from cardiovascular medications. Antiarrhythmic, inotropic, and antihypertensive medications are commonly prescribed for children with congenital and acquired cardiac and renal diseases, and are often used in a context of multiple therapies. Altered drug clearance, a change in the underlying disease, or the addition or alteration of another therapy may provoke drug toxicity. The symptoms of intoxication may be difficult to distinguish from an acceleration of the underlying condition or intercurrent illness, leading to uncertainty as to whether or not a symptom is the consequence of the disease or of the therapy. The pitfall for the emergency physician is the failure to consider that new symptoms, such as vomiting or mental status change, might represent drug toxicity. Children may also

present with the ingestion of a medication intended for an adult. Accidental antihypertensive ingestion is among the most common of pediatric intoxications. More than 20,000 exposures to cardiovascular medications were reported to poison control centers in 2003.¹ The therapeutic index of these drugs may be sufficiently narrow such that the ingestion of 1 pill may provoke toxicity in a child. The emergency physician also commonly uses these drugs in clinical practice. A general understanding of the acute toxicity of these agents is essential to their safe use in the emergency department (ED).

A broad overview of cardiac drugs leads one to approach them in two distinct classes: antihypertensives and antiarrhythmics. While this approach may provide some cognitive separation, it is of less practical use, as many drugs serve in both roles. The calcium channel blockers and β -blockers, for example, serve both roles. Some drugs, such as the nitrate vasodilators, bipyridine inotropes, amrinone, and milrinone, are rarely encountered in the outpatient setting but deserve individual mention. Digoxin, the most commonly prescribed cardiac glycoside, is important because of its widespread use as an inotrope and antiarrhythmic. In this overview of the cardiac medications, emphasis is placed on toxicity rather than therapeutic utility.

Selected Pediatric Overdoses

- Antiarrhythmics
- Antihypertensives
 - Clonidine
 - Angiotensin-converting enzyme inhibitors
 - Vasodilators
 - Diuretics
- Digoxin
- Miscellaneous agents
 - Amrinone and milrinone
 - Adenosine

Discussion of Individual Overdoses

Antiarrhythmics

Antiarrhythmic drugs affect cardiac automaticity by altering the flux of sodium, potassium, and calcium as they cross the myocardial cell membrane during an action potential. These agents are classified by the component of the action potential altered. Class IA agents, for example, decrease sodium

conductance during depolarization, thereby decreasing automaticity, additionally slowing calcium flux, and thereby impairing contractility. Class IB agents decrease sodium and potassium flux. A basic understanding of the mechanism of each class of agent is helpful in predicting an agent's toxicity and planning for the therapeutic interventions.

Class IA Drugs: Quinidine, Procainamide, and Disopyramide

Quinidine, procainamide, and disopyramide comprise the drugs in class IA. Their low therapeutic index and idiosyncratic pharmacokinetics limit their usefulness. They are still widely prescribed, however, and are used in both adult and pediatric patients for the control of atrial arrhythmias. All class IA agents inhibit fast sodium channels and decrease the rate of rise of the action potential, inhibiting automaticity of the heart. QRS and QT prolongation may be observed at therapeutic doses.² All drugs of this class, but most importantly disopyramide, have negative inotropic effects and may exacerbate heart failure. Side effects of these drugs, especially quinidine, are significant and may limit their utility. "Quinidine syncope" and hypersensitivity are potentially life threatening. Procainamide is associated with drug-induced lupus.³

Quinidine is well absorbed orally and widely distributed. Its metabolism is by hepatic hydroxylation. Both its therapeutic effect and toxicity are related to the concentration, but therapeutic drug monitoring is not usually performed. Quinidine's potential for toxicity increases when additional medications that inhibit hepatic oxidation are used. Such drugs include ketoconazole, cimetidine, and drugs that affect sodium influx, such as macrolide antibiotics, neuroleptics, and tricyclic antidepressants.⁴

Similarly, procainamide is well absorbed orally and distributed widely. Its plasma half-life is approximately 3 hours. It is both excreted unchanged in the urine and metabolized by hepatic acylation; the metabolite is excreted at a lower rate than the parent compound. The rate of acylation is genetically determined. Both the plasma concentration of procainamide and that of its acylated metabolite are commonly available for therapeutic drug monitoring.

Disopyramide is well absorbed orally and has a small volume of distribution. It is also metabolized by renal excretion and hepatic metabolism.

Manifestations of toxicity due to class IA antiarrhythmic drugs are numerous and frequently life threatening. Most characteristic is a polymorphic ventricular tachyarrhythmia termed *torsades de pointes*, in which the QRS complexes appear to twist about an isoelectric line (Fig. 137-1). Polymorphic ventricular tachycardia appears to be the cause of quinidine syncope. It may occur at therapeutic levels.⁵ Its etiology is not completely understood, but it is likely due to transient arrhythmias that spontaneously resolve. Patients who experience syncope should be considered toxic. Prolongation of the QRS complex is common with quinidine therapy, but an increase of 25% over baseline may be considered evidence of toxicity.⁶ Depression of myocardial function is dose related. Severe overdose is accompanied by hypotension and shock. The acylated metabolite of procainamide is capable of causing torsades in the absence of accumulation of the parent compound. Disopyramide has more negative inotropic potential than either quinidine or procainamide.

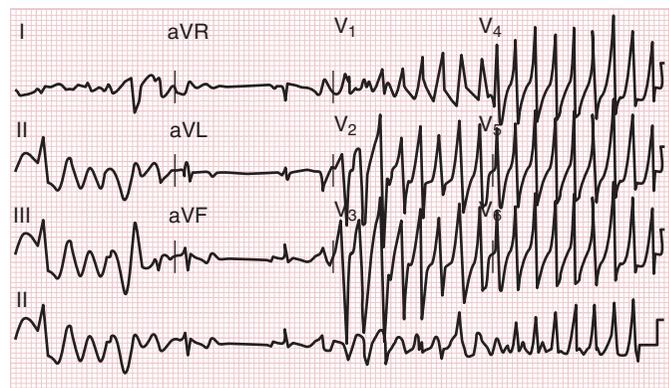

FIGURE 137-1. Torsades de pointes.

Overdoses of all three agents are accompanied by cardiovascular collapse and ventricular arrhythmias.

Extracardiac manifestations of quinidine toxicity include cinchonism, a syndrome consisting of tinnitus, vertigo, blurry vision with altered color perception, and confusion.⁷ Procainamide at therapeutic doses may cause hallucinations and anticholinergic side effects. Gastrointestinal side effects are common. Hypersensitivity reactions and blood dyscrasias, most commonly agranulocytosis, are commonly associated with quinidine. Fever may appear shortly after the initiation of a class IA medication, and may be accompanied by rash and eosinophilia. Both quinidine and procainamide are associated with the development of antinuclear antibodies and drug-induced systemic lupus erythematosus. Rarely, antiphospholipid antibodies may be associated with thrombosis.⁸

Because of the narrow therapeutic index of these agents, intoxication in a child may accompany the accidental ingestion of 1 pill. Therefore, decontamination with activated charcoal is indicated in all patients suspected of exposure, irrespective of symptoms. All patients should be admitted for observation.⁹ Hypokalemia and hypomagnesemia may provoke the development of torsades, and should be corrected. Intoxication with any of the class IA agents may present with dramatic, life-threatening torsades de pointes. Magnesium sulfate and sodium bicarbonate are the first-line treatment of drug-induced torsades.¹⁰ Their efficacy is multifactorial, altering intracellular potassium concentration and increasing protein binding of the drug. Treatment should be undertaken in patients with ventricular tachyarrhythmias. Magnesium may assist in preventing the early afterdepolarizations that are thought to initiate torsades.¹¹ Lidocaine has been recommended for the treatment of torsades, but should be undertaken, if at all, with caution, as it may be proarrhythmic (see the next section). Overdrive pacing has also been used successfully.¹²

Class 1B Drugs: Lidocaine, Tocainide, and Mexiletine

Lidocaine is the most commonly used drug among the class IB antiarrhythmic drugs, both as an antiarrhythmic and an analgesic. Intoxication, however, is relatively uncommon. Life-threatening events (LTEs) have been observed after the accidental administration of an intravenous overdose. More commonly, they are observed during the administration of

therapeutic doses in the context of impaired clearance, as in the case of congestive heart failure, or intravenous injection of a local anesthetic. LTEs are occasionally observed after the topical administration of analgesic jelly to a mucous membrane.

Although oral lidocaine is poorly bioavailable, oral intoxication has been reported.¹³ Mexiletine and tocainide are both well absorbed. All undergo extensive hepatic metabolism. The half-life of lidocaine is between 1.5 and 2 hours, but may be altered in the face of hepatic disease, circulatory disturbances, or heart failure.¹⁴ Therapeutic drug monitoring of lidocaine is widely available.

Central nervous system manifestations of lidocaine toxicity include dysarthria, tremors, seizures, respiratory depression, and coma.¹⁵ Similar toxicity has been reported with mexiletine and tocainide. Cardiovascular toxicity of class IB agents includes sinus bradycardia, conduction disturbances, heart block, and asystole.¹⁶ Arrhythmias may occur at therapeutic doses in patients with underlying rhythm disturbances. Ventricular tachycardia, ventricular fibrillation, and torsades de pointes have been observed. None of the class IB agents alters the QT interval or affects the QRS duration.

Management of class IB intoxication consists of discontinuation of the drug, and, in the case of ingestion of tocainide or mexiletine, decontamination of the bowel with activated charcoal. Stabilization of the comatose patient should be undertaken with endotracheal intubation and mechanical ventilation. Seizures may be treated with benzodiazepines or barbiturates. Symptomatic bradyarrhythmias necessitate cardiac pacing. Hypotension may be due both to cardiac depression and vasodilation, and should be treated with fluid administration and vasopressor agents, such as dopamine and epinephrine. Extracorporeal support may be considered in severe cases.¹⁷

Class IC Drugs: Flecainide, Encainide, and Propafenone

Poisoning with the class IC antiarrhythmic drugs, flecainide and encainide, has rarely been reported in childhood. An infant who ingested 1 pill of encainide was reported to have ventricular tachycardia.¹⁸ Seizures have been reported with flecainide toxicity.¹⁹ Decontamination of the potentially exposed child with activated charcoal is standard. Supportive management and therapy for arrhythmias and hypotension is the same as with class IA and IB agents. Extracorporeal membrane removal of the class IC drugs has been suggested for the seriously intoxicated patient.²⁰

Class II Drugs: β -Blockers

β -Blocking agents are widely used in children and adults to control hypertension and arrhythmias. Additionally, they are used in the management of congestive heart failure, cardiomyopathies, and (in adults) angina. Their common mechanism is the blockade of membrane β receptors, modulating calcium-mediated excitation-contraction. Clinical effects are expressed by the location of the receptor, and the affinity of the drug for it. Classically, two receptors exist; β_1 -receptors are located in the myocardium, kidney, and eye, while β_2 -receptors are found in smooth and skeletal muscle, pancreas, liver, and adipose tissue. Stimulation of the former receptors increases cardiac chronotropy and inotropy, while stimulation of the latter receptors relaxes smooth muscle in the

bronchial tree, uterus, and blood vessels. β -blockers may also have centrally mediated effects as well as membrane-stabilizing ability, which is apparent in overdose. Some have intrinsic sympathomimetic activity.²¹

β -Blocker toxicity manifests as decreased cardiac contractility and conduction delay. Sinus bradycardia is common in most ingestions, but may be absent in overdose of agents with partial agonist activity. QRS prolongation and conduction abnormalities may be present, especially in poisoning with propranolol. Hypotension, often profound, is secondary to negative inotropy. Paradoxical hypertension secondary to partial agonist activity may occur.

Depressed level of consciousness and seizures may occur, especially with propranolol overdose.²² Respiratory depression may be centrally mediated. Bronchospasm is common, especially in agents that are not β_1 selective. Patients with underlying reversible obstructive airway disease may experience worsening symptoms at therapeutic doses.²³ Hypoglycemia may occur in toxicity with nonselective agents such as atenolol and propranolol.²⁴

Overdose in children is relatively common. Despite its frequency, serious intoxication is rare. No case of fatal β -blocker intoxication in a child has been documented in the literature.²⁵ In a review of self-poisonings, all patients who developed toxicity did so within 6 hours of ingestion.²⁶ The seriously intoxicated patient may present a significant therapeutic challenge. Basic measures for the treatment of overdose should be undertaken, including decontamination with activated charcoal. Enhanced elimination techniques such as dialysis may be feasible for selected agents with a small volume of distribution and little protein binding. Seizures may be treated with conventional agents such as benzodiazepines and barbiturates. Hypoglycemia, if present, should be corrected. Respiratory failure may be treated with conventional supportive therapy, including mechanical ventilation and inhaled bronchodilators. Catecholamines have been a mainstay of therapy for β -blocker overdose, with variable results.²⁷ Isoproterenol, a pure β -agonist, is rational therapy but is not uniformly successful at restoring blood pressure. Epinephrine has been used in high doses, beginning at 1 mg/kg/min.²⁸ Optimal dosing should be determined by blood pressure and tissue perfusion. Dobutamine has not been well studied. Glucagon has been reported useful as a noncatecholamine inotrope with a mechanism unrelated to catecholamines, but has not been subjected to clinical trials. A review of the case literature reports a total of seven adult patients given between 1 and 80 mg of glucagon, all of whom survived.²⁹ If used, experts recommend a starting dose of 50 mcg/kg diluted and infused over 1–2 minutes \times 1–2 doses, then begin an infusion of 50 mcg/kg/min. The impact of glucagon on survival, however, has been questioned.³⁰ Atropine is safe, but rarely effective at improving the heart rate. The experience with amrinone in augmenting cardiac output is limited. Transvenous pacing may be attempted, but capture may not be possible.³¹

Class III Drugs: Sotalol and Amiodarone

Amiodarone and sotalol, class III antiarrhythmic drugs, are being used with increasing frequency in the pediatric setting. Amiodarone, in particular, has become more prominent in the management of arrhythmias refractory to other agents. All class III agents prolong the action potential without

affecting depolarization. These drugs may be proarrhythmic and should be used in the context of defined indications.^{32,33} Amiodarone acts by inhibiting the slow outward current of potassium, delaying intraventricular conduction and reducing cardiac automaticity. Significant childhood poisoning has been rarely reported. Overdose of both class III drugs has generally been accompanied by an exaggeration of the primary effects. Massive overdose has been accompanied by bradycardia, hypotension, and cardiovascular collapse.³⁴ The level of consciousness may be unimpaired in the absence of symptomatic bradycardia. The electrocardiogram generally shows bradycardia and, rarely, heart block or QT interval prolongation. Prolongation of the PR interval is considered a therapeutic and not a toxic effect. Symptoms are related to the plasma level and generally disappear within 12 hours. Torsades de pointes has been described as occurring with both drugs,^{35,36} and has been successfully treated with lidocaine. Hypotension is associated with amiodarone administration and is generally the result of rapid intravenous administration. The hypotension is attributed to the benzyl alcohol additive. Oral amiodarone has no hypotensive effect.

Chronic amiodarone administration is associated with multiple problems. In children followed during amiodarone therapy for an average of 1.5 years, toxicity was reported in 29%. Complaints included cataracts, thyroid abnormalities, pulmonary fibrosis, hypertension, rash, peripheral neuropathy, and vomiting. Skeletal dysplasia has been reported, but its significance may have been overestimated.³⁷ These problems resolved with reduction of the dose or cessation of the drug. Emergency physicians should be aware of the possible relationship of these complaints to the administration of amiodarone.

Acute intoxication with a class III antiarrhythmic agent rarely presents with life-threatening problems. Activated charcoal significantly reduces the bioavailability of both amiodarone and sotalol. Cholestyramine may shorten the half-life of amiodarone by interrupting its enterohepatic circulation.³⁴ An unstable rhythm such as profound bradycardia, attributed to amiodarone, may be treated with the cautious administration of magnesium or potassium. Lidocaine may be helpful in the therapy of torsades de pointes. The treatment of hypotension during intravenous administration of amiodarone is supportive. Class IA agents are contraindicated.

Class IV Drugs: Calcium Channel Blockers

Calcium channel–blocking agents are a chemically diverse group of drugs used in the treatment of hypertension and arrhythmias. Verapamil, diltiazem, and nifedipine are three of the most commonly prescribed and have different structures. They act by inhibiting calcium flux through low-voltage channels in cardiac and smooth muscle, as well as pacemaker cells in the sinoatrial and atrioventricular nodes. Therefore, all share the properties of vasodilation, myocardial depression, and slowed atrioventricular nodal conduction. Each, however, has characteristics that render one effect more prominent than others. None of the currently available agents has a demonstrated effect on skeletal muscle. They are poorly bioavailable and undergo principally hepatic metabolism, and drugs that inhibit hepatic cytochromes may increase calcium channel blocker bioavailability and potentiate toxicity.³⁸ Many are marketed in sustained-release preparations.

In childhood, they are used in the management of hypertension and the control of supraventricular tachycardia. In adults, they are used additionally in the management of angina.

Poisoning in childhood is relatively common. In 2003, the American Association of Poison Control Centers reported 9650 exposures, 57 of which resulted in death.¹ Little agreement exists on the toxic dose or time to onset of symptoms. As these drugs are intended to lower blood pressure, it would be expected that symptoms might occur at or near the therapeutic dose. In a recent review of calcium channel blocker poisoning in children, the majority of symptomatic children ingested doses at or near what might be considered the therapeutic range.³⁹ Symptoms generally develop within 5 hours of ingestion, but may be delayed as long as 15 hours in the event of the ingestion of a sustained-release product. Their effects are additive with other antihypertensive agents, and may be aggravated by hypovolemia, as may occur with concurrent diuretic administration, or a concurrent disease such as gastroenteritis.

Symptoms of intoxication consist of an exaggeration of the effects of the drug. Cardiovascular collapse with hypotension, which may be profound, and bradycardia resistant to conventional therapy may occur. Noncardiogenic pulmonary edema has been reported.⁴⁰ Lethargy, nausea, and vomiting have been observed, but severe central nervous system depression is usually present only in the context of cardiovascular collapse. Electrolyte abnormalities are not generally present. Metabolic acidosis is observed as a consequence of low cardiac output, and, if severe or unremitting, carries a poor prognosis.

Therapy for the child who has ingested a calcium channel blocker is largely supportive. One study suggests that children who ingest less than 12 mg/kg of verapamil or 2.7 mg/kg of nifedipine may be monitored at home.³⁹ The same study indicates that children who are asymptomatic 3 hours after ingestion of a regular-release product or 14 hours after ingestion of a sustained-release product may be discharged. Activated charcoal has been advocated for all patients, but gastric lavage and emesis should be undertaken with caution, if at all, as the resulting vagal maneuver may worsen preexisting bradycardia. Multiple doses of activated charcoal should be considered in the patient who has ingested a sustained-release preparation. Correction of hypovolemia should be a priority. Calcium salts have been advocated as specific therapy, although reports of benefit are conflicting.⁴¹ Administration of calcium salts to maintain at least normal calcium is reasonable. Alternately, administer calcium gluconate at 20–40 mg/kg (0.2–0.4 ml/kg of 10% solution) IV over 5 minutes, with an infusion of 20–40 mg/kg/hr if there is a favorable response. Care should be undertaken to avoid extravasations of peripherally administered calcium, and monitor carefully its serum concentration, especially in the context of concurrent digoxin administration. Insulin and glucagon have both been recommended for calcium channel blocker overdose. The latter is thought to directly affect myocardial contractility. If used, administer a regular insulin bolus of 1.0 U/kg, followed by an infusion of 1.0 U/kg/hr for the first hour, then 0.5 U/kg/hr until toxicity resolves. At the same time a 0.5 g/kg bolus of glucose is administered with an additional 0.5 g/kg/hr until insulin is discontinued. Frequent monitoring of glucose (hourly during treatment and hourly until 6 hours after treatment) and potassium is required with this regimen.

Supportive care of the child with a calcium channel blocker intoxication is challenging. Many strategies have been advocated with varying success. Fluid replacement should be undertaken with caution to avoid pulmonary edema. Inotropic support with dopamine, epinephrine, or norepinephrine may be required; however, myocardium and vascular smooth muscle may be resistant to conventional doses. No consensus exists regarding the superiority of one drug over another. Amrinone in conjunction with glucagon was reported successful in treating one patient with refractory hypertension secondary to verapamil overdose.⁴² No controlled studies have been published to date suggesting their routine use. Atropine may be administered for appropriate arrhythmias, although its benefit is unproven. Cardiac pacing may be undertaken for bradyarrhythmias resistant to therapy.⁴³ Both intra-aortic balloon counterpulsation and cardiopulmonary bypass have been reported as successful in restoring hemodynamic stability.⁴⁴ A retrospective study of patients with symptomatic calcium channel blocker overdose reported that both calcium and dopamine were effective in restoring blood pressure and cardiac rhythm to all patients who received them.⁴⁵

Antihypertensives

Clonidine

Clonidine is a centrally acting antihypertensive agent. Its mechanism of action is the stimulation of central α receptors. It has no peripheral α receptor activity. It is widely used in the treatment of hypertension, and is useful in the management of narcotic withdrawal. Its widespread use makes it a frequent source of pediatric poisonings. α -Methyldopa, another clinically useful centrally acting antihypertensive, is far more infrequently prescribed and is therefore uncommonly accidentally ingested.

Clonidine therapy in adults is commonly initiated at a dose of 0.1 mg, and 1 tablet may be sufficient to cause symptoms in a small child. Overdose may occur when a small child has access to the pills of a parent or caregiver, or as the result of an intentional overdose in an older child. Symptomatic clonidine overdose presents as bradycardia, hypotension, lethargy, coma, and miosis. Respiratory depression sufficient to require mechanical ventilation is common in severely intoxicated patients. Hypotension may be modest or absent, but may occasionally require therapy. A large review of 10,060 clonidine exposures reported to the American Association of Poison Control Centers revealed that 60% of the patients were symptomatic, lethargy being the most common symptom (80%).⁴⁶ Bradycardia, hypotension, and respiratory depression were each observed, in decreasing frequency.

Basic management of clonidine poisoning includes decontamination with activated charcoal. Airway protection and mechanical ventilation are needed in the unconscious or severely lethargic patient. Hypothermia may be corrected with surface warming. Hypotension is usually responsive to fluid administration. Occasionally, vasopressor agents may be indicated. As the mechanism of clonidine resembles that of opioid (narcotic) agonists, naloxone has occasionally been recommended.⁴⁷ It may be diagnostically useful, but supportive measures will frequently be satisfactory until the drug is eliminated. Tolazoline, an α -adrenergic antagonist,

has been considered as theoretically useful⁴⁸ but has also failed to be of benefit in individual case reports.⁴⁹ The outcome of conservatively managed clonidine overdose is generally good, and death is rare.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors are among the most commonly prescribed drugs in the management of hypertension and congestive heart failure in adults, and are frequently used in combination with other agents such as β -blockers and centrally acting agents. Captopril and enalapril are commonly used in children for these indications. Symptomatic hypotension is rare, but acute overdose may be accompanied by profound and prolonged hypotension.⁵⁰ ACE inhibitors reduce systemic vascular resistance, but may induce renal insufficiency.⁵¹ Hyperkalemia has been observed at therapeutic doses, and renal insufficiency may occur as a consequence of ACE inhibition.⁵² The emergency physician should be mindful of the possibility that preexisting disease and concurrent therapy in the patient prescribed an ACE inhibitor may compound the risk for renal insufficiency and hyperkalemia.⁵³

Hypotension in the patient who has acutely ingested an ACE inhibitor is frequently responsive to fluid administration. Vasopressors are occasionally required.⁵⁴ Hypotension encountered in the patient who is using an ACE inhibitor for therapeutic purposes is similarly managed, keeping in mind that symptoms of congestive heart failure may be worsened in doing so. Hyperkalemia and renal insufficiency should be addressed with the appropriate laboratory studies and acute interventions. There is no accepted antidotal therapy.

Vasodilators

Oral vasodilators are less commonly prescribed in the management of hypertension in children and adults, and, therefore, infrequently seen as causes of pediatric poisonings. Hydralazine overdose has only been reported in the adult literature. Hypotension is the predominant symptom, but electrocardiographic changes suggestive of ischemia are also described.⁵⁵ There is no consensus on therapy, but the aforementioned patient, who was additionally ethanol intoxicated, responded to conservative management. Hydralazine has been implicated in drug-induced lupus, which is characterized by arthralgia, myalgia, pleurisy, rashes, fever, and a positive antinuclear antibody screen. Procainamide, and to a lesser extent β -blockers, methyldopa, quinidine, and numerous other drugs, have also been implicated.⁵⁶ Recognition by the emergency physician is important, as resolution of the syndrome occurs within a few weeks of discontinuation of the drug.

Nitrates are used in the management of angina, congestive heart failure, and hypertension in adults. Children who have ingested an oral nitrate preparation may present with flushing, headache, tachycardia, and hypotension resulting in syncope. As the effect is short lived, the symptomatic patient may improve prior to arrival in the ED. Management is similar to that of other vasodilators. In addition to inadvertent overdose, the nitrates are also drugs of abuse (see Chapter 135, Drugs of Abuse). Methemoglobinemia and hemolytic anemia have been reported.^{57,58} The intoxicated patient presents with cyanosis and acidosis, but normal external oxygen

tension. Diagnosis is confirmed by the demonstration of an elevated methemoglobin concentration by co-oximetry. Hereditary deficiency in the enzyme glucose-6-phosphate dehydrogenase may predispose the individual to this occurrence. Limited experience with nitrite-induced methemoglobinemia suggests that it responds to the administration of methylene blue in a manner similar to other etiologies⁵⁹ (see Chapter 133, Common Pediatric Overdoses).

Nitroprusside is widely used in the management of a hypertensive emergency. Chronic complications include methemoglobinemia and hemolytic anemia, which are not encountered in the acute overdose, and are unlikely to be seen in the emergency management of children. The degradation of nitroprusside releases cyanide, which is once again rarely problematic in the ED. Thiocyanate is formed with the degradation of nitroprusside after administration. Levels are of no use in predicting nitroprusside toxicity. Hypotension is treated by decreasing or discontinuing the medication, which has a half-life of minutes.⁶⁰

Minoxidil is a potent vasodilator prescribed for the treatment of severe hypertension. It is rarely used in childhood. Hirsutism is a side effect that accompanies its chronic use and, it has been marketed as an over-the-counter drug intended for topical use. Overdose in childhood has rarely been observed, but intentional ingestion of the hair treatment by an adult produced severe hypotension and tachycardia that required massive fluid administration, vasopressor support, and mechanical ventilation.⁶¹

Diuretics

Diuretics are widely used in both children and adults in the management of hypertension and congestive heart failure. Their availability makes them frequently seen in accidental overdose. Additionally, the emergency physician may be called upon to evaluate a child with a preexisting illness for which diuretic therapy has been undertaken.

Diuretics are commonly classified as either potassium wasting or potassium sparing. The former consist of the potent loop diuretics, including furosemide and ethacrynic acid, and the thiazide diuretics. Potassium wasting is commonplace, and secondary metabolic alkalosis is frequently seen as a consequence of attendant urinary hydrogen ion excretion. Calciuria also occurs with the loop agents, but hypocalcemia is rarely a problem in the acute setting. Potassium-sparing agents include the aldosterone antagonist spironolactone, and acetazolamide, a carbonic anhydrase inhibitor. As their classification implies, therapeutic use of these drugs is not accompanied by hypokalemia.

The child with acute overdose is rarely a therapeutic challenge. Ingestion of loop diuretics and thiazides present more acute problems than do the potassium-sparing agents. Dehydration may occasionally be seen, as well as electrolyte disturbances. Hyponatremia is generally mild. Hypokalemia may be present after an acute ingestion, but is more common with chronic therapeutic use. Appropriate fluid and electrolyte replacement should be undertaken.⁶²

Chronic complications of diuretic use include hypokalemia, severe metabolic alkalosis, and, with loop diuretic use, hypocalcemia. Occasionally tetany may be seen, requiring the cautious administration of intravenous calcium (see Chapter 115, Hypocalcemia). Seizures and hypocalcemic prolongation of the QT interval are rarely seen.⁶³ Chronic use

of loop diuretics is associated with pancreatitis.⁶⁴ Renal insufficiency may be worsened by diuretic therapy when administered concurrently with an ACE inhibitor.⁶⁵ Caution should be undertaken in the fluid replacement of a child who presents with diuretic-induced dehydration, renal insufficiency, and the concurrent use of a loop diuretic and potassium-sparing agent.

Acetazolamide is infrequently used as a diuretic, but more commonly prescribed in the control of intraocular pressure and pseudotumor cerebri. Acetazolamide toxicity may present with significant metabolic acidosis, manifesting as lethargy and Kussmaul's respirations. A toddler reported to have ingested 10 g of acetazolamide recovered completely with the administration of sodium bicarbonate.⁶⁶

Digoxin

Digoxin is a member of a group of glycosides derived from the foxglove plant and increases cardiac contractility and automaticity. Digoxin and digitoxin are the sole agents currently in use. Therefore, they are still widely used in the management of congestive heart failure and arrhythmias in both children and adults. They have a narrow therapeutic index, and poisoning is common both in the setting of clinical use and in accidental ingestion. Cardiac glycosides are found in many common decorative plants such as yellow oleander, and accidental ingestion presents with symptoms similar to digitalis poisoning. Because of its prolonged kinetics, digoxin therapy is frequently initiated by a loading dose, commonly 35 to 50 mcg/kg, given in divided doses over several days, followed by maintenance therapy of 7 to 10 mcg/kg/dose every 12 hours. The dose is adjusted in the face of renal insufficiency.

Digoxin has a large volume of distribution, being concentrated in the muscle mass. Bioavailability after oral ingestion is variable, depending substantially on the manufacturer. For that reason Lanoxin is the most widely prescribed agent, in which nearly 90% of an oral dose is absorbed. Onset of effect is between 1.5 and 6 hours. It is slowly excreted intact by the kidneys. A decrease in renal function or significant dehydration may provoke digoxin intoxication in the patient who has previously been safely taking a given dose. In this setting, peritoneal dialysis may be useful in addition to the other measures undertaken to treat digitalis intoxication.⁶⁷ Digoxin impairs the Na⁺/K⁺ membrane pump, increasing intracellular sodium and impairing Na⁺-Ca²⁺-dependent egress of calcium from the cell, thereby enhancing contractility. The transmembrane potential is raised, increasing automaticity. Digoxin also increases cardiac vagal tone, slowing the heart rate and delaying atrioventricular nodal conduction. As digoxin's effect is dependent on its membrane-bound fraction, serum digoxin levels, although widely available, are poor prognostic indicators for the development of digitoxicity.⁶⁸ Intracellular electrolytes, although not widely available, may be a sensitive indicator of the risk for digitoxicity.⁶⁹ Therapeutic drug monitoring may be more useful in specific settings, such as the management of congestive heart failure in a patient with renal impairment. Elevated digoxin levels in the correct clinical setting may be of assistance in establishing the diagnosis of digitoxicity, but too great an overlap exists between therapeutic and toxic levels to use the digoxin level as a sole index of toxicity.⁷⁰

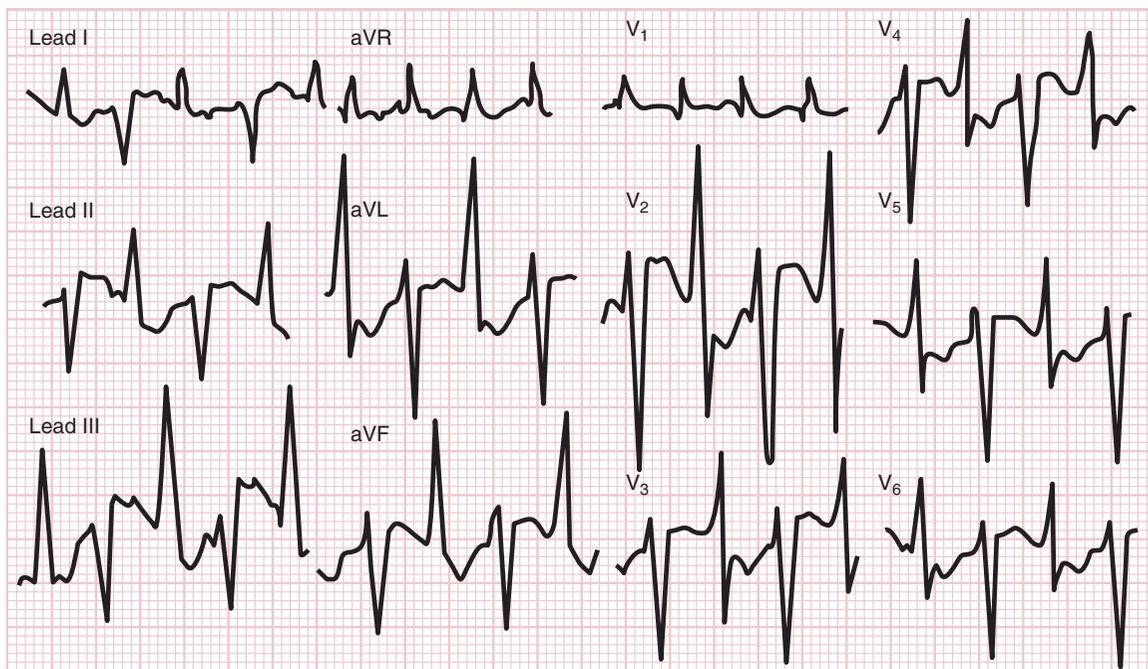

FIGURE 137-2. Bidirectional ventricular tachycardia.

Acute digoxin poisoning presents with vomiting, bradycardia, and arrhythmias, frequently heart block and bradycardia, although virtually any cardiac rhythm disturbance may be attributed to digitalis poisoning. Hyperkalemia is frequently observed and may be life threatening. Chronic digoxin poisoning may present with an array of bizarre complaints, including vomiting, anorexia, weakness, altered mental status, and visual disturbances such as altered color perception. Cardiac manifestations of poisoning include ventricular arrhythmias, heart block, and nodal escape rhythms. Rhythm disturbances commonly manifest some form of myocardial irritability with delayed conduction. Bidirectional ventricular tachycardia is thought to be particularly characteristic of digitalis poisoning⁷¹ (Fig. 137-2).

Emesis is not recommended in digoxin poisoning, as it may increase vagal tone, exacerbating bradycardia. Activated charcoal binds digoxin well, and should be given. Multiple-dose activated charcoal is not clearly beneficial.⁷² There are no data on the efficacy of catharsis. Dialysis is of no benefit.

The development of digoxin-specific antibody fragments (Fab) has significantly altered the management of digoxin poisoning. Administration rapidly reverses bradycardia, arrhythmias, and hyperkalemia associated with digoxin poisoning and related, naturally occurring, cardiac glycosides.^{73,74} It is effective in the treatment of poisoning due to digoxin, digitoxin, and congeners, as well as the naturally occurring glycosides.⁷⁵ Fab should be given to patients with any dysrhythmia causing hemodynamic compromise or with a serum potassium level greater than 10 mEq/L.⁷⁶ It should be given after ingestion of more than 4 mg in a child without underlying disease, and may be given intravenously or by the intraosseous route. The amount administered may be determined by the following formula if the dose taken is known⁷⁷:

$$\text{Number of Fab vials (38 mg/vial)} = \frac{\text{amount ingested (mg)}}{0.48 \text{ (mg neutralized/vial)}}$$

If the dose is unknown, the amount given may be determined by the steady state serum digoxin concentration 6 hours after the ingestion:

$$\text{Number of Fab vials} = \frac{\text{serum digoxin level (ng/ml)}}{\text{body weight (kg)/100}}$$

Fab is also useful in the treatment of chronic digoxin intoxication. The previous equation may be used, obtaining the steady state concentration. If the dose ingested is unknown, 5 vials may be given to a child, 10 to 20 vials to an acutely intoxicated adult, or 10 vials to an adult with chronic toxicity.

Atropine is useful as an antidote and is indicated for severe bradycardia. Phenytoin and lidocaine were both previously considered primary therapy for the treatment of ventricular dysrhythmias, and may still be useful in the absence of Fab, or as adjunctive therapy.⁷⁸ Amiodarone has been reported to be of assistance in the conversion of ventricular fibrillation.⁷⁹ Magnesium has occasionally been reported to be of assistance in the conversion of ventricular arrhythmias attendant to chronic digitalis poisoning.

Miscellaneous Agents

Amrinone and Milrinone

Amrinone and milrinone are bipyridine derivatives useful in the management of congestive heart failure, and have both inotropic and vasodilator properties. Although commonly used in inpatient settings for the management of shock and low cardiac output postoperative states, they are also used in the outpatient setting and may rarely present as an overdose. Oral overdose is usually well tolerated. Amrinone is associated with thrombocytopenia. Milrinone, which is not associated with this adverse effect, is more commonly prescribed.

Administration of milrinone has been rarely associated with hypotension. Vasopressor support and fluid administration may rarely be required. One fatality was reported after a massive intravenous overdose,⁸⁰ manifesting as hypotension unresponsive to fluid administration and vasopressors. Peritoneal dialysis was ineffective. An adult who had tachycardia attributed to milrinone was successfully treated with β -blockers.⁸¹

Adenosine

Adenosine is useful in the conversion of supraventricular tachyarrhythmias sustained by atrioventricular reentry by prolonging atrioventricular nodal conduction time. In a large series of cardioversions, 72% of patients with presumed supraventricular tachycardia were successfully converted.⁸² The half-life of adenosine is short, limited to a single pass through the circulation. It is therefore administered by rapid intravenous injection. The usual dose is 0.1 mg/kg. Repeated administration may be undertaken, with incremental increases of 0.05 mg/kg, to a dose of 0.2 mg/kg or until an effect is observed. In another study, 96% of children were successfully converted, but recurrent tachycardia and other significant complications, including atrial fibrillation, accelerated ventricular tachycardia, apnea, and asystole, occurred.⁸³ Continuous monitoring and equipment should be available in this event. Prolonged heart block and ventricular fibrillation may be encountered in the setting of administration of adenosine with digoxin, calcium channel blockers, or class IA antiarrhythmics.^{84,85} Adenosine can cause cardiac arrest in de-innervated hearts (post-transplant), high degree heart block in patients who already have second degree heart block or who are on carbamazepine, and bronchospasm in asthmatics (especially if they are taking theophylline preparations).

Summary

Complications of cardiac drugs are fortunately infrequent. When they do occur, they are frequently managed in the ED. The principles of management revolve around attention to basic hemodynamic stabilization, followed by specific therapy based on knowledge of the drug. Correction of hypotension, restoration of a stable rhythm, attention to fluid and electrolyte balance, and support of ventilation will optimize therapy directed toward an individual agent.

Near Drowning and Submersion Injuries

T. Kent Denmark, MD and Steven C. Rogers, MD

Key Points

The literature predicting outcome of submersion injury is contradictory.

Rare, evidence-based, guideline-defying recoveries occur.

Technological advances have not affected outcomes.

Patients who remain asymptomatic for 4 to 6 hours may be discharged home.

Introduction and Background

While more common in temperate climates, submersion injuries and drowning will be encountered and managed by every emergency physician at some point during his or her career. Drowning deaths occur throughout the United States, in decreasing order, from the South, West, Midwest, and Mid-Atlantic to New England.¹ Drowning is the second leading cause of injurious deaths in children 1 to 14 years of age. The Centers for Disease Control estimates that over 2000 children less than 4 years of age seek medical attention for near drowning per year. In addition, 1000 children ages 5 to 14 years, and approximately 900 adolescents, will also be treated for near drowning.² The most dangerous water exposures occur with children less than 4 years of age in either pools or bathtubs.³⁻⁵ In contrast to the exploratory behavior of children, adolescents who have submersion injuries or drown are usually intoxicated and swimming at lakes or rivers.⁶ Adolescent incidents tend to occur while swimming or boating and are usually witnessed.³ There is an additional sense of tragedy when these cases are encountered in the emergency department (ED) because drowning is one of the most preventable causes of morbidity and mortality.

Drowning and submersion injuries continue to occur in large part due to lack of recognition of the danger on the part of parents and caregivers. A study of parental beliefs and practices regarding home safety showed that the potential

injury severity and extent of effort required to implement the safety practices determined which precautions were undertaken.⁷ Parents simply do not believe their particular child is at risk, and their assumptions about the inherent safety of an above-ground pool are inaccurate.⁷ Partial preventative efforts may not be enough to prevent submersion or drowning from occurring. For example, two thirds of 4-year-olds can scale a smooth 48-inch barrier in less than 2 minutes.⁸ Appreciation of this information may enable emergency physicians to serve as an important resource for home safety education.⁹

One of the most distressing decisions in managing a patient who has drowned is the decision to discontinue the resuscitation. While clinical guidelines exist, several cases have been reported in the medical literature and in the popular media that defy these guidelines. First documented by Kvittingen in 1963, there are several reports of “near drownings” in patients who fully recovered from significant submersion events of up to 66 minutes.^{10,11} Therefore, family members’ expectations of resuscitation outcome may be inaccurate and overly optimistic. The media have contributed to these beliefs by focusing on the dichotomous outcomes from arrest while completely ignoring the severe neurologic impairment that may result from a significant cardiopulmonary arrest.¹² The reality is that hospitalized near-drowning victims in the United States have a high case fatality rate (~25%) and high rate of subsequent sequelae (10%).⁴ This is consistent with a comprehensive study in the British Isles that found that greater than one third of admitted patients either expired or had residual neurologic deficits following a near-drowning incident.¹³ Therefore, the treating physician should be mindful of these faulty beliefs when informing the family about management decisions. In spite of an increase in understanding of the pathophysiology of submersion injuries and advances in therapy, the mortality has not significantly decreased, but the number of neurologically impaired children who survive may be increasing.^{4,14,15}

Recognition and Approach

The physiologic response to submersion has been studied extensively. The initial response to a cold water submersion is tachypnea, tachycardia, and hypertension for 1 to 2 minutes

followed by apnea 3 minutes after submersion and finally hypotension and asystole between 6 and 8 minutes postsubmersion.¹⁶⁻¹⁸ Either electroencephalographic silence or seizure activity occurs with hypotension prior to asystole.¹⁸ The rapidity of significant physiologic changes in submersion victims underscores the necessity of supervisory vigilance and prevention.

Some children survive prolonged submersions, and a number of explanations for this phenomenon have been offered. The diving reflex, defined as apnea, generalized marked peripheral vasoconstriction, and bradycardia, is well described in marine mammals and has been generally accepted as the mechanism for survival.¹⁹ However, given that breath-holding duration is decreased by 25% upon rapid exposure to water colder than 15° C, the theory of the diving reflex as an explanation for remarkable recoveries is questionable.^{17,20} In addition, it has been proven that, even with the greater body surface area of infants, surface cooling does not occur quickly enough to be cerebroprotective.²¹⁻²³ Hypothermia is only protective if the central nervous system (CNS) temperature drops by greater than 7° C in 10 minutes.²⁴ Aspiration of cold water causes rapid cooling when compared to submersion.¹⁶

Dog studies have shown that rapid, involuntary respirations occur following submersion for a little more than a minute.²⁵ Extremely rapid core cooling can occur within 2 minutes of submersion when cold water is aspirated, leading to rapid core cooling to protective levels, which occurs about 1 minute before cardiac arrest.^{16,18} Microaspiration with initial tachypnea will cause rapid cooling of circulation, which is preferentially shunted to the CNS.¹⁹ Animals resuscitated with cold solutions following 20 minutes of arrest have good functional recovery compared those resuscitated with room-temperature fluids.²⁶ Pulmonary vasoconstriction and pulmonary hypertension following aspiration are attenuated when cold fluid is aspirated.²⁷ This may help explain the miraculous cases of full recovery from extended submersions.

Studies of military and competitive swimmers show that even body-only immersion increases cardiac preload and pulmonary arterial pressure from peripheral vasoconstriction.²⁸ Subsequently, ventilation-perfusion (V/Q) mismatch, hypoxemia, and pulmonary vasoconstriction will lead to a decrease in functional residual capacity.²⁸ This clinically manifests itself as tachypnea to compensate for inefficient gas exchange. Swimming-induced pulmonary edema occurs in about 2% of healthy competitive swimmers and presents with dyspnea, cough, and hemoptysis.²⁹ The effects may still be detected on pulmonary function tests for up to a week.²⁹ Patients who are actually submerged have more extensive sequelae. Surfactant loss or inactivation decreases pulmonary compliance, and there may be significant V/Q mismatch, with 75% of blood flow to nonventilated areas.^{30,31}

Clinical Presentation

In most cases, the history of submersion is known or apparent as relayed by rescue personnel, parents, or bystanders. History can be especially helpful in a witnessed event when trying to differentiate between primary submersion injury and an event secondary to another process such as seizure or arrhythmia. While seizures can occur from anoxia, seizure

activity prior to submersion or in a patient with a history of epilepsy should raise concern for a primary neurologic process.¹⁸ Patients with a history of seizures or epilepsy have a 10-fold increased risk for drowning.³² Typical epileptic submersion victims are older than 5 years of age and in the bathtub, although children and adolescents with epilepsy are also at increased risk of drowning in pools.³² Patients with a known seizure disorder should never be left unattended near water. In particular, patients with a history of febrile seizures should not be left unattended while receiving “cooling measures” in the bathtub.

Complaints of palpitations prior to submersion or a history of arrhythmia should prompt a more thorough cardiac investigation. In teenagers, a significant percentage of submersion injuries involve alcohol or other drugs.^{6,15} This potentially complicates mental status assessment and evaluation for associated trauma. A serum alcohol level and urine drug screen should be obtained in all adolescents with submersion injury to aid in management decisions. Cervical spine injuries in adolescents do not occur without a significant mechanism; the routine activation of the trauma team without a suspicious mechanism (such as diving or submersion in ocean surf) is not useful, nor are routine cervical spine radiographs in nontraumatic submersions.³³

A subpopulation at high risk for associated traumatic injuries are those patients who are submersed in bathtubs. In a landmark study, two thirds of bathtub drownings seen at one facility over a 10-year period had historical findings consistent with neglect and one third had physical findings of child abuse.³⁴ In this population, 49% either expired or had significant neurologic sequelae.³⁴ It is therefore prudent to have concern for abuse and/or neglect in these patients.

Chest radiographs do not predict disposition or clinical course.^{35,36} Specifically, the presence or absence of radiographic findings does not correlate with clinical findings, pulse oximetry, or length of oxygen requirement and is not useful. Although electrolyte disturbances do occur, the presence of an abnormality does not automatically necessitate hospitalization, and should not alter initial fluid resuscitation. Similarly, the initial pH is not prognostic in predicting morbidity or mortality, so that routinely obtaining blood gases in submersion patients is not beneficial.^{35,36} However, patients who have been intubated should be monitored appropriately, including regular evaluation of arterial blood gases and electrolytes.

Management

Immediate airway management and initiation of CPR are unequivocally the most effective interventions for the submersion victim (Table 138-1). Bystander cardiopulmonary resuscitation (CPR) has been shown to significantly affect patient survival, and even rescue breathing or cardiac compressions alone are superior to no intervention.³⁷⁻³⁹

All patients should be transported to the hospital for evaluation. Basic life support protocols and standard trauma protocols must be followed, including cervical spine immobilization when there is a history suggestive of an injury or suspicion of a traumatic mechanism.³³ Wet clothing should be removed to minimize heat loss. Airway protection must be a high priority due to the high frequency of vomiting (up to 86%) with chest compressions.⁴⁰ Early placement of a

Table 138–1 Clinical Pearls and Pitfalls**Pearls**

- “Just do something”: chest compressions and assisted ventilation improve outcome in asphyxial arrest.³⁷
- Cardiopulmonary resuscitation prior to Emergency Medical Services arrival is associated with significantly better neurologic outcome.^{38,39,69}

Pitfalls

- Ending a resuscitation too soon risks an inadequate chance for return of spontaneous circulation in very cold water submersions.⁵⁵⁻⁵⁷
- Continuing resuscitation too long creates neurologically devastated survivors.⁴
- Decrease in core temperature during rewarming is not necessarily a sign of inadequate therapy.⁴⁵
- Pulse oximetry does not always correlate with hypoxemia in severe hypothermia.⁴⁴

nasogastric tube to decompress the stomach will decrease the risk of vomiting in patients who have received rescue breaths. Early tracheal intubation is recommended for airway protection, to ensure removal of any foreign material from the airway, and to institute continuous positive airway pressure or positive end-expiratory pressure as needed for respiratory failure.⁴⁰ Once the airway is controlled, hypoxia and acidosis are better tolerated than hypoxia and hypotension. Permissive hypercapnia is preferable to avoid hypotension secondary to high mean airway pressures, which impede preload.⁴¹

No literature specifically addresses the use of bronchodilators for wheezing in a submersion victim. A reasonable approach is a one-time trial of bronchodilator therapy, with repeated treatments for the patients who improve clinically. In patients with a history of reactive airways disease or asthma, bronchodilators should be considered beneficial despite a dearth of evidence to support this recommendation.

Pediatric submersion victims are frequently hypothermic upon arrival to the ED. Due to significant peripheral vasoconstriction, rectal temperature lags behind true core temperature.^{16,18} Jugular bulb temperature reflects body temperature, not true CNS temperature, but determining true CNS temperature is impossible without invasive monitoring.⁴² An exaggerated response to warming occurs, making hyperthermia after resuscitation common.⁴³ When monitoring the hypothermic patient, the clinician should remember that pulse oximetry is not reliable under 27° C.⁴⁴

“Afterdrop” is a phenomenon that occurs during rewarming when a patient experiences a drop in core temperature secondary to mobilization of cold blood from the peripheral circulation. Afterdrop has been associated with sudden death in otherwise intact hypothermia survivors.⁴⁵ Care must be taken not to be overly aggressive during the rewarming process. Rewarming with forced air (Bair Hugger) can increase temperature at a safe rate of 1.7° C/hr.⁴⁶ This method requires circulation to be effective. In cases of severe hypothermia or cardiac arrest, extracorporeal rewarming may be beneficial.¹¹ This technique has been available outside the surgical suite since 1993.⁴⁷ Extracorporeal rewarming has a 50% intact survival rate for adults with severe accidental nonsubmersion hypothermia but presents obvious logistic difficulties for ED care.⁴⁸

Alternatively, therapeutic hypothermia is potentially beneficial and neuroprotective for submersion victims.^{49,50} The

stipulation is that the hypothermia must occur within 7 minutes of hypoxemia to be beneficial.²⁴ However, hypothermia can also decrease peripheral circulation and may inhibit adequate distribution of rescue medications. Caution must be exercised to not overmedicate based on lack of effect at time of administration in patients with compromised circulation or peripheral vasoconstriction.

Multiple secondary therapeutic interventions have been investigated. High-dose barbiturate therapy has been shown to help control intracranial pressure (ICP), but neither barbiturate therapy nor ICP monitoring appears to improve neurologic outcome.^{40,51} Prophylactic steroids and antibiotics have been studied extensively and do not increase the odds of survival⁵² (see Chapter 9, Cerebral Resuscitation).

Patients who are initially hypothermic must be continually monitored to gauge the success of intervention and to guard against hyperthermia. An initial decrease in temperature as a result of afterdrop is not uncommon and should not be equated with inadequate rewarming.⁴⁵ During rewarming from profound hypothermia, care must be taken so that rewarming does not occur too quickly and precipitate arrhythmias. Overly rapid rewarming also leads to hypotension from peripheral vasodilation, hypoxemia, and sinus bradycardia.⁵³

Aspiration, whether of gastric contents or from the body of water, is a risk in any patient with an altered level of consciousness (Table 138–2). Tachypnea secondary to the pulmonary effects of submersion and the possibility that some rescuers will perform the Heimlich maneuver increases the odds of an aspiration.

Awake, alert patients who are asymptomatic after 4 to 6 hours of observation may be safely discharged home.^{35,36} Historically, there have been reports of “secondary drowning” in otherwise normal-appearing patients, but similar cases have not been seen in subsequent research. Upon review, such cases were not clinically subtle or suitable for discharge.⁵⁴

Patients who are clinically symptomatic after 6 hours require inpatient care in a monitored bed. The emergency physician should communicate early with pediatric intensivists and/or referral centers for children with persistent symptoms or severe initial condition to arrange for admission or transport to a capable facility. Bathtub drownings or other cases suspicious for nonaccidental injury or neglect should be evaluated in conjunction with social work and law enforcement in accordance with local protocols. As noted earlier, maintaining high concern for abuse and/or neglect is the key to identifying these cases.

When a patient has a clear traumatic mechanism of injury associated with submersion, surgical consultants should be involved in evaluation and management. Other subspecialty services should be consulted as needed for patients with identifiable predisposing factors such as seizures or arrhythmias. If possible, the emergency physician should contact the patients' primary care physician to identify any unknown history and to arrange for adequate follow-up or ongoing care of more severe patients. The primary care physician may also be helpful in assisting the family in making important decisions about termination of life support when neurologic devastation is apparent.

Consensus exists for poor prognostic signs and symptoms, yet it is important to acknowledge that there will be outlying cases that defy all predictions of survival despite meeting all poor prognostic criteria.⁵⁵⁻⁵⁷ These cases occur very rarely and must be weighed against the more frequent occurrence of survival with neurologic devastation.

There are no absolutely reliable indicators of intact survival with cold water submersions.⁵⁸ Positive prognostic indicators include submersion time less than 10 minutes, no evidence of aspiration, and body core temperature less than 35° C.⁵⁸ Younger age of the victim as a positive prognosticator is supported in some studies but not others.⁵⁸⁻⁶⁰ Hypothermia that is delayed 15 minutes does not have the same protective effect (only moderate disability) as immediate hypothermia.⁶¹ Severe acidosis, with a pH as low as 6.33, has been reported with full recovery, reinforcing the poor prognostic value of this particular test.⁶² Mean time to return of spontaneous circulation for hypothermic submersion patients requiring CPR upon arrival at the ED is 58 minutes.⁶³ It seems prudent to continue resuscitation of the hypothermic patient from a cold water submersion for a total of at least 1 hour.

In the ED, outcome of patients who have spontaneous circulation without spontaneous respirations cannot be reliably predicted. Children may experience an unexpected full recovery following a prolonged vegetative state.⁶⁴ Dilated pupils 6 hours after injury and seizures 24 hours after admission have been associated with poor outcome, but again, case reports with exceptions have been published.^{13,55,57,65} The Pediatric Risk of Mortality (PRISM) score is somewhat helpful, but often does not differentiate neurologically intact survival among patients with median scores.^{14,66,67} There is universally poor neurologic outcome for patients who were normothermic, pulseless, and apneic upon arrival in the ED, although some still recommend continued support for 24 hours.⁶³ The prognosis for children requiring CPR regardless of etiology is poor, and patients requiring more than two doses of epinephrine or resuscitation longer than 20 minutes also have a very poor prognosis.^{39,68} All patients with spontaneous respirations on presentation to the ED recover, and reactive pupils support a good prognosis.¹³

Summary

Submersion injuries in children are common and are likely to be seen in geographically diverse practice settings. Patients who are asymptomatic 4 to 6 hours after submersion may be discharged home, while all others require admission to a monitored bed. Since near-drowning patients may be difficult to ventilate, it is prudent to expeditiously transfer symptomatic patients to a tertiary care facility.

In spite of advances in knowledge and technology, the prognosis of near-drowning patients has not changed. While there is a possible role for therapeutic hypothermia, the most effective strategy in minimizing morbidity and mortality from drowning is obviously prevention. Once a near drowning has occurred, immediate bystander CPR is the most effective intervention.

Chapter 139

Hyperthermia

Paul Ishimine, MD

Key Points

The hallmark of heatstroke is central nervous system dysfunction, but children with heatstroke may only have subtle neurologic findings and may be sweating profusely.

Cooling measures should be initiated immediately in patients with heatstroke even in the prehospital environment.

Heatstroke should be considered in children who collapse while exercising, even if their temperature is minimally elevated upon emergency department presentation.

flow and increased rate of sweating, which in turn results in a decrease in evaporative cooling. *Convection* is the transfer of heat from skin to circulating air and water vapor molecules. Convective heat loss directly varies with wind velocity, and once the air temperature exceeds the skin temperature, convection results in heat gain. *Radiation* refers to the transfer of heat between the body and its surroundings by electromagnetic waves, and this represents a substantial source of heat gain in hot environments. *Conduction* is the transfer of heat from warmer to cooler objects via direct physical contact. This generally represents a minimal source of heat transfer, unless the skin is in contact with water.

Heat regulation is mediated by thermosensors, a central integrative area, and thermoregulatory effectors. Thermosensors are located peripherally in the skin and centrally in the preoptic area of the anterior hypothalamus, brainstem and spinal cord, and abdominal viscera. The central integrative area interprets information from the thermosensors and regulates thermoregulatory effectors. The thermoregulatory effectors stimulate sweating, vasodilation, and cold-seeking behavior, which are the main means by which heat loss is accelerated.

Several key anatomic and physiologic differences exist between children and adults. Children have a higher surface area-to-mass ratio, resulting in a greater rate of heat loss by convection than adults. In extreme conditions this results in a higher rate of heat absorption in hot environments. Children have both a smaller absolute blood volume and a smaller blood volume relative to body mass and surface area, which limits potential heat transfer from the body core to the body surface, where it can be dissipated.⁶ Children have a lower rate of sweating than adults as a result of a lower sweat rate per gland,⁷ and they take longer than adults to acclimatize to hot environments.⁸ Children have higher energy expenditure and heat production compared with adults. Exercising children, who are dehydrated, have a greater rise in rectal temperature than adults who are exercising in the heat even when corrected for body weight.⁹ They inadequately replenish fluid losses during exercise.¹⁰ Children are also susceptible to heat-related illness because of an inability to escape from hot environments. Young children are at high risk for morbidity and mortality when left unattended in vehicles, as intraventricular temperatures rapidly rise to dangerous levels.^{11,12} Heavily bundled young children have also died from hyperthermia while in bed.¹³ Teenage athletes are another group that is at high risk for exertional heat-related illness.

Introduction and Background

Heat-related illness results from excessive heat stress. This may occur from an increased environmental burden or from an inability of the body to dissipate endogenous heat. The spectrum of heat illness ranges from minor to life threatening. Heat-related morbidity and mortality increase significantly during periods of high environmental temperature¹⁻³ Heat-related morbidity and mortality also increases in the presence of comorbid disease and increasing age; the highest rate of death is in the elderly population.^{4,5} However, children are also susceptible to heat-related morbidity and mortality because of unique anatomic and physiologic characteristics.

Recognition and Approach

The human body is remarkably homeostatic and constantly regulates body temperature through a balance of heat production, absorption, and dissipation. Heat transfer occurs by four mechanisms: evaporation, convection, radiation, and conduction. Evaporation is the conversion of a liquid into a gas. The *evaporation* of sweat is the primary means of heat loss as ambient temperature rises, but this mechanism of heat transfer becomes less effective as ambient humidity increases. Additionally, dehydration results in decreased skin blood

Clinical Presentation

The degree to which children develop signs and symptoms from heat stress depends on a number of factors. Much of the risk for heat illness is attributable to the environment, such as the ambient temperature and humidity level. However, individual variables also place the child at risk for heat-related disease. Children with special health care needs are especially vulnerable to heat-related illness (Table 139–1).

Miliaria (“prickly heat” or “heat rash”) is an inflammatory rash resulting from blockage and subsequent rupture of sweat glands. *Miliaria crystallina* occurs typically in neonates and in sunburned areas. This rash is characterized by clear, small, sweat-filled vesicles. *Miliaria rubra* is an erythematous papular rash typically seen in intertriginous areas or in truncal areas covered by clothing. The sweat glands enlarge and rupture within the lower epidermis, resulting in an erythematous rash.

Heat cramps are muscle cramps that usually occur several hours after exertion and commonly involve the large muscle groups of the legs. These are thought to occur because of dilutional hyponatremia from rehydration with free water but not salt, but the exact etiology is unclear.¹⁴ While these can be quite uncomfortable, heat cramps do not lead to significant morbidity. Heat cramps are often confused with *heat tetany*, which is caused by hyperventilation associated with heat stress, resulting in respiratory alkalosis, circumoral and extremity paresthesias, and carpedal spasm.

Heat edema and *heat syncope* are heat-related conditions found more commonly in the elderly than in children. Heat edema, which causes swelling of the hands and feet, results from vasodilation and pooling of increased interstitial fluid in dependent extremities, as well as an increase in aldosterone and antidiuretic hormone secretion. Heat syncope results from volume depletion, peripheral vasodilation, and decreased vasomotor tone.

Sickle cell disease³⁶⁻³⁸

Heat exhaustion is characterized by volume depletion, and is usually (but not always) associated with a slightly elevated body temperature. Heat exhaustion can be further subclassified as water-depletion heat exhaustion (characterized by inadequate water replacement) or salt-depletion heat exhaustion (characterized by salt loss and replacement by hypotonic solution), but most patients have combined water-salt depletion. Symptoms are nonspecific and include thirst, weakness, fatigue, dizziness, irritability, headache, nausea, and vomiting. Patients with water-depletion heat exhaustion typically have elevated sodium and chloride levels, while those patients with salt-depletion heat exhaustion have hyponatremia and hypochloremia.

Heatstroke is typically defined as a core temperature $\geq 40^{\circ}\text{C}$ and central nervous system (CNS) dysfunction. This must be continuously monitored with a rectal probe thermometer that is accurate to high temperatures. While anhidrosis is commonly present, this is not an absolute criterion for making this diagnosis.¹⁵ Signs of heatstroke may occur abruptly. Classic heatstroke arises from environmental exposure to heat and is more common in younger children who are unable to escape from hot environments. Exertional heatstroke results from strenuous exercise and is more common in older children and adolescents. The differential diagnosis for heatstroke is presented in Table 139–2.

Heatstroke is associated with a systemic inflammatory response, with a predominance of CNS symptoms. While CNS symptoms may be subtle and manifest as impaired judgment or inappropriate behavior, children commonly present with more significant neurologic symptoms such as seizures, delirium, hallucinations, ataxia, or coma. Anhidrosis results from severe dehydration and sweat gland dysfunction, but profuse sweating may precede anhidrosis. Patients are tachycardic and tachypneic. Vomiting, diarrhea, and gastrointestinal bleeding are thought to be consequences of impaired perfusion to the mesentery. Patients may be incontinent and have hematuria, oliguria, or anuria. Coagulopathies may result in purpura, subconjunctival hemorrhage, and other signs of bleeding.

Patients with heatstroke have abnormal laboratory tests, reflecting the systemic inflammatory response and end-organ damage as a result of heat stress. Hematologic findings include hemoconcentration and elevated white blood cell count. Thrombocytopenia and disseminated intravascular coagulation are seen frequently in heatstroke, although these findings are seen 18 to 36 hours after the initial heat stress.^{16,17} Electrolyte disturbances are frequent. Patients are usually hypokalemic but may be hyperkalemic. While hyponatremia may be present, normal sodium levels are common as well. Serum calcium levels can be either high or low. Elevated blood urea nitrogen and creatinine levels indicate acute renal failure, which occurs from a combination of factors, including dehydration and direct renal injury. Rhabdomyolysis, with an accompanying rise in creatine kinase, contributes to renal failure. Patients can be hyper-, normo-, or hypoglycemic. Metabolic acidosis is the most commonly observed acid-base disturbance and is associated with the degree of hyperthermia; respiratory alkalosis is seen frequently as well.¹⁸ Elevation of liver enzymes is common in heatstroke,¹⁹ but liver failure is much less common. The presence of hepatic injury has been suggested as a criterion to distinguish between heat exhaustion and heatstroke. A computed tomography scan of the head should be obtained if a child has persistently altered mental status despite cooling, or if a neurologic cause of hyperthermia (e.g., intracranial hemorrhage) is suspected.

Important Clinical Features and Considerations

The diagnosis of heat illness is usually straightforward with the acute onset of symptoms in the setting of heat stress, but may be more difficult in other circumstances. In the presence of elevated body temperature and nonspecific symptoms, these patients are sometimes misdiagnosed as having infectious illnesses. The diagnosis may be difficult or missed when children undergo cooling interventions in the prehospital setting, as they may arrive in the emergency department with near-normal body temperature. There is some overlap of symptoms between heat exhaustion and heatstroke. While the distinction between heat exhaustion and heatstroke is sometimes unclear, the hallmark of heatstroke is CNS dysfunction. Children with elevated body temperature and CNS abnormalities should always be treated as having heatstroke, given the significant morbidity and mortality associated with this condition. Heat stroke must be distinguished from malignant hyperthermia and neuroleptic malignant syndrome which are induced by medications (phenothiazines, anesthetics, succinylcholine) and cause fever and muscle rigidity.

While complications with minor heat illness are uncommon, patients with heatstroke are prone to many significant complications. Heatstroke patients have hyperdynamic cardiovascular systems with low peripheral vascular resistance. This low peripheral resistance persists even after cooling, leading to speculation that this is similar to a postshock or sepsis state, and this can lead to high-output cardiac failure. Heatstroke patients frequently have pulmonary edema, which is likely due to a combination of capillary leak and overaggressive fluid resuscitation, and this may progress to acute respiratory distress syndrome. Rhabdomyolysis and oliguric renal failure are common findings in heatstroke as well. The

gastrointestinal system plays a key role in the pathogenesis of heat injury. Intestinal mucosal injury from heat stress, with subsequent release of toxic substances into the circulation, is thought to contribute to the systemic response to heat injury.²⁰ For patients with heatstroke-associated liver failure, hepatic transplantation has been performed, but experience in children and young adults is limited. Two case reports described unsuccessful liver transplantation in teenagers.²¹⁻²³ Both liver dysfunction and coagulation abnormalities are seen in a delayed fashion after the initial heat injury.

Management

Most patients with minor heat illness can be treated and discharged home. Treatment for miliaria entails allowing the skin to dry, use of lightweight clothing, and avoidance of further sweating. Superinfection of miliaria occasionally occurs and should be treated with antistaphylococcal antibiotics. Heat cramps are usually treated sufficiently with oral salt solutions, although some patients may need intravenous normal saline. The treatment for heat tetany is removal from the heat, which allows the patient to cease hyperventilation. Treatment for heat edema entails elevation and compressive stockings as well as removal from the heat source. Heat syncope is usually treated with either oral or intravenous fluids depending on the degree of symptoms. Heat exhaustion should be treated with cooling measures and hydration. Correction of fluid and electrolyte abnormalities with replacement of free water deficit and electrolyte losses is the therapeutic goal.

Children with heatstroke need to be treated aggressively since the extent of CNS damage is related to the duration of hyperthermia. After the usual resuscitative maneuvers addressing airway, breathing, and circulation, heatstroke patients need aggressive cooling measures. The most commonly utilized modalities for rapid cooling are evaporative cooling and cold water immersion. The goal of therapeutic cooling is to bring the core temperature down to 40° C as quickly as possible. Treatment should always be initiated in the prehospital setting if possible.

Immediate therapeutic interventions include removal of the patient from the heat source and removal of all clothing. Evaporative cooling is quickly accomplished by spraying tepid water (to minimize shivering) over patients and then using high-flow fans to circulate air to facilitate evaporation. Both spray bottles and fans are usually available from hospital housekeeping services. Cold water immersion of the trunk and extremities is an effective cooling mechanism as well.²⁴ Children can be immersed in wading pools that are commonly found in supplies used for chemical decontamination. Logistically, however, monitoring and performing interventions on submerged patients is challenging. Additional methods of cooling include covering patients in ice, and selective application of ice packs to the neck, axillae, and groin. The latter technique can be used in conjunction with evaporative cooling techniques.²⁵

Theoretically, the most effective method of lowering the core body temperature quickly is the use of cardiopulmonary bypass. Cold water gastric^{26,27} and peritoneal²⁸ lavage have been proposed as additional means of invasive cooling, but these techniques have not been well studied in humans. Consider dantrolene administration (2–3 mg/kg IV to maximum

of 10 mg) if malignant hyperthermia or neuroleptic malignant syndrome are a consideration.²⁹ There is no role for isopropyl alcohol sponge baths or antipyretic medications in the heatstroke patient. Anticipate and treat rhabdomyolysis as needed (see Chapter 99, Rhabdomyolysis).

Care must be taken to prevent shivering, since this physiologic response will increase endogenous heat production. Shivering is best treated with benzodiazepines. Another complication associated with cooling measures is overshoot hypothermia. A decrease in measured body temperatures generally lags behind the actual drop in core temperature, and for this reason, cooling measures are generally stopped once the core temperature reaches 40° C. While heatstroke patients are generally dehydrated, they also have low peripheral resistance because of cutaneous vasodilation and may be hypotensive. Consequently, these patients often receive large amounts of fluids, which may lead to pulmonary edema if these fluids are not administered judiciously.

Simple preventive measures may forestall significant complications associated with excessive heat. Children become dehydrated when exercising in hot environments, even when allowed to drink water freely.^{9,10} Flavoring water and adding both carbohydrates and sodium chloride may eliminate hypohydration.³⁰ Restricting physical activity during hot times of the day and wearing loose-fitting, light-colored clothing reduces the risk of heat-related illness. Children should be encouraged to drink approximately 10 ml/kg prior to engaging in a period of intense exercise in hot ambient temperatures and to maintain hydration at 5 ml/kg/hr throughout the duration of the exercise.

Summary

Most patients with heat-related illness have minor symptoms that are correctable in the emergency department and can thus be discharged home. Some patients with heat exhaustion may need to be admitted to the hospital if they have significant electrolyte abnormalities or if there is a concern about recurrence.

All children with heatstroke must be admitted to the hospital. Patients with heatstroke generally have dysfunction of multiple organ systems and therefore need to be monitored closely. Specifically, these patients need close hemodynamic and neurologic monitoring. Because of these monitoring requirements and the potential for delayed complications (e.g., coagulopathies, hepatic dysfunction), these patients may require transfer to a pediatric critical care facility.

The prognosis in patients with heatstroke is directly related to the duration of hyperthermia, and for this reason, heatstroke must be treated aggressively. Poor prognostic indicators include persistent CNS dysfunction despite cooling and persistent hypotension despite adequate fluid resuscitation.

Hypothermia

Paul Ishimine, MD

Key Points

Hypothermia can occur in any climate during any season.

While environmental exposure is the predominant cause of hypothermia in older children, other causes, especially sepsis, should be considered in the hypothermic neonate.

Severely hypothermic children without signs of life have been successfully resuscitated, but severe primary hypothermia resulting from cold exposure must be differentiated from secondary hypothermia resulting from prolonged cardiac arrest; the latter rarely responds to resuscitative efforts.

Introduction and Background

Hypothermia is defined as a core temperature of less than 35° C (95° F).¹ Primary (“accidental”) hypothermia is a result of environmental exposure, while secondary hypothermia is a result of underlying disease. Hypothermia is more frequently seen in cold environments and in winter months,^{2,3} but children may become hypothermic in any location or climate. While the role of therapeutically induced hypothermia is an area of ongoing investigation for a number of different medical conditions,⁴⁻¹² this discussion focuses on accidental hypothermia.

Recognition and Approach

Hypothermia is further categorized as mild (32.2° C to 35° C), moderate (28° C to 32.1° C), and severe (<28° C) hypothermia.¹ This represents a continuum of illness; the patient is able to compensate to some degree in mild and moderate hypothermia, but with severe hypothermia, the patient’s compensatory mechanisms have failed. Cold stimuli sensed by thermoreceptors, located both in the skin and centrally, lead to compensatory responses mediated by the hypothalamus and include shivering, autonomic nervous system responses (primarily vasoconstriction), and endocrinologic and adaptive behavioral changes.^{13,14}

The rate of hypothermia-associated death increases with age, and the majority of patients who die from hypothermia are elderly.^{2,15} While children are less likely to have some of the risk factors associated with hypothermia in adults (e.g., alcohol use, homelessness, mental illness), children have certain anatomic, physiologic, and behavioral differences from adults that place them at higher risk for hypothermia. Because heat transfer between the body and environment is related to the exposed body surface area (BSA), the increased BSA-to-mass ratio in children leads to relatively greater heat loss than in adults. Young children have less subcutaneous tissue than adults, leading to less insulation of the body core. Shivering increases the metabolic rate to five to six times that observed at rest, and this involuntary muscle contraction leads to heat production.¹⁶ Young children are unable to shiver, precluding this highly effective mechanism of endogenous heat production. Young infants increase thermogenesis by lipolysis of brown adipose tissue. Depending on a child’s age and developmental level, he or she may not be able to adapt behaviorally to cold stimuli, such as seeking a warmer environment or putting on additional clothing.

Clinical Presentation

Frequently, the diagnosis of hypothermia is suspected when there is a history of environmental exposure, but the diagnosis can be subtle, especially in preverbal children. Paradoxically, the signs and symptoms may be even more difficult to appreciate with decreasing body temperature. In addition to feeling cold, patients may complain of lethargy or confusion. Other vague symptoms include dizziness, nausea, or hunger.

Hypothermia affects all of the organ systems and leads to numerous physical examination abnormalities. The severity of symptoms generally correlates with the degree of hypothermia, and the most prominently affected systems are the cardiovascular and neurologic systems. Patients who are hypothermic initially present with tachycardia and peripheral vasoconstriction. As they become more hypothermic, bradycardia develops with an accompanying decrease in mean arterial pressure and cardiac output. The drop in body temperature typically leads to atrial fibrillation or atrial flutter with slow ventricular response rates, which is then followed by ventricular fibrillation and asystole. This risk is most pronounced when the core temperature drops below 30° C.

Hypothermia depresses the central nervous system, resulting in decreased cerebral metabolism. This results in impaired judgment and memory as well as depressed mental status. Paradoxical undressing has been noted in hypothermic patients.¹⁷ Hyperreflexia is followed by hyporeflexia, ultimately resulting in the loss of reflexes in severely hypothermic patients. Fine motor control is lost early in hypothermia. Shivering is initially stimulated with mild hypothermia, but as hypothermia progresses, shivering thermogenesis ceases and patients become poikilothermic. Because hypothermia depresses cerebral metabolism, this offers some degree of cerebral protection, but the amount of this protection is difficult to predict clinically.

Other organ systems are also involved. The respiratory rate in patients with mild hypothermia initially increases, but is followed by a progressive decline in minute ventilation as hypothermia worsens. Hypothermia also induces bronchorrhea, decreased ciliary motility, and noncardiogenic pulmonary edema. With the accompanying decrease in mental status, patients are at risk for aspiration pneumonia. Peripheral vasoconstriction initially leads to relative central hypervolemia. This phenomenon, along with a decrease in renal concentrating ability and a decrease in antidiuretic hormone, is thought to contribute to cold-induced diuresis. There is an accompanying shift of intravascular fluid to the extravascular space, and this contributes to the development of hypovolemia. Gastrointestinal effects of hypothermia result in poor intestinal motility, leading to ileus and abdominal distention. Hepatic dysfunction and pancreatitis are also seen with hypothermia.

Multiple hematologic derangements are associated with hypothermia. Activated clotting factors are depressed by cold, and, along with thrombocytopenia that accompanies hypothermia, this can lead to significant coagulopathy. Conversely, blood viscosity increases after diuresis, leading to increased rates of thromboembolic phenomena. Disseminated intravascular coagulation may occur as well. Musculoskeletal findings include increased tone, shivering, and muscular rigidity. Dermatologic findings include erythema, pallor, cold urticaria, and frostbite.

In neonates, common presenting complaints include refusal to eat and drowsiness. Physical examination findings include

coldness to touch, extremity edema, and a ruddy appearance. Bradycardia, hypotension, and periodic breathing with apneic episodes are commonly noted upon initial presentation.¹⁸ The newly born are at particularly high risk for hypothermia, especially those born in the prehospital or emergency department setting. Half of these patients are hypothermic when their rectal temperatures are initially taken.^{19,20}

The definitive diagnostic test for hypothermia is accurate measurement of the core temperature. The core temperature must be measured with a low-temperature-reading thermometer and is most commonly obtained by rectal measurements, although these measurements are not as accurate as esophageal measurements. Other diagnostic tests may yield additional information, but the core temperature is the cornerstone in making this diagnosis.

The white blood count and platelet counts are commonly low or normal in hypothermia, and the hematocrit is elevated because of hemoconcentration. Coagulation studies may be normal because blood is warmed in the laboratory when prothrombin and partial thromboplastin times are measured. This will not reflect the coagulopathy caused by cold-induced inhibition of the enzymes of the clotting cascade.

Serum electrolytes can be abnormal. Both hypokalemia and hyperkalemia are seen in hypothermic patients. The blood urea nitrogen and creatinine levels are often elevated. Initially, patients may develop hyperglycemia, as cold cells are initially insulin resistant, but this is followed by hypoglycemia. A urine toxicology screen may be helpful when drug exposure is a consideration. Patients who are hypothermic can be acidotic or alkalotic, and arterial blood gases should be interpreted without correction for temperature.²¹

The electrocardiogram (ECG) reveals prolongation of the PR, QRS, and QT intervals. The J wave (“Osborn wave”) is an extra deflection noted at the junction of the QRS complex and the beginning of the ST segment. This finding is seen frequently in hypothermic patients, and the amplitude of this wave is inversely correlated with the core temperature²² (Fig. 140–1). However, the J wave is not pathognomic of hypothermia,²³ and may persist in hypothermic patients who have been rewarmed to normothermia.²⁴ Muscle tremor artifact is seen commonly, resulting in fine oscillation of the ECG baseline, even in the absence of clinically evident shivering.

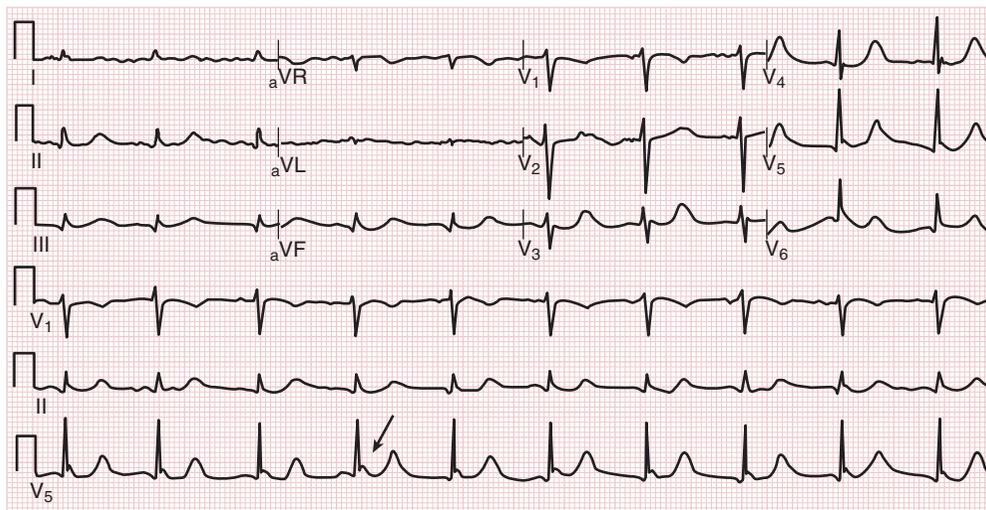

FIGURE 140–1. Hypothermia. Electrocardiogram in a patient with a core temperature of 30° C featuring bradycardia, Osborn waves (arrow), and prolongation of the QRS complex and QT interval.

Important Clinical Features and Considerations

Hypothermia in children can develop rapidly in the setting of environmental stressors. Appropriately, these patients need interventions to increase core temperature. Conversely, a common pitfall is focusing solely on warming interventions without addressing the underlying etiology of the hypothermia. While most children who are hypothermic are hypothermic from environmental causes, there are many other etiologies (Table 140–1). Warming interventions will not be successful without treatment of underlying precipitants, such as sepsis or hypoglycemia. Additionally, hypothermia is frequently iatrogenic; during the course of treating a sick child, an unclothed patient in an emergency department treatment area may quickly become hypothermic.

Management

Many recommendations generated for the treatment of hypothermia have been derived from case series, animal models, or small laboratory investigations with healthy human (almost always adult) volunteers, and the recommendations for management of hypothermic children should be interpreted with these limitations in mind.

Initial management of the hypothermic patient entails assessment of airway patency and adequacy of ventilation.

The pulse and respiratory rates in patients with significant hypothermia will generally be slow and difficult to detect. The airway needs to be secured in hypothermic patients as with any other patients. There is little evidence to support the contention that endotracheal intubation precipitates ventricular fibrillation,³ but patients should be handled carefully, as the hypothermic myocardium is irritable and prone to dysrhythmias. Because these patients may be profoundly bradycardic, the clinician must search for a pulse for at least 1 minute before initiating cardiopulmonary resuscitation. Alternatively, if a cardiac monitor reveals a nonperfusing rhythm, defibrillation and cardiopulmonary resuscitation should be initiated as indicated. Patients in ventricular fibrillation should initially receive one shock. If the patient is severely hypothermic (<30° C), current guidelines suggest deferring further shocks until the core temperature rises, as hypothermia may contribute to refractory ventricular fibrillation.²⁵

Hypothermic patients need to be rewarmed, and the general presumption is that rapid rewarming (as opposed to gradual rewarming) is desired. Three categories of warming interventions exist: passive rewarming, active external rewarming, and active core rewarming. In general, active core rewarming techniques raise core temperature faster than active external techniques, which, in turn, are more effective than passive measures. For these reasons, colder children require more aggressive warming techniques.

Children with mild hypothermia can be treated with passive rewarming techniques. These interventions include maintaining a warm environment, drying patients who are wet, removing wet clothing, and covering patients with insulating material in order to minimize heat loss. Especially in neonates, large amounts of heat are lost from the head, and during passive rewarming of the young child, a head covering is helpful in preventing heat loss.²⁶ A significant limitation of passive rewarming techniques is that they are dependent on endogenous heat production in order to be successful. Hypothermic patients stop shivering and become functionally poikilothermic as their core temperature drops, and therefore passive rewarming is ineffective in more severely hypothermic patients.

Active external rewarming entails utilization of an external heat source on the body surface and is used primarily for mild hypothermia. A commonly used technique is forced air rewarming through specialized blankets. Heated air is forced through semi-closed blanket covers and exits onto the patient, allowing for convective heat transfer and limitation of radiant heat loss. This technique has been used successfully in the emergency department without core temperature afterdrop.^{27–29} Immersion in warm water is an effective, albeit impractical, method of active external rewarming.

Active core rewarming entails application of heat to internal surfaces and is used for moderate and severe hypothermia. Inhalation of heated air is typically accomplished by the use of nebulizers and ventilators with the capacity to heat and humidify air. This technique minimizes respiratory heat loss. Controversy persists as to the efficacy of airway rewarming, and the role of this technique is most appropriate as an adjunct to other warming techniques.^{30,31} Hypothermic patients are frequently hypovolemic and require fluid resuscitation. Intravenous infusion devices with countercurrent heat exchangers may be used to warm intravenous fluids.³²

Alternatively, intravenous fluids that are warmed in microwave ovens^{33,34} may be used if prewarmed fluids are not available. Irrigation of the stomach through nasogastric or orogastric tubes, or gastrointestinal decontamination tubing, can be used to rewarm the core by gastric lavage with warmed fluids. Similarly, bladder irrigation with warm fluids may be used. However, the relatively small surface area available for heat exchange limits these warming techniques. Peritoneal lavage with warmed fluids has been used in the treatment of severe hypothermia.³⁵ Using standard open or closed techniques for diagnostic peritoneal lavage, a large catheter is placed into the peritoneal cavity, and warmed fluid is infused into the abdominal cavity and then withdrawn. Pleural irrigation has also been used in the treatment of hypothermia in children.³⁶ This treatment requires placement of two chest tubes; one is placed anteriorly in the second intercostal space in the midclavicular line, and the second is placed in the posterior axillary line at the level of the fifth intercostal space. Warm fluid is infused in the anterior tube and suctioned or drained out of the posterior tube. Thoracotomy with mediastinal lavage has been described as a warming technique in adults.

The treatment of choice in patients with hypothermic cardiopulmonary arrest is extracorporeal warming via cardiopulmonary bypass.³⁷ Typically this is achieved with femoral-femoral bypass, although in younger children, circulatory access may be more easily achieved via median sternotomy.³⁸⁻⁴⁰ In patients with adequate perfusion pressures, continuous arteriovenous warming with countercurrent heat exchangers interposed between femoral artery and femoral vein catheters is another option, as is standard hemodialysis.

There is a strong association between hypothermia and sepsis in young infants, and empirical therapy with broad-spectrum antibiotics in this age group is warranted.^{18,41} While hypothyroidism and adrenal insufficiency are associated with hypothermia, empirical treatment with levothyroxine or steroids is not indicated, as these are rare causes of hypothermia in children.

Therapeutic Complications

When the core temperature continues to decline after initiation of warming maneuvers, this phenomenon is known as core temperature afterdrop. The temperature gradient between the warmer core and cooler periphery contributes to this drop as the cooler blood returns to the core. This is coupled with a drop in the mean arterial pressure and peripheral vascular resistance.⁴²

Atrial and ventricular arrhythmias are common in patients with hypothermia, but these generally convert spontaneously during rewarming. Ventricular dysrhythmias occur frequently as well. The drug of choice for treatment of ventricular fibrillation remains unclear. The most recent American Heart Association guidelines recommend withholding antiarrhythmic medications if the core temperature is less than 30° C, and to give medications at longer intervals for temperatures above 30° C. Bretylium is no longer recommended.²⁵ Alternative medications such as vasopressin^{43,44} and amiodarone,^{45,46} which are now recommended for treatment of normothermic ventricular fibrillation, have been proposed as treatment modalities for hypothermia, but results from experimental studies have been inconclusive.

Summary

Predicting which patients will survive severe hypothermia is difficult. Patients with significant underlying medical illness, longer duration of cold exposure, lower core temperature, and depressed mental status, as well as those failing to rewarm rapidly and those requiring cardiopulmonary resuscitation, are thought to have a lower likelihood of survival,^{3,47} but dramatic cases of hypothermic patients surviving prolonged cardiac arrest have been described.^{38,48,49}

Nonetheless, most patients who present in cardiopulmonary arrest from hypothermia are not successfully resuscitated.^{47,50} Patients who sustained a lethal insult prior to the onset of accidental hypothermia will not be resuscitated with warming therapy. Evidence of intravascular thrombosis, elevated ammonia, and severe hypokalemia have been suggested as markers for death in patients with hypothermia.^{47,50,51} However, while some people are indeed “dead when they’re cold and dead,”⁵² there are no consistently accurate variables that predict an irreversible state in hypothermic patients in cardiopulmonary arrest. In a resuscitation, clinicians must also recognize that hypothermia occurs secondary to prolonged cardiac arrest from other etiologies and should consider that prolonged resuscitation under these circumstances may not be warranted.

Children with mild environmental hypothermia can be discharged home from the emergency department after correction of the core temperature. Neonates and hypothermic children who require more aggressive warming techniques, those who have significant laboratory abnormalities, and those in whom the etiology of the hypothermia cannot be identified should be admitted to the hospital for further evaluation, monitoring, and treatment.

Chapter 141

Snake and Spider Envenomations

Sean P. Bush, MD and James A. Moynihan, MS, DO

Key Points

First, do no harm: Many historically recommended interventions add insult to injury when applied to snakebite. Make sure that the potential benefits exceed risk.

Antivenom is the definitive treatment for serious snake envenomation. The sooner antivenom is given, the more likely that irreversible damage can be prevented.

Envenomation is an uncommon occurrence, so available resources (such as regional poison centers) should be consulted as necessary.

The diagnosis of spider bite is overused for wounds of uncertain etiology. There is no accepted specific treatment for brown recluse spider bite in the United States.

Envenomations and the treatment of such can cause severe allergic reactions, so be prepared to treat these potentially life-threatening complications.

Selected Diagnoses

- Snakebites
- Spider bites
 - Widow spider bites
 - Recluse and other spider bites

Discussion of Individual Diagnoses

The general principles of envenomation medicine are similar around the world, although the availability of resources varies widely. A comprehensive discussion of all available antivenoms is beyond the scope of this chapter, so the discussion will focus on U.S. antivenoms.¹ However, readers are encouraged to become familiar with the prescribing information for the antivenom(s) available in their area(s) of practice for the envenomations they may encounter.

Snakebites

Introduction and Background

Snakebite is a particularly challenging clinical problem because of the wide variety of toxic effects. Children with snakebites may suffer little more than a fang puncture mark or they may develop multisystem failure and die.^{2,3} In part this is due to the extreme variability of snake venom, even within the same species.⁴ Unfortunately, it is difficult to predict at the time of the bite which patients will have relatively mild symptoms and which will develop a rapidly progressive and potentially fatal envenomation syndrome.

Snakebite envenomation syndromes can be loosely associated with snake families. Viperidae includes old world vipers and pit vipers (collectively referred to as “viperids”). The vast majority of snakebites in the United States are inflicted by pit vipers, which include rattlesnakes, cottonmouths (also known as water moccasins), and copperheads.⁵ All pit vipers have a heat-sensing pit between the eye and nostril.⁶ Elapidae (“elapids”) includes the cobras, coral snakes, kraits, and mambas.⁷ Their venom effects can be as diverse as the species that comprise this family of snakes. Cobras are hooded, high-profile snakes inhabiting Africa and southern Asia. The coral snakes of the Americas and kraits of Asia and India are often small, shy, colorfully banded snakes. Mambas in Africa are long, lean, and fast-moving. Australian elapids can be large and nondescript. Sea snakes are found in waters around Southeast Asia and Australia. Sea snakes possess some of the world’s most toxic snake venom, although few bites occur, mostly because of this family of snakes’ marine distribution and nonaggressive temperament. Most snakes from the Colubridae family (“colubrids”) are considered harmless, although many species possess venom and some have primitively specialized teeth to facilitate venom delivery. Some, such as the boomslang in Africa, are considered dangerous to humans, and antivenom is produced.

It is often stated that children are more severely affected by snakebite than adults.⁸ Indeed, some preliminary data suggests that smaller patients present with increased severity. However, there is not much in terms of evidence to support the assertion that outcomes for children are worse than those for adults. For example, of the 104,750 exposures and 23 deaths described by the American Association of Poison Control Centers (AAPCC) since its first report in 1983, there have only been 2 deaths described in pediatric patients.⁹ In some respects, children are no different than adults when it

comes to snakebite. For instance, antivenom dosing is not based on the patient's weight.^{10,11} Yet there are a few concerns specific to pediatric patients. For example, young children may not be able to give a good description of the snake or circumstances so that it is unclear whether a venomous snake has bitten them.

Although viper and pit viper venom composition varies from snake to snake, components can lead to capillary leak, abnormal clotting, inefficient muscle movement, or neurotoxicity. Capillary leak and abnormal clotting can lead to tachycardia, hypotension, or even hemorrhagic shock. Neurotoxicity or inefficient muscle movement can lead to respiratory difficulty or distress.¹² Meanwhile, proteolytic enzymes, predominant in viper and pit viper venoms, digest tissue. The longer that enzymatic components of venom have time to work, the more tissue damage is sustained. Therefore, "time is tissue."¹³ The sooner that antivenom can be started, the sooner irreversible injury can be prevented.¹⁴ However, once tissue is injured by way of digestion, antivenom will not reverse the damage—it will require time to heal.¹⁵ Myotoxicity and rhabdomyolysis can also ensue.

Envenomation by most elapids is notable for severe neurologic dysfunction, such as cranial nerve abnormalities, paralysis, and respiratory arrest. However, the venom of some elapids (such as spitting and monocellate cobras) can cause local necrosis as well. Most elapid envenomations do not induce coagulopathy. Other symptoms and signs may include swelling, lethargy, vomiting, chest pain, and shock. Some cobras and cobra-like species can "spit" venom toward the face of an antagonist, which can result in eye pain and visual impairment. Sea snake envenomation can cause profound neurotoxicity and myotoxicity but generally does not induce coagulopathy or result in serious local injury. Additionally, some individuals may experience anaphylactic or anaphylactoid reactions to venom.^{16,17} Finally, some responses can be attributed to anxiety, although this should be a diagnosis of exclusion.⁶

Clinical Presentation

Immediately after a snakebite, the only apparent manifestation may be fang puncture wounds. If a patient presents very early, an envenomation syndrome might not have developed yet. Symptoms and signs can begin very rapidly or they may be insidious. Generally, the more severe an envenomation, the more rapidly it progresses. However, even a slowly progressing envenomation can lead to severe sequelae. If a patient presents very late, the envenomation could have already run its course and antivenom will not be as effective.¹⁴

Typically snakebites by pit vipers and vipers cause pain around the bite site as tissues distort with swelling (Fig. 141-1). There may or may not be associated taste changes. Difficulty breathing can follow many types of venomous snakebites and can progress to respiratory distress or failure in some cases. Patients may experience nausea, vomiting, or diarrhea, and venom-induced coagulopathies (often associated with viper and pit viper envenomation) can lead to hematemesis and/or hemochezia. Certain snakebites (such as those inflicted by most elapids and some populations of rattlesnakes) can also be associated with neurologic symptoms, such as ptosis, motor weakness, or paresthesias. Syncope or lethargy can result from severe or prolonged hypotension.⁶

FIGURE 141-1. Tissue distortion and swelling on site of pit-viper bite.

Vital signs may reflect tachycardia, hypo- or hypertension, tachypnea, or hypoventilation. On physical examination, there may be one, two, or more fang puncture wounds or there may be none discernable. There is usually tenderness and swelling surrounding the bite site, which expands as the venom spreads locally. Other local signs can include erythema, ecchymosis, and bullae after viperid envenomation. Systemic viperid envenomation may manifest in many ways. There may be abnormal bleeding, such as prolonged bleeding from fang puncture wounds or intravenous line sites. Patients may have epistaxis or gingival bleeding. Serious and potentially life-threatening bleeding may manifest as gastrointestinal tract or intracranial hemorrhage. In extremely rare instances, snakebite can also cause hypercoagulability, which can lead to infarcts. Additionally, there may be neurologic signs, such as ptosis and muscle fasciculations.⁶

Initial laboratory studies after pit viper or viper envenomation should include a complete blood count, prothrombin time, international normalized ratio (INR), fibrinogen, and a type and screen. Venom-induced coagulopathies are common after many types of viperid envenomations (although not after elapid or sea snake envenomations) and are most typically characterized by thrombocytopenia and hypofibrinogenemia. Venom-induced coagulopathies can develop late, recur, or persist. Repeat laboratory testing is often used to gauge response to treatment. The same laboratory tests as initially drawn should be ordered, plus creatine kinase (CK), electrolytes, blood urea nitrogen, and creatinine. Patients with just about any kind of snakebite can develop rhabdomyolysis, which usually responds to aggressive fluid hydration but can require dialysis if myoglobinuria leads to renal failure. In certain regions, such as Australia, venom detection kits (such as enzyme-linked immunosorbent assays) may be available to help identify species and guide specific antivenom selection. Other diagnostic studies may be indicated on the basis of a patient's past medical history or special circumstances.⁶

It is possible that a snakebite might be mistaken for a puncture wound from another etiology (e.g., plant thorn) if the patient presents very early or if the envenomation is very mild, or if there are difficulties obtaining a reliable history. If there is any question about whether a patient has been bitten by a venomous snake, an observation period and diagnostic studies may help clarify the diagnosis. Patients with snakebites usually progress if significant envenomation has

occurred. Certain signs (e.g., ecchymosis), symptoms (e.g., local paresthesias), and laboratory data (e.g., thrombocytopenia or hypofibrinogenemia) are fairly consistent with viperid envenomation. If a bite by an elapid is suspected, envenomation should be assumed.

Management

The factors that most reduce snakebite-related injury and mortality in the United States are rapid transport, intensive care, and antivenom.¹⁸ All patients with snakebites should be transported to the hospital as expeditiously as safely possible, preferably by calling 911 where available to activate Emergency Medical Services. The following measures are not recommended for first aid: incision, suction, tourniquets, electric shock, ice directly on the wound, alcohol, or folk therapies.¹⁹⁻²¹ Insufficient evidence exists for splinting and/or positioning (e.g., above or below the level of the heart). Therefore, the extremity should initially be maintained in a neutral position of comfort.

The Australian technique of pressure immobilization resulted in significantly longer survival, but higher intracompartmental pressures, after artificial intramuscular western diamondback rattlesnake envenomation in a pig model.²² This technique involves immediately wrapping the entire snakebitten extremity, starting at the bite site and proceeding proximally, with an elastic Ace wrap or crepe bandage as tightly as one would for a sprain, then splinting and immobilizing the extremity. While pressure immobilization is not recommended widely, certain scenarios may warrant its use. It is generally not recommended for most viper bites or for bites by spitting cobras, but is recommended for most types of Australian fauna, cape cobras, kraits, coral snakes, mambas, and sea snakes. Once pressure immobilization is instituted, it should not be removed until antivenom is ready to infuse (if asymptomatic) or infusing (if symptomatic) because of a potential bolus effect after its removal.

Although it is difficult to predict snakebite severity at the time of the bite, certain factors may reflect increased likelihood of a more severe envenomation: large snake size, dangerous snake species, small patient size, prolonged fang contact, previous snakebites (treated or not) or exposures to snakes, or delays in medical care. All emergency personnel should be able to distinguish a venomous from a nonvenomous snake. If there is uncertainty about whether a particular snake is venomous or not, consider taking photographs of the snake from a safe distance of at least 6 feet away using a digital or instantly developing camera. These images can be seen immediately and may aid in clinical decision making. Although it may be helpful to identify the species of snake,^{15,23} transporting it (alive or dead) is discouraged because of inherent dangers. On scene, snakes should only be moved or contained if absolutely necessary. A snake hook or long shovel may be helpful to move the snake into a large, empty trash canister where it can be recovered by a professional, such as an animal control agent.

Appropriate airway support should be provided as needed. Severe respiratory difficulty may require intubation and mechanical ventilation. Vital signs should be checked frequently, oxygen provided, and monitors placed. Two intravenous lines should be started, and central venous or intraosseous access should be considered if peripheral access proves difficult to achieve and maintain. However, the clini-

cian should avoid placing a central line in a noncompressible site (e.g., subclavian) after viperid envenomation because of the risk of bleeding from venom-induced coagulopathy. A 20-ml/kg normal saline fluid bolus should be given. If there is evidence of shock, a second 20-ml/kg fluid bolus of normal saline should be given. Because viperid envenomation can induce coagulopathy and bleeding, transfusion may be required after treatment with two fluid boluses; 10 ml/kg packed red blood cells should be given for acute, life-threatening blood loss. Persistent hypotension may require vasopressors. Urine output of 1 to 2 ml/kg/hr for infants and young children and 0.5 to 1 ml/kg/hr for older children and adolescents may be used as a measure of adequate hydration. The patient should take nothing by mouth until it has been determined that he/she will not need to be mechanically ventilated.

After pit viper or viper envenomation, any rings or other constricting jewelry and clothing should be removed in anticipation of severe swelling. The expanding area of swelling and tenderness can be used to follow the progression of viperid envenomations. Tenderness is more sensitive than swelling for detecting progression. By palpating until the advancing edge of tenderness is found, marking this leading edge with a permanent marker and the time, and repeating this every 15 to 20 minutes initially, progression can be gauged. Once antivenom is started, the advancing edge of tenderness should still be followed every 1 to 2 hours. Serial measurements of circumference may be helpful as well.

ANTIVENOM

All hospitals should stock at least enough antivenom to treat a patient. This should be arranged ahead of time if possible, although sometimes there are antivenom shortages and other resource challenges. Two agents are available in the United States for treatment of pit viper envenomation: Crotalidae Polyvalent Immune Fab (Ovine), which goes by the trade name CroFab, and Antivenin Crotalidae Polyvalent (Equine).²⁴ CroFab is manufactured by Protherics Inc. (Nashville, TN) and distributed by Fougere (Melville, NY; 1-800-231-0206). A similar formulation is produced for European vipers. Antivenin Crotalidae Polyvalent, manufactured by Wyeth-Ayerst, is still available on the shelves of many hospital pharmacies, but is no longer being produced. Coral snake antivenom manufacture was reportedly discontinued by Wyeth-Ayerst in 2004; however, a new antivenom is being developed. Several manufacturers produce antivenom for elapid bites in Africa, Asia, Europe, and Australia (e.g., Commonwealth Serum Laboratories in Melbourne, <http://www.allergytest.com/index.cfm>) and in the Americas (e.g., Instituto Bioclon in Mexico, <http://www.bioclon.com.mx>; Instituto Clodomiro Picado in Costa Rica, <http://www.icp.ucr.ac.cr/indice.shtml>; and the Butantan Institute, <http://bernard.pitzer.edu/~lyamane/butantan.htm>). A polyvalent sea snake antivenom (Commonwealth Serum Laboratories) is the drug of choice for sea snake envenomation. Haffkine Institute in Bombay, India, produces an alternate sea snake antivenom.

A new resource recently became available for assistance in managing exotic envenomations: the Online Antivenom Index (OAI), developed by the AAPCC and the American Zoo and Aquarium Association. By calling any regional poison control center (1-800-222-1222), the OAI can be

accessed, and antivenom stocked by zoos for exotic snakes can be emergently located. This will facilitate determining, locating, and obtaining exotic antivenoms in a timely manner, potentially improving the care of patients with uncommonly encountered and very challenging envenomations. Additionally, zoos can continuously update the OAI with their antivenom stock and have access to contact information, replacing a 7-year old hardcopy reference.

Fifty or more non-native, venomous snake exposures are reported to U.S. poison centers each year, a third of which result in serious clinical effects, including deaths. Exotic snakes are easily obtained, both legally and illegally, at trade shows or via the Internet. The AAPCC Toxic Exposure Surveillance System reported more bites from exotic venomous snakes than from native U.S. coral snakes last year. Antivenom may not always be available for all species. Supplies have limited shelf life and may be expensive, and several are no longer in production. The Food and Drug Administration considers foreign antivenoms investigational and/or unapproved. Information on antivenom should be researched ahead of time, and practitioners should be familiar with sources and administration techniques for the antivenoms available. Each antivenom has varying specificity, efficacy, and safety. Some antivenoms developed for one species may have some efficacy against other closely related species.

If antivenom is unavailable, a patient with an elapid or sea snake envenomation may need ventilatory support for days or even weeks. Hypotension should be treated with intravenous fluids, then vasopressors. Edrophonium may temporarily improve weakened muscles of respiration after elapid envenomation while awaiting antivenom (after pretreatment with atropine). The need for antivenom must be determined in each patient. Many grading scales are available, but it is better to treat a patient based on envenomation progression or potential. Grading scales should not be used for elapid or sea snake envenomations. Antivenom should be given promptly for best results, although it may have benefit for days to weeks after an envenomation. Any time antivenom is given, allergic reactions should be anticipated. It may be helpful to know whether the patient has allergies or previous exposures to serums or other agents used to make antivenom. Informed consent must be obtained, and the potential for an allergic reaction discussed with the patient and caregivers.

Because many of the principles are similar for other antivenoms (although dosing may vary), the technique for administering CroFab is given as an example. A starting dose of CroFab is 4 to 6 vials.²⁵ There is no change in the dose for children, although fluid volume may need to be adjusted for very small infants and children. Each vial is reconstituted with 10 ml of sterile water for injection. It can take anywhere from 10 to 30 minutes to go into solution. It is best to swirl or roll the vials between the hands rather than shake them. Once each vial goes into solution, it should be further diluted into a total volume of 250 ml of normal saline. No skin test is recommended for CroFab, although manufacturers of many other types of antivenom recommend skin testing. With CroFab, the infusion is started slowly, at a rate of 25 to 50 ml/hr for the first 10 minutes. While the infusion is started, a physician skilled in resuscitation should be immediately available. Equipment for a difficult airway, epinephrine and diphenhydramine, and a histamine₂ (H₂)-blocker

(such as cimetidine) should also be readily available. As the infusion is initiated, the physician should watch for signs of any adverse reaction (see later). If the infusion is tolerated for the first 10 minutes without evidence of an adverse reaction, the rate should be increased to a maximum of 250 ml/hr.

If there is a problem at any time, the infusion should be stopped and the adverse reaction treated accordingly, with reassessment of the need to continue antivenom treatment. A physician should be nearby at all times during the remainder of the infusion. The infusion is repeated with 4- to 6-vial increments until initial control is achieved. "Initial control" is defined as the arrest of progression of any and all components of the envenomation syndrome (i.e., no further advancement of swelling, improvement of systemic effects, and improving coagulopathy). The patient should be assessed at up to 1 hour after each dose. After initial control is achieved, a maintenance dose of 2 vials of CroFab every 6 hours for three doses is recommended.²⁶ The package insert may be consulted for additional details.²⁵

Important Clinical Features and Considerations

For pharmacokinetic reasons that are not entirely understood, recurrence phenomena are often associated with antivenoms.²⁷⁻²⁹ "Local recurrence" is the return of new progressive swelling after initial control; that is, the leading edge of tenderness or swelling begins to advance again. An additional 2 vials of CroFab should be given as soon as progressive swelling recurs, and more antivenom may be needed to regain control. Patients with rattlesnake bites commonly develop thrombocytopenia and hypofibrinogenemia, which can resolve with CroFab and then recur ("coagulopathy recurrence"). Indications for an additional 2 vials of CroFab are serious abnormal bleeding, fibrinogen less than 50 µg/ml, platelet count less than 25,000/mm³, INR greater than 3.0, multicomponent coagulopathy, worsening trend in a patient with prior severe coagulopathy, high-risk behavior for trauma, or comorbid conditions that increase bleeding risk. Coagulopathy can recur as late as 2 weeks or more after treatment.

The patient should be transfused if antivenom does not correct coagulopathy or if there is an imminent risk of serious bleeding. Transfusion of the appropriate blood product is generally recommended for life-threatening bleeding, platelets less than 10,000 to 30,000/mm³, or hemoglobin less than 7 g/dl. Additionally, fresh frozen plasma and/or platelets may be required to treat venom-induced coagulopathy if antivenom does not promptly resolve. Computed tomography of the brain should be considered if the patient has a severe headache or an altered level of consciousness with a severe coagulopathy.

Ocular exposure to venom necessitates prompt and copious irrigation and an ophthalmologist's evaluation.

Pain relief is provided with an opioid while maintaining a respiratory rate and blood pressure that is appropriate for age. Nonsteroidal anti-inflammatory drugs are contraindicated for approximately 2 weeks after viper and pit viper envenomation because they can contribute to venom-induced coagulopathy and bleeding. Tetanus prophylaxis should be updated as appropriate.

Prophylactic antibiotics are unnecessary. However, if an infection develops, aerobic and anaerobic wound cultures should be obtained. Empirical therapy should then be started

pending culture and sensitivity results. If an abscess occurs, it should be drained in standard fashion. A suggested outpatient regimen would include amoxicillin-clavulanate plus a dose of ceftriaxone. For penicillin-allergic patients, an extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole plus clindamycin should be selected. An infected snakebite should prompt a further examination of the wounds for potential retained teeth or fangs.⁵

Envenomations by vipers and pit vipers are remarkable for the amount of swelling they can produce. With prompt and adequate antivenom treatment, surgical intervention is rarely indicated, even after severe viperid envenomation.³⁰⁻³³ Compartment syndrome is diagnosed using clinical examination and compartment pressure, and treated with additional antivenom and pressure monitoring. Antivenom has been shown to limit the decrease in perfusion pressure associated with compartment syndrome.³⁴ Surgical consultation may be needed. Fasciotomy and/or digit dermatomy should be considered a last resort. It may be difficult to distinguish compartment syndrome from the effects of envenomation. Similar to compartment syndrome, viperid envenomation may cause a bluish discoloration of the skin or pallor (because of subcutaneous bruising), severe swelling, paresthesias, and pain. If effects are only caused by envenomation and the patient does not have compartment syndrome, capillary refill should be normal and compartmental pressures should not be elevated.

Antivenoms can induce immediate anaphylactic (type I hypersensitivity) or anaphylactoid reactions, which can be rapidly life threatening. Airway swelling, wheezing, shock, and/or urticaria characterize these reactions. Anaphylactic and anaphylactoid reactions are treated with antihistamines, H₂-blockers, epinephrine, steroids, and ventilatory/circulatory support as needed. Antivenoms can also cause serum sickness, a delayed (type III hypersensitivity) reaction characterized by fever, urticaria, lymphadenopathy, and polyarthralgias days to weeks after treatment. Although serum sickness can be a very uncomfortable experience, it is usually benign and self-limited and is treated on an outpatient basis with antihistamines and steroids. Adverse reactions are much less common after treatment with Fab-based antivenoms than they are with whole immunoglobulin formulations.¹⁴ All commercially available antivenoms in the United States use mercury (in the form of thimerosal) as a preservative, which in high doses can cause nerve and kidney toxicities in small children.²⁵ The manufacturer of CroFab is investigating alternative preservatives and plans to remove thimerosal from its product sometime in the near future. The AAPCC may assist in management of envenomations. A regional poison control center may be contacted at 1-800-222-1222.

All children with snake envenomations should be admitted to the hospital. Serious effects can be delayed and can recur even after treatment with antivenom. Therefore, a regimen of very close observation with monitoring, frequent measurements of swelling/tenderness, and neurologic checks for at least 24 hours is recommended. This degree of monitoring may require transfer to a pediatric intensive care unit. Some hospitals may have intermediate intensive care units or observation units that may be appropriate for patients with less severe envenomations. Patients with bites by less toxic vipers, such as copperheads, are probably best managed as inpatients as well, although this may change as more expe-

rience is gained with safer, more effective antivenoms.³⁵ Patients believed to have “dry bites” in which no venom effects develop should be observed for at least 8 hours.⁶ Several reports in the literature have documented instances in which patients who initially were discharged with apparent nonenvenomations or mild envenomations returned in several hours with significant injury and required antivenom and admission.

Upon discharge, the patient should be instructed to return immediately for further swelling, severe pain, abnormal bleeding or bruising, dark tarry stools, petechiae, or severe headache. Also, patients should be given wound care instructions and told to return for signs of wound infection. Signs of serum sickness should be outlined, and the patient should return or follow up if these signs develop any time in the few weeks after treatment with antivenom. The patient should be told not to take nonsteroidal anti-inflammatory drugs for 2 weeks after a pit viper or viper bite. Instead, acetaminophen with or without a combined opioid analgesic should be prescribed. The patient should not engage in contact sports or schedule any elective surgery or dental work for 2 weeks after viperid bites. The patient should be instructed to drink plenty of liquids and warned to return for decreased urination or cola-colored urine.

Some patients may need referral to a physical therapist. Blisters, blebs, and bullae should be left in place, but may need débridement along with necrotic tissue after several days, so surgical referral as appropriate is suggested.³⁰ Skin grafting is sometimes necessary. If the patient was bitten on the foot or leg, crutches and crutch training should be provided. However, the patient should be encouraged to bear weight and mobilize the extremity as tolerated. In some cases, a next-day wound check may be appropriate. Otherwise, the patient should return or follow up in a few days.²⁸ At that time, laboratory tests may need to be repeated, depending on the clinical scenario. The patient should be re-treat with antivenom as needed. Most patients recover fully after snakebite. However, viperid envenomation results in tissue loss, deformity, or loss of function in a clinically significant percentage of patients.⁸

Preventative measures should be explained to parents and children. Children should be taught to leave snakes alone. They should never touch, handle, or try to kill venomous snakes. Many people are bitten when they are intentionally interacting with the snake. Even after a snake is believed to be dead, fangs still can inject venom. Snakes that were presumed dead have bitten many people and delivered serious, even fatal, envenomations. Additionally, a snake can strike faster and farther than one might think—about half its body length—so children should be warned to stay at least “two giant steps” away from snakes. If a child finds a snake, he/she should tell an adult. Additionally, children should be told not to reach or step into places that they cannot see into. Wearing boots and jeans may prevent some (but not all) snakebites. Emergency physicians practicing in a snake territory should inform the patient population that, although there is no way to completely eliminate exposure to snakes, there are a few things that may make a property less appealing for snakes. For example, one can eliminate places where snakes can hide (e.g., log piles or heavy vegetation). Children should be educated about what to do if a snake bites them (i.e., it is very important that they tell an adult right away).

Spider Bites

Widow Spider Bites

Widow spiders belong to the genus *Latrodectus* and are represented in the United States by the black widows, the brown widow, and the red-legged widow.³⁶ The redback spider is endemic to Australia. Other species, such as the kara kurt and black button spider, are found in other parts of the world, including Europe, South America, and South Africa. The adult female black widow spider is approximately 2 cm in length and shiny black with a red-orange hourglass or spot on the ventral abdomen. The male is much smaller, brown, and much less commonly implicated in human envenomation. Juvenile females are also brown, with yellow and white markings, but have the general body morphology of the adult. Males and juveniles have a pale hourglass shape, similar to adult females. Webs are irregular, low-lying, and commonly seen in garages, barns, outhouses, and foliage. Other widow spiders around the world are generally black but may have red spots, such as the kara kurt, or a dorsal red stripe, such as the redback spider. The brown widow is brown with red and yellow markings. Similar species include the false black widow or cupboard spider (*Steatoda* species), which can produce symptoms that are similar in character to but milder in intensity than widow spiders. No deaths caused by widow spider envenomation have been reported to the AAPCC since its first annual report in 1983. However, recent deaths have been reported elsewhere.^{37,38}

CLINICAL PRESENTATION

The envenomation syndrome caused by the various species of widow spiders around the world is similar.^{39,40} The predominant clinical effects are neurologic and autonomic. Typically, the bite site has a “target” appearance. There may be a central reddened, indurated area around fang puncture site(s) surrounded by an area of blanching and an outer halo of redness (Fig. 141–2). The findings around the bite wound may be quite subtle, and the wound does not become necrotic. The predominant symptoms frequently involve painful muscle cramping. If the patient is bitten on the lower extremity, pain usually progresses from the foot, up the leg, and into the back and abdomen. If bitten on the upper extremity, pain usually progresses from the hand, up the arm, and into the chest and abdomen. Abdominal pain may be so severe as to mimic an acute abdomen, with tenderness and rigidity.⁴¹

Diaphoresis locally around the bite site is distinctive for widow spider envenomation, although diaphoresis may be diffuse and profuse, or it may manifest in unusual patterns

FIGURE 141-2. “Target appearance” of widow spider bite.

remote from the bite site. Local piloerection is sometimes seen. Patients may exhibit “*Latrodectus facies*” (Fig. 141–3), characterized by spasm of facial muscles, edematous eyelids, and lacrimation, which may be mistaken for an allergic reaction. Other common symptoms and signs include high blood pressure, rapid heart rate, nausea, vomiting, headache, and anxiety. In a typical progression, symptoms begin within an hour, reach maximum intensity by about 12 hours, and can last for days to weeks. Unusual presentations have been described following widow spider envenomation, including pulmonary edema, myocarditis, and priapism.^{37,42}

It has been suggested that there may be increased danger to pediatric patients with widow spider bites and that this population may require more aggressive treatment and hospitalization, although this assertion has been challenged.⁴³ Very little evidence supports either argument. The only recent documented fatalities from widow spider envenomation involved a healthy 19-year-old woman and an elderly male.

Rhabdomyolysis has been reported after widow spider envenomation,⁴² so CK should be determined if severe envenomation develops. If the patient has respiratory difficulty, a chest radiograph should be obtained. Electrocardiography or echocardiography may detect the rare case of venom-induced myocarditis in a critically ill patient. Otherwise, diagnostics are not particularly helpful. If the diagnosis is uncertain, evaluation should be aimed uncovering other etiologies (such as an acute abdomen). Misdiagnosing an acute abdomen in a patient with a widow spider envenomation could lead to unnecessary surgery.

MANAGEMENT

In the prehospital setting, the airway, breathing, and circulation should be supported with oxygen, monitors, and intravenous access as necessary. First aid is not particularly helpful for widow spider envenomation. Electric shock and various folk and herbal remedies lack therapeutic value and are potentially harmful. There are two basic definitive treatment options: antivenom, or a combination of pain medications and sedatives. There are risks and benefits associated with

FIGURE 141-3. “*Latrodectus facies*” resulting from widow spider bite.

each alternative. Management with an opioid analgesic and a benzodiazepine is generally considered safe. However, this treatment option is purely palliative, and symptoms may persist for days or even weeks. The pain and discomfort associated with widow spider envenomation can be quite severe.

In contrast, antivenom is remarkably effective. Unfortunately it can be associated with very severe side effects, including death.⁴⁴ Because death is so rare after widow spider envenomation, it may be argued that the treatment is more dangerous than the bite itself. Historically, intravenous calcium was recommended, although it is believed to be ineffective.⁴⁴ Several antivenoms have been manufactured, including Black Widow Spider Antivenin (Equine) in the United States; Australia Red-back spider Antivenom, USSR Monovalent (*L. tredecimguttatus*); and South Africa spider antivenom (button spider).¹ Indications for antivenom use and routes of administration vary around the world. To give Black Widow Spider Antivenin according to the package insert, one vial should be reconstituted in 2.5 ml of the sterile diluent supplied. It is further diluted into a volume of 10 to 50 ml saline and administered intravenously over 15 minutes. Patients usually experience dramatic relief within an hour of treatment with one vial, although sometimes two and rarely three vials are needed. It may be effective days, weeks, or possibly even months after the envenomation.⁴⁵ The risk of allergy to antivenom must be weighed against the benefit of relieving prolonged discomfort, avoiding hospitalization, and preventing complications.

Although most widow spider envenomations can be managed with opioid analgesics and benzodiazepines, antivenom may be indicated for patients who have severe envenomations with pain refractory to these measures. Antivenom should be given if there is an imminent risk of a severe complication of envenomation. Factors that could increase the risk of antivenom include allergy or previous exposure to horse serum, or a past medical history of reactive airways.⁴⁶

Serious, even fatal, adverse reactions have been documented after treatment with black widow spider antivenom. Anaphylactic and anaphylactoid reactions to antivenom can occur and may even be more life threatening than the envenomation itself. Skin testing, by injecting 0.02 ml of the test material supplied intradermally and observing for an urticarial wheal in 10 minutes, variably predicts immediate hypersensitivity to antivenom and may influence the decision regarding its administration. Increasing the volume of dilution and slowing the rate of infusion may reduce the chance that an allergic (anaphylactoid) reaction will occur. Additionally, premedication with antihistamines (H₁- and H₂-blockers) may reduce the likelihood that an acute allergic reaction will occur. Serum sickness, characterized by fever, urticaria, lymphadenopathy, and polyarthralgias, can occur days to weeks after treatment and is treated with antihistamines and steroids.

Antibiotics are not indicated for widow spider envenomation. Tetanus prophylaxis should be updated as appropriate. The regional poison control center may be helpful with management of widow spider envenomations and can be contacted at 1-800-222-1222.

Because it so effectively resolves symptoms, antivenom has been shown to decrease the need for hospitalization after widow spider envenomation. Admission to the hospital and possibly the pediatric intensive care unit is prudent for

severely symptomatic children, those with intractable pain and contraindications to antivenom, those with unusual complications of envenomation, and those who develop anaphylaxis to antivenom. Patients who experience relief with opioid analgesics, benzodiazepines, and/or antivenom may be discharged. Upon discharge, signs of serum sickness should be outlined and the patient should return or follow up if these signs show up any time in the few weeks after treatment with antivenom. The envenomation syndrome usually resolves completely, with or without treatment, and does not leave the patient with long-term sequelae. Death is very rare.

Spider bites may be prevented by eliminating the spider's food and habitat; by shaking sheets, shoes, and clothing before donning; by keeping a child's bed away from the wall; and by brushing spiders off rather than crushing them. Safer, effective antivenoms are being developed and investigated.

Recluse and Other Spider Bites

The diagnosis of brown recluse spider bite is overused for dermonecrotic wounds of uncertain etiology.⁴⁷ In addition, reports of presumptive brown recluse spider bites reinforce improbable diagnosis in regions of North America where the spider is not endemic.⁴⁸ There are so many published accounts of "suspected," "presumed," or "possible" spider bites that it has led to a poor understanding of the true pathophysiology of spider envenomation. The literature on the topic is contradictory, and little is evidence based. Fewer than 100 recluse spider bites have been confirmed and documented in the literature. The true incidence, morbidity, and mortality are unknown. Reported deaths are questionable.⁴⁹ This overdiagnosis of spider bites occurs in pandemic proportions in many parts of the world, including the Americas, Australia, Africa, and Europe. The primary toxin in recluse spider venom is sphingomyelinase D.

CLINICAL PRESENTATION

Brown recluse spider (*Loxosceles reclusa*) bites are thought to produce a dry, irregular, sinking blue-gray/white patch with ragged edges, surrounded by erythema—the "red, white, and blue" sign. After a bite, the typical progression is thought to start with mild stinging for 6 to 8 hours followed by aching. The lesion develops a violaceous center, with a ring of pallor and a halo of erythema and edema. There may be a gravity-influenced eccentric ring of redness. After about 24 to 72 hours, an eschar forms. After approximately 2 to 5 weeks, it sloughs, leaving an ulcer. Systemic loxoscelism has been described, but it is rare and very poorly understood.

No routine laboratory tests are indicated in the evaluation of a spider bite. Experimental venom detection assays are in development. Because so many things can be mistaken for spider bites, diagnostics should be used as necessary to evaluate for other conditions. Appearances can be deceiving. It is difficult (if not impossible) to diagnose a recluse spider bite just by looking at the wound. Dozens of conditions resemble a spider bite, and many conditions, including treatable ones, have been misdiagnosed as a brown recluse bite (cellulitis, necrotizing fasciitis, Lyme disease, cancer, cutaneous anthrax, sporotrichosis, Lyme disease, cancer, cutaneous anthrax, sporotrichosis, chemical burns, vasculitis, stasis ulcerations, poison ivy dermatitis, and many more).⁵⁰

Certain features make it less likely that a recluse spider caused a lesion. The spider's range should be taken into

account. If an unexplained wound developed in a geographic area where there are no native recluse spiders or populations, then it is much less likely to be a recluse spider bite. It is possible that spiders may occasionally be transported out of their range, but this happens much less often than could account for the number of lesions attributed to these spiders.^{48,51} In the absence of recluse spiders in the Pacific Northwest of the United States, the hobo spider (*Tegenaria agrestis*) became the scapegoat for idiopathic lesions and grew to urban legend proportions. However, there is no evidence that hobo spiders cause necrotic wounds at all.⁵² Similar extrapolation to other spiders has occurred in Australia with the black house spider (*Badumna insignis*) and the white-tailed spider (*Lampona cylindrata*). Other spiders possibly implicated in necrotic wounds in other parts of the world include the sac and running spiders (*Cheiracanthium* species) as well as the six-eyed spiders (*Sicarius* species) in South Africa. Bites from the vast majority of spiders do not cause necrotic wounds.⁵³

Spider behavior should be taken into account as well when considering the likelihood that a spider caused a wound. For example, because spiders are not parasitic and generally only bite humans out of defense, multiple lesions are suggestive of an etiology other than spider bites. Recluse spiders are non-aggressive, and there are reports of people living in homes infested with hundreds, even thousands, of brown recluse spiders with no bites. Certain wound features should move a spider bite lower in the differential diagnosis. Large (>10 cm in diameter) ulcers are less likely to be spider bites. Early ulceration, within a week, is suggestive of an etiology other than spider bite.⁵⁴ If a spider is caught in the act of biting, it may be helpful to identify it or have it identified by an entomologist or arachnologist (if available). Recluse spiders have 6 eyes grouped in pairs, whereas most other spiders have 8 eyes.

MANAGEMENT

Electric shock was once proposed as a treatment for brown recluse spider bite, but no benefit has been shown from it and it can injure the patient. Treatment recommendations in the literature vary widely. Most agree that routine wound care is standard. If there is any question regarding the diagnosis, the actual etiology should be sought and treated. Sphingomyelinase D activity may be attenuated with cooling measures and augmented with heat. Therefore, a cooling pack may reduce the effects of recluse spider envenomation, although cold-induced injury should be avoided. Conversely, factors that increase warmth to the area, such as infection, should be treated. Although a spider bite itself is not infectious, antibiotics are indicated if a wound appears infected. Dapsone has been recommended for treatment of confirmed brown recluse spider bites, but it is not approved for this use, has serious side effects (such as methemoglobinemia and hemolysis), and is contraindicated in children. Furthermore, its efficacy is unclear. Similarly, hyperbaric oxygen has been suggested on a theoretical basis, but there is no evidence that it is effective for treatment of spider bites.^{55,56} Surgical excision may be necessary once a necrotic lesion declares itself. However, early surgical excision (i.e., to prevent venom effects) is strongly discouraged. Skin grafting may be needed for wound defects. Steroids are not helpful for cutaneous loxoscelism. Antivenom is available for *Loxosceles laeta* (Peru Antiloxoscelico).¹ An investigational Fab antivenom has been

developed in the United States, but it has to be given within 4 hours to be effective. This is generally not clinically practical. Venom detection tests are being researched. One such assay is sensitive enough to tell if a patient has a venomous arthropod bite, but it is nonspecific such that false positives occur with venoms of many other spider species and even scorpion species.⁵⁴

Most patients with suspected or actual recluse spider bites can be managed on an outpatient basis. However, because of the difficulties associated with diagnosis, it is important for patients with suspected spider bites to follow up closely for further evaluation. The vast majority of spider bites heal completely, although a small percentage can develop into a chronic, ulcerative or necrotic wound. However, many chronic idiopathic wounds of other etiologies are attributed to spider bites, and so the actual prognosis is hard to estimate.

A tarantula may have a formidable, intimidating appearance, and its bite may be painful, but it is not particularly dangerous to humans. Basic wound care and tetanus prophylaxis are generally all that is needed. However, urticating hairs flicked from the abdomen can irritate the eyes, skin, and mucous membranes. Ocular exposure can necessitate removal of the hairs by an ophthalmologist.

Electrical Injury

Kenneth T. Kwon, MD and Carl H. Schultz, MD

Key Points

Blunt traumatic and multisystem injuries can be associated with electrical injury in children.

Alternating current electrical injuries have a much higher fluid requirement than dictated by standard burn formulas.

Oral cavity burns in infants and small children may require reconstructive surgery.

Proper triaging of a multivictim lightning injury scene involves caring for victims in cardiopulmonary arrest first.

Introduction and Background

Electrical injuries from natural causes have existed since ancient times, but it was not until the worldwide distribution of man-made electricity beginning in the late 1800s that electrical injuries became commonplace. Electricity can be divided into alternating current (AC) and direct current (DC). Household electrical current is AC with a standard frequency of 60 Hertz (Hz) in the United States. Examples of DC include lightning, medical defibrillation, and batteries. Although some believe that lightning is unique and not specifically DC, it will be categorized as DC for purposes of this chapter. Lightning strikes the United States approximately 25 million times per year.¹

Children are especially prone to electrical injuries. The skin is thinner with higher water content, which predisposes them to greater internal tissue damage than adults. The oral and exploratory nature of toddlers makes them prone to electrical cord and outlet injuries. Adolescents and young adults have a high rate of electrical injuries due to their increased risk-taking behavior in electrical environments and at work relative to other age groups. Throughout their young lives, frequent outdoor group recreational activities expose children to lightning injuries in inclement weather.

Recognition and Approach

In the United States, electrical injuries comprise over 20,000 emergency department (ED) visits per year and account for up to 4% of all admissions to major burn centers.² In 2001, there were 409 deaths attributable to electric current, with 10% of victims less than 20 years of age, and 44 lightning deaths, with 8 (18%) under 20 years of age.³ Lightning injury statistics are poorly tracked, but it is believed that 70% to 80% of lightning strike victims survive, two thirds of whom are left with permanent sequelae.⁴ Most injuries in younger children are due to mouthing a live electrical cord or placing a metallic object into an outlet.⁵⁻⁷ High-voltage injuries tend to occur in older children while exploring building or utility structures, or with specific recreational activities such as kite-flying.⁸

The pathophysiology of these injuries is best appreciated by reviewing electricity physics. Electrical energy is defined using Ohm's law, $V = I \times R$, or voltage (energy possessed by each electron, in volts) = current (number of electrons moving per time, in amperes) \times resistance (ability of a material to slow electron flow, in ohms). Each component contributes to the severity of injury, as does the type of current, duration of contact, and surface area exposed to the current.

Voltage is usually the only variable that is readily known at the time of injury. Typically, high voltage is defined as greater than 1000 volts (V), although some use a lower cutoff of 500 V. Most U.S. household circuits use 110 V, with some larger appliances using 220 V. In comparison, residential power lines carry greater than 7000 V. A lightning strike is estimated to carry up to 100 million V. In general, high voltage is more dangerous than low voltage. Current flow determines heat production and is considered the greatest danger to life of all components, but cannot be quantified during an acute injury. Current follows the path of least resistance, and tissues more susceptible to injury are somewhat predictable. Different body tissues offer different degrees of resistance to current flow. In decreasing order of resistance, they are bone $>$ fat $>$ tendon $>$ skin $>$ muscle $>$ blood vessels $>$ nerves. Skin resistance, however, is extremely variable depending on moisture, thickness, and age. Wet skin can decrease resistance by over 100-fold,⁵ and a neonate's skin provides relatively lower resistance due to its thinness and high water content. Resistance will also determine the pathway of current, with the most dangerous circuit being

from hand to hand with heart involvement, or head to toe with brain and respiratory drive involvement.

The type of current, AC or DC, also plays a major factor in determining injury severity. AC current is generally more dangerous due to the “locked-on” phenomenon. This results from simultaneous tetanic contractions of both hand flexors and extensors. Since the flexors are stronger, the hand cannot be opened and gets “locked on” the electricity source. This phenomenon is associated with standard 60-Hz household current and increases duration of contact. Lightning has an extremely short duration of contact (<0.001 second) and generally imparts less energy to its victims than AC shock. Blunt traumatic injuries are more common with lightning and high-voltage AC due to victims being thrown from the source of contact by muscular contractions. Lastly, surface area of contact will also determine burn type and severity. A small area of contact, such as current passing through a hand, will create more localized heat production and more severe local injury. A large area of contact, such as bathtub electrocution, can result in no localized injury but significant systemic effects.

Lightning can strike a victim by different mechanisms. Aside from a *direct strike*, in which the victim is the primary point of contact of the electrical discharge, lightning can create a *side flash* when it hits a nearby object and then discharges from object to person. Lightning can also cause *step voltage*, or *stride potential*, when it spreads along the ground and flows into one foot, through the body, and out the other foot. Side flash and step voltage can explain why lightning injuries occur in groups. Lastly, lightning can cause *flashover*, which is rapid heating of skin moisture and vaporization. Wet clothes can be blown off, shoes can explode, and blunt trauma may result from the blast effect.

Clinical Presentation

Electrical burns can be categorized into several different types. A true electrical burn, or *conductive burn*, is caused by

electron flow through tissue with resultant heat generation. Temperatures have been measured up to thousands of degrees Celsius. Conductive burns can cause cellular damage or coagulation necrosis of surrounding tissues. Entrance wounds, exit wounds, or both are frequently seen, but may be absent or inconspicuous. Entrance wounds tend to take on a smaller charred appearance, with exit wounds more extensive and sometimes explosive in nature. The amount of damage to underlying tissues and organs is not always evident by looking at the skin, as the path of current flow cannot be determined. Conductive burns should be considered as a crush-type injury, because they cause more swelling than a true thermal burn. An *arc burn* is caused by electrons moving through the air instead of through the body, and injury occurs when the body contacts the arc. Arc burns can generate temperatures up to 4000° C. A *flame burn* occurs with ignition of clothing by arcs or sparks, causing direct thermal injury. Both arc and flame burns are usually seen with high-voltage injuries.

Lightning strikes can present with unique characteristic burns. Linear burns are due to the vaporization of sweat; this phenomenon can also blow articles of clothing off victims. Punctate burns can be seen, which appear like cigarette burns 3 to 10 mm in diameter. Feather burns, also called Lichtenberg figures, are not actual burns but staining of the skin caused by a shower of electrons creating a branch or fernlike pattern. These feather burns fade within 24 hours of injury and are considered pathognomonic for lightning injury.

Electrical injuries tend to affect multiple organ systems (Table 142–1). With significant AC injury, the typical presentation includes transient loss of consciousness with possible apnea or ventricular fibrillation, neurologic symptoms or deficits, and external evidence of trauma. Fractures or dislocations, particularly of the shoulder, are commonly seen due to the tetanic forces caused by AC electricity. The conductive burns can be deep and extensive, causing coagulation necrosis and predisposing to compartment syndrome and infection. Rhabdomyolysis and cardiac dysrhythmias may ensue and need to be considered early in management.

Table 142–1 Patterns of Electrical Injuries

	AC Current	Lightning (DC Current)
Cardiac	Dysrhythmias including ventricular fibrillation, asystole, MI (rare)	Dysrhythmias including asystole, hypertension (transient)
Neurologic	Apnea, LOC or mental status changes, motor paralysis/paresis/paresthesia, seizure, intracranial hemorrhage, cerebral edema Delayed symptoms: ascending paralysis, transverse myelitis, ALS-like syndrome	Apnea, LOC or mental status changes, keraunoparalysis*, autonomic instability, seizure, intracranial hemorrhage, antegrade amnesia, peripheral neuropathy
Musculoskeletal	Compartment syndrome, tendon rupture, fracture/dislocation	Compartment syndrome (rare)
Cutaneous	Entrance/exit wounds, flexor crease burn, oral commissure burn	Linear, punctuate, and feather burns, serious burns (rare)
Pulmonary	Diaphragm/thoracic muscle tetany, ARDS, pneumothorax, aspiration	Diaphragm/thoracic muscle tetany, ARDS, pneumothorax, aspiration
Gastrointestinal	Ileus, bowel perforation, GI bleeding, solid organ injury, stress ulcers	Blunt abdominal trauma
Renal	Rhabdomyolysis, acute renal failure	Rhabdomyolysis (rare)
Vascular	Vasospasm (transient), thrombosis, progressive amputations	Vasospasm (transient)
HEENT	Fixed/dilated pupils (transient), visual changes, optic neuritis, intraocular hemorrhage, cataract	Fixed/dilated pupils (transient), tympanic membrane rupture, tinnitus, cataract, corneal lesion

*Keraunoparalysis is a syndrome consisting of limb paralysis, mottled skin, and pulselessness.

Abbreviations: AC, alternating current; ALS, amyotrophic lateral sclerosis; ARDS, acute respiratory distress syndrome; DC, direct current; GI, gastrointestinal; HEENT, head, ears, eyes, nose, and throat; LOC, loss of consciousness; MI, myocardial infarction.

Lightning injuries have several differences from AC injury patterns. Asystole is the usual life-threatening rhythm. If treated quickly, patients have an excellent prognosis, unlike other causes of asystole. When asystole resolves spontaneously, it usually does so prior to the return of spontaneous respirations. Autonomic dysfunction can be quite marked in lightning strikes, causing transient absence of extremity pulses or even hypertension. Keraunoparalysis is an early manifestation of autonomic instability characterized by bilateral lower extremity paralysis associated with mottled or pulseless extremities, which usually resolves within a few hours. Although paraplegia is characteristic, unilateral hemiplegia is unusual and should be aggressively investigated for another acute cerebrovascular cause. The single muscular contraction effect of DC energy can powerfully throw a victim; thus blunt trauma is more likely associated with lightning injuries. Severe burns rarely occur, and extensive local tissue damage and rhabdomyolysis are not commonly seen. Tympanic membrane rupture is a characteristic examination finding following lightning injury. Although previously thought to be the result of the lightning's blast effect, rupture is now considered to be the result of direct conductive damage.⁹

Because electrical injuries are usually evident based on historical factors, an exhaustive differential diagnosis or etiologic search is usually not necessary. Exceptions can occur with bathtub electrical injury, in which circumstances may be unclear and external evidence of injuries are usually minimal, and with high-voltage injury, in which a victim may be thrown far enough away from the source as to create confusion as to the cause of injury.

Important Clinical Features and Considerations

Contact burns to the mouth and lips, especially the oral commissure, are commonly seen in infants and toddlers. The mouth was the second most frequent site of injury, after the extremities, in pediatric burn admissions in one retrospective review,² while another study found 38% of hospitalized pediatric burn patients were admitted due to oral burns.⁵ Extension cords are the most common source, with injury occurring either by biting into the cord itself or by mouthing the female live end of a connected cord. Saliva significantly lowers the resistance of the oral mucosa and lips, and tissue damage occurs from a combination of direct conductive and arc mechanisms. Commissure burns are usually full thickness, initially appearing as a painless, pale, yellow-gray coagulated patch with a depressed center and surrounding edema and erythema (Fig. 142-1). Bleeding almost never occurs at the time of presentation. Delayed bleeding of the labial artery can occur as the eschar sloughs off 1 to 4 weeks postinjury. The rate of this complication in oral burns is up to 23%.¹⁰ Granulation tissue fills the wound, but disfiguring scarring and loss of function can be seen, often necessitating reconstructive plastic surgery. Other late complications of oral burns include dental devitalization, microstomia, oral adhesions, and speech problems.

Pregnant patients, both teenagers and adults, deserve special consideration. Fetal skin has much less resistance than postnatal skin, and, combined with a gravid uterus filled with amniotic fluid, makes the fetus particularly sus-

FIGURE 142-1. Oral commissure burn.

ceptible to serious injury. Because of limited studies with small numbers and unknown exposure data, the significance of electrical injury in pregnancy remains unclear. A review of 15 pregnant victims of AC injury showed minimal harm to mothers but fetal death in the majority of cases.¹¹ Fetal demise has been reported after lightning injuries as well.^{4,12} Of note is that emergent iatrogenic DC cardioversion in pregnant patients is generally considered safe because the current path does not include the pelvic area.

Management

In the prehospital setting, rescuers need to ensure their own safety while providing care. Any source of electricity needs to be shut off, and the voltage and type of current should be determined. The child victim should be evacuated from a higher to lower risk area when possible, particularly during a lightning storm. In the case of multiple victims and suspected lightning injury, normal mass casualty triage guidelines should be reversed, with initial focus on those in cardiopulmonary and respiratory arrest. Whether cardiac activity returns spontaneously or due to intervention, it is likely to restart prior to respirations, so early and proper respiratory management is of paramount importance. Because lightning and high-voltage injuries can result in transient autonomic dysfunction, fixed and dilated pupils, apnea, and absent pulses on scene are not reliable indicators for death. Any child with suspected major electrical injury should be treated similar to a multisystem trauma victim in the field and ED setting.

In the ED, diagnostic evaluation of the moderately to severely injured child should include a complete blood count, electrolytes, blood gases, urinalysis, and urine myoglobin. Urine testing may reveal the classic finding of heme in the absence of red blood cells suggestive of myoglobinuria and rhabdomyolysis. Blood creatine phosphokinase (CPK) is

frequently obtained to help determine the degree of muscle breakdown, but CPK levels have no relationship to burn severity or overall prognosis.² Radiographic studies should be obtained as indicated. Cardiac monitoring, electrocardiogram (ECG), and cardiac enzyme tests should be initiated if a transthoracic electrical current is suspected.

In children with minor household electrical injuries or isolated burns, the need for diagnostic studies and cardiac monitoring is controversial. Some authors suggest that routine cardiac monitoring is not required in most children sustaining household electrical injuries.¹³⁻¹⁶ However, an ECG and cardiac monitoring should be considered in cases in which there was loss of consciousness, tetany, wet skin, or current flow crossing the chest.¹³ A retrospective review suggested that pediatric victims of minor low-voltage household current who are asymptomatic or have only minor burns do not require cardiac monitoring or laboratory evaluation of any kind and can be safely discharged home.¹⁵

Initial ED treatment should focus on burn care and fluid management. Patients with high-voltage AC injuries should be aggressively fluid resuscitated, as they tend to have substantial third spacing and tissue swelling. Traditional burn formulas will grossly underestimate the fluid requirement in these patients. Therefore, maintaining urine output at a rate of at least 1 ml/kg/hr should dictate the amount of intravenous crystalloid fluid administered. Placement of a central venous pressure catheter should be considered. If rhabdomyolysis is suspected, urine alkalization should be undertaken. Sodium bicarbonate can be used, first as a bolus of 1 mEq/kg, followed by one to two ampules (50 to 100 mEq) in 1 L of 5% dextrose in water at a rate to maintain adequate urine output and a urine pH \geq 7.45. Diuretics such as mannitol (0.25 to 1 g/kg) or furosemide (1 mg/kg) can be used intermittently to ensure adequate urine output, assuming hypotension is not a concern (see Chapter 99, Rhabdomyolysis). Electrical burn wounds should be loosely dressed in sterile gauze per standard burn care management (see Chapter 26, Burns), and tetanus prophylaxis administered as needed. Extremity injuries should be carefully monitored, as compartment syndrome and the need for emergent fasciotomy occasionally occur (see Chapter 22, Compartment Syndrome). With high-voltage AC injuries, vascular thrombosis may necessitate progressive amputations of an extremity over the course of 7 to 10 days, so parents should be informed early of this possible complication.

Lightning injuries usually do not involve as much tissue swelling or fluid shifts as AC-type injuries, thus aggressive fluid resuscitation is usually not necessary. Similarly, fasciotomies are rarely needed in lightning injuries, and compartment pressures should be checked prior to performing a fasciotomy, as the absence of extremity pulses may be due to lightning-induced autonomic instability (i.e., keraunoparalysis).

Summary

All high-voltage and lightning injuries in children require hospitalization, as do low-voltage exposures with significant burns or associated injuries. Admission with cardiac monitoring or in an intensive care setting is indicated with any suspected transthoracic current injury, history of cardiopulmonary arrest or dysrhythmias in the field or ED, large or

deep burns, altered mental status, hypotension, severe acidosis, or rhabdomyolysis. When possible, transfer to a specialized inpatient burn center is recommended, especially in young children. All patients with viable pregnancies need fetal monitoring and obstetric consultation, as these mothers will be considered high risk for the remainder of their pregnancies.

Low-voltage household injuries in children who are asymptomatic or have just minor burns can usually be managed as outpatients. The utility of cardiac monitoring in the ED is limited. Clinical experience suggests it is reasonable to observe these patients for dysrhythmias or symptoms in the ED for 2 to 4 hours prior to discharge. Exceptions would include patients with an abnormal initial ECG, loss of consciousness during the event, voltage exposure greater than 240 V, or a known cardiac condition. Admission and monitoring for at least 24 hours is recommended in these cases.¹⁴ Oral commissure burns not involving deeper oral structures can generally be discharged home with strict parental instructions concerning delayed bleeding complications and with close plastic surgery follow-up.

Prevention of electrical injuries centers on parental supervision, childproofing measures at home, and education about lightning safety guidelines. The increased use of ground fault circuit interrupters and outlet protectors has helped reduce household injuries, although not all outlet protectors are fail-safe, and they may give parents a false sense of security.^{6,17} During a lightning storm, expert consensus recommends the following: seek cover in large enclosed structures, such as a house or office building, or in a car with the windows rolled up; avoid being near or in water, areas near tall structures, open fields, open structures, or open vehicles; seek the lowest spot and get in a curled position if outdoors, and disperse when in a group.^{1,18}

Chapter 143

Inhalation Exposures

Mark A. Hostetler, MD, MPH

Key Points

The main mechanisms by which inhalation exposures cause injury are asphyxia, direct injury to the pulmonary tree, and systemic toxicity.

Inhalation injury patterns are closely related to volatility, water solubility, and viscosity.

Volatile agents more easily vaporized, making them subject to inhalation.

Highly water-soluble agents are more rapidly absorbed in the upper airway and produce immediate local irritation; water-insoluble agents are not readily absorbed, and produce lower respiratory tract symptoms that are usually delayed.

Aspiration risk is inversely proportional to viscosity: low-viscosity agents have the highest aspiration risk.

Selected Inhalation Exposures

- Smoke
- Carbon monoxide
- Cyanide
- Chlorine gas

Discussion of Individual Inhalation Exposures

Smoke

Inhalation injury occurs when the respiratory tract is exposed to one or more toxic substances (toxicants) with resultant anatomic or physiologic damage. Although these toxicants are primarily gases, volatilized products of combustion and inhaled particulate matter also cause injury. Oxygen depletion and direct thermal injury also play a role in inhalation injuries. House fires are a major cause of serious smoke inhalation injuries^{1,2} (see Chapter 26, Burns). Mortality rates,

particularly in children, have declined over the last 2 decades.³ Still, approximately 4000 Americans die each year in residential fires.⁴ Most of these fatalities occur in adults.¹ Approximately 25% of these fatalities occur in children younger than 18 years, with 17% occurring in children younger than 5 years.¹ Inhalation injury is a primary contributor to pediatric burn mortality.^{5,6} Many cases of smoke inhalation involve exposure to a mixture of gases as well as particulate matter and heat.⁷ The most common fatal gas involved in smoke inhalation is carbon monoxide (CO). Other toxic gases are hydrogen cyanide (HCN), and hydrochloric acid (HCl). HCl is commonly released when polyvinyl chloride is burned. Polyvinyl chloride is found in many household products and construction materials, including flooring and siding. When polyvinyl chloride is burned, HCl is released as a dense white smoke. As polyvinyl chloride continues to burn, white smoke is followed by a dense black smoke with a very high CO content.

Clinical Presentation

Physical examination may reveal facial burns, singed nasal hairs, pharyngeal soot, and carbonaceous sputum. The clinician should evaluate the airway for thermal injury and monitor the patient for impending airway obstruction (Table 143–1). Before respiratory failure occurs, intubation for airway protection is prudent in many cases. Signs of respiratory distress may be delayed for 12 to 24 hours, but may include tachypnea, cough, and stridor. Auscultatory abnormalities may include wheezing, rales, and rhonchi. Acute respiratory failure may occur at any point. Pneumonia may develop days after the initial insult and carries a high mortality rate.^{8–10} Pulse oximetry can be falsely reassuring in patients poisoned by CO. This has been called the “pulse oximetry gap.”¹¹ When CO is suspected, arterial blood gas analysis should be performed with co-oximetry to measure carboxyhemoglobin (COHb). The presence of hypoxemia, hypercarbia, and an elevated COHb level are hallmarks of smoke inhalation. Metabolic acidosis may be due to respiratory insufficiency, or cellular asphyxia due to CO or HCN may lead to a metabolic acidosis.^{8,12}

A chest radiograph obtained shortly after exposure is an insensitive indicator of smoke inhalation injury.^{8,13} Auscultatory abnormalities may precede abnormalities on chest radiography by 12 to 24 hours. When present, radiographic abnormalities include diffuse interstitial infiltration or local areas of atelectasis and edema.

Table 143–1 Management of Inhalation Injuries**Initial Management**

Remove patient from contaminated environment
 Rapid cardiopulmonary assessment
 Cardiopulmonary resuscitation as needed
 Provide humidified 100% supplemental oxygen
 Primary survey—ABCDEs (airway, breathing, circulation, disability, exposure)
 Assess for other injuries

Diagnostic Evaluation

Arterial/venous blood gas analysis (co-oximetry)
 Carboxyhemoglobin level
 Complete blood count, electrolytes
 Urinalysis for myoglobin
 Chest radiograph

Continuous Cardiopulmonary Monitoring

Heart rate
 Electrocardiogram
 Respiratory rate
 Blood pressure
 Pulse oximetry

Treatment

Humidified 100% oxygen
 Continuously re-evaluate for airway edema, obstruction, failure
 Meticulous pulmonary toilette
 β_2 -Agonist bronchodilator therapy
 Fluid therapy to maintain urine output > 1 ml/kg/hr
 Consider antidotal therapy as indicated

Management

When burned children with inhalation injuries receive mechanical ventilation, permissive hypercapnia may minimize barotrauma.¹⁴ Continuous positive airway pressure or positive end-expiratory pressure (5 to 15 cm H₂O) is recommended for refractory hypoxemia.^{8,9} Inhaled β_2 -agonist bronchodilators are useful for acute bronchospasm. There is no documented benefit from steroids or prophylactic antibiotics.^{8,12}

All symptomatic children should be admitted to the hospital. Clinical experience suggests observing asymptomatic children for a minimum of 4 to 6 hours and admitting them to the hospital if signs or symptoms of inhalation injury develop during this observation period. Family members who survive house fires should be encouraged to develop an emergency plan and use smoke and CO detectors in their homes.

Carbon Monoxide

CO is a colorless, odorless, tasteless, and nonirritating gas formed as a by-product of incomplete combustion of fossil fuels or materials such as wood or charcoal. CO poisoning is most commonly due to smoke inhalation, but also occurs from exposure to malfunctioning or improperly vented heating and cooking appliances, automobile exhaust fumes, and methylene chloride (found in paint strippers). CO exerts its potentially lethal effects via several different mechanisms. CO binds to hemoglobin 250 times as tenaciously as oxygen; therefore, it greatly reduces the ability of hemoglobin to carry oxygen. CO also shifts the oxyhemoglobin dissociation curve to the left, making it more difficult for oxygen to be released from hemoglobin to the cells. As a result of binding to myoglobin, there is impaired diffusion of oxygen to cardiac and

skeletal muscles, resulting in the victim's reduced ability to move and escape.⁷

Analysis of data from the National Center for Health Statistics for the years 1994 to 1998 identified an average of 516 annual deaths from unintentional non-fire-related CO poisoning in the United States.¹⁵ These fatality figures do not include intentional poisoning and deaths from fire and smoke inhalation, some of which were undoubtedly the result of CO toxicity. Unintentional CO toxicity and deaths are more common in northern climates and during the winter months. The mortality rate among patients with severe CO poisoning is about 30%. Most patients who die do so at the scene of exposure. Up to 11% of survivors develop persistent gross neurologic or psychiatric deficits. A larger number may develop more subtle pathology such as personality changes or memory impairment. Up to 25% of treated patients will experience delayed neurologic deterioration following a period of apparent recovery. Although most delayed sequelae will resolve, the course may span years.¹⁶

Clinical Presentation

Clinical signs and symptoms of CO poisoning are relatively nonspecific and correlate only roughly with the COHb level. The longer the interval between exposure and evaluation in the emergency department, the more likely that the symptoms and COHb level will be discordant. Many patients with relatively mild CO intoxication complain of flulike symptoms with headache, nausea, and fatigue. More severe symptoms include unexplained alterations of mental status, neurologic abnormalities, syncope, and metabolic acidosis. In infants, the only suggestion of toxicity may be irritability or feeding difficulties. COHb levels do not correlate with clinical signs and symptoms in children.¹⁷

COHb levels are measured using co-oximetry. COHb levels are adequately reflected in both arterial and venous samples. Chest radiography is not indicated unless there is clinical evidence of pulmonary edema or a concern about related smoke inhalation injury. A urinalysis and serum creatine kinase are indicated for patients with prolonged unconsciousness or those otherwise at risk for rhabdomyolysis (see Chapter 99, Rhabdomyolysis). Computed tomography may be performed for other indications (see Chapter 9, Cerebral Resuscitation), but is not specifically indicated in the acute management of suspected CO poisoning.^{16,18}

Management

The cornerstone of treatment is high-flow supplemental oxygen. The short-term administration of high concentrations of oxygen is indicated as soon as the diagnosis of CO poisoning is suspected as this treatment offers little, if any, risk to most patients. In the awake patient, a fraction of inspired oxygen (FiO₂) of nearly 100% can be achieved using a tight-fitting non-rebreathing mask with a reservoir. The half-life of COHb is approximately 3 to 4 hours while breathing room air, 60 minutes while breathing 100% oxygen, and 20 minutes breathing hyperbaric oxygen (HBO) at 2.5 atmospheres of pressure.

HBO treatment of CO poisoning is controversial. Traditional recommendations for HBO treatment were based on COHb levels. This approach is no longer advocated.^{19–21} It is not currently clear that HBO treatment is beneficial for patients for CO poisoning.^{19–21} Until these treatment issues

are resolved, a hyperbaric specialist or poison control center it is reasonable to consult for cases of severe CO toxicity. U.S. emergency physicians can find the location of the nearest hyperbaric chamber by calling the Divers Alert Network (DAN), Duke University, Durham, NC, at 1-919-684-8111 (see Chapter 144, Dysbarism). An absolute contraindication to HBO treatment is an untreated pneumothorax. Complications of HBO treatment include rare seizures, vascular gas emboli, and barotrauma to the ears, sinuses, and lungs. The use of HBO typically involves transport to another facility with the inherent risks incurred during transport.

Clinical experience suggests that CO-exposed patients who are asymptomatic or manifest mild, flulike symptoms may be discharged if a repeat CO level is less than 5 mg/dl after 4 hours receiving 100% FiO₂. All other patients with CO exposures should be admitted. Severely ill children should be transferred to a pediatric tertiary care center.

Summary

CO poisoning is common, but the diagnosis is not always obvious. It should be suspected when multiple victims or family members present with headache and vague flulike symptoms. Accurate testing requires co-oximetry, which can accurately be performed on arterial or venous blood. A hyperbaric specialist or poison control center should be consulted for severe cases.

Cyanide

Cyanide is a cellular asphyxiant. Cyanide binds with the ferric ion of mitochondrial cytochrome oxidase enzymes and halts aerobic cellular respiration. This shift to anaerobic metabolism results in a severe lactic acidosis. Cyanide also shifts the oxygen-hemoglobin dissociation curve to the left, further impairing oxygen delivery to the tissues. HCN gas is formed when wool, silk, synthetic fabrics, and some building materials catch fire. It is estimated that up to 35% of all house fire victims may have been exposed to cyanide.²² Cyanide also is used in the mining and photographic chemical recycling industries. Industrial firms in the United States manufacture over 300,000 tons of cyanide each year. As a terrorist weapon, cyanide gas could be generated in an enclosed space via the addition of an acid to a solid cyanide salt, but is highly volatile and rapidly disperses in air. In the 10-year period between 1993 and 2002, the Toxic Exposure Surveillance System compiled by the American Association of Poison Control Centers recorded 3165 human exposures to cyanide.²³ Eighty (2.5%) of these exposures resulted in death and 413 (13%) resulted in serious morbidity. In the Union Carbide pesticide plant disaster in Bhopal, India, there were an estimated 1800 to 5000 deaths and almost 200,000 injuries.²⁴

Clinical Presentation

The onset of symptoms following inhalation exposure to HCN gas is immediate. Low concentrations (e.g., < 50 parts per million) cause restlessness, anxiety, palpitations, dyspnea, and headache. Very high concentrations result in marked tachypnea, immediately followed by severe respiratory depression, convulsions, respiratory arrest, and death.⁷ Patients who are alert may hyperventilate and complain of breathlessness. Since cyanide prevents tissue extraction of oxygen from the blood, the oxygen content of venous blood approaches that of arterial blood, resulting in the brightening of venous blood. The typical seriously poisoned patient is hyperventilating, hypotensive, and bradycardic without cyanosis.

There is no rapid or readily available diagnostic test for cyanide exposure. In the absence of a known cyanide exposure, the diagnosis must be made empirically (e.g., smoke inhalation with high lactate, enclosed space, or mass casualty). A high anion gap metabolic acidosis and plasma lactate levels greater than 10 mmol/L (90 mg/dl) are consistent with cyanide toxicity.²⁵ Comparing arterial and venous blood gases may demonstrate a diminished arterial-venous O₂ difference.

Management

The mainstay of therapy for cyanide poisoning is aggressive supportive care (see Table 143–1) and prompt administration of the cyanide antidote kit (Table 143–2). The antidotal action of the cyanide antidote kit is at least in part due to nitrites causing methemoglobinemia. Caution must be used in the administration of the cyanide antidote kit to fire victims with possible simultaneous CO and cyanide poisoning. Since COHb does not carry oxygen, the creation of methemoglobin can further decrease oxygen delivery. In this situation, sodium thiosulfate should be used alone.²⁶ The reported death of a child from methemoglobinemia following aggressive treatment of a nonlethal ingestion has led to the recommendation of adjusting the pediatric dose of sodium nitrite according to the patient's hemoglobin level (Table 143–3).

Side effects of nitrite administration include headache, blurred vision, nausea, vomiting, and hypotension. Methemoglobin levels of 20% to 30% are associated with symptoms of headache and nausea. Weakness, dyspnea, and tachycardia occur at levels of 30% to 50%. Dysrhythmias, central nervous system depression, and seizures occur at levels of 50% to 70%. Death typically occurs at methemoglobin levels above 70%. In contrast to the nitrites, thiosulfate has few if any side effects other than burning at the injection site, localized muscle cramping, and occasional nausea and vomiting.²⁷ There are limited data on hydroxocobalamin use in children.

Table 143–2 Cyanide Antidote Kit: Contents and General Instructions for Usage

Antidote	Quantity/Form Supplied	Pediatric Dose
Amyl nitrite	12 perles (0.3 ml/perle)	Crush 1–2 perles in gauze and hold under patient's nose or over ET tube for 15–30 sec every minute until sodium nitrite is infusing
Sodium nitrite	2 ampules of 3% solution (300 mg/10 ml)	0.3 ml/kg (9 mg/kg), not to exceed 10 ml (300 mg), IV at 2.5 ml/min, or over 30 min, in smoke inhalation victims with CO poisoning
Sodium thiosulfate	2 ampules of 25% solution (12.5 g/50 ml)	1.6 ml/kg (400 mg/kg), up to 50 ml (12.5 g), at rate of 3–5 ml/min

Abbreviations: CO, carbon monoxide; ET, endotracheal; IV, intravenously.

Table 142–3 Dose Adjustment Recommendations for Sodium Nitrite Based on Hemoglobin Level

Hemoglobin Level (g/dl)	3% Sodium Nitrate (NaNO ₂) (ml/kg)	25% Sodium Thiosulfate (Na ₂ S ₂ O ₃) (ml/kg)*
7	0.19	1.65
8	0.22	1.65
9	0.25	1.65
10	0.27	1.65
11	0.30	1.65
12	0.33	1.65
13	0.36	1.65
14	0.39	1.65

*There is a uniform dose for sodium thiosulfate for all hemoglobin levels.

Chlorine Gas

Chlorine gas is a pulmonary irritant. Pulmonary irritants are among the most common toxic inhalants. Chlorine is a yellow-green gas that is slightly water soluble and has a pungent, irritating odor. With a density almost twice that of air, it descends and remains near ground level. Chlorine gas is 20 times more potent and irritating than HCl. When chlorine gas and mucosal water react, HCl and hypochlorous acid (HOCl) are produced and are responsible for the caustic effects. As particle size and water solubility decrease, progressively lower regions of the airways are affected, and resultant symptoms are more insidious and severe. The potential sources of exposure to chlorine are multiple and include industrial operations, inappropriate mixing of household cleaning agents, emissions during transport, school chemistry experiments, and mishaps in the chlorinating of swimming pools. Chlorine is shipped widely by truck, train, and barge, making transportation and storage accidents ever-present dangers.

Chlorine exposures are most frequently due to industrial (pulp mills), household cleaner, and swimming pool exposures.²⁸ Children and adolescents younger than 18 years constitute the majority and most severely affected of patients.^{29,30} The medical literature is replete with household exposures involving cleaning agents. Household ammonia and bleach are two of the most common cleaning agents. Combining them releases chloramine gas. When inhaled, chloramine gas reacts with the moisture of the respiratory tract to release ammonia, HCl, and oxygen free radicals. Typically, exposures to low concentrations of chloramines produce only mild respiratory tract irritation. In higher concentrations, the combination of HCl, ammonia, and oxygen free radicals may cause corrosive effects and cellular injury, resulting in pneumonitis and edema.^{31,32} Aside from the initial cough and irritation, serious morbidity is rare and no deaths have been reported from household cleaning agents.^{31,32}

Toxic manifestations of chlorine gas may be significant, and occur within seconds or minutes of exposure, depending on the concentration. Upper airway symptoms include irritation of the eyes, nose, and throat. Stridor and upper airway swelling leading to obstruction may occur. Lower airway manifestations include cough, shortness of breath, chest pain, and wheezing. Pulmonary edema and death may occur with significant exposure. Burns and corneal abrasions have

resulted from skin and eye exposures. Various nonspecific symptoms, such as headache and nausea, may be present.^{30,31} Clinical manifestations are predictable and typically resolve within 6 hours after mild exposures. Blood gases are generally normal. Mild hypoxemia and hypercarbia or respiratory alkalosis may be seen.^{30,32,33} Chest radiographs are generally normal.³³

Standard treatment of acute chlorine gas exposure includes removal of the patient from the source and respiratory support measures as needed. Eye and skin exposure requires copious irrigation with water or saline. Bronchospasm usually responds to standard β_2 -agonists (e.g., albuterol). Corticosteroids and nebulized sodium bicarbonate have no clear efficacy and are not recommended.^{30,33} Long-term effects after acute and chronic exposures to chlorine do not appear to be clinically significant, and the risk of reactive airways disease is undefined.^{28,33}

Exposures to chlorine gas and other pulmonary irritants are relatively common. Symptoms are usually acute and short lived. Humidified oxygen and β -agonist applications are the best supportive therapy for chlorine gas exposure. Acute household cleaning agent exposures are generally benign. More severe injuries are possible with industrial exposures to more highly concentrated chemicals.

Dysbarism

John P. Santamaria, MD

Key Points

Pediatric divers are at special risk for serious diving injuries due to emotional immaturity.

Patients tend to minimize the importance of vague symptoms and may fail to associate them with diving.

Patients with dysbarism may present days after a dive with relatively vague complaints.

Recompression treatment should begin as soon as decompression illness is suspected.

Introduction and Background

Dysbarism is a term for any clinical syndrome caused by a difference between the atmospheric pressure and the total gas pressure in a body tissue, fluid, or cavity.¹ Although the term could be applied to changes in atmospheric pressure such as occurs during a space walk,² the most common situations in which emergency physicians will encounter children and adolescents with dysbarism is either at high altitudes in mountainous regions (see Chapter 145, High Altitude–Associated Illnesses) or after scuba diving.

Given that the symptoms of diving-related illnesses can arise several hours after a dive and that patients may present days after diving, emergency physicians working several hours' travel from the coast may occasionally see patients with diving-related illnesses. Although many interesting and serious conditions can arise from spending time in the ocean³ (see Chapter 140, Hypothermia), this discussion focuses on those conditions related to changes in atmospheric pressure associated with scuba diving.

Recognition and Approach

The vast majority of scuba divers are middle-aged adults.^{4–8} Not surprisingly, most dive-related injuries and fatalities occur in middle-aged adults.^{4–8} However, increasingly younger children have been accepted into scuba certification courses and encouraged to dive. In 2000, diving certification organizations lowered the minimum training age from 12 to 8

years.^{9,10} Although still relatively rare, serious pediatric diving injuries and fatalities occur. Of 423 diving-related fatalities reported to the Divers Alert Network from 1999 through 2003, 7 (2%) occurred in children ≤ 19 years^{4–8} (Table 144–1). From data on citizens of the United States and Canada, the age of the youngest child to sustain a diving injury is 11 years and the age of the youngest child to suffer a diving fatality is 14 years.³

Emotional maturity, appropriate training, and tight supervision appear to be key components to successful pediatric diving. Many children and adolescents are intellectually capable of completing and excelling in the cognitive portions of scuba diving classes. The concern is that a child or adolescent will react badly to unexpected, uniquely stressful experiences under water or take unnecessary, dangerous risks. Poor decision making, lack of proper training, ignoring proper procedures for safe diving, and panicking at a critical moment are recurrent themes in fatal adolescent dives (see Table 144–1).

The pathophysiology of dysbarism falls into two general categories. The first category involves pressure changes in relatively fixed body spaces. These disorders are generally referred to as “barotrauma.” These types of injuries are reasonably straightforward and based on a well-described physical principle, Boyle’s law.^{11,12} Boyle’s law states that, at a constant temperature, volume and pressure are inversely proportional. Every 10 meters of sea water in depth adds 1 additional atmosphere of pressure. So, if an air-filled ball is taken down 10 m in the ocean, the volume of the ball would be half of its volume at the surface because the air in the ball would be exposed to twice the atmospheric pressure. The same principles apply to body cavities such as sinuses. Unfortunately, the bony walls of a sinus cannot easily accommodate large changes in volume. The signs and symptoms will reflect the body cavity involved.

The second category in the pathophysiology of dysbarism involves gases dissolved in liquids. Affecting one or more body regions, the constellation of problems arising from nitrogen dissolving in body tissues is typically referred to as “decompression illness.”^{9,11} The relevant physical law in this instance is Henry’s law.¹³ Henry’s law states that the amount of gas dissolved in a liquid is proportional to the partial pressure of that gas in contact with the liquid.¹³ The higher the pressure, the more gas dissolved in that liquid. When diving, the higher atmospheric pressure drives nitrogen into the body tissues. Since nitrogen is not metabolized by the body,

Table 144–1 Deaths Associated with Scuba Diving by Children and Adolescents ≤ 19 Years, 1999–2003

Year	Age (yr)	Gender	Prior Diving Experience	Circumstances
2003	18	Male	Certified for 18 mo; 130 dives completed	Shore-entry night dive using nitrox. Third dive of the day. Depth to 93 feet of sea water (28 m) for 25 min. Rapid ascent after running out of breathing gas. Unconscious upon surfacing.
2001	19	Male	Completed open water certification the morning of the day he died	Without prior planning, separated from an instructor and entered an underwater cave with 35-yr-old diving buddy. Ran out of air after becoming lost in the cave.
2001	17	Male	No formal dive training or experience	Did not dive with a buddy. Did not use a buoy or any other mark for his location. When his body was found 2 days later, his tank was empty.
2001	17	Female	No formal dive training or experience	Collecting sand dollars at a depth of 10 feet. Did not wear fins. Began with a partially empty tank. Was holding hands with another equally inexperienced diver during the dive, but let go at the surface. Her body was found 8 hr later.
2001	19	Female	Completed certification course; participating in her first dive after certification and first dive in cold water	Strong current and poor visibility. Planned a dive to 50 feet of sea water (15 m), but descended to 200 feet of sea water (60 m). She lost consciousness after appearing to panic and have difficulty with her buoyancy compensator. She was too heavy for the dive buddy to lift. Her body was never recovered.
2000	16	Male	Certified by an organization with no national affiliation 1 year prior	Second dive of the day that went past 200 feet of sea water (60 m). Shot an extremely large fish and attached it to his buoyancy compensation device. Struggle with the fish resulted in him being hit in the face and neck. Unconscious when his dive buddy reached him. Went beyond maximum for depth and time based on buddy's dive computer.
1999	19	Male	Open-water certified for 2 wk	Made a dive to 227 feet of sea water (69 m) with two other divers. Ascended to 190 feet of sea water (57.8 m). He ran out of air and began to buddy breath with one of the other divers. Then made a rapid ascent to the surface from 170 feet of sea water. Pronounced dead at a local hospital.

Data source: Divers Alert Network: Report on Decompression Illness, Diving Fatalities and Project Dive Exploration (2001 through 2005 editions). Available at <http://www.DiversAlertNetwork.org>.

if ascent is too rapid, the nitrogen may be released rapidly from tissues and bubbles may form. These bubbles can obstruct arteries, veins, and lymphatics or distort local tissue architecture. The signs, symptoms, and clinical syndrome relate to the body parts involved.

Clinical Presentation

The feature most strongly affecting the clinical presentation and severity of dysbarism is the body part affected. The degree to which the dysbarism is life threatening can be deduced directly from the body part involved. Overall, the most common symptoms reported by divers are pain and paresthesias.⁴ The most immediately life-threatening conditions involve loss of consciousness or loss of motor function while underwater.

Brain

The most serious manifestations of dysbarism in the brain are acute stroke, altered mental status, and loss of consciousness.¹⁴ An acute stroke arises when a bubble of gas (i.e., a gas embolism) occludes a critical artery supplying the brain. The symptoms will reflect the area of brain injured (see Chapter 44, Central Nervous System Vascular Disorders). Unconsciousness may be the dominant sign and is often fatal if this occurs while the diver is underwater (see Table 144–1). Patients with a patent foramen ovale are at increased risk for strokes from arterial gas emboli.^{15–17} Arterial gas emboli occur during ascent. Another condition affecting the brain is nitrogen narcosis. At depths of 30 m or greater, dissolved nitrogen

alters the ionic conductance through neuronal membranes.¹¹ This leads to a clinical condition similar to alcohol intoxication. Impaired judgment, clumsiness, light-headedness, euphoria, and disorientation are common symptoms. Divers may misuse their equipment, fail to acknowledge low air in their tanks, become trapped, or go deeper and lose consciousness. Nitrogen narcosis occurs during the deepest portions of a dive.

Spinal Cord

The spinal cord is particularly vulnerable to decompression sickness.¹⁸ Symptoms can range from limb paresthesias to paraplegia. Spinal cord injuries occur during ascent.

Inner Ear

Vertigo, nausea, vomiting, unsteadiness, tinnitus, and hearing loss are common symptoms of inner ear decompression sickness.¹⁹ In adults, the onset of symptoms is usually within the first hour or two after a dive, but symptoms may arise after more than 5 hours.¹⁹ Inner ear decompression sickness occurs during ascent.

Middle Ear and Ear Canal

If a diver's eustachian tubes are partially or completely occluded, spontaneous equalization of the pressure in the middle ear with the environmental pressure encountered during a dive will be impaired. This condition is the most common form of dysbarism, affecting 30% of new divers on their first dive and 10% of experienced divers.²⁰ This condition is commonly referred to as "barotitis media" or "middle

ear squeeze.” Signs and symptoms of barotitis media include ear pain, tympanic membrane injury or rupture, and blood in the ear canal. If the tympanic membrane ruptures, cold water may enter the middle ear and lead to life-threatening severe vertigo and disorientation during a dive. A similar phenomenon may occur if ear plugs or a wax plug completely occlude the external ear canal, creating a pocket of air.²¹ Middle ear and canal injuries more frequently occur during descent, but may occur during ascent.

Sinuses

If the sinus ostia are occluded, spontaneous equalization of the pressure in a sinus with the environmental pressure encountered during a dive will be impaired. The maxillary sinus is the most frequently affected. The most common symptoms are facial pain and epistaxis. Decreased facial sensation in the area innervated by the infraorbital nerve may also occur.²² Sinus barotrauma is also known as “sinus squeeze.”^{21,23} Sinus barotrauma occurs twice as frequently during descent as ascent.

Teeth

Air pockets may be present in teeth due to recent dental work or from pathology such as cavities. Pressure changes during a dive may cause pain with or without tooth fracture.²³ This condition is referred to as “barodontalgia” or “tooth squeeze.” Barodontalgia typically occurs during descent.

Tongue

An arterial gas embolism may leave a well-circumscribed area of pallor on the tongue. This physical finding is also called Liebermeister’s sign.²⁴

Lungs

Pulmonary barotrauma is the most life-threatening form of barotrauma. The classic example of pulmonary barotrauma occurs when a diver takes a breath at depth and then rapidly ascends while holding his or her breath. As the diver ascends, the pressure and volume of gas in the lungs will progressively increase due to the continually decreasing environmental pressure as the diver approaches the surface. Resulting injuries include simple pneumothorax, tension pneumothorax, pneumomediastinum, alveolar rupture, and the release of gas emboli into the central circulation. Signs and symptoms include chest pain, dyspnea, cardiovascular collapse, stroke, hemoptysis, and unconsciousness.¹¹ Divers with uncontrolled asthma or wheeze precipitated by exercise, cold, or emotion are at increased risk for pulmonary barotrauma.²⁵ Pulmonary barotrauma occurs during ascent.

Gastrointestinal Tract

The gastrointestinal tract is a distensible tube containing air and liquid. As the environmental pressure changes during a dive, the air in the gastrointestinal tract will contract or expand. Although serious conditions such as rupture of the stomach have been reported,²⁶ most cases of gastrointestinal dysbarism result in crampy abdominal pains or dyspepsia. Gastrointestinal dysbarism occurs during ascent.

Skin

Cutaneous manifestations of decompression illness most commonly occur on the torso. Itching is the most common

symptom.¹² Examination of the skin may reveal an erythematous, macular rash or patchy mottling.¹²

Localized lymphedema may be present.¹¹ The onset of cutaneous manifestations of decompression illness is variable, but may occur after a dive has concluded.

Extremities

Deep, aching pains in the extremities due to decompression illness may occur up to an hour after surfacing from a dive.¹¹ The severity is variable, but the pain may be severe. A common name for this syndrome is “the bends.” The bends occurs after resurfacing.

Face

When a mask is tightly adhered to a diver’s face at the surface, this air-filled space is vulnerable to dysbarism. If a diver does not properly ventilate his or her mask by exhaling through the nose during descent, a “mask squeeze” may occur.^{27,28} Signs and symptoms of a mask squeeze include periorbital pain, conjunctival and periorbital edema, subconjunctival hemorrhages, periorbital ecchymoses, and petechial hemorrhages in the distribution of the mask on the face.²⁸ Mask squeeze occurs during descent.

Important Clinical Features and Considerations

When a diver presents to the emergency department after a dive, reviewing his or her dive table may have some utility. The risk for dysbarism is directly related to the duration and depth of a dive. Dive tables offer a rough estimate of safe dive plans based on duration and depth.²⁹ Identifying a diver who has substantially deviated from a published dive table helps risk-stratify that patient. However, divers are notorious for underestimating and underreporting depth and “bottom times.” There are significant differences among various decompression tables that are used by different dive agencies and in different parts of the world. Dive computers used during a dive to estimate the duration and depth of a dive extrapolate values from various dive tables. This, in turn, results in more bottom time and a greater risk of dysbarism.

Management

The management of dysbarism is based on the clinical syndrome. In general, serious signs and symptoms warrant the immediate application of high-flow oxygen and transfer to the care of a dive specialist at a facility capable of recompression therapy in a hyperbaric chamber.³⁰ In anticipation of transfer, the only test indicated is a chest radiograph to identify a pneumothorax. If a patient with a small, unrecognized pneumothorax undergoes recompression therapy, the patient may develop a tension pneumothorax in the hyperbaric chamber. Identifying a pneumothorax and placing a thoracostomy tube (see Chapter 168, Thoracostomy) allows the patient to undergo recompression therapy more safely. The performance of other tests that do not clearly meet other indications (e.g., a glucose check in a known diabetic diver) only delays recompression therapy without offering the patient additional benefit. Unconsciousness after a rapid ascent or acute stroke symptoms are obvious indication for recompression therapy. Other indications for consultation

with a dive specialist regarding recompression therapy that are less obvious to emergency physicians who do not dive are numbness and tingling in the extremities, dizziness and vertigo, crampy extremity pains, joint pains, Liebermeister's sign, and skin mottling. Inexperienced divers may not associate their symptoms with dysbarism. Experienced divers may minimize their symptoms. A dive specialist should be consulted if these or other vague symptoms arise within days of a dive. Untreated dysbarism can lead to permanent injuries, particularly to the central nervous system. Recommendations regarding returning to diving should be deferred to a dive specialist.

Relatively minor diving injuries, including the "squeezes," rarely require emergent treatment. Barotitis media should be treated symptomatically, and follow-up arranged with a primary care doctor. Tympanic membrane rupture may be an indication for follow-up with an otolaryngologist. Barodontalgia, including most dental fractures, should also be treated symptomatically. The patient can follow up with a dentist at his or her convenience. Mask squeeze and sinus squeeze should be treated symptomatically.

Summary

An increase in the number of children and adolescents experiencing dysbarism is expected given the recent lowering of the minimum scuba training age. Emotional maturity, appropriate training, and tight supervision appear to be key components to successful pediatric diving. Poor decision making, lack of proper training, ignoring proper procedures for safe diving, and panicking at a critical moment are recurrent themes in fatal adolescent dives. Signs and symptoms of dysbarism, although often dramatic and unmistakable, may also be subtle. Children and adolescents with dysbarism may present to emergency departments far from the coast days after diving.

High Altitude–Associated Illnesses

William M. McDonnell, MD, JD and Mark G. Roback, MD

Key Points

A history of rapid onset of nonspecific symptoms shortly after ascent to high altitude suggests acute mountain sickness.

It is important to rapidly recognize acute mountain sickness, because it may progress to the life-threatening conditions of high-altitude pulmonary edema and high-altitude cerebral edema.

Preventative strategies are available for acute mountain sickness.

Severe complications of acute mountain sickness can be treated effectively with transport to lower elevation, and less effectively with supportive care and pharmacotherapy.

Selected Diagnoses

- Acute mountain sickness
- High-altitude pulmonary edema
- High-altitude cerebral edema

Discussion of Individual Diagnoses

Acute Mountain Sickness

Altitude illness historically affected explorers and a few extreme sport adventurers, with little impact on the broader population. However, with increasing access to high-altitude recreation and tourism destinations, there is increasing potential for altitude-related illness in the general population, including children. Substantial research has been done regarding the incidence, etiology, treatment, and prevention of altitude-related illness in adults. However, little has been reported in these areas with respect to children. Therefore, pediatric health care providers, in many cases, must care for their pediatric patients based on elements of adult practice.

Although quite variable,¹ the incidence of altitude illness is approximately 25% in travelers to altitudes above 6500 feet (2000 m),² and up to 60% above 14,000 feet (4200 m).³ Both

hypoxia and the lower atmospheric pressure contribute to acute mountain sickness (AMS).⁴ A history of travel to altitude is the most important factor in recognizing altitude illness. The most common of the acute altitude illnesses, AMS includes the nonspecific symptoms of headache, anorexia, nausea, dyspnea, sleep disturbance, low-grade fever, and malaise. In young children, AMS may manifest as tachypnea,⁵ increased fussiness, sleep disturbance, decreased playfulness, and decreased appetite.⁶ Symptoms in both adults and children typically develop within 1 to 2 days of exposure to altitude, with the majority of those affected first experiencing symptoms within 12 hours of arrival at altitude.^{2,6}

The primary risk factors for developing AMS are rapid rate of ascent to high altitude, lack of acclimatization at moderate altitude, and previous altitude illness.⁷ Strenuous exercise at altitude may result in increased incidence and severity of AMS.⁸ Dehydration also increases the risk of AMS and worsens its symptoms. Dehydration stimulates increased renal sodium and bicarbonate reabsorption, and the resulting relative metabolic alkalosis reduces the patient's ability to compensate for the hypoxia of altitude with an appropriately increased ventilatory response.⁹ Although obesity has been associated with a greater risk for the development of AMS,¹⁰ physical fitness does not appear to be protective.⁷

It is uncertain whether children are at greater risk of developing AMS than adults. One study observed a higher rate of AMS symptoms among children ages 6 to 48 months than among adolescents and adults.¹¹ This study also noted more pronounced hypoxemia among the children with AMS than among the adults and adolescents with the same condition. However, other studies have found no significant difference in the incidence of AMS between preverbal children and adults.^{6,12} Nevertheless, it is clear that children can and do develop AMS.

Clinical Presentation

A history of rapid onset of headache and other symptoms such as anorexia, nausea, dyspnea, sleep disturbance, low-grade fever, and malaise shortly after travel to high altitude strongly suggests AMS, which may progress to the more severe acute altitude illnesses, high-altitude pulmonary edema (HAPE) and high-altitude cerebral edema (HACE). Evaluation of the patient should include a careful assessment of vital signs, and a physical examination with particular scrutiny of respiratory, cardiovascular, and neurologic status.

Physical examination findings common in AMS include mild temperature elevation, tachypnea, tachycardia, and mild hypoxia. Chest auscultation may reveal diminished aeration, diffuse crackles, or both.

AMS may mimic conditions commonly encountered in lower altitude settings, including pneumonitis of viral, bacterial, fungal, or chemical etiologies; dehydration; intracranial hemorrhage or infarction; cerebral edema; and migraine headache. Many of these diagnoses remain in the differential diagnosis, and may be systematically distinguished from altitude illness.

An extensive laboratory and radiologic evaluation is rarely warranted. A chest radiograph may help identify the progression of AMS to HAPE, but the findings of AMS or HAPE may be difficult to distinguish from pneumonia. Pulse oximetry helps in assessing the degree of respiratory compromise.

Management

For all patients with AMS, further ascent is contraindicated, and patients should promptly descend to lower altitude if symptoms worsen. Indications for immediate descent to lower altitude include hypoxia unresponsive to supplemental oxygen, worsening dyspnea, ataxia, and mental status changes. Children's AMS symptoms resolve quickly after return to lower elevation.⁶ Moreover, brief AMS from high-altitude exposure produces no lasting neuropsychological impairment or anatomic changes of the brain.¹³

Patients with mild AMS symptoms may be treated at altitude. Therapy consists of supportive care. Rest and oral hydration are frequently sufficient treatment for mild AMS. As dehydration has been noted to worsen AMS, rehydration with intravenous normal saline may be indicated. However, progression to pulmonary edema is a risk of AMS, and it is prudent to avoid excessive fluid administration. Analgesics such as acetaminophen and ibuprofen typically provide effective relief from the headaches and nausea generally associated with AMS.^{14,15} However, common migraine headache therapies such as sumatriptan are not effective in treating high-altitude headaches.¹⁵

Prevention of AMS is more effective than treatment. The best preventative strategy for AMS is gradual ascent, allowing time for acclimatization. A few days' acclimatization at altitude generally allows resolution of mild AMS symptoms and may prevent progression of symptoms. An overnight stay at an intermediate altitude has been shown to reduce the incidence of subsequent AMS symptoms.² The acclimatization effect is generally attributed to increased ventilation and diuresis.¹⁶ Similar acclimatization effects have been observed in subjects exposed to brief simulated intermittent altitude exposures in a hypobaric chamber over a period of 3 weeks.¹⁷

Acetazolamide has been demonstrated to be useful in preventing AMS, with treated adult subjects showing a decrease in symptoms and greater oxygen saturation levels at altitude.¹⁸⁻²⁰ However, no specific data regarding efficacy or dosing recommendations exist for children. Low-dose glucocorticoids hold promise for prophylaxis against AMS,²¹ and one adult study has shown that prophylactic acetazolamide in combination with low-dose dexamethasone is more effective in preventing AMS than is acetazolamide alone.²² Another adult study investigating the use of prophylactic nifedipine to prevent HAPE also found a significant reduction in AMS symptoms.²³

Although there is some evidence that the use of the herbal supplement ginkgo biloba before and during ascent may reduce the severity of AMS symptoms in healthy adults,²⁴ this finding is not conclusive. A recent large, prospective, randomized controlled study concluded that ginkgo is not effective in reducing either the incidence or severity of AMS, and there are some indications that ginkgo may worsen AMS symptoms.²⁰

Summary

Generalized, nonspecific symptoms following ascent to high altitude suggest AMS. The primary risk factors for AMS are rapid ascent to high altitude and a prior history of AMS. Although AMS is generally self-limited, and responds well to acclimatization, as many as 5% to 10% of patients with AMS may develop the more serious altitude illnesses of HAPE or HACE if they do not promptly return to lower altitude.¹

High-Altitude Pulmonary Edema

With extended exposure to high altitude, a patient with AMS may develop HAPE, with progression to severe hypoxemia. HAPE is a form of rapidly progressive hydrostatic pulmonary edema.^{25,26} HAPE is characterized by the marked elevation of pulmonary artery and capillary pressures, and changes in left ventricular diastolic function.²⁶⁻²⁸ Insufficient hypoxic ventilatory response at high altitude, combined with impaired gas exchange resulting from pulmonary edema, produces the severe hypoxemia seen with HAPE.¹⁶ Untreated, HAPE may rapidly progress to respiratory failure and death. Although the reported incidence of HAPE is somewhat variable, most individuals will probably experience HAPE if the rate of ascent, maximum elevation attained, and physical exertion are great enough.²⁹ People who exhibit an increased pulmonary artery pressure response to exercise are more likely also to have an increased pulmonary artery pressure response to altitude-related hypoxia, and thus are more prone to develop HAPE.³⁰ It may be possible to identify these individuals at increased risk of developing HAPE by Doppler echocardiography during strenuous exercise.³⁰ For children, the risk of developing HAPE is exacerbated by a concomitant upper respiratory viral infection, while adults seem to face no such increased risk.³¹

Clinical Presentation

The usual progression to HAPE includes the typical nonspecific signs and symptoms of AMS, and the development of a cough that may be productive of blood-tinged mucus, increasing tachypnea, dyspnea at rest, and marked hypoxia.²⁸ Crackles and wheezes are often detected on chest auscultation. Some patients with HAPE have described a "gurgling" sensation in their chests.³²

When HAPE is suspected, the patient's respiratory, hemodynamic, and neurologic status are the focus of the evaluation. Preparations for transport to lower elevation are indicated. As with AMS, only limited laboratory and imaging studies are needed. Chest radiographs show dilation of the central pulmonary arteries, and patchy, peripheral, bilateral or unilateral infiltrates that are often asymmetric.³³ Electrocardiography may show evidence of right ventricular strain, with extensive T-wave negativity in precordial leads,³⁴ which is consistent with autopsy studies that have demonstrated right ventricular dilation.³⁵

Management

With the progression of AMS to HAPE, further ascent is absolutely contraindicated. Appropriate treatment includes supplemental oxygen at the maximum available concentration, stabilization of hemodynamic status, and prompt descent to lower elevation. Although some patients with mild HAPE may be treated at moderate altitudes (below 10,000 feet/3000 m) with bed rest and supplemental oxygen, any significant deterioration requires immediate transport to lower elevation.³⁶ Portable fabric hyperbaric chambers can be used to provide increased atmospheric pressure while awaiting transport or en route to a lower altitude. With the progression of substantial pulmonary edema, some patients may develop inadequate ventilation and severe hypoxia despite supplemental oxygen, requiring endotracheal intubation and positive pressure ventilation.

High pulmonary artery pressure is key to the development of HAPE.^{26,28} In adults with HAPE, nifedipine reduces pulmonary vascular resistance and pulmonary artery pressures, and thereby reduces symptoms such as dyspnea and chest pain, as well as improving oxygen saturation.³⁷ Although transport to lower elevation remains the definitive treatment for HAPE, nifedipine is generally accepted as an appropriate temporizing therapy in adults when transport is unavoidably delayed. The benefits of nifedipine therapy in children with HAPE have not been established.

The signs and symptoms of HAPE typically reverse completely after patients are transferred to low altitude.²⁶ However, patients who have experienced HAPE are at an increased risk of recurrence on return to high altitude.²³ Prophylactic inhalation of a β -adrenergic agonist (e.g., albuterol) may reduce the risk of recurrence of HAPE.³⁸ The prophylactic use of nifedipine has also been shown to be effective in preventing HAPE in adults.²³ Some victims of HAPE may slowly reascend after a few days at lower altitude and after complete resolution of their symptoms, without recurrence.³⁹ However, such patients should immediately descend at the first sign of recurrence.

In summary, patients with AMS who remain at high altitude may develop the worsening pulmonary symptoms of HAPE. Although unrecognized HAPE may be fatal, prompt recognition and transport to lower elevation typically results in complete resolution of symptoms.

High-Altitude Cerebral Edema

Patients with AMS who remain at high altitude or who continue to climb may progress to HACE. HACE is generally considered to be the end-stage progression of AMS, and is characterized by reversible brain white matter edema, particularly in the corpus callosum.^{32,40} The mechanism appears to be vasogenic, with movement of fluid and proteins out of the vascular compartment.⁴⁰ There is some evidence that patients with early AMS are already experiencing minor cerebral edema, which can be demonstrated by subtle cognitive changes on psychomotor testing.⁴¹

HACE is usually preceded by the generalized, nonspecific symptoms of AMS. Signs and symptoms of HACE include severe headache, cognitive-behavioral changes, and ataxia, which may quickly progress to obtundation and coma.³² Patients may experience vivid hallucinations.³² The time period for progression from mild neurologic symptoms to

deep coma is variable, from hours to days.³³ HACE is often comorbid with HAPE.^{32,35}

Management

As with AMS and HAPE, the initial approach to a patient with HACE includes careful evaluation and stabilization of respiratory and circulatory functions, including securing the patient's airway in the case of significant depression of mental status. Supplemental oxygen is indicated, and preparations for immediate medical evacuation to lower altitude should be started. Pulse oximetry and arterial blood gases may be useful in evaluating respiratory function. As in any setting of altered mental status, evaluating serum glucose levels is appropriate. Brain imaging studies of HACE patients reveal a picture of cerebral edema. Computed tomography shows diffuse edema, with a paucity or absence of sulci, small ventricles, and diffuse low density of white matter.^{32,42} Brain magnetic resonance imaging shows increased T2 signal in the white matter, with a characteristic marked increased signal in the corpus callosum.^{32,40} HACE can usually be diagnosed based on a history of ascent to high elevation and the progression of signs and symptoms, making brain imaging studies unnecessary.

HACE is a potentially fatal, but easily reversible, illness. The optimal and definitive management includes immediate transport to lower elevation. After prompt return to low altitude, HACE patients typically have no appreciable residual central nervous system impairment on brain magnetic resonance imaging and neuropsychological testing.¹³ However, when transport to lower elevation is delayed, HACE may progress to brain herniation and death. Accordingly, transport should not be delayed by any therapy other than assuring adequate respiratory and circulatory function. In the event that transport is unavoidably delayed, oral or parenteral dexamethasone may be of benefit.^{32,40,41} As with HAPE, portable hyperbaric chambers may be used to simulate lower elevation while awaiting transport.

In summary, the development of neurologic signs in a patient with AMS signals the onset of HACE. Although unrecognized and untreated HACE can be fatal, patients who are promptly transported to lower elevation typically have complete resolution of their HACE without sequelae. Immediate transport to lower elevation is universally indicated in cases of HACE.

The Sick or Injured Child in a Community Hospital Emergency Department

Alfred Sacchetti, MD, John A. Brennan, MD,
and Neil Schamban, MD

Key Points

Tertiary children's hospitals and community hospitals have different available resources.

Different diagnostic and therapeutic strategies exist in a children's hospital emergency department versus a community hospital's emergency department.

The lack of tertiary pediatric services in a community hospital is countered by increased capabilities within the community emergency department.

Appropriate interactions with consultants from a children's hospital will favorably impact the care of a critically injured or ill child.

Pediatric emergency medicine leadership is very important in a community-based emergency department.

Introduction and Background

There are over 31 million pediatric emergency department (ED) visits per year, most of which are treated in facilities that may be described as community hospitals.¹ Many of these visits will be for relatively minor ambulatory complaints, although an important minority will be critically ill or injured children. The principles of resuscitation and stabilization do not vary between a tertiary children's hospital and a community ED, although the manner in which these fundamentals are accomplished can differ dramatically.

Issues and Solutions

Institutional Differences

Tertiary children's hospitals and community hospitals are intrinsically different.² One of the hallmarks of a children's

hospital is immediate access to subspecialists from almost every discipline. More importantly, pediatric anesthesiologists, intensivists, and surgeons maintain a continuous presence in the hospital for assistance with resuscitation attempts. By contrast, the community ED frequently has limited subspecialty resources available, and resuscitation attempts are the exclusive domain of ED personnel.^{3,4} Ironically, this clinical situation mandates a greater degree of individual competence in the community ED than is required at the tertiary care center. Stated more simply, the ED capabilities of any hospital are an inverse function of the hospital's inpatient capabilities. This rule of ED functional capacity is applicable to any area of medicine and is summarized in Figure 146-1. The ability of the community ED to deliver care equivalent to that of a tertiary care hospital requires motivated clinicians with access to appropriate equipment, medications, diagnostic studies, and timely transfers.

The qualifications and roles of ED personnel needed to optimize pediatric care are contained in the joint American Academy of Pediatrics–American College of Emergency Physicians publication “Care of Children in the Emergency Department: Guidelines for Preparedness.”⁵ To provide appropriate care with good outcomes, though, any group of clinicians will require appropriate institutional support. It is important to recognize the need for specialized pediatric equipment in the emergency department, even in facilities with no inpatient pediatric capabilities (see Chapter 154, The Child Friendly Emergency Department: Practices, Policies, and Procedures).

These same considerations need to be given to medications not typically contained in the formulary of a nonpediatric hospital. Because of its responsibility in the extended stabilizations of critical children, the ED requires access to a wider assortment of procedural sedation and resuscitation medications. The best example of such a need might be the use of prostaglandin E to reopen the ductus arteriosus in a cyanotic neonate. Unless specifically requested by the ED, no hospital without obstetric services is likely to stock this medication.

Procedural sedation medications must be given special consideration in EDs with expanded pediatric responsibilities.

ED capabilities = $f(1/\text{Hospital capabilities})$

FIGURE 146–1. Law of emergency department (ED) functional capacity. To optimize patient outcomes, the capabilities of the ED vary inversely with the capabilities of the hospital.

Table 146–1 Essential Procedural Sedation Medications

Propofol or methohexital
Etomidate
Ketamine
Fentanyl
Rocuronium
Vecuronium

Simple sedation for diagnostic imaging, analgesia for painful conditions, procedural sedation for invasive procedures, or extended sedation for ventilator cooperation all require unrestricted access to an extended formulary to optimize patient outcomes. At the very least, emergency physicians should be granted privileges for and unrestricted access to the medications listed in Table 146–1.^{6,7}

Diagnostic studies unique to the ED must also be available to accommodate unusual pediatric presentations. In particular, the ability to handle micro-sized specimens for blood counts, electrolytes, and basic metabolic analysis must be assured. The introduction of single-drop blood analyzers can resolve this issue for institutions hesitant to purchase expensive pediatric-specific laboratory equipment.⁸ Radiology departments may also be required to provide pediatric-specific imaging studies applicable only to ED pediatric patients. Although it is unreasonable to expect a hospital to purchase expensive equipment simply for a potential ED need, it is appropriate to request basic pediatric imaging capabilities. In some institutions the problem may not be with the technical component of an imaging study, but with the staff radiologist, who may be uncomfortable interpreting certain pediatric studies. This problem may be solved through the use of teleradiology to a remote pediatric center.^{9–11} For some EDs, access to appropriate diagnostic studies may just not be possible. In these instances, the emergency physician may be required to transfer a child to a pediatric center for a simple diagnostic study to exclude a potential disease condition.

The expanded responsibilities of the ED or emergency personnel may require modifications of hospital policies. If patient outcomes are to be optimized, then the ED must be equipped and the emergency physicians must be credentialed to perform all of the initial stabilization activities not provided by the remainder of the hospital. This credentialing of emergency physicians for procedures reserved only for hospital subspecialists may be the only way to assure that a critical child receives all of the necessary support in a timely manner. Credentialing for deep sedation, ultrasonography, fluoroscopy, and fiberoptic evaluations must be provided for the emergency physicians or be immediately available from other members of the medical staff.

Finally, emergency physicians may find themselves in the role of children's advocate at hospitals that lack any in-patient pediatric services. As the sole providers for this "orphaned" subset of patients, they will need to compete for hospital resources that may not be shared by other departments or

medical staff. In these institutions a representative emergency physician will need to assume a leadership position in the acute management of the sick or injured child. Fortunately, this is a role that emergency physicians are uniquely qualified to assume.

Clinical Skills

Maintenance of clinical capabilities is a problem in all aspects of medicine. In certain surgical specialties, evidence exists that a minimum number of procedures must be performed annually to assure successful outcomes.^{12–17} The ED is unique in that emergency physicians do not have the ability to arrange elective patient encounters to maintain certain skills. However, unlike studies involving surgeons or other interventionalists, there are no data to indicate any outcome differences in children managed in EDs with limited pediatric encounters.

The clinical skills of any practitioner are a function of his or her past experiences and ongoing patient encounters. General emergency physicians may draw on their ability to perform resuscitative procedures on adults to assist them in performing the same procedures in children. Arguments about children not being small adults aside, procedural differences between adults and children are relatively minor and easily incorporated into clinical practice. Recognition of the subtle signs of diseases can be difficult for clinicians with limited pediatric exposures. Ongoing contact with ambulatory children remains the best means to improve recognition of a sick child. However, in critically ill children, the degree of distress will generally be obvious and unlikely to be missed.

Unique Clinical Aspects of Community ED Stabilization

The principles of pediatric stabilization do not change, although the manner in which the care is delivered can vary greatly between institutions. For a number of reasons, treatment in a community ED trends towards more aggressive management of critical children.

For facilities without an onsite pediatric intensive care unit (PICU), extended observation is not an option. Immediate access to tertiary care support provides an opportunity to initially provide more conservative care in a critical care setting and withhold interventions until they are unavoidable. In contrast, the need for an actual physical transfer requires immediate reversal of any downward physiologic trends in order to minimize the risk of decompensation once the child leaves the sending hospital. The concept of waiting to see if a child turns around on his or her own is unrealistic for anyone anticipating an extended ground or air transport. The actual performance of a resuscitative procedure is also more easily accomplished in a hospital setting than in a moving transport vehicle.

An in-house PICU also provides another set of hands to assure expedient management of the child regardless of the point at which the child decompensates. In contrast, in an ED with only one physician, and no in-house critical care backup, watchful waiting can jeopardize the care of the child if a sudden change occurs and multiple procedures are immediately required, or if a second emergent patient presents to the ED.

An underappreciated aspect of the single-coverage community ED, which directly affects the timing of procedures,

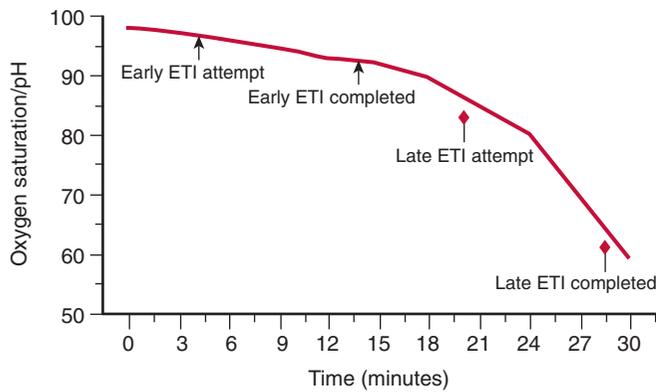

FIGURE 146–2. Loss of reserves in a child with progressive respiratory failure. Initiation of endotracheal intubation (ETI) attempt early will permit completion of even a very difficult procedure while the child still has acceptable physiologic parameters. A late intubation attempt may lead to exhaustion of any reserves and cardiac arrest prior to completion.

is the continuing responsibility for all patients within the department. Early completion of potential procedures permits a lone emergency physician to manage a critically ill child from a distance. For example, a ventilated child with secure vascular access and proper electronic monitoring may be managed by a bedside nurse who can relay information back and forth to a physician elsewhere in the department. The same child, with less aggressive care, will require a near-continuous bedside presence from that single attending physician regardless of what other patient responsibilities may arise.

Earlier procedure attempts also increase the odds of successful outcomes, particularly in children with rapidly evolving findings. As a child's condition deteriorates so, too, do his or her reserves. Figure 146–2 presents the physiologic decline of a child progressing from respiratory failure toward respiratory arrest. If endotracheal intubation is begun before the child's pH and oxygen saturation have begun to drop, even a time-consuming, difficult intubation will be completed before premorbid physiologic conditions develop. However, if airway attempts are delayed until the child is severely hypoxic and acidotic, then that same time-consuming intubation may not be completed until the child has progressed on to a cardiac arrest.

Aggressive medical management will also help define further treatment options when care is relinquished to the tertiary care facility. Defining what has been attempted and what has not worked places an accepting physician much further along a treatment algorithm than if only first-line therapies were applied. Determining that benzodiazepines and barbiturates failed to control a child's seizures moves the consultant immediately to more advanced interventions without having to recommend each of the earlier treatments and waiting to see an effect.

Managing Patient Transfers and Consultation

Like every other aspect of patient care in a community ED, the transfer of a patient must be coordinated with other ongoing activities in the department. The extent to which the transfer process can be streamlined will impact greatly the amount of time nurses and physicians will be diverted from direct patient care. Ideally, clinicians should be involved only in conversations related to patient management while support

personnel address administrative and logistic issues. Development of transfer agreements with specific institutions and internal policies governing individual ED staff responsibilities during patient transfers decreases medical errors and improves patient outcomes.

The degree of interaction between the sending and receiving medical staffs will be determined by the nature of the transfer. In some instances the management of a child is straightforward and the transfer is strictly for services unavailable at the community hospital. A stable child with an isolated femur fracture being moved to a hospital with inpatient pediatric facilities exemplifies such a transfer. The communication between the emergency physician and receiving physician will likely be minimal and focus primarily on the logistics of the transfer. In other instances the emergency physician may require management consultations as well as transfer arrangements. In these instances the emergency physician and consultant interactions may become as important as the management of the patient.

All tertiary care institutions have protocols in place to assist facilities transferring patients. Depending on the receiving facility, a call to initiate a transfer is coordinated by a nurse, a transfer center, a resident or fellow in training, or a subspecialty attending physician. If immediate management advice is required, it is important for the emergency physician to gain access to the necessary consultant as efficiently as possible. Valuable time can be wasted with extended delays on telephone hold or working up through a resident hierarchy to reach the consultant needed. Transfer agreements or policies to assist unit secretaries in locating the appropriate personnel at the receiving hospital can help to resolve these types of problems.

When discussing the specifics of the clinical scenario with a consultant, it is imperative for the sending emergency physician to direct the conversation. In presenting the case, the sending emergency physician should begin with the suspected diagnosis and a very succinct summary of care to that point. This can be followed by any questions or solicitations for recommendations. The more focused the sending emergency physician can keep the conversation, the quicker patient care issues can be addressed. An example of a concise presentation might be: "We have a 9-month-old male with septic shock, diffuse purpura, intubated, fluid resuscitated with 60 ml/kg of NSS, on a 10-mcg/kg dopamine infusion, with a blood pressure of 60/20, who has received 100 mg/kg of ceftriaxone. We are preparing to begin a neosynephrine infusion; do you wish to change this?" This presentation sets the tone for a very efficient conversation. In addition, the description of the interventions and management of the case cues the consultant as to the capabilities of the clinicians in the sending ED. This is useful in helping the consultant determine the sophistication of the advice to be given. In contrast, a less effective conversation may begin "We have a 9-month-old who's been less active for 2 days and then developed a slight fever yesterday." Such an introduction takes far too long to move the consultant to the current point in the child's treatment and will provide extraneous information not needed for the immediate care. A consultant can always ask for additional information or clarification as the conversation progresses.

Once a consultant has been contacted, determination of a child's ongoing treatment is by mutual agreement. It is

perfectly reasonable for a sending physician to ask for justification for unusual recommendations, just as it is appropriate for a consultant to request specific procedures be accomplished prior to transfer.

The logistics of the actual transfer will vary with the complexity of the case, the arrangements between the sending and receiving facilities, and the degree of stabilization accomplished at the community hospital.

Summary

Community hospital EDs manage the majority of critically sick or injured children presenting for acute care. The community hospital ED must be appropriately equipped with physicians and nurses capable of caring for these children. Community EDs provide the key management link between their community and a tertiary children's hospital care.

Emergency Medical Services and Transport

Michael G. Tunik, MD and George L. Foltin, MD

Key Points

Physicians, nurses, and other practitioners should understand the components and capabilities of their Emergency Medical Services (EMS) system, which plays a critical role in caring for acutely ill or injured children.

Improving the EMS system will improve the care of ill or injured children.

Appropriate EMS equipment and protocols and a quality program are essential components of a successful EMS program.

Effective communications with and transfer of care from the out-of-hospital setting to the emergency department are essential components of a successful EMS program.

Introduction and Background

Definitions

Emergency Medical Services (EMS) System

Emergency Medical Services (EMS) systems are groups of organizations responsible for delivering emergency care in the out-of-hospital setting. The collaboration of these organizations delivers appropriate out-of-hospital care, triage, and transport of children who are acutely ill or injured.

Medical Control

Off-line, or indirect, medical control includes the development and modification of equipment lists, treatment protocols, criteria for dispatch, the system's quality and safety programs, and triage.

On-line, or direct, medical control is the real-time communication between EMS care providers and authorized medical personnel who assist out-of-hospital providers with interventions, triage, and transport decisions. Communica-

tion is usually by radio or telephone. Medical personnel are typically based in the receiving hospital, or a centralized EMS system communications facility.

Protocols for Out-of-Hospital Care

Out-of-hospital protocols are written guidelines that are the standing medical orders directing the interventions, triage, and transport of acutely ill or injured children. These protocols are written by physicians participating in off-line or indirect medical control.

Emergency Medical Services for Children (EMSC)

Emergency Medical Services for Children (EMSC) is not a separate EMS system, but is the integration of the special needs of children into existing EMS system. The components of an EMS system that may need specific modifications for children¹ are listed in Table 147-1.

Trauma System

A trauma system is a system of care involving out-of-hospital stabilization, care, triage (based on trauma severity scores), and transport to trauma centers capable of addressing the unique needs of traumatized patients, including emergency care, surgical care, anesthesia care, critical care, and rehabilitation.

Transport

Primary transport is the movement of a patient from the out-of-hospital location of an injury or illness to a hospital emergency department (ED). Secondary transport occurs when the patient is moved from the ED or hospital ward to a specialty center (e.g., trauma center, burn center) or definitive care center.

Issues

History of EMS

The need for systemized EMS was first identified in the 1960s.^{2,3} Surgeons returning from Korea and Vietnam observed the inadequate care that victims of vehicular trauma were receiving in comparison to the care of injured military personnel. This resulted in the publication of a milestone

Table 147–1 Components of an EMS System

Independent review (continuous quality improvement)

paper, “Accidental Death and Disability: The Neglected Disease of Modern Society” which explicitly delineated the inadequate level of EMS.⁴ This publication stimulated the development of a systems approach to EMS.

Pioneering work in EMS systems development was taking place in the late 1960s and early 1970s funded by the Department of Transportation and the Robert Wood Johnson Foundation, among others. The federal government provided funding for the development of EMS systems with the Emergency Medical Services Act of 1973 (PL 93-154). The program specified patient populations that would benefit from specialized care at regional hospitals within an integrated EMS system. This included seven populations: patients with trauma, cardiac disease, burns, spinal cord injuries, poisonings, and behavioral emergencies, and those requiring neonatal care.⁵ Neonatal care patients were the first nonmilitary population in which the process of regionalization, specialty transport, and secondary transport was successfully utilized.

The EMS system components developed included manpower, training, communications, transportation, facilities, critical care units, public safety agencies, consumer participation, access to care, patient transfer, coordinated patient record keeping, public information and education, review and evaluation, and disaster planning. These components were to be found in a spectrum of independent organizations, and the success of a given EMS system was a result of these organizations’ ability to work interdependently.⁶

Ill and injured children were *not* initially included as a target population for regionalized care, nor did developing EMS systems recognize their special needs. No pediatric specialists other than neonatologists became involved at that time.⁷ Studies of children’s needs and outcome after EMS care were not available; children were simply overlooked.

To effectively provide care for children, their needs must be identified and methods to provide for those special needs integrated into already existing EMS systems. Adult needs that have been demonstrated to improve outcome include rapid defibrillation of ventricular dysrhythmias, and immobilization and rapid transport of multisystem trauma patients to definitive care. Recent studies have also demonstrated that adults benefit from advanced life support (ALS) for complaints of chest pain and respiratory difficulty.^{8,9}

Table 147–2 Personnel Providing EMS for Children

Parents (medical home)
Public
Primary care physician
“911” operators/medical dispatch
Out-of-hospital personnel (first responder, EMT, paramedic)
Medical control physicians (direct and indirect)
Emergency department physicians, nurses
Hospital inpatient physicians, nurses, respiratory therapists, and other health care providers
Secondary transportation team
Pediatric critical care/trauma center
Rehabilitation team

A goal for EMS for children is to identify the etiologies of morbidity and mortality and to incorporate interventions into the already existing EMS system that will improve outcome.

Models of Care

The trauma model of out-of-hospital care is to provide a patent airway and adequate ventilation, to control hemorrhage, and to transport the patient to an appropriate trauma center, which provides definitive care. Out-of-hospital interventions should not prolong transport time, as this may be deleterious to patient outcome.⁷

In the medical (cardiac) model of care, the priority in adults includes rapid delivery of defibrillation to treat ventricular dysrhythmias and reverse sudden cardiac death.

Emergency Medical Services for Children

Historical Perspective

The needs of children in EMS systems were not initially addressed. In 1985 the federal government recognized the need for improved EMSC and passed legislation that funded the EMSC program. Senator Daniel Inoué (D–Hawaii), his aide Patrick DeLeon, and Calvin Sia, MD, provided the impetus for EMS. Senators Orrin Hatch (R–Utah) and Lowell Weicker (R–Connecticut) joined Senator Inoué in writing the EMSC legislation (PL 98-555), which established a national EMSC program.

Other organizations have also targeted resources and personnel toward improved EMSC; these include but are not limited to the American Academy of Pediatrics (Committee on Pediatric Emergency Medicine), the American College of Emergency Physicians (Section on Pediatric Emergency Medicine), the Ambulatory Pediatric Association (Special Interest Group on Pediatric Emergency Medicine), the National Association of EMS Physicians (Pediatric Committee), and the National Association of Emergency Medical Technicians.

To be effective in integrating EMSC into EMS, individuals and members of organizations must be involved in improving EMSC care based on their area of expertise (Table 147–2). The process of education about the special needs of children and the provision of formal education are critical steps to ensure that all these individuals deliver the best care possible.

Pediatric Model of Care

Respiratory distress, failure, and arrests are relatively infrequent events in the out-of-hospital care of children. However, recent studies demonstrate a high rate of respiratory arrest in children, compared to cardiac arrest, with the rate and absolute numbers of survivors from respiratory arrest far surpassing the rate and absolute numbers of survivors from pediatric cardiac arrests.¹⁰⁻¹² Airway management skills are critical for out-of-hospital providers caring for children. The pediatric out-of-hospital care model should be conservative (providing basic life support [BLS] care, focusing on airway and ventilation, and on transport to pediatric-capable hospital EDs) yet permissive (providing ALS) when the life-saving benefits are clearly present (e.g., treating ventricular dysrhythmias with defibrillation, reactive airways disease with bronchodilators, and anaphylaxis with epinephrine).⁷

Solutions: EMSC System Development

Epidemiology

The epidemiology of pediatric illness and injury encountered by the EMS system dictates the training, equipment, and protocols for treatment, triage, and transfer, as well as the capabilities of the transport system. Studies of the epidemiology of illness and injury in the out-of-hospital setting have demonstrated similar patterns.

Children are frequently transported by their caregivers for emergency evaluation, which accounts for approximately one third of all ED visits nationally. In the out-of-hospital setting, children account for approximately 6% to 10% of all ambulance runs.¹³⁻¹⁵ The acuity level for pediatrics in the out-of-hospital setting is lower than for adults. Approximately 0.3% to 0.5% of transported children require tertiary care, and 5% of these cases involve life- or limb-threatening problems. Most children are transported between 12 noon and 12 midnight.¹³ Children present in a bimodal age distribution, with the most frequent transports for ages less than 2 years and greater than 10 years. Younger children frequently present with medical problems; above age 2 years, trauma predominates. Most pediatric patients are managed by first responders and emergency medical technicians (EMTs) providing BLS, and about one third are managed by paramedics and receive ALS. Children transported to emergency departments by EMS personnel are three to four times more likely to require admission than are those who arrive by other methods.¹⁶

Injury mechanisms include motor vehicle accidents (including vehicle occupant, pedestrian struck, or bicyclist struck), burns, and falls. Medical complaints include seizures, respiratory difficulty (choking, stridor, lower airway disease, apnea), submersion injuries, and poisonings. Other problems include pregnancy-related problems, out-of-hospital births, and abdominal pain. These patterns of illness and injury are different than adult patterns, requiring education and treatment protocols that meet the needs of children.^{13,17}

Early EMSC System Development

In 1978, Los Angeles County EMS developed guidelines for out-of-hospital care of pediatric emergencies, a pediatric equipment list for out-of-hospital care providers, a curricu-

lum for the education of paramedics in pediatric emergencies, and a plan for integration of EMSC into the existing EMS system. Through their work, guidelines for a two-tiered system developed with facilities designated as Emergency Departments Approved for Pediatrics (EDAPs) or Pediatric Critical Care Centers (PCCCs). EDAPs are emergency facilities that provide basic emergency services and also voluntarily meet minimum standards for staffing, education, equipment, supplies, and protocols appropriate for the initial care and stabilization of critically ill and injured children. PCCCs must meet EDAP criteria and, in addition, have specialized pediatric services, including a pediatric intensive care unit and dedicated pediatric medical and surgical specialists.¹⁸

Others cities were also involved in improving EMSC (Mobile, Alabama; New York City; and Milwaukee, Wisconsin) through cooperative efforts initiated by and involving pediatricians, emergency physicians, and EMS physicians in the area.^{7,10,19} The Maryland Institute for Emergency Medical Service Systems (MIEMSS) also became a model for a successful and fully integrated EMS/trauma system and was one of the first to incorporate pediatric trauma receiving hospitals.

EMS System Stages of Care

There are seven stages of care for children in EMS systems: entry (recognition and activation), response, treatment and triage, transport, hospital, rehabilitation, and prevention.

Entry (Recognition and Activation) Phase

A parent, teacher, sibling, or bystander must recognize the urgency of signs and symptoms in ill or injured children that begin the entry stage of care. Advice on when to activate the EMS system is readily available.²⁰ In many regions, a “911” or a “911”-enhanced telephone system exists and provides direct access to the EMS system. Parents, caregivers, and schools should be familiar with this number and its correct use.²¹ Physicians should provide information for parents regarding when to contact the physicians’ office versus “911”²⁰ (Table 147-3), as well as which EDs are most appropriate for children. A call to “911” for a minor ailment can cause potentially life-threatening delays in the EMS response to a serious injury requiring emergent care.

Table 147-3 Example Situations Requiring Activation of the EMSC System

Acting strangely, less alert
Less and less of a response when you talk to your child
Unconsciousness or lack of response
Rhythmic jerking and loss of consciousness (a seizure)
Increasing trouble with breathing
Skin or lips that look blue, purple, or gray
Neck stiffness or rash with fever
Increasing or severe persistent pain
A cut or burn that is large or deep, or involves the head, chest, or abdomen
Bleeding that does not stop after applying pressure for 5 minutes
A burn that is large or involves the hands, groin, or face
Any loss of consciousness, confusion, headache, or vomiting after a head injury

Response Phase

The response phase includes activation of the “911” system to elicit an ambulance dispatch, which should be medically directed and coordinated. EMS systems may be one, two, or three tiered, composed of first responders, BLS, and/or ALS units. The type of unit dispatched, and the priority of the dispatch (high, medium, or low priority, response with lights and sirens, etc.) should be based on predetermined guidelines developed by a regional medical control physician.^{22,23} Standardized dispatch protocols include standard prearrival instructions, allowing the dispatcher to assist the on-scene parent, caregiver, or bystander to deliver optimal care. Adult-oriented ambulance dispatching may not adequately triage pediatric calls in determining which patient requires an ALS unit versus a BLS unit.¹⁶ More research is needed to determine the optimal dispatch protocols for children as these should be part of every EMS-EMSC integrated system.

There are five levels of EMS providers with regard to training and care. First responders can clear and maintain the airway, perform assisted ventilations and cardiopulmonary resuscitation (CPR), and establish hemorrhage control. Emergency Medical Technicians–Basic (EMT-Bs) provide these skills and, in addition, perform patient assessment, administer oxygen, assist ventilation using a bag-mask device, immobilize the spine, and transport patients. In some EMS systems, EMTs are trained to assist in administering autoinjected epinephrine to treat anaphylaxis, and to administer inhaled bronchodilators. EMT-Ds (providers of BLS) possess all the skills of EMT-Bs, and are also trained to use an automated external defibrillator and defibrillate. EMT-Intermediates (EMT-Is) are trained to an intermediate level between EMT-Ds and paramedics. The level of training varies with the state and EMS system. EMT-Is may perform endotracheal intubation and obtain vascular access. Paramedics (EMT-Ps) are trained to obtain vascular access and deliver medications via inhaled, intraosseous, intravenous, intramuscular, and endotracheal routes. Paramedics perform endotracheal intubation, and in some EMS systems are trained to perform intubation using sedative and paralytic medications. Care by EMS providers (first responder, EMT, paramedic) includes a scene assessment and assessment of the child (standard assessment approach now includes the Pediatric Assessment Triangle; see Chapter 2, Respiratory Distress and Respiratory Failure). Initial interventions include maintenance of the airway, adequate ventilation, and circulation. Other interventions depend on the particular medical illness or traumatic injury. Treatments are determined by the training of EMS providers (assessment skills, technical skills), as well as protocols for allowable interventions, appropriate equipment on the ambulance, and on-line medical control communication to guide therapy and transportation decisions.

Treatment and Triage Phase

The National Association of EMS Physicians (NAEMSP) has developed model protocols for out-of-hospital care of children. The conditions covered are listed in Table 147–4. Protocols and policies are available from NAEMSP at <http://www.naemsp.org> and from the American College of Emergency Physicians (ACEP) at <http://www.acep.org>. Recommended pediatric equipment lists have also been published^{24,25} (Table

Table 147–4 Model Pediatric Protocols

General patient care
Trauma
Burns
Foreign body obstruction
Respiratory distress, failure, or arrest
Bronchospasm
Neonatal resuscitation
Bradycardia
Tachycardia
Nontraumatic cardiac arrest
Ventricular fibrillation or pulseless ventricular tachycardia
Asystole
Pulseless electrical activity
Altered mental status
Seizures
Nontraumatic hypoperfusion (shock)
Anaphylactic shock/allergic reaction
Toxic exposure
Near drowning
Pain management
Sudden infant death syndrome

147–5). Other priorities include maintenance of temperature, triage decisions (based on severity of illness or injury), and primary transport to a hospital ED or pediatric critical care or trauma center. The scope of training necessary for EMS personnel to appropriately care for children has been developed through a national consensus process. Recommended curriculum content for paramedics²⁶ can be found in Table 147–6. Paramedic skills necessary for caring for children²⁶ are listed in Table 147–7. Treatment priorities include airway maintenance, providing oxygen, assisting ventilation, spinal immobilization, prevention of hypothermia, and transport to definitive care.

Triage includes the identification of an appropriate hospital destination and method of transport and is based on the patient’s age and medical problem or type of trauma, an objective measure of the acuity of the condition, and the distance from an ED. Triage decisions can be made by protocol or with direct (on-line) medical control. An important aspect of an EMSC system is having trained physicians, nurses, and EMTs to provide direct medical control for the unique issues that arise in the care of children in the field. These include pediatric treatment protocols, medication dosing, and triage protocols. Validated pediatric trauma scores exist (e.g., Pediatric Trauma Score), though currently no triage score for medical illness has been developed or validated for children in the out-of-hospital setting. Very few systems currently triage children for medical problems based on severity. Preliminary studies suggest that, whether their problems are medical or traumatic, children have improved outcomes when triaged and transported to tertiary care facilities.¹⁴

Transport Phase

Transport to a hospital involves triage decisions to determine the type of facility the child should be transported to, and the type of transportation used (ground ambulance vs. helicopter vs. fixed-wing aircraft). Most pediatric EMS transports are by ground ambulance. When severity of the child’s condition dictates transport in a short period of time, the use of a helicopter may be required. For greater distances, fixed-

Table 147–5 Basic Life Support (BLS) and Advanced Life Support (ALS) Ambulance Equipment for Children

BLS Equipment and Supplies

Essential

Oropharyngeal airways: infant, child, adult (sizes 00–5)
 Self-inflating resuscitation bag-valve devices: child and adult sizes
 Masks for bag-valve resuscitation devices: infant, child, and adult sizes
 Oxygen masks: infant, child, and adult sizes
 Non-rebreathing masks: pediatric and adult sizes
 Stethoscope
 Backboard
 Cervical immobilization devices: infant, child, and adult sizes
 Blood pressure cuffs: infant, child, and adult sizes
 Portable suction unit with regulator
 Suction catheters: tonsil-tip and 6F–14F
 Extremity splints: pediatric sizes
 Bulb syringe
 Obstetric pack
 Thermal blanket
 Water-soluble lubricant

Desirable

Infant car seat
 Nasopharyngeal airways: sizes 18F–34F, or 4.5 mm–8.5 mm
 Glasgow Coma Scale reference
 Pediatric Trauma Score reference
 Small stuffed toy
 Computer w/CD ROM capability and EMSC training CDs at base station for pediatric continuing medical education

ALS Equipment and Supplies

ALS ambulance equipment includes everything on the BLS list, plus the following items:

Essential

Transport monitor
 Defibrillator with adult and pediatric paddles
 Monitoring electrodes: pediatric sizes
 Laryngoscope with straight blades (0–2) and curved blades (2–4)
 Endotracheal tube stylets: pediatric and adult sizes
 Endotracheal tubes: uncuffed sizes 2.5–6.0, cuffed sizes 6.0–8.0
 Magill forceps: pediatric and adult sizes
 Nasogastric tubes: 8F–16F
 Nebulizer
 Intravenous catheters: 16–24 gauge
 Intraosseous needles
 Length/weight-based drug dose chart or tape (e.g., Broselow tape)
 Needles: 20–25 gauge
 Resuscitation drugs and intravenous fluids that meet local standards of practice

Desirable

Blood glucose analysis system
 Disposable CO₂ detection device

wing aircraft are needed. Paramedics providing ALS should be available in such circumstances. Additional treatments, including vascular access and fluid resuscitation for shock, are frequently provided en route or if there is unavoidable transport delay due to an extrication problem. Occasionally, when prolonged transport times are anticipated, endotracheal intubation or vascular access may be performed prior to transport as these procedures are more difficult to perform in a moving vehicle.

Ambulance transportation of children has risks. Principles of transport should include a balance between the risk of transportation and the benefit of rapid arrival. High speeds and the use of lights and sirens, which potentially results in ambulance crashes that may injure or cause the death of patients, providers, pedestrians, or other motor vehicle occupants, are con-

 Transport Considerations
 Destination issues, methods for transport (safety seats and parental transport)
 Infants and Children with Special Needs
 Technically Assisted Children (TAC): tracheostomy care, apnea monitors, central lines, chronic illness, gastrostomy tubes, home artificial ventilators and shunts

cerns. To make ambulance transport safer, guidelines are currently being developed. A list of recommendations is available from the EMSC program²⁷ and includes the following:

1. Drive cautiously at safe speeds, observing traffic laws.
2. Tightly secure all monitoring devices and other equipment.
3. Ensure that available restraint systems are used by EMTs and other occupants, including the patient.
4. Transport children who are not patients, properly restrained, in an alternate passenger vehicle whenever possible.
5. Encourage utilization of the Department of Transportation National Highway Traffic Safety Administration Emergency Vehicle Operating Course (EVOC), National Standard Curriculum.

Ongoing therapy and reassessment are performed during transport. Radio or telephone communication with a medical control physician or the receiving facility is not standardized, but communication with direct medical control may be optimal in certain circumstances. Contact with poison control centers for instructions on correct management of a pediatric poisoning during transport is a good example. Once at the receiving hospital, EMS providers report the child's current status, detailed information from the scene, treatments performed en route, and changes in the child's

status during transport. Patient care is then transferred to hospital personnel, which begins the next stage of care.

Hospital Phase

The hospital phase includes stabilization in a hospital ED and, if needed, transfer (secondary transport) to a pediatric-capable trauma center or critical care center. Hospital care also includes definitive therapy, which may be in an operating room, an intensive care unit, or an inpatient hospital ward. Hospitals capable of caring for critically ill or severely injured children are pre-identified. Preferential transport to these hospitals should be part of written triage protocols and/or included in on-line medical control communications and triage. EMS systems contain hospitals with varying levels of pediatric capability and resources. Improvements in the care of children within EMS systems have been achieved through regionalization of pediatric care. Other approaches include improving the pediatric capability of all EDs in the EMS system. ED guidelines to improve pediatric preparedness exist.²⁸⁻³¹ Unfortunately, there is evidence that not all hospitals follow available guidelines.³²⁻³⁴

Rehabilitation Phase

Appropriate physical or mental rehabilitation is needed to allow patient to continue receiving care for illness or injury in a family-centered care environment whenever possible.

Boating safety
Poisoning
Education
Safety caps on containers
Falls
Mandatory window guards

Prevention Phase

Emergency and intensive care to treat critically ill and injured children is expensive in terms of both personal anguish and societal cost.³⁵ Prevention is the least expensive intervention possible and has the best outcome. A functioning EMS system should be involved in identifying, developing, improving, and supporting successful prevention activities. The key to prevention is education. Parents, children, the lay public, pediatricians, family physicians, and emergency physicians, nurses, and EMS providers can all be involved in this phase by delivering anticipatory information concerning prevention in many areas (Table 147-8). Parents can be taught CPR, how to recognize significant illness and injury, what to do for particular medical emergencies, when to call for help ("911"), and what to do until help arrives.

The EMSC Program and Improvements in EMSC

The EMSC program has facilitated significant changes in EMS systems and EMS organizations in the United States. Some of these include educational programs for out-of-hospital providers in pediatrics. The EMSC Program's National Education of Out-of-Hospital Providers Task Force makes recommendations for EMS educational curricula.²⁶ Pediatric out-of-hospital education programs developed based on this model include the following:

1. Teaching Resource for Instructors in Prehospital Pediatrics (TRIPP) and Paramedic TRIPP from the Center for Pediatric Emergency Medicine (<http://www.cpem.org>)^{36,37}
2. Pediatric Education for Prehospital Professionals (PEPP) course (<http://www.PEPPsite.com>) from the American Academy of Pediatrics (<http://www.aap.org>)³⁸
3. Pediatric Prehospital Care (PPC) course from the National Association of EMTs (<http://www.naemt.org>)³⁹

The Institute of Medicine's report on EMSC published in 1993 recognized these improvements and recommended further changes in access to care, equipment, educational programs, and research.³⁴ The National Association of EMS Physicians, supported by the EMSC program, developed model protocols for out-of-hospital care of children (see

Table 147–4). Ambulance equipment was recommended by a multidisciplinary committee for out-of-hospital care of children²⁴ (see Table 147–5). Guidelines for EDs to prepare for pediatric patients have been developed by several national organizations.^{28–31} The EMSC program has also supported a landmark study, one of the few randomized controlled trials in out-of-hospital care for children. This study examined the outcomes of children who had out-of-hospital endotracheal intubation versus bag-mask ventilation performed by paramedics in California and showed that there were no outcome differences in patients who were intubated versus those who had appropriate bag-valve-mask ventilation performed.⁹

Despite these accomplishments, not all EMS systems or EDs are prepared to care for children.^{32,33} Emergency physicians and pediatricians must continue to provide leadership for local EMS systems and receiving hospitals so that the resources, guidelines, and products designed for children are used and incorporated into all EMS systems and EDs in the United States.

Summary

The development of resources, products, system changes, and research networks has improved the care children receive in our nation's EMS systems. More research is needed to demonstrate the positive impact that many EMSC programs and initiatives have already produced. Maintaining the collaboration of national, public, and government organizations and programs that have concentrated on improving children's out-of-hospital and emergency care will ensure continued improvements in the outcome of children cared for in our EMS system.

End-of-Life Issues

Jill M. Baren, MD, MBE

Key Points

It is the responsibility of the emergency physician to develop prognostic information and to convey it, accurately and comprehensively, to children and families so that the most well-informed decisions can be made at the end of life.

Physicians should never delegate the task of death notification to another emergency department (ED) staff member.

Implementing palliative care in the ED can alleviate the feeling that “there is nothing we can do” for dying children.

Introduction and Background

Each year in the United States, approximately 53,000 children die.¹ Pediatric deaths can be delineated into three categories: the deaths of infants (babies born prematurely through 1 year of age), deaths from illness, and traumatic deaths. Of these, the most likely to occur in emergency departments (EDs) are traumatic deaths. Almost 17,000 children die each year from traumatic injuries.¹ Sudden infant death syndrome continues to be the leading cause of postneonatal infant death, accounting for about 25% of all deaths between 1 month and 1 year of age, and many of these infants are pronounced dead in the ED.² The epidemiology of pediatric death from medical illness in the ED is not well studied.

Decision making about the goals of care immediately following traumatic injury is rarely complicated. For a previously healthy child who sustains injuries in a motor vehicle crash or from a gunshot wound, a fall, blunt force trauma, or any other cause, all efforts to cure are made under most circumstances. Decisions about whether cure is possible may arise, but generally occur after the patient is admitted to the hospital. The same principles apply in the case of cardiopulmonary arrest or critical illness such as meningitis or sepsis. When a child is dying from a chronic illness in the ED, such as cancer, muscular dystrophy, cystic fibrosis, or another previously diagnosed condition, as opposed to an acute infectious process, the clinical picture—especially whether cure

is possible—is often not clear upon presentation. The difficult question confronting the ED staff is, “What is the appropriate goal for this child at this time?”

For children with life-threatening conditions in the ED, several factors must be considered in decision making:

- What were the goals of treatment or care, if any, before the child came to the ED?
- Who is aware of these goals?
- Are these goals appropriate given the child's pathophysiology at this time?
- How do these goals fit with this child's current visit to the ED?
- Who is appropriate and available for decision making?
- What can and should the ED staff do to facilitate these goals?

A framework for answering these questions is provided in this chapter.

Issues

Death occurs more frequently in the ED compared with many other health care environments, even in the pediatric population. Many barriers make the provision of empathic and timely end-of-life care more difficult to provide in the ED. Care in the ED is characterized by rapid turnover of patients and complex interactions both within and outside of the ED. ED patients frequently experience acute changes in their condition, and there may be little available information and little time for gathering additional information before decision making. The impact of this incomplete physiologic database may be further complicated by medical conditions that render ED patients incapable of participating in the process of decision making. Furthermore, appropriate surrogate decision makers may be unknown, unprepared, or unavailable, which, in the case of children, is the major issue.

The lack of a prior physician-patient-family relationship contributes to the complexity of the emotionally and medically difficult situations of dying children. The unpredictability of conditions in the ED at any given time leads to great difficulty in establishing relationships between clinicians and patients and among clinicians with different areas of expertise and different clinical end points. This may be the greatest barrier in establishing effective care for dying patients as it these relationships that provide the necessary foundation of trust.

Despite these limitations, it remains the responsibility of emergency physicians to provide high-quality and compassionate care and support to terminally ill and acutely dying patients and their families. Professional organizations have strongly endorsed this concept by creating codes of ethics and professional statements. The Code of Ethics for Emergency Physicians, established by the American College of Emergency Physicians in 1997, acknowledges that the fundamental moral responsibility of emergency physicians includes embracing patient welfare as the primary professional responsibility; respecting the rights and best interests of patients, particularly those most vulnerable and those unable to make treatment choices due to diminished decision-making capacity; and communicating truthfully with patients.³ This code establishes the obligation that emergency physicians have to be “patient and family focused” in situations in which there is the greatest need for this level of commitment.⁴

Solutions

To arrive at the best possible solutions for the difficult issues raised in the care of dying patients in the pediatric ED, an informed, structured, and empathetic approach is needed in the clinical practice of pediatric emergency medicine. Three particularly important aspects of this approach are communication, palliation, and education. Excellence in these three areas is likely to lead to a high degree of professional and family satisfaction regardless of clinical outcome.

Communication

Most adults have never confronted the death or dying of a child. This applies not only to families, but also to health care providers. Physicians, nurses, social workers, chaplains, and others may lack the skills to engage in conversations about such deaths. A belief that children do not/should not die often results in an extremely aggressive pursuit of an extremely improbable or even impossible cure. As with adults, the burdens to the child must be weighed against the likelihood of benefit. Clinicians should engage in this calculation before bringing the discussion to the family and the child if appropriate. While this suggestion is often met with protestations—“That’s the family’s decision, not ours!”—part of the decision does lie with clinicians. Any clinical decision exists only in the context of physiologic parameters. It is the responsibility of providers, even in the ED, to develop this information and to convey it accurately and comprehensively to children and families, so that the most well-informed decisions can be made.

Adults faced with critical illness or injury may have established advance directives as a mechanism to formulate and communicate health care preferences. Advance directives have two components: (1) naming a surrogate decision maker, and (2) conveying information to guide health care decision making if the patient is unable to, or chooses not to, participate. Living wills, durable powers of attorney for health care, Do Not Resuscitate (DNR) or Do Not Attempt Resuscitation (DNAR) orders, and informal documents are all widely accepted types of advance directives.

Certain advance directives apply to more than end-of-life situations. Most, however, are prepared with considerations of what one wants or does not want when dying. In clinical practice, advance directives are often not helpful for a number

of reasons. Many advance directives (especially living wills) are written with categorical statements (I ____ do/do not want ____ . . .) that are difficult to apply to a specific clinical situation. Similarly, advance directives are also likely to contain well-meaning but murky phrases such as “no heroic measures” or “no extraordinary means.” While the author may have had some notion of what was intended, in reality these statements cannot be construed as a comprehensible conveyal of the patient’s preferences for health care.

More importantly for this discussion, advance directives are not intended to be written by, or used for children, at least from a legal perspective. A return to the intent of advance directives, however, reveals a way that advance directives can be wisely and appropriately used with and for children.

For most children who come to the ED, the goal is to save lives. However, there will be children for whom all the best curative efforts are not enough to restore or prolong life.¹ These children either will die, or will live with sequelae (physical, psychological, and/or cognitive) of the illness or injury. Second, for certain children, the goals of care, and of medical interventions, must shift from cure to comfort.

From a clinical perspective, children may have the wherewithal to make informed decisions about their care at the end of life. It has been demonstrated that dying children, even of preschool age, know they are dying.⁵ Often, the adults involved in dying children’s lives are slower to recognize the inevitability of the death. The responsibility of health care providers is to be honest about prognosis, with ourselves, and with our patients and their families. Often this is not the case. Not only are prognoses calculated inaccurately, but there is a tendency to convey more optimistic data about prognosis than is truly believed.⁶ If objective criteria lead to the conclusion that a patient has a poor prognosis, clinicians should not attempt to find a reason why that poor prognosis does not apply, nor should they allow that to dominate the conversation.

Before a parent, guardian, and even a child is engaged in a discussion about end of life, the providers must be clear about the prognosis. In the ED, a team approach often makes this difficult activity more feasible. When an infant or child presents to the ED in cardiopulmonary arrest, parents should receive information in a stepwise fashion, hearing first that the situation is grave but that everything possible is being done. This information can be delivered by a social worker, nurse, or caring and trained administrative person prior to the clinician meeting with the family. When it becomes inevitable that death is the outcome, the physician involved in the child’s care should deliver that message. Physicians should never delegate this task to another ED staff member.

In the unusual case of a dying child or adolescent who is capable of speaking with the clinician, it is often helpful to pose the following question, “What do you think is going on with your disease?” When given the opportunity, children will often speak at length about their feelings and what they know. If a child does wish to discontinue life-prolonging therapies, the child’s experienced-based knowledge allows one to consider him/her an informed and appropriate decision maker. What must be assessed is whether the child understands the decision about which he/she is being asked; if the child understands the burdens/costs and benefits of the treatment being offered, or of refusing the treatment; and whether the child responds consistently in conveying the

decision. Many children who have lived with life-threatening illnesses or the sequelae of injuries do have this expertise, perhaps with a stronger base in reality than the adults around them.

Palliation

Understanding of palliative care has evolved markedly over the past decade. Palliative care is now understood as distinct from hospice, though many of the same concepts apply. Palliative care, like hospice, focuses on the patient's life being lived as well as is possible. What distinguishes them is that hospice care is provided with and for patients whose expected life span is limited. Prognosis is often difficult to develop and even more difficult to convey. Calculating life expectancy is more difficult still in the case of children.¹ Palliative care refers to aggressive symptom management across the trajectory of disease. Palliative care can and should be pursued concurrently with curative therapies.

Palliative care for children in the ED includes aggressive symptom management while pursuing whatever goals of treatment are physiologically indicated. Dying children often have a high symptom burden.⁷ When children come to the ED, palliative care must be considered. Fear and lack of knowledge often result in children's pain being grossly undertreated.^{8,9} The claim that one cannot manage pain and other symptoms because of a need to assess and diagnose is frequently misapplied and results in undue burden of suffering. In most cases, optimal pain management will not interfere with an assessment of level of consciousness. The American Academy of Pediatrics, in conjunction with the Canadian Pediatric Society and the American Pain Society, have developed guidelines for the management of pain and stress in neonates, children, and adolescents.^{8,9}

In the most difficult cases when a child is dying, parents are often told, "We've done everything we can. There is nothing else we can do." To the contrary, there is always something else that can be done. Understanding palliative care as a mandate for broad-based, aggressive symptom management shapes interventions with dying children. Whether the death of a child is from a progressive neurodegenerative disease, advanced cancer, or trauma, a focus on relieving pain, dyspnea, anxiety, and other symptoms benefits both the child and the family. Most providers are not trained in these skills in the context of dying. Developing a paradigm shift toward implementing palliative care in the ED can alleviate the feeling that "there is nothing we can do."

Emergency physicians have a duty to preserve life, but must recognize that there are key differences between withholding and withdrawing treatment in the pediatric emergency setting that may differ from the moral equivalence that has been afforded to these actions in other medical settings.¹⁰ From a societal viewpoint, there is an expectation that emergency physicians will act to preserve life in the absence of a few well-established conditions (rigor mortis, decapitation, failed cardiopulmonary resuscitation [CPR]). The withholding of treatment often feels like a public event and has been described as the most traumatic of all decisions in the practice of emergency medicine.¹⁰

From a practical standpoint, the lack of information about a child presenting to an ED is a frequent characteristic in life-threatening situations. Clinicians have little insight regarding patient identity, wishes, and prognosis, and there-

fore aggressive therapy aimed at preserving life should be immediately instituted with one exception—the intervention is unequivocally judged to be nonbeneficial or futile. If and when surrogate decision makers or additional information become available, treatment options can be discussed and modified. Terminally ill children who are actively dying, who do not possess advance directives or other clearly articulated wishes for their care, who are not accompanied to the ED by surrogate decision makers, or who have multiple surrogate decision makers in conflict about withholding specific interventions should have life-saving care initiated until additional information is available and conflict can be mediated. This does not imply that such care will always be successful in reversing the life-threatening condition. Withdrawal of life support in the ED is a viable option depending on the subsequent information and circumstances. Treatments should be chosen and implemented within the context of what is physiologically indicated.

A vast array of ethical issues surrounds the process of CPR in children. Fortunately, pediatric cardiopulmonary arrest is rare. Outcomes from pediatric cardiac arrest are well documented in the literature and are dismal.^{11,12} The underlying medical condition of the patient, the presenting cardiac rhythm, and response to prehospital advanced life support measures are important factors affecting both the outcome of CPR and medical decisions surrounding CPR.¹³ Approximately one to two traumatic or medical pediatric cardiopulmonary arrests occur in busy EDs per month, thus the skills involved are not easily practiced let alone perfected.

In the early stages of resuscitation, when few to no data are available, the emergency physician must be primarily concerned with the restoration of circulation and life of the patient. As additional data are gathered, medical decision making can be broadened to include new information such as the underlying condition of the patient and the likelihood of survival. An important but often overlooked part of the resuscitation process is the need for lessening the guilt of survivors and providing a sense of closure. This involves developing important skills for incorporation into resuscitation protocols: recognition of futility, procedures for stopping the resuscitation, and ability to communicate with families.

Numerous studies in the emergency medicine literature indicate that patients, families, and health care providers believe that a supported, structured environment for the presence of family members during resuscitation and other medical encounter is both feasible and desirable.^{14,15} Although this concept has been fraught with controversy and resisted in many health care environments, there appears to be a general trend in many institutions toward the development of protocols to allow families to be present, albeit with assistance (see Chapter 153, Family Presence).

Mishandling the events surrounding a pediatric death can set the stage for an abnormal bereavement for survivors. To facilitate a family's recovery, various postmortem activities have been suggested for ED staff. Surveys of families whose children were either pronounced dead on arrival or underwent unsuccessful resuscitation showed the following activities to be highly desired and helpful¹⁶: strong preference that the news of a patient's death be delivered by a physician, viewing the body, having the child's clothing be returned to them even after it was used as part of the investigation of the

cause of death, having a physical memento such as a lock of hair or a mold or print of the baby's hand, and a follow-up phone call from the ED after the death.¹⁶ These are not things that parents are capable of thinking about during the acute event, so there should be processes in place to make sure they are offered.

These activities can be time consuming but could be accomplished by a few dedicated individuals. Although the impact of such practices on bereavement and long-term coping by survivors has not been studied, they may at the very least contribute significantly to the perception that the ED, the hospital, and its health care providers are caring entities.

Request for Autopsy and Organ/Tissue Donation

Request for autopsy and organ/tissue donation is often viewed by physicians as one of the more difficult tasks in the death of a patient in the ED. Some of the barriers inherent in asking for an autopsy, when it is not required by law, are fear of offending the family, fear of legal retribution for care that resulted in death, and avoidance of contact with the family after the death notification has occurred. Autopsies are mandated by law whenever an unexpected death has occurred or when there are suspicious circumstances surrounding the death (suicide, homicide, child abuse). Emergency physicians must be aware of the specific cases that need to be referred to their local medical examiner's office.

Learning the results of an autopsy can be extremely helpful for grieving families, providing them with closure or some explanation for a terribly tragic and seemingly inexplicable event. In addition, there are some myths regarding autopsy that should be dispelled. The autopsy is not disfiguring and will not interfere with funeral arrangements as it is typically performed within 24 to 48 hours. Autopsy is not disallowed by most major religions; families should be encouraged to consult with hospital chaplains or their own religious advisors to confirm this. Finally, the performance of an autopsy does not result in additional cost to the family. The cost is absorbed by either the hospital or the medical examiner. The emergency physician can offer to meet with the family to go over the results; alternatively, the results can be forwarded to the pediatrician or family physician for discussion. Physicians should not discount how valuable autopsy results are for their own closure and continued medical knowledge.

Request for organ/tissue donation has a different set of associated issues. Many states have laws mandating the request for organ/tissue donation. In the case of a beating heart potential donor, and in some cases a non-beating heart donor, trained specialists from organ procurement agencies can be dispatched to the ED to make the request in person. These individuals have expertise in the language necessary to obtain permission for donation and the knowledge to answer difficult questions when they arise. In addition, having the request come from someone distinct from the patient care team can provide valuable separation of the death and the events that must occur for organ harvest. The initial idea, however, must be introduced by the emergency physician. Many families view organ donation as a way to bring about some good from a bad situation, and may be waiting for the opportunity to be asked; therefore, both organ/tissue donation and autopsy requests should be a standard part of the death encounter.

Education

There is much evidence to support the fact that physicians in training and in practice still feel relatively uneducated and largely unsupported on issues of death and dying. In 1993, the American Medical Association reported that only 26% of primary care residencies offered training in the care of dying patients.¹⁷ Yet studies have indicated that exposure to dying patients is high, with pediatric residents caring for an average of 35 dying children during the first 2.5 years of residency training. The specific exposure of emergency physicians to dying patients is not known. However, neither high nor low exposure rates will necessarily be associated with a greater level of comfort in dealing with death and dying for any given physician. Training must not only address knowledge and skills to improve interactions with families, but examine personal reactions as well.

Programs such as Education for Physicians on End-of-Life Care (EPEC), End of Life Nursing Education Consortium (ELNEC), and Toolkit for Nursing Excellence at End of Life Transition (TNEEL) are formal, albeit relatively brief mechanisms for education. If knowledge and skills are lacking, both children and families will suffer, physically and otherwise. Education, however, is not enough in that it does not always translate into practice. Optimal end-of-life care must be integrative. There must be an expectation of excellence within institutions, at the levels of attending physicians, clinical directors, and chief medical and nursing officers. There must be integration into practice at the levels of staff nurses, house officers, and beginning providers. Real excellence will require a change in culture within disciplines and health care systems. Death should not be viewed as a failure, and excellence in the provision of end-of-life care is the responsibility of all providers in an ED.

Summary

The death of a child is not a common event, but there remain variations across populations, geography, and socioeconomic status. For most people, however, the death of a child is almost unheard of and leaves the family at risk for complicated bereavement.¹⁸ While the provision of excellent end-of-life care for children is not likely to alter families' grief significantly, the absence of excellence will leave families with memories and impressions of their child's suffering. The knowledge and skills exist to provide excellent end-of-life care to children even, and perhaps especially, in the ED.

Chapter 149

Patient Safety, Medical Errors, and Quality of Care

David P. John, MD, John A. Brennan, MD, Nancy E. Holecek, RN,
and Patricia Sweeney-McMahon, RN, MS

Key Points

The “culture of blame” has done little to improve quality and patient safety. Malpractice litigation, morbidity and mortality rounds, and physician profiling drive errors underground. A “just culture” error reporting system with data tracking must be in place in order to understand, categorize, and decrease system failures.

Individual institutions should use data to understand the problems within their health care system.

Hospitals’ administration, physician, and nursing leadership should be directly involved and drive these changes. However, true culture change occurs with staff involvement.

Quality and safety initiatives should focus on system re-evaluation that ensures safe, effective, patient-centered, efficient, timely, and equitable health care for all patients.

Pediatric patients are particularly prone to medication errors secondary to miscalculations.

- Between 44,000 and 98,000 Americans die from medical errors annually.³⁻⁵
- Medication-related errors for hospitalized patients cost roughly \$2 billion annually.^{3,6}
- The lag between the discovery of more effective forms of treatment and their incorporation into routine patient care averages 17 years.^{7,8}

Now, however, the public, health care regulatory agencies, and the federal government are aware of the shortcomings in quality and safety in medicine. Additionally, the Agency for Healthcare Research and Quality, the Institute of Healthcare Improvement, and Six Sigma have also been instrumental in addressing the patient safety and quality process change and developing best practices (Table 149–1).

Joseph M. Juran and W. Edwards Deming pioneered quality improvement in industry. In post–World War II Japan, “Made in Japan” was synonymous with inexpensive, mass-produced, poor-quality goods. Under the guidance of Deming and Juran, Japan redesigned systems and developed a culture of quality in their businesses. Companies such as Sony and Toyota equaled, and perhaps surpassed, some of their American counterparts.

In the 1960s, 1 in 1000 airline takeoffs had some form of system flaw. Many of these resulted in crashes, causing loss of human life, loss of million-dollar aircraft, and countless dollar losses in profit to the industry.^{9,10} “Aviation safety was not built on evidence that certain practices reduced the frequency of crashes. Instead it relied on the widespread implementation of hundreds of small changes in procedures, equipment, training, and organization that aggregated to establish an incredibly strong safety culture and amazingly effective practices.”³

Over the last 20 years, the specialty of anesthesia has reduced its death rate from 1 in 20,000 to 1 in 200,000. Anesthesiologists developed processes that helped them better understand and measure the effectiveness of their systems.¹¹⁻¹³ With this basic knowledge, they standardized procedures, orders, monitoring capabilities, competencies, and recovery room criteria. Their systems became simpler, with multiple checks and balances to help avoid adverse events. Standardizing anesthesiology carts and making it mechanically impossible to hook up the wrong gas to the

Introduction and Background

Quality and safety in medicine have not evolved to anywhere near the standards of other industries. Medicine has always been viewed as a “calling” or “art” rather than a business. As such, it has not been subject to the scrutiny of the business model (productivity, efficiency, and quality) . . . until now.¹ An Institute of Medicine (IOM) report² and pay-for-performance initiatives have suddenly made quality and patient safety top priorities in medicine. The IOM report *To Err is Human: Building a Safer Health System*³ brought to light what most health care workers already know: errors occur and patients are harmed, and occasionally die.

wrong tube are just two examples of how system changes can prevent adverse events.

In emergency medicine, the development of the color-coded tape is one of the first pediatric safety initiatives. Medication dosing and equipment size are based on the weight and length of the child. Calculations are difficult, cumbersome, and not readily available during an emergency, and errors can result in patient harm. To help prevent this, a color scheme based on the length of the child was developed to aid in accessing the proper-sized equipment and medication doses for the child. These length-based, color-coded systems have been placed in many emergency departments (EDs) in the country because¹⁴

- The system is easy to use.
- It is not prohibitively expensive.
- It improves patient outcomes.

Issues

Since the IOM report *To Err is Human*, quality and patient safety issues have come to light in the media, in hospital boardrooms, and among consumers. This report, as well as the IOM's report *Crossing the Quality Chasm: A New Health System for the 21st Century*,² has refocused the government, regulatory agencies, and private payers on health care reform.

The Joint Commission on Accreditation of Healthcare Organizations, along with state and federal governments, has recently implemented a mandatory reporting system for medical errors. This initiative, like the current medical liability system, seems intuitively to drive disclosure underground. Why would a health care provider openly report a medical

error in this system? The individual reporting the error could be sued, lose his or her ability to practice medicine, and be publicly reported. The airline industry has a “just culture” with mandatory error reporting and they study “near misses” and malfunctions in an effort to improve quality and safety.

No medical practitioner intends to harm patients. Providers of emergency care work in a chaotic environment. They are overworked, understaffed, and overcrowded. They handle numerous sound bytes of information from every direction and, not unusually, the unexpected occurs.¹⁵ These events occur in every ED across the country every day. To prevent adverse events, one needs to understand what went wrong, categorize it, collect data on it, and then, most importantly, put systems in place to prevent or minimize harm to patients.¹⁶ Some of the chief impediments to reporting errors include the fear of punishment by state licensing boards and regulatory agencies, embarrassment, and being branded as a troublemaker. In order to analyze and decrease errors, a just culture environment must be created.

Evidence-based clinical guidelines and pathways have been shown to improve quality and patient safety.^{17,18} Like the Emergency Medical Treatment Act and Labor Act, quality and patient safety are largely unfunded mandates. In a time of decreasing reimbursement, who is going to pay for the infrastructure changes needed to implement sweeping reforms and new technology? Despite the financial implications, emergency medicine needs to embrace this concept in all aspects of patient care. As Karl Albrecht noted, “You seldom improve quality by cutting costs, but you can often cut costs by improving quality.”

EDs are frequently in an overcapacity state. This was referred to initially as ED overcrowding when it was actually a systems issue within the individual hospital. The unintended consequence of overcapacity is ambulance diversion. Ambulances are asked to take sick patients to other hospitals, often a distance away. The quality and safety issues inherent in this situation are numerous (Table 149–2). Diversion is a symptom of, not a solution to, overcrowding. Numerous problems have an impact on crowding, but one of the most critical is access of care (Table 149–3). Emergency departments are the last safe harbor for economically challenged parents with children, the frail elderly, and patients with urgent needs whose doctors cannot see them.

When the ED/hospital is over capacity, waiting times increase, the number of patients who have “Left Without Being Seen” increases, and the fixed staff cannot provide the type of care that they have been trained to give. In an overcapacity situation, the criteria for a disaster or mass casualty incident are often met but not matched with a prescribed action plan. Additionally, hours and even days go by without

Table 149–3 Reasons for Lack of Access to Health Care

Doctor’s offices are full.
 Doctor’s offices are closed.
 Offices are not accepting new Medicare patients.
 Patient cannot afford outpatient care or prescription drugs.
 The “clinic system” has failed.

Table 149–4 Selected Hospital-Related Opportunities to Decrease Overcrowding

- Measure each step of the admission process to identify the opportunities for improvement.
- Include key members of the multidisciplinary team in all process improvement discussions.
- Create units that can expand to accept greater number of patients and avoid adding nonclinical ancillary personnel.
- Improve the accuracy of forecasting beds for elective surgery and the resources to support it.
- Expand the elective surgery schedule for nonpeak hours; negotiate with the surgical staff to comply.
- Assign accountability for timely discharges, efficient room turnover, and adequate resources for timely transportation.
- Assign executive leadership to adopt or “own” a project or process.
- Analyze operational data as they relate to quality and safety outcomes and report regularly.

any relief, giving the impression that overcrowding is “status quo” for the ED. As a result, quality and safety are compromised, and hospital-related opportunities to decrease overcrowding should be strategically discussed and accountability assigned (Table 149–4).

EDs/hospitals must have an overcapacity or surge plan that includes the ability to increase resources and obtain additional staff. The senior management of the ED/hospital must streamline and reallocate resources throughout the hospital, including the canceling of elective surgeries, to focus on the overcapacity. They must establish the importance and priority of the ED, prior to overcapacity, as part of a strategic plan. Additional areas of the hospital must be opened up for patient care, including the creation of transition areas for admitted and discharged patients. Preparation for overcapacity and the prevention of the errors resulting from overcapacity includes education planning and the hospital’s commitment to patient safety and quality. This preparation is mandatory, and the operational effort required to implement an overcapacity plan must be simple and administratively supported. At the very least, there should be an “ED dashboard” or mechanism in place to communicate the real-time current condition of the ED to all members of the management team responsible for patient throughput (Table 149–5).

Solutions

Benchmarking quality indicators, measuring them, and making system changes to improve compliance are fundamental components of an ED quality improvement program. It is necessary to understand best practices and share successes to improve the way care is delivered. The department must do away with the “culture of blame,” and develop an

environment in which “near misses” are reviewed in a just culture reporting system and systems are put into place to prevent harm.

In order to implement national best practices, there must be a complete facility buy-in to achieve the desired quality and/or safety outcomes. The Institute for Healthcare Improvement describes one such example as the “Plan-Do-Study-Act” cycle. This process tests a quality/safety change in the real work setting—by planning it, trying it, observing the results, and acting on what is learned. This is the scientific method used for action-oriented learning.

The department focuses on a desired outcome that is presently challenging and maps the process to help define critical steps that are captured and measured for analysis. A multidisciplinary team is selected that best represents key stakeholders, and changes for improvement are defined. A trial is implemented and the results are used to support a permanent change in process or policy.

All successful quality programs must have the support of their hospital’s leadership. As stated by L. L. Leape, “Management must ‘manage’ for patient safety and quality just as they manage for efficiency and profit maximization. Safety must become part of what a hospital or healthcare organization prides itself on.”¹⁹ Successful organizations have implemented the following practices and created a culture of quality and safety:

Collaborative Environment: Create an environment in which every member of the patient care team is empowered to provide information, ask questions, and question orders or a patient disposition.

Just Culture Error Reporting Systems: Incident reports must be simple to complete. Root-cause analysis must be

completed to understand system errors. An anonymous reporting system provides practitioners with a “safe harbor” reporting environment. Staff education will raise the level of awareness about medication errors and near misses.

Dashboard: An ED dashboard should reflect the current/real-time condition of the ED and be accessible to all appropriate leadership via a shared computer hard drive or Intranet. This report should help facilitate the appropriate actions to decompress the ED and allocate the appropriate resources to meet patient care demands (see Table 149–4).

Report card: The ED report card must include financial, operational, quality, and satisfaction data, with the appropriate benchmarks to provide leadership with the insight to identify opportunities for improvement and processes that are successful. The data points selected to create the measurement should adequately reflect the processes of the department and the results should be validated (Table 149–6).

Clinical Information System: Electronic information systems should facilitate easy documentation of assessments, care, and treatment of ED patients and access to that information in an organized and retrievable format. Additionally, they should provide tools to prevent error, improve the staff’s ability to communicate, and provide up-to-date clinical best practices to drive quality outcomes.

Quality Program: The most successful quality programs include executive leadership with multidisciplinary representation, evidence-based care paths, the appropriate tools to assure successful implementation, and a process to measure outcomes and communicate them to all departments involved in the care path.

Safety Program: A successful safety program is one that promotes a collaborative and patient-centric culture throughout the entire organization.

Patient Callbacks: Radiology discrepancies, positive cultures, and patients who left without being seen all provide useful quality and follow-up data.

Clinical Guidelines and Pathways: Best practices should be developed for frequent and high-risk/complex patient presentations. Asthma, fever, and dehydration are examples for which specific evidence-based medicine protocols should be tracked and linked to outcomes.

Sign Out/Change of Shift: Every patient must have a physician and nurse who understand his or her problem and treatment plan. A policy on how a patient’s care is transitioned from one health care provider to another is critical to prevent errors.

Improvement of All Communications: Improving written and verbal exchange of information applies to how one communicates to other medical personnel as well as to the patients and their families.

- **Written:**
 - Utilize electronic ordering systems where possible.
 - Safety protocols implemented at the institution should include:
 - Discontinuing the use of all error prone abbreviations.
 - Never using a trailing “0” (1.00 mg/kg).
 - Always using a leading “0” (0.1 mg/kg).
 - Do not write or accept poorly written orders or charts.
 - Always customize discharge instructions to include a simple but explicit follow-up plan regarding outpatient care and medication. To enhance understanding, choose the appropriate language and grade level for all people involved in the care.

Table 149–6 Selected Emergency Department (ED) Report Card Measurements: Monitoring of the ED Over Time

Financial	Quality & Safety	Operational	Satisfaction
<p>Volume</p> <ul style="list-style-type: none"> • Month to date (MTD) • Year to date (YTD) • Include % increase and decrease • Expected vs. actual • Track specialty service utilization <ul style="list-style-type: none"> • Fast track • Orthopedics <p>Resource Utilization</p> <ul style="list-style-type: none"> • Patients per physician hour • Patients per provider hour <p>Charge Capture: Assure adequate resources are available to maintain quality:</p> <ul style="list-style-type: none"> • Adequate central line kits to support recommendations to decrease central line-associated primary bloodstream infections • Foley kits with urimeter attached to catheter to prevent UTIs associated with breaking the sterile field 	<p>Core Measure Outcomes Driven by Care in the ED</p> <ul style="list-style-type: none"> • AMI • Pneumonia • Infectious disease <p>Monitor changes to the course of treatment implemented in the ED vs. inpatient and link to outcomes</p> <p>Safety Culture Measurement (CUSP)</p> <p>Physician- and Nurse-to-Patient Ratios</p> <ul style="list-style-type: none"> • Measure by acuity • In real time, by time of day <p>Map to outcomes</p>	<p>Turnaround Times</p> <ul style="list-style-type: none"> • Admitted • Discharged • ED area <ul style="list-style-type: none"> • Fast track • Pediatrics • Laboratory • Radiology <p>Quality-Linked Operations</p> <ul style="list-style-type: none"> • Door to ECG • Door to PCI • Door to thrombolytics <p>Admission Process</p> <ul style="list-style-type: none"> • Process map each step • Analyze by service • Analyze by destination 	<p>Patient Satisfaction</p> <ul style="list-style-type: none"> • By question • By time of day • By staff member <p>Employee Satisfaction</p> <ul style="list-style-type: none"> • By discipline within the department • By shift <p>Medical Staff Satisfaction</p> <ul style="list-style-type: none"> • Monitor formally with a survey that reflects the distinction between ED and hospital process • Allow for ongoing monitoring

Abbreviations: AMI, acute myocardial infarction; ECG, electrocardiogram; PCI, patient controlled infusion; UTIs, urinary tract infections.

- **Verbal:**
Use appropriate time-out policy during procedures. Minimize use of verbal orders. Always do a read back of a verbal order.
Introduce yourself and know your coworkers.
Create a collaborative, not hierarchical, working environment.
Identify high-risk or very unstable patients.
When speaking to a patient, always follow verbal instructions with a written version.

Emergency Medicine–Specific Quality Guidelines: Develop indicators based on chief complaint or clinical presentations versus the diagnosis.

Patient-Centered Care: Historically, the environment of care was based on staff convenience (nursing stations, lack of test availability at night, etc.). The focus needs to change to “what is best for the patient.”

Telephone and Verbal Orders: Limit these wherever possible and have them repeated and confirmed.

ED Medications: Institute measures to prevent medication errors:

- Reduce the number of medications with similar indications.
- Consider having a pharmacist in the ED to mix all medications, similar to the intensive care unit.
- Place concentrated electrolyte solutions from the ED in secured areas.
- Clearly label medications and do not store look-alike/sound-alike medications near each other.
- Limit interruptions, if possible, during medication preparation and administration.

On-Call Specialist and Follow-up Care: The hospital administration and physician leadership must ensure that there is adequate subspecialty care and follow-up.

Table 149–1 is a resource for finding EM best practices. Systems must be in place to minimize human factors. As stated by W. A. Foster, “Quality is never an accident. It is always the result of high intention, sincere effort, intelligent direction, and skilled execution.”

Summary

Individual EDs need to use the evidence, information, and technology that have already been demonstrated to improve patient outcomes. If the hospital administration is not visibly advocating for quality and patient safety, they must be motivated to become involved. Joseph Juran stated that “every successful quality revolution has included the participation of upper management. We know of no exception.” This is a cultural change and requires hospital-wide participation.

Health care providers need to be patient advocates and provide patient-centered care. As with patient satisfaction, it is not enough to be good clinicians; they must make the

system work for their patients. As Aristotle noted several centuries ago, “We are what we repeatedly do. Excellence, then, is not an act but a habit.” Continuous improvement in patient care must be embraced by the entire health care industry.²⁰

Emergency Medical Treatment and Labor Act (EMTALA)

Todd B. Taylor, MD

Key Points¹

The original intent of the Emergency Medical Treatment and Labor Act (EMTALA) is consistent with standards of medical care.

The EMTALA obligation is voluntarily accepted by hospitals as part of the Medicare Conditions of Participation Agreement. Physicians are duty-bound by EMTALA, by virtue of their voluntary agreement with the hospital, to serve on call and/or by agreement or contract with the hospital to provide emergency services.

EMTALA requires Medicare-participating hospitals with emergency departments to provide screening for and treatment of emergency medical conditions in a nondiscriminatory manner to any individual regardless of ability to pay, insurance status, national origin, race, creed, color, and the like.

EMTALA requires individuals with similar medical complaints or conditions to be treated similarly. It applies to all individuals at Medicare-participating hospitals, not just those covered by Medicare.

As a federal statute, EMTALA supersedes state and local laws, including peer-review protections, certain tort reform limitations, and statutes of limitations. It grants every individual a federal right to emergency care and creates additional rights when hospitals or physicians fail to comply.

EMTALA violations can result in significant penalties for hospitals and physicians, including civil monetary penalties of up to \$50,000 per violation and/or Medicare participation termination.

EMTALA is an unfunded mandate and does not require health insurance companies, governments, or individuals to pay for mandated emergency services.

Emergency physicians on average provide \$138,300 of uncompensated EMTALA-related medical care each year, and one third of emergency physicians provide more than 30 hours of EMTALA-related care each week.²

Introduction and Background

EMTALA's Original Intent

A hospital is charged only with the responsibility of providing an adequate first response to a medical crisis [which] means the patient must be evaluated and, at a minimum, provided with whatever medical support services and/or transfer arrangements that are consistent with the capability of the institution and the well-being of the patient.³

The Emergency Medical Treatment and Labor Act (EMTALA) was enacted by Congress in 1986 as part of the Consolidated Omnibus Budget Reconciliation Act of 1985 (42USC§1395dd). Often referred to as the patient “anti-dumping” law, it was originally designed to prevent hospitals from transferring uninsured or Medicaid patients to public hospitals without, at a minimum, providing a medical screening examination (MSE) and treatment to assure that such transfers could be done safely.

The concern for patient safety at that time was not unwarranted. Studies showed that, in the early 1980s, of transfers to public or Veterans Administration hospitals, 87% were for economic reasons. Only 6% of patients gave informed consent, 24% of patients were unstable at the time of transfer, mortality was three times that of other patients, and 250,000 such transfers were occurring annually.⁴⁻⁷

Congress has amended and expanded the scope of EMTALA five times. For example, until 1989, EMTALA did not require hospitals or physicians to provide on-call services, nor did it require hospitals with specialized services to accept patients in transfer. Over the years, additional amendments enhanced the ability to impose fines, increased penalties, provided whistle-blower protections, and expanded the reach of the law and the mandated duties of providers.

Despite passage in 1986, there was little enforcement of EMTALA for the first 10 years.^{8,9} Enforcement increased significantly after the Centers for Medicare & Medicaid Services (CMS; formerly the Health Care Financing Administration) published rules for the enforcement of EMTALA in the Code of Federal Regulations (CFR) in 1994 [42CFR§489.xx]. (The full statute and definitions of terms are available at <http://www.gpoaccess.gov/cfr/index.html>.) By 1999, there had been more than 2000 EMTALA investigations and more than 1000 confirmed violations.¹⁰

In June 1996, a diverse national EMTALA Task Force was formed to clarify the regulations with new Interpretive Guidelines published in July 1998. The Interpretive Guidelines did not carry the force of law and, while well intentioned, left many issues vague. As a result, federal and state civil courts continued to have a significant influence on EMTALA interpretation. Consequently, EMTALA now has little resemblance to its original intent of regulating economically motivated transfers.¹¹

On November 10, 2003, CMS published a final rule revising the 1994 EMTALA CFR. In large part, these revised rules simply codified interim CMS guidance, but in addition they revised the definition of an “emergency department,” clarified what is considered “hospital property,” recognized certain limitations of on-call specialists and on-call panels, added a “prudent layperson” standard with regard to the request for services, and clarified applicability to hospital-owned ambulances. In addition, although EMTALA has never applied to inpatients, the new rules drew a “bright line” at admission for when the EMTALA obligation ends [42CFR§489.24(d)(2)]. Once a patient is admitted, other Medicare Conditions of Participation requirements apply, making EMTALA superfluous for hospital inpatients [42CFR§482.55].

While EMTALA is a complex law with many ambiguities, one would need to read no further if only one principle were adopted for EMTALA compliance: “Take care of the patient.” EMTALA is a “medical anti-discrimination” law. Anytime one considers treating any patient differently for other than a good medical reason, EMTALA is in jeopardy of being violated. The difficulty comes in properly documenting such reasoning and in achieving technical compliance. EMTALA is of special concern to hospitals with limited, focused, and special capabilities, such as pediatric-only hospitals and general hospitals that provide “specialized” pediatric services (e.g., a pediatric emergency department [ED]).

This chapter presents the basics of EMTALA, drawing heavily upon the actual statutory language. It has been written primarily for physicians, and additional references and CRF and United States Code (USC) citations are provided for more detailed reading and study.

Issues: Implications of EMTALA for American Health Care

According to Rep. Pete Stark (D-CA), co-sponsor of EMTALA:

Patient dumping is but a symptom of a much larger problem. Thirty-seven million Americans [47 million in 2005] are without health insurance. Low income sick people are finding it increasingly difficult to get needed

health care, and the burden of caring for them is falling on fewer and fewer hospitals.¹²

Access should be the government’s responsibility at the federal, state, and local levels. We cannot and should not expect hospitals to be this nation’s National Health Service.¹³

From a legal perspective, EMTALA’s original purpose was simply to create a duty to provide an MSE to assure that either no emergency medical condition (EMC) exists or, if an EMC is present, it is “stabilized” prior to the patient’s transfer to a public hospital. With significant changes in payment mechanisms in the early 1980s (e.g., “diagnosis-related groups”), the onslaught of managed care, and increasing numbers of uninsured patients, private hospitals felt compelled to limit their exposure to revenue losses from uninsured and Medicaid patients. This led to a “wallet biopsy” being performed prior to offering even emergency care. Ultimately, this mistreatment of patients prompted the creation of a clever “voluntary” governmental solution we now know as EMTALA.

EMTALA was the first time Congress had used the Medicare statute to create public policy extending beyond Medicare recipients. As a result, it became a national standard of care for emergency services and a federal right to emergency care.¹¹ While noble in its intent, and representing what most would find to be ethical and a standard of medical care obligation, in the ensuing years the EMTALA statute and regulations resulted in many unintended and even untoward consequences.

EMTALA now regulates virtually every aspect of care provided on hospital property, but by design has no bearing on payment. It allowed local and state governments to abdicate responsibility for charity care, thereby shifting this public responsibility to the private sector. Subsequently, many public “free” clinics were closed due to budgetary concerns, and public hospitals use EMTALA as a shield against accepting indigent patients. In essence, EMTALA made every Medicare-participating hospital a “public” hospital. EMTALA has become the de facto national health care policy for emergency care and for the uninsured. It also forced America’s EDs to become the safety net of the health care system.¹⁴⁻¹⁷

Until recently, the federal government had never accepted any direct financial responsibility for EMTALA. The Medicare Modernization Act of 2003¹⁸ for the first time provides financial relief to hospitals burdened with undocumented aliens due to EMTALA. Nevertheless, the financial strain of EMTALA continues to plague hospitals and their associated physicians with over \$25 billion in uncompensated care annually,¹⁹ and “55 percent of emergency services go[ing] uncompensated.”²⁰ Furthermore, the traditional cost-shifting mechanism to compensate for this burden has largely been eliminated by managed care, and many managed care practices are irreconcilable with the requirements of EMTALA.

The direct and indirect impact of EMTALA continues to mount. Specialists are fleeing hospital medical staffs to avoid ED on-call duties, hospitals are limiting the scope of services or creating “specialty” hospitals to carve out a niche with less EMTALA exposure, efforts are made to “manage” the financial risk with ED “triage-out” procedures for “nonurgent” conditions, and medical repatriation programs have been devised for foreign nationals; these are but a few examples.

After more than two decades of EMTALA, two fundamental principles are clear:

1. How health care is funded (and litigated) drives health care availability and delivery.
2. America cannot solve the EMTALA conundrum until it addresses the reason EMTALA exists—a failure to appropriately fund and provide for indigent and uncompensated emergency medical care.

General EMTALA Duty

EMTALA creates a duty that otherwise would not exist for hospitals. Ethical duty aside, prior to enactment of EMTALA, there was no legal duty for a hospital to provide medical care (even emergency care) to anyone not already accepted as a patient. EMTALA was specifically design to create such a duty for any “individual” that arrived on hospital property and requested treatment for a “medical condition.” It should be noted that the statute does not say “emergency medical condition.” Whether the medical condition is an “emergency” must be determined by an MSE, and, if an EMC is present, additional EMTALA obligations are imposed.

Under EMTALA, hospitals voluntarily accept this duty by virtue of their “contract” with Medicare, called the Medicare Conditions of Participation. In doing so, they agree to be investigated, sanctioned, and fined for noncompliance without due process. Physicians do not have a similar Medicare requirement; therefore, EMTALA is the sole burden of Medicare-participating hospitals. Nonparticipating hospitals, such as the Veterans Administration, certain military hospitals, non-hospital owned urgent care centers, and the like, are not obligated under EMTALA.

Since EMTALA applies only to hospitals, administration must make arrangements to provide physician services as part of this duty. Ironically, EMTALA provides no formal

mechanism or requirement for this to be accomplished. So, while the law mandates that hospitals provide on-call physicians, it does not require physicians to provide on-call services. As a result, most hospitals do so via contract (e.g., with emergency physicians or employed physicians) or by imposing duties by voluntary participation in the medical staff and the ED on-call roster. Because EMTALA is “voluntary” (i.e., hospitals can choose not to participate in Medicare and physicians can choose not to be on the medical staff or choose not to take ED call), it avoids the U.S. Constitution’s XIIIth Amendment prohibition against involuntary servitude and slavery.

Voluntary or not, EMTALA often creates opportunities for discord between hospitals, between a hospital and its medical staff, and among the medical staff itself, particularly between the ED and on-call physicians. This discord is often exacerbated by the threat of fines and sanctions, which are equally onerous for physicians as for hospitals.

Statutory Definitions

Increasingly, EMTALA is now controlled by statutory definitions that often have little basis in medical science [42CFR§489.24(b)]. Table 150–1 lists the potential sanctions and fines. Table 150–2 lists the regulatory agencies overseeing EMTALA.

EMTALA-Mandated Responsibilities for Hospitals and Physicians

As a federal statute, EMTALA supersedes conflicting and contradictory state and local laws [42USC§1395d(f)], including peer-review protections, certain tort reform limitations, and statutes of limitations. It grants every individual a federal right to emergency care and creates additional rights when hospitals or physicians fail to comply.

Table 150–1 Potential EMTALA Sanctions and Fines (42CFR§1003.102)

Action	Amount/Duration	Comment	Regulation
Medicare & Medicaid program termination	Up to 2 yr	This can be a financial “death sentence” for any hospital or physician.	42CFR§489.24(g) & 42CFR§1003.105
Civil monetary penalties	Up to \$50,000 for each violation (not each patient)	A malpractice insurance carrier may cover defense of the action, but fines are almost never covered without an EMTALA rider.	42CFR§1003.103(e) & 42CFR§1003.106
Hospital vs. hospital	A hospital “dumped on” can recover all costs for the patient’s care.		42USC§1395dd(d)(2)(B)
Private cause of action	Depends on proven damages	Allows a civil case to be brought in federal court under “strict compliance with the law.” Strict liability is less open to “expert” defense and easier to prove.	42USC§1395dd(d)(2)(A)
Injunctions		The court may impose an injunction requiring certain remedies to correct future violations or public notice of nondiscrimination policies.	
Hill-Burton Act funds	Varies	EMTALA violations may result in government action to recover loans and grants made to the facility.	
Civil rights	Fines and/or incarceration	EMTALA violation based on discrimination may result in referral to the Civil Rights Division of DHHS, resulting in criminal prosecution under the Civil Rights Act.	State Operations Manual: Appendix V—Interpretive Guidelines ²⁵

Abbreviation: DHHS, Department of Health and Human Services.

Duty to Provide an “Appropriate” Medical Screening Examination [42CFR§489.24(a)(1) & (a)(1)(i)]

The sole purpose of the MSE is to determine if an EMC exists. If the ED has the ability to rule out an EMC and documents this in the medical record, then EMTALA no longer applies. At that point the patient may be dispositioned in accordance with community standards of medical care, hospital policy, and local regulations. It is important to recognize that, even if EMTALA no longer applies, other regulations may, and many states have passed similar and even more stringent regulations regarding emergency care.

The MSE is all encompassing and includes all the available hospital resources necessary to make a determination of an EMC, including on-call specialists. However, hospitals are not required to provide all services 24 hours a day, if these services are not routinely provided after hours.

Application of the EMTALA MSE requirement now depends upon “where” the individual presents on hospital property. If they present to the “dedicated emergency department” and request examination or treatment for a “medical condition,” this duty applies. If they present anywhere else, the duty only applies if the request is for what may be an EMC. In actual practice, this differentiation is only important for legal defense purposes, but documentation to that effect may assist in such defense. Although not necessarily required by EMTALA, the safest course of action may be to take any individual who presents with anything remotely resembling a request for medical care to the appropriate area in the hospital (i.e., ED, pediatric ED, obstetrics triage, psychiatry, etc.) for a formal MSE.

Perhaps the easiest way to train staff in this regard is to instruct them to ask such individuals, “Do you want to see a doctor?” If the answer is “yes,” then the individual should be taken to the ED or other appropriate department. If the answer is “no,” then staff should inquire further as to what the individual wants or needs. If there is any uncertainty, the safest course of action is to let the ED sort it out.

Pediatric EDs, particularly those that are part of a pediatric hospital, must understand their obligation to medically screen and stabilize any “individual” (regardless of age) that “comes to the emergency department” and requests evaluation for a medical condition. While such a facility is only required to provide such screening and stabilization that is within their capacity and capability, it is assumed that any hospital ED can and will do as much as they can while making arrangements for transfer to a more appropriate facility. If an EMC cannot be ruled out, then the patient should be considered “unstable” for the purposes of transfer and an “appropriate” formal EMTALA transfer accomplished.

Special Circumstances Related to the MSE

NO DELAY IN PROVIDING A MEDICAL SCREENING EXAMINATION OR TREATMENT [42CFR§489.24(d)(4)]

The “no delay” provision is often a misconstrued requirement. Some hospitals have taken the approach that, to be completely “safe,” no insurance information may be obtained until the MSE has been initiated. Clearly this is not a requirement and may itself delay treatment since managed care often utilizes certain specialty consultants that may be unknown until insurance information is available. Nevertheless, whatever information is obtained cannot alter the usual course of examination and treatment.

This provision clearly prohibits prior authorization for at least the initial MSE and treatment. Also, the determination as to whether a patient has an EMC or is stable remains the purview of the on-site examining physician. Therefore, it is not appropriate for an off-site managed care gatekeeper to make such a determination.

Once the MSE has determined that there is no EMC or the EMC has been stabilized, then authorization (e.g., for admission or nonemergent testing) may be obtained if necessary. However, this may become a very delicate situation when authorization for admission is denied and an “economic transfer” is requested by the health plan. For truly “stable” patients this should not be an EMTALA issue, but “stability” is often reviewed retrospectively if anything adverse occurs during or even after the transfer. Under strict EMTALA statute interpretation, an “economic transfer” is allowable, but the physician must always be correct about “stability.” In the current EMTALA and medical-legal climate, such transfers should be severely limited (i.e., to the absolutely most stable patients) or initiated after admission once stability is assured and EMTALA clearly no longer applies.

If such “economic transfers” are to be contemplated, it is prudent to identify additional legitimate reasons for the transfer, such as “continuity of care,” and to assess the patient’s desire to be transferred to an in-network facility by his or her formal request to be transferred. Emergency physicians compelled by the hospital to initiate economic transfers for the hospital’s benefit may wish to seek indemnification by the hospital for any untoward EMTALA or other legal action.

Regardless, it is always prudent to clearly document that the patient is “stable” and that he or she is aware of the reasons for transfer along with the risks and benefits. The following acknowledgment statement has been recommended: *The physician has determined that my condition is stable and that there is no significant risk to my being transferred. I want the cost of further treatment to be covered by my health plan. My health plan has agreed to cover the cost of treatment at the receiving facility, but denied payment for services at this facility.*

AVAILABILITY OF ON-CALL PHYSICIANS [42CFR§489.24(j)]

On-call specialty coverage for EDs and hospital inpatients has emerged as a major health care issue^{21,22} but is beyond the scope of this chapter. While EMTALA is neither the cause nor the solution, along with other stresses in the health care system it continues to have a significant impact on ED specialty coverage.²³ Increasingly, hospitals are finding it neces-

sary to compensate or employ physician specialists in order to comply with the EMTALA mandate. Under EMTALA, the hospital and not its medical staff or individual physicians is responsible for maintaining an on-call roster for the ED [42 USC§1395cc(a)(1)(I)(i) & (iii)]. EMTALA case law requires hospitals to cajole, force, or otherwise negotiate and procure physician services to operate their EDs and provide on-call specialty care.²⁴

USE OF DEDICATED EMERGENCY DEPARTMENT FOR NONEMERGENCY SERVICES [42CFR§489.24(c)]

If an individual comes to a hospital's dedicated ED and a request is made on his or her behalf for examination or treatment for a medical condition, but the nature of the request makes it clear that the medical condition is not of an emergency nature, the hospital is required only to perform such screening as would be appropriate for any individual presenting in that manner, to determine that the individual does not have an EMC. This clarifies that hospitals are not required to provide EMTALA-related services for "nonemergencies." However, this is a "chicken and egg" conundrum and in no way alleviates hospitals from performing an appropriate MSE for what may seem at triage to be the most trivial complaint yet later turns out to be an EMC.

QUALIFIED MEDICAL PERSON PERFORMING THE MSE [42CFR§489.24(a)(1)(i)]

A hospital must formally determine who is qualified to perform the initial MSE, that is, a "qualified medical person" (see also "Duty to Transfer" section). While it is permissible for a hospital to designate a nonphysician practitioner as the qualified medical person, the designated nonphysician practitioners must be set forth in a document that is approved by the governing body of the hospital. Following governing body approval, those health practitioners designated to perform MSEs are to be identified in the hospital bylaws or in the rules and regulations governing the medical staff. It is not acceptable for the hospital to allow the medical director of the ED to make what may be informal personnel appointments that could frequently change.

Duty to Stabilize [42CFR§489.24(a)(1)(ii) & 489.24(d)]

If the MSE determines that an EMC exists, then additional EMTALA duties apply. However, it should be noted that the statutory definition of "emergency" medical condition is quite restrictive, in that it requires that the "absence of immediate medical attention" will result in bad things happening. This fact is useful from a legal defense perspective, but from a practical standpoint almost any acute medical condition should be treated to an appropriate conclusion in the ED prior to discharge. While not required by EMTALA, this approach is prudent in light of aggressive CMS EMTALA enforcement, the impact of an EMTALA investigation, the potential severity of penalties, and the current medial-legal climate. It should also be noted that other Medicare Conditions of Participation, state regulations, and general medical liability may apply even if EMTALA does not.

Furthermore, a failure to follow hospital policy is often considered a per se EMTALA violation, even if the policy in question is not otherwise required by the EMTALA statute. Therefore, hospitals should construct their policies and procedures with extraordinary care to assure universal compli-

ance. For example, an ED triage policy that requires every patient to be triaged within 5 minutes of arrival may be unrealistic in the current overcrowded ED environment. A requirement for on-call physicians to arrive within 30 minutes is unrealistic for most communities. Nevertheless, under EMTALA, 6 minutes to triage or 31 minutes for the specialist to arrive could both be potential violations for failing to comply with hospital policy.

As with the MSE requirement, the duty to stabilize is all encompassing, including necessary on-call specialists. If the EMC can be resolved in the ED and is documented as such, then EMTALA no longer applies. If the EMC cannot be resolved in the ED and the hospital has inpatient services appropriate to resolve it, then the patient must be admitted. At the point of admission, the EMTALA obligation ends and is superseded by other Medicare Conditions of Participation requirements [42CFR§489.24(a)(1)(ii) & (d)(2)].

If the hospital does not have inpatient or emergency services (i.e., capacity and/or capability) necessary to stabilize the EMC, then an appropriate formal EMTALA transfer must be accomplished unless refused by the patient.

Duty to Transfer [42CFR§489.24(e)]

There are only three circumstances under which a patient may be transferred.

1. The patient is "stable" under the statutory EMTALA definition, in which case theoretically EMTALA does not apply.

This is theoretical because transferring a "stable" patient for admission or for further ED workup begs the question as to why the patient is being transferred instead of simply being discharged home. Again, this makes for an excellent legal argument when a transfer "goes bad," but in practice can be risky. While not required by EMTALA, it is prudent to document a legal "appropriate" transfer on all patients not otherwise being routinely discharged from the ED. While in many instances transferred patients will be declared "stable," if in retrospect the patient deteriorates, the transfer documentation will help protect the transferring hospital. In addition, some states require similar documentation on all transfers regardless of stability.

In an ill-conceived ploy, some have tried to circumvent EMTALA by "discharging" a patient with instructions to "go to the 'county' hospital." For EMTALA purposes, a "discharge" is a transfer, and such behavior invariably raises suspicion and results in an investigation.

2. The individual (or legal representative) requests to be transferred and accepts, in writing, the documented risks.

EMTALA does not empower hospitals to force involuntary treatment, admission, or transfer. However, it does require specific documentation and informed risk should a patient request to be transferred or refuse transfer, examination, or treatment. While this may seem relatively straightforward, an EMTALA conundrum can be created when a patient requests to be transferred to a hospital that then refuses to accept him or her based on the premise that the sending facility has the ability to treat. If the patient cannot be dissuaded, the best course of action is to have him or her sign out "against medical advice"; complete as much of the transfer documentation as is possible, including sending medical records; and notify the receiving facility of the situation.

3. The transfer is medically indicated (i.e., the risk of transfer is outweighed by the benefits) as certified by a physician (or qualified medical person in consultation with an off-site physician).

If the ED does not have the ability (capacity or capability) to determine if an EMC exists or to stabilize an identified EMC, then the patient should be considered unstable and an “appropriate” formal EMTALA transfer to a hospital with ability should occur unless refused by the patient.

“Appropriate” Formal EMTALA Transfer **[42CFR§489.24(e)(2)]**

This section of the EMTALA statute lists the four required elements of an “appropriate transfer”:

1. Ongoing medical treatment until transfer
2. Confirmation of capability, capacity, and acceptance at the receiving facility
3. Sending of all available pertinent medical records
4. Assurance that the transfer is effected through qualified personnel and equipment

Once the decision to transfer has been made, ongoing treatment and monitoring are required within the ability of the transferring facility until the transfer can be effected. This includes all available services, including on-call specialists even if they will not ultimately admit the patient. If the on-site physician requests the presence of an on-call specialist to help care for a patient while waiting for transfer, the specialist is required by EMTALA to come in within a “reasonable” time. There is a requirement to provide the name of any on-call physician that failed to appear whether or not that is the inciting reason for the transfer.

Documentation that the receiving facility has the ability and has acknowledged acceptance of the transfer is required. While it is perhaps good medical practice under many circumstances, there is no specific requirement that a physician be contacted or accept the patient in transfer at the receiving facility. Anyone authorized at the receiving facility to accept the patient may do so, even a clerk in the admitting office.

As with all medical encounters, documentation is important. For example, failure to document that medical records were sent is a per se EMTALA violation whether they were actually sent or not.

The method of transport will depend upon the situation, but in most cases an ambulance is required. If for some reason an “unstabilized” patient is not being sent by ambulance (such as an eye injury sent with family to an ophthalmologist’s office with better equipment), careful documentation as to the reason for and safety of such method of transfer should be done.

Documenting the required elements of an “appropriate transfer” in the medical record is sufficient, but difficult to consistently accomplish. While an EMTALA “Transfer Form” is not required, it is perhaps the best method to ensure technical compliance in documenting the three elements of a transfer: (1) request for transfer, (2) consent to transfer, and (3) certification of stability and/or risk/benefits of transfer.

Special Circumstances Related to Transfers

REFUSAL TO CONSENT TO TRANSFER [42CFR§489.24(d)(5)]

A hospital meets the EMTALA requirements if the hospital offers to transfer the individual to another medical facility

and informs the individual (or a person acting on his or her behalf) of the risks and benefits of the transfer, but the individual does not consent to the transfer. The hospital must take all reasonable steps to secure the individual’s written informed refusal.

Duty to Accept Transfers

Recipient Hospital Responsibilities **[42CFR§489.24(f)]**

A participating hospital that has specialized capabilities or facilities—including, but not limited to, facilities such as burn units, shock-trauma units, neonatal intensive care units, or (with respect to rural areas) regional referral centers—may not refuse to accept from a referring hospital within the boundaries of the United States an appropriate transfer of an individual who requires such specialized capabilities or facilities if the receiving hospital has the capacity to treat the individual.

The “duty to accept” is an often misunderstood and perhaps poorly defined requirement. The operative words are “including, but not limited to” and “if the receiving hospital has the capacity.” Pediatric hospitals, hospitals with pediatric EDs, and community hospitals that provide inpatient pediatric services should all be considered “hospitals with specialized services.”

With increasing hospital ED and inpatient capacity issues, it is not uncommon for hospitals with “specialized services” to lack “capacity.” The issue becomes how to document such transfer refusals for individuals who never become patients. Another issue is who does this documentation if private on-call specialists screen these calls. There is no accepted standard and, in fact, most hospitals rely upon the good will of the calling facility to do this documentation for them. Nevertheless, some facilities have established “transfer coordinators” who document these calls and file a nonaccepted patient form by date of call for retrieval if necessary.

Transfers Between the Same Hospital’s **Departments or Facilities²⁵**

The movement of the individual between hospital departments is not considered an EMTALA transfer since the individual is simply being moved from one department of a hospital to another department or facility of the same hospital.

Transfer Agreements

Although transfer agreements are not required by EMTALA, they are mentioned in the State Operations Manual Interpretive Guidelines. They have been suggested as a way for specialized hospitals, such as pediatric hospitals, to expedite appropriate transfers of adults when necessary. They are useful because they allow for an established, well thought-out process before it is needed in the “heat of the moment.” However, transfer agreements are not the panacea that some may hope. First, there may be little incentive, and perhaps a disincentive, for a receiving hospital to cooperate without payment issues being addressed. Second, having a transfer agreement does not guarantee acceptance of a patient, because EMTALA requires services (i.e., inpatient beds) to be granted on a “first come, first served basis.” It is fundamentally dis-

criminary to give preference to one hospital over another in accepting transfers, and “holding beds” for this purpose will likely be construed as a violation of the section on “recipient hospital responsibilities” [42CFR§489.24(f)]. For these and other reasons, transfer agreements are rarely executed.

Other EMTALA Duties for Medicare-Participating Hospitals

Duty to Report [42CFR§489.20(m)]

A hospital must report to CMS or the state survey agency any time it has reason to believe it may have received an individual who has been transferred in an unstable EMC from another hospital in violation of EMTALA.

Whistle-Blower Protection [42CFR§489.24(e)(3)]

A participating hospital may not penalize or take adverse action against a physician or a qualified medical person because he or she refuses to authorize the transfer of an individual with an EMC who has not been stabilized, or against any hospital employee because the employee reports an EMTALA violation.

Only *hospitals* have the duty to report suspect violations, and then only for patients transferred *to them* (i.e., not for a refusal to accept an outgoing transfer). Although permitted to do so, physicians and hospital employees do not have a duty to report under EMTALA. However, they may have an obligation to report to hospital administration under hospital policy. Regardless, a hospital cannot take an adverse action against a physician or employee for complying with EMTALA or voluntarily reporting.

Signage Requirement [42CFR§489.20(q)(1)]

Hospitals must post conspicuously in any ED or in a place or places likely to be noticed by all individuals entering the ED, as well as those individuals waiting for examination and treatment in areas other than traditional EDs (i.e., entrance, admitting area, waiting room, treatment area), a sign specifying rights of individuals under EMTALA with respect to examination and treatment for EMCs and women in labor. Also, they must post conspicuously information indicating whether or not the hospital or rural primary care hospital participates in the Medicaid program under a state plan approved under Title XIX.

Maintenance of Information [42CFR§489.20(r)(1)]

Medical records related to individuals transferred to or from the hospital must be maintained for a period of 5 years from the date of the transfer. Also, a list of physicians who are on call for duty after the initial examination to provide treatment necessary to stabilize an individual with an EMC must be maintained, as well as a central log on each individual who comes to the ED seeking assistance and whether he or she refused treatment, was refused treatment, or was transferred, admitted and treated, stabilized and transferred, or discharged. Although perhaps not intuitively obvious, the “list of physicians on-call” must identify specific physicians’ names (i.e., not the group name and not a mid-level provider taking “first call”).

Although most hospitals keep medical records indefinitely, the statute of limitations for an EMTALA violation is 2

years [42USC§1395dd(d)(2)(C)], although penalties may be assessed up to 6 years [42USC§1320a-7(a)(c)(l)] after the incident.

State Operations Manual Interpretive Guidelines

The interpretive guidelines serve to interpret and clarify the responsibilities of Medicare participating hospitals in emergency cases. They contain authoritative interpretations and clarifications of statutory and regulatory requirements and are to be used to assist in making consistent determinations about a provider’s compliance with the requirements. These interpretive guidelines merely define or explain the relevant statutes and regulations and do not impose any requirements that are not otherwise set forth in the statutes or regulations. The revised guidelines clarify and provide detailed interpretation of the EMTALA provisions located at 42CFR§489.24 and parts 489.20 (l), (m), (q), and (r).²⁶

The Interpretive Guidelines assist state surveyors (those who investigate potential EMTALA violations) and providers to better understand how CMS will enforce EMTALA and conduct investigations. The Guidelines do not carry the force of law and are ignored by the courts. Nevertheless, they are an important resource in avoiding an EMTALA citation. There are a few areas in which the Guidelines appear to overreach the EMTALA statutes.

EMTALA Enforcement

An EMTALA investigation, and the resulting citation process, can be quite complicated and is beyond the scope of this chapter. However, it should be noted that defending oneself in an EMTALA action can be expensive, often exceeding the amount of the potential civil monetary penalty. Furthermore, Medicare participation termination is a reality for both hospitals and physicians and a potential financial “death sentence.”

EMTALA enforcement is fundamentally a complaint-driven process, so the principle objective in managing EMTALA risk should be to avoid being investigated. This requires that hospitals take an aggressive, yet very conservative approach to EMTALA compliance and at times implement policies more restrictive than technically required by the statute. Also, because of its complexity, the challenge for EMTALA is to achieve fail-safe compliance, but not interrupt the usual and reasonable ED process (Tables 150–3 and 150–4).

Summary: Ten Strategies for Successful EMTALA Compliance

EMTALA continues to represent an ever-changing paradigm shift in how hospitals and physicians deliver emergency care and requires new ways of thinking, planning, and documentation.¹¹ Regardless of its complexities, solutions are relatively straightforward:

1. Hospitals and physicians must acknowledge EMTALA’s existence and pervasiveness.
2. Area hospitals and medical staffs must act cooperatively because EMTALA compliance is impossible without cooperation from the medical staff leadership and hospital administration.

Table 150–3 EMTALA Principles for Hospital Staff and Emergency Physicians**Inquiries about Any Medical Condition on Hospital Property**

- Ask, "Do you want to see a doctor?"
- If "Yes," take individual to the ED.

In the ED

- Log ALL patients.
- Provide MSE for ALL patients by a physician or a "qualified medical person."
- If not, document why (i.e., left without treatment, refused MSE and/or treatment).
- Treat ALL patients to a reasonable disposition in the ED.

Transfers

- Obtain acceptance from the receiving facility and complete a transfer form on ALL patients not otherwise being routinely discharged.
- Accept ALL transfers if the hospital has the capacity (bed available and ever done it before) to treat the presenting problem. If not, document why.

Reporting

- Set up a system for reporting suspicious transfers.
- Report ALL suspicious transfers to you.
- Document ALL incoming and outgoing transfers.

Table 150–4 EMTALA Principles for Medical Staff Physicians***If you are called, you are chosen.**

- Respond appropriately.
- The emergency physician dictates appropriateness unless or until you assume care of the patient.

Transfers

- Accept ALL incoming transfers if the hospital has the capacity (bed available and ever done it before) to treat the presenting problem. If not, document why.

ED Patient Outpatient Follow-Up

- Do what you agreed to do in your office or risk being required to always come to the ED.
- Do not demand payment up front or refer back to the ED if the patient is unable to pay or is a member of a noncontracted health plan. Do what the patient needs that day and make definitive arrangements for further care if necessary.
- **The best response to any inquiry from a hospital emergency department is, "How can I help you with this patient?"**

*These principles only apply when the physician is on call for the hospital emergency department.

3. Hospital EMTALA compliance policies and procedures, including forms, medical staff on-call responsibilities, and acceptance of patients in transfer, must be developed with extreme care.
4. Hospitals should require EMTALA education for anyone who may come into contact with individuals seeking medical care, including all hospital employees (nursing, ancillary, security, cafeteria, and administrative) and all medical staff.
5. Hospitals and physicians must document using the EMTALA paradigm, including appropriate legal terminology, new definitions of medical terms, and required norms and practices.

6. Hospital capabilities, including on-call services, must be defined and reviewed on a regular basis.
7. An in-house EMTALA compliance program should be created as part of the regular quality improvement process, and an EMTALA "hot line" should be established.
8. EMTALA issues must be addressed aggressively as they occur. It is not if, but when, so staff should prepare for an EMTALA investigation BEFORE it occurs by identifying resources. Preparing a model "corrective plan of action" may be worthwhile.
9. The emergency physicians are the hospital's first, best, and final defense against an EMTALA violation. They must be empowered to do whatever is necessary to mitigate a developing EMTALA situation at the time it occurs.
10. Hospitals and physicians should always "take care of the patient" first.

Chapter 151

Issues of Consent, Confidentiality and Minor Status

Cynthia R. Jacobstein, MD, MSCE

Key Points

Consent for medical care of minors may be waived in four general situations: emergency need for care, emancipated minor status, conditions covered by minor treatment statutes, and cases involving mature minor doctrines.

Minor treatment statutes and definitions of emancipation vary from state to state. The emergency physician should be familiar with the specific regulations of his or her state(s) of practice.

Minors are more likely to seek health care when they are assured of confidentiality. The provision of confidential care, when appropriate, should be practiced in the emergency department treatment of minors.

Psychosocial assessment is a key portion of the emergency department evaluation of most minors.

legal guardian will be obtained prior to medical treatment of minors. This requirement is not always easily or readily accomplished in the ED setting as minor patients may present alone or with adults other than their parents, such as teachers or day care providers.

Consent for medical care of minors may be waived for multiple reasons. Minors may be treated without the consent of a parent or guardian if they present with an emergency medical condition.²⁻⁸ Emergency medical conditions include those with potential threat to life or limb, as well as conditions in which extreme pain is present or in which the potential for a harmful outcome exists if the condition is not immediately treated. Furthermore, there are a number of presenting complaints or conditions for which minors may seek and be granted health care without parental consent. These categories include mental health care; testing and treatment for STIs, including human immunodeficiency virus; contraceptive services; and drug and alcohol dependency treatment.^{2-5,9} It is important to note that there are state-by-state variations with respect to the provision of confidential care for these treatment categories. The ED physician should be familiar with the laws of his or her state of practice regarding the treatment of such conditions. The GovSpot web site (Table 151-1) or individual state government web sites may serve as resources for this information. The Guttmacher Institute web site includes a table that lists the specific consent regulations for all 50 states.³

A subset of minors who may give their own consent for medical care are emancipated minors. Emancipated minors have living situations that suggest some degree of independence.^{2-6,8-10} Examples of reasons for emancipation include marriage, military service, legal ruling, financial independence and residence apart from parents, and parenthood. As with the specific medical conditions for which minors may seek care without parental consent, the definition of emancipation varies from state to state. The GovSpot web site (see Table 151-1) or individual state government web sites may serve as resources for this information.

A further category of minors who may be allowed to consent to medical care is that of the mature minor.^{2-7,9,10} A mature minor is generally 14 years of age or older and deemed mature enough to understand the risks, benefits, and treatment options of a given medical condition. Other factors

Introduction and Background

Minors commonly present to the emergency department (ED) for medical care. While adult guardians frequently accompany them, minors may also seek care in the ED on their own or without legal guardians. A 1991 study looking at ED visits by minors to pediatric and general EDs found that approximately 3% of the visits by minors were unaccompanied.¹ More recently, it has been estimated that this number may be even higher.² In addition, the reasons for which minors seek care in the ED often involve complex psychosocial issues, such as sexually transmitted infection (STI) or undiagnosed pregnancy. Thus, it is imperative that the emergency physician is knowledgeable about the issues related to consent in the treatment of minors.

A minor is defined as an individual who is younger than the age of consent. This age is 18 years in all but four states.³ It is generally expected that informed consent by a parent or

that should be considered when deciding if a patient qualifies as a mature minor include the seriousness of the illness and the risks and benefits of potential therapies.

The provision of confidentiality in the treatment of minors in the ED is of utmost importance. The American Medical Association published a guideline for confidential health services for adolescents that outlines many of the important issues and recommendations regarding this topic.¹¹ In addition, a number of medical societies, including the American College of Obstetricians and Gynecologists, the American Academy of Pediatrics, and the American Academy of Family Physicians, support the provision of confidentiality to adolescents seeking health care.¹² The American College of Emergency Physicians also recognizes the importance of confidentiality in patient care but refers to confidentiality and the care of minors as a “problem area.”^{13,14}

Adolescents are more likely to seek medical care and provide a complete and true history if their confidentiality is respected.^{11,15} Parents or guardians should be asked to leave the adolescent patient’s room when sensitive areas of the history are being obtained. A discussion of the availability and limits of confidentiality should be held with all minors and their guardians prior to asking potentially personal information as part of the medical history. Reasons that confidentiality may be breached include cases of potential injury to self (suicidality) or others (homicidality) or abuse. These exceptions should be included in discussions of confidentiality.

Issues

While the provision of confidentiality is of utmost importance to minors seeking care in the emergency department, situations often arise in which inclusion of a parent or guardian is essential to ensuring the best care for the minor. One example of such a scenario is the new diagnosis of pregnancy in a young adolescent. The treating physician may believe that it is in the minor’s best interest to involve a mature adult

in the ongoing evaluation and care of such an issue. In cases such as this, the emergency physician should try to work with the teen to find a way to discuss the diagnosis with a parent or guardian. Possible solutions include having the physician tell the parent about the diagnosis with the adolescent’s permission, involving another mature relative (e.g., older sister or aunt) who may help the minor with the issues at hand, or involving a social worker to help with the discussion and follow-up.

Other situations in which confidentiality may be inadvertently breached involve events that occur after the minor has been discharged from the ED. When there are pending test results at the time of discharge (e.g., STI results), it is important to discuss a follow-up plan with the adolescent. This may involve obtaining a mobile phone or pager number or some other way to reach the teen directly to discuss test results. Adolescent patients who are using the family insurance card should also be informed that their parents or guardians might receive an itemized bill that may contain specific information about the care provided, such as pregnancy or STI testing.

One difficult situation that may arise in the care of minors in the ED is the request by a parent or guardian to have their child tested for drug use. There are some situations in which ED testing for drug use is appropriate. It is reasonable to test for substance use when the goal to be achieved is the diagnosis of and subsequent referral for treatment for substance abuse. In such cases, it is expected that the adolescent would give informed consent regarding the testing to be performed. In general, involuntary testing in an adolescent who is thought to be capable of making informed judgments is not approved or recommended by the American Academy of Pediatrics.¹⁶ Involuntary testing may be considered in cases in which the minor “lacks decision-making capacity” or in which “there are strong medical indications or legal requirements to do so.”¹⁶ Medical need for involuntary drug testing implies that identification of a particular substance would potentially avoid harm to the affected individual.

Solutions

The psychosocial assessment of minors in the ED is an extremely important part of their medical care. A thorough psychosocial interview often uncovers significant stressors or problems that might not otherwise be brought up by the adolescent patient, including but not limited to depression and suicidality. The mnemonics HEADSS (*home, education, activities, drug use and abuse, sexual behavior, and suicidality and depression*) and SHADSSS (*school, home, activities, depression/self-esteem, substance abuse, sexuality, and safety*) are helpful reminders of the important issues to be considered and discussed when providing medical care to minors in the emergency department.^{17,18} The emergency physician must decide how much of the psychosocial assessment is necessary for any given patient care episode. At a minimum, it is important to consider the topics of safety, depression, and suicidality.

Summary

Treatment of minors in the ED often requires the emergency physician to consider and apply a number of legal and ethical

principles that are unique to this patient population. The emergency physician needs to be familiar with consent and confidentiality issues with respect to the treatment of minors. These issues take on even greater importance with a number of more sensitive patient complaints, such as STIs, pregnancy, and mental health issues. It is vital that the physician be aware of the specific exceptions to standard consent issues when a minor presents for emergency care so that these may be incorporated into practice. Likewise, the importance of confidential care for adolescent minors, when appropriate, cannot be overemphasized. However, this should not preclude involving a parent or responsible adult in the care of minors when it is important to ensure the best possible outcome for the given problem. The emergency physician may need to work with the teen and other support personnel to find the best way to involve an adult in the care when it is deemed necessary.

Disaster Preparedness for Children

Stuart B. Weiss, MD and Ryan S. McCormick, BS, EMT-P

Key Points

Physicians caring for children during a mass casualty event will face challenges due to the unique anatomic, physiologic, cognitive, and behavioral characteristics of children.

The needs for pediatric mass casualty care are often inadequately addressed in hospital and community disaster plans.

All hospitals must adopt an incident management system that seamlessly integrates with community response agencies.

All facilities are equally at risk to receive large influxes of children during a disaster, so all emergency department staff must receive adequate education and training in mass casualty pediatric care.

Introduction and Background

Children are commonly involved as victims of both natural and man-made disasters. However, in many instances, hospital and community planners have not considered disasters that generate large numbers of sick or injured children.¹ Hospitals run exercises utilizing adult patient scenarios and rarely exercise with scenarios that include a pediatric patient surge. Government plans often lack specific sections that deal with the unique characteristics of mass casualty care for children.² As children constitute approximately 29% of the population in the United States, we can expect significant pediatric casualties in natural disasters.³⁻¹¹

The growing problem with school violence has led to an increase in pediatric mass casualty events as well. In Columbine High School in Littleton, Colorado, on April 20, 1999, two students utilizing a combination of guns and homemade improvised explosive devices killed 14 students, seriously injured 23 others, and terrorized an entire community.¹² Since then, concern about school violence and incidents involving weapons being brought into schools has been increasing. It is reported that 17% of high school students

carry a weapon (knife, gun, or club) to school and 5% carried a gun to school in the past month.¹³

With large numbers of children involved in natural disasters and increasing risk to children from terrorist events or school violence, it is imperative that emergency physicians play an active role in developing hospital and community plans that include policies and procedures for delivering care to large numbers of affected children.

Emergency Medical Services (EMS) field triage may not distribute children to the correct receiving facility. Inadequate or incorrect triage of children may result in a mismatch of injuries to health care assets. In the Avianca Airline crash of 1990, for example, pediatric survivors were neither adequately triaged nor transported to appropriate facilities that could have optimized their care.¹⁴

Issues

Unique Characteristics of Children in Disasters

Children are uniquely susceptible to terrorist events and disasters due to a combination of anatomic, physiologic, developmental, and psychological characteristics.^{2,15,16} Additional factors that complicate pediatric care include caregiver issues and facility issues.

Anatomic and Physiologic Differences

Children are shorter and therefore are closer to the ground, resulting in high doses of some chemicals and radiation. Many chemical agents (including some that are commonly listed as potential terrorist agents, such as Sarin, mustard, chlorine, and phosgene) are heavier than air¹⁶ and would have a higher concentration closer to ground level. In addition, radiologic fallout material settles on the ground, emitting more radiation to children whose vital organs are closer to the particles. With certain types of cancer (e.g., thyroid cancer), children are especially more susceptible than adults.¹⁷ In both of these cases, children would receive a higher dose of the agent than adults.

Children also have a proportionately larger body surface area-to-mass ratio than adults. For those agents that are absorbed through the skin, this results in a higher concentration per kilogram in an exposed child. Additionally, due to the larger surface area, children have a much higher risk for rapid body cooling and hypothermia if cold water is used during decontamination or if rapid drying and sheltering do not occur when decontamination is performed in cold environments.

Children's skin is less keratinized than adults' skin, resulting in potentially greater injury from vesicants and corrosives. In addition, children have an increased respiratory rate as compared with adults. This increased minute ventilation results in more rapid uptake and higher accumulated doses of a chemical, biologic, or radiologic agent by the lungs as well as a more rapid onset of effects.

Developmental and Psychological Differences

Due to physical developmental limitations, infants, toddlers, and young children may lack the motor skills to escape from the site of the disaster. For example, in the 2004 disaster in India and East Africa caused by tsunamis, young children were unable to grab onto stationary objects to prevent themselves from being swept underwater. Older children who may possess the motor skills to walk or evade the disaster may lack the cognitive ability to understand the events around them or appreciate the need to flee. Older children may also be frightened by the circumstances around them and refuse to cooperate with rescuers or will not take necessary protective actions, such as wearing a mask. Finally, curious children may actually migrate toward an event to better see a pretty colored gas, or to investigate noise or other chaos.

Caregiver Issues

Efforts are often made to keep children with their caregivers. This may result in pediatric emergency departments caring for adult patients or adult emergency departments caring for pediatric patients. In addition, most children older than 4 to 5 years spend most of their days away from their parents or caregivers in school or day care. In the devastating daytime earthquake in Armenia in December 1988, approximately 32,000 children were temporarily evacuated and had to be reunited with their parents at a later time.¹⁸ Tremendous logistical challenges are involved with reuniting displaced children with their parents. Young children may not know their last name or address and may not have any identifying items on them. Finally, issues related to treating minors without parental consent must be addressed in advance.

Operational Issues

In a large-scale disaster, especially one with a multiagency response, an incident management system or incident command system (ICS) must be utilized to manage the many problems that arise and the varied resources that come into play. Several incident management systems have been developed and utilized. The system that has been most widely adopted for health care facilities has been the Hospital Incident Command System (HICS). It is vital that hospital systems adopt some type of formal incident management system so that they seamlessly integrate into the community ICS structure.

NIMS and ICS

The National Incident Management System (NIMS) is a federally mandated structure designed to assist responders with coordination and resource management during a disaster. One component of NIMS is the ICS, a standardized framework for organizing resources during an event. ICS was developed for the fire service in the 1970s based on sound, tested business practices adapted for the changing needs of emergency services. This version of ICS (fire ICS) has been

widely adopted by fire departments and other public agencies across the country. To meet the needs of hospitals, in 1993 the HICS was developed.¹⁹ Fire ICS and HICS are based on many of the same principles; however, HICS applies only to hospitals and was not widely adopted by other response agencies. Under a federal mandate issued in 2003, all response agencies must adopt the NIMS.²⁰ The HICS system is currently being adapted to meet NIMS requirements.²¹

ICS in Hospitals

During a public health emergency or disaster, hospitals may find themselves inundated with patients, medical professionals, and resources. If each is not managed effectively, chaos, misuse of resources, or poor patient care may result. Management practices and systems in place during daily operations may not be adequate to manage a disaster, which often requires higher levels of coordination, control, and communication. It also may be necessary for hospital leadership to work with and direct the actions of personnel and agencies they do not typically oversee. In order to effectively manage incidents, hospital leadership must utilize a standardized management and organizational system such as NIMS or HICS. The use of such a system will allow for easier integration of outside resources and leadership into the hospital organizational structure.

Several regulatory bodies require the adoption of an ICS. The Joint Commission on Accreditation of Healthcare Organizations requires that facilities adopt a command structure that links with that of the community.²² Also, while the 2003 federal NIMS mandate does not specifically require hospitals to adopt NIMS, it does link future federal funding to NIMS compliance. Use of an ICS by hospital personnel assures that the hospital will better interface with local, state, and federal agencies during a crisis. Training in NIMS and the ICS is available in many formats, including self-study and on-line courses from the Federal Emergency Management Agency at <http://www.fema.gov/nims>.

Benefits of Adopting Standardized ICS

There are several advantages to adopting a standard ICS. First, an ICS utilizes a common vocabulary and terminology across all responding agencies. This eliminates any confusion about job titles and responsibilities. Similar positions in fire, police, EMS, or the hospital have the same job title and similar responsibilities.

Secondly, the ICS creates a uniform reporting hierarchy and employs a standardized set of job action sheets. HICS, for example, manages hospital responsibilities through predefined jobs with clearly written job action sheets. Job action sheets clearly outline the roles and responsibilities of each position in the HICS structure. When disasters occur, designated responders can quickly read an assigned job action sheet and immediately understand what is required of them.

Finally, the ICS provides a method for expanding and contracting the command staff based on the requirements of the crisis.

Facility Issues

While children make up 29% of the U.S. population,⁷ they are essentially healthy and do not utilize a similar proportion of health care resources. In addition, while pediatric cases

make up approximately 20% of emergency department volume,²³ few facilities have excess pediatric capacity to cover a pediatric patient surge. This results in fewer pediatric beds, fewer pediatric specialists, and less overall experience in pediatric critical care. Thus, in many regions of this country, a true pediatric disaster would result in a critical shortage of pediatric resources.¹

Patient Care Issues

Change in Level of Patient Care

During a true disaster, a fundamental change in the level of patient care delivered within an affected region must take place. This unavoidable change must occur when the medical needs of the affected population overwhelm the available medical resources. In this scenario, caregivers must shift from their normal practice mode, in which maximal care is given to few people, to a disaster mode, in which minimal care is given to many people. This transition is difficult to achieve when dealing with adult victims and even more challenging with pediatric casualties. Clinicians must plan to implement true pediatric triage and a decreased level of care during a disaster. Some children who require significant health care resources, and might otherwise be saved, may not be resuscitated during a true disaster. This transition in level of care is extremely difficult for emergency department staff to make and must be discussed and practiced well in advance of a disaster.

Triage

In disasters that produce many casualties, it is necessary to quickly determine which patients have the most severe injuries and require immediate treatment versus those who have minor injuries and can wait for medical attention. This process of categorizing patients is called *triage*, a French word meaning “to sort.” During a disaster, a more rapid type of triage is instituted to allow for the accelerated classification, treatment, and transport of patients.

The main goal of triage is to determine where the limited medical resources available during a disaster would best be applied. If triage is not performed properly, critical patients may be overlooked while less acute patients receive minor treatment. A clinical staff member should be assigned the role of triage as soon as multiple patients are discovered. This staff member does not necessarily have to be the most highly trained medical professional available. Triage can be effectively performed by a physician, a nurse, an emergency medical technician, or other allied health professionals trained in triage methods. There are two widely recognized triage systems in use today, Simple Triage and Rapid Treatment (START) for adult patients and JumpSTART for pediatric patients. Both triage systems use a combination of respiratory function, pulse, and neurologic function to determine triage classification. The original START system (Fig. 152–1) was developed for adults at Hogue Memorial Hospital in California.²⁴ It is universally used by EMS and other first responders to classify patients. Due to physiologic and cognitive differences between adults and children, the START system was modified to be appropriate for pediatric patients. This modified system is called JumpSTART²⁵ (Fig. 152–2). Both systems require training and practice prior to an actual disaster to be efficient (see Chapter 155, Triage).

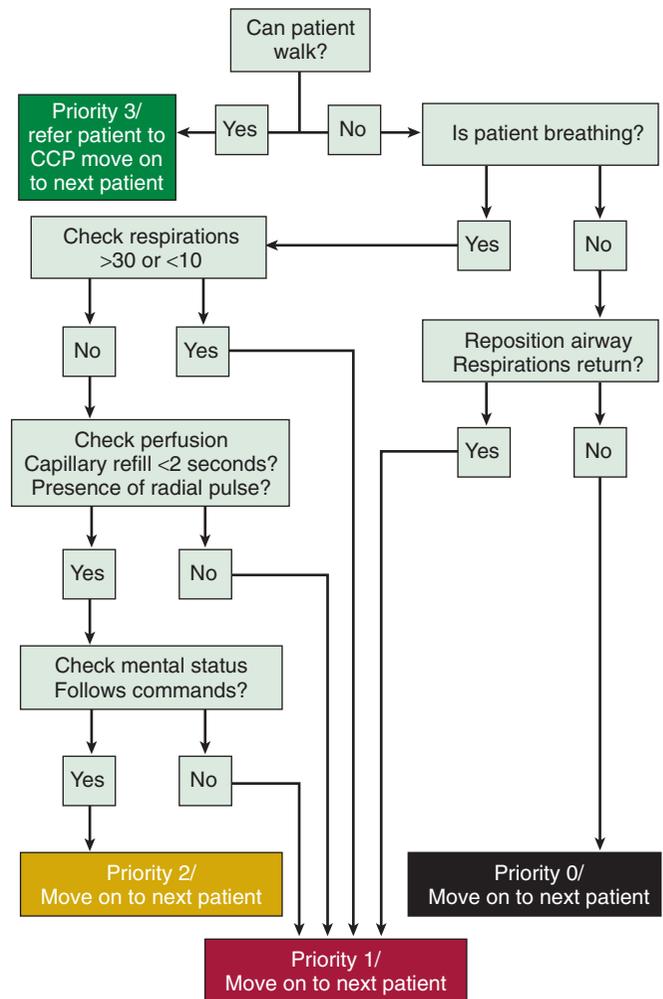

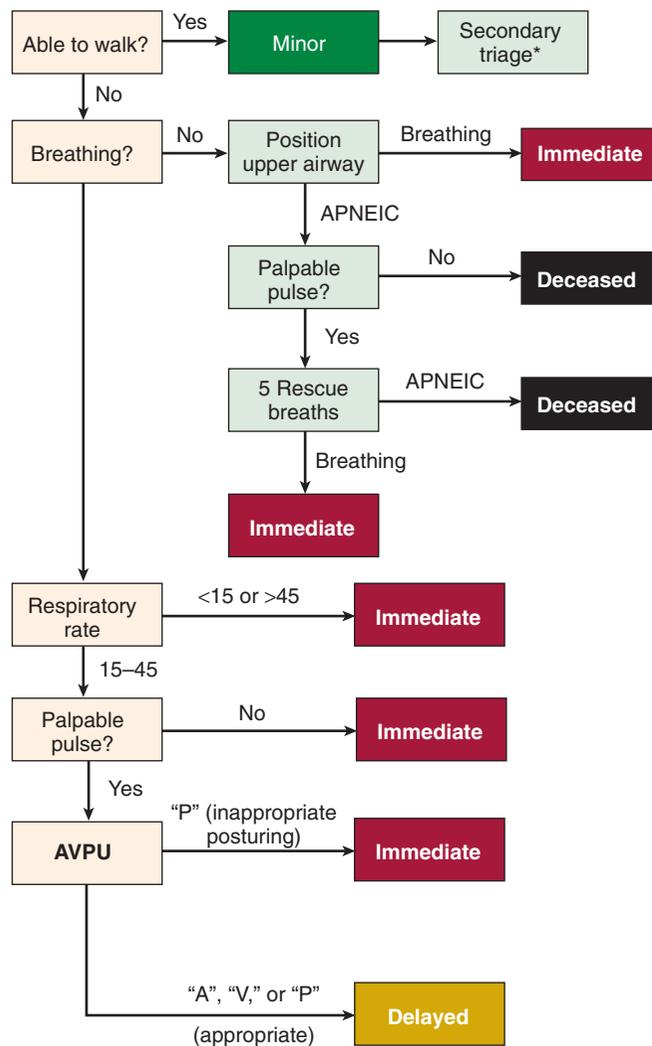

FIGURE 152–1. The Simple Triage and Rapid Treatment system (START) was developed by the Newport Beach Fire Department and Hoag Memorial Hospital. The system uses clinically significant objective findings to sort patients into four categories based on severity. Abbreviation: CCP, casualty collection point.

Chemical, Biologic, and Radiologic Agents

For quite some time, bacteria, viruses, biologic toxins, and toxic chemicals have been used by military forces to gain an advantage over an enemy.²⁶ Currently, considerable concern surrounds their possible use on civilian populations.^{27–29} A chemical attack tends to be an acute, obvious event. Typically, the onset of signs and symptoms is rapid, the event is quickly recognized, and there is a “lights and sirens” response from traditional first responders (police, fire, and EMS). In contrast, a covert biologic attack would occur as a slow, insidious event that would present as a public health crisis. Depending on the incubation period of the agent utilized, there may be some delay in onset of illness. As a result, people may travel far from the initial release site and, if the disease is contagious, may transmit it to others. First responders in this case will be emergency departments, clinics, pediatricians, and other physicians. Radiologic events may have characteristics of either a chemical or a biologic event depending on the method of dispersal of the radioactive material. Events involving an explosive dispersal of radioactive material will have an obvious, sudden onset. Events in which

*Evaluate infants first in secondary triage using the entire JS algorithm

FIGURE 152-2. The JumpSTART Triage algorithm was designed as a method to triage pediatric patients. The system can be used for any patient 1 to 8 years of age. Abbreviation: AVPU, alert, responsive to verbal stimuli, inappropriate posturing, unresponsive.

radioactive material is surreptitiously spread in the environment may appear insidiously, similar to a biologic event.

Emergency physicians caring for childhood victims of biologic, chemical, or radiologic attacks will encounter some pediatric-specific problems. For example, many of the drugs helpful in treating casualties are not commonly used in children, while others are not available in pediatric formulations or have relative contraindications. There is also a lack of widely accepted pediatric-specific guidelines for the treatment of these victims.

Biologic Agents

Biologic agents have the potential to create large numbers of casualties that could quickly overwhelm the medical delivery system. In the past, large numbers of people have died as a result of naturally occurring disease outbreaks. Intentional outbreaks could have similar results. While virtually any microorganism could be used as a biologic weapon, most

would be difficult to weaponize and disseminate effectively. A Centers for Disease Control and Prevention (CDC) working group has considered which biologic agents would constitute the gravest threats to public health and classified the agents into three groups.³⁰ This categorization is based on a combination of factors including availability, potential for morbidity and mortality, and ease of dissemination.³¹ Category A agents have the highest potential for use as a biologic weapon, and category C agents have the lowest. These agents are listed in Table 152-1.

Most of the category A agents have been the subject of comprehensive reviews. Treatment recommendations for all agents are evolving. The CDC maintains a web site (<http://www.bt.cdc.gov>) and a 24-hour hot line (1-770-488-7100) that provide the latest disease reviews and treatment recommendations.

Fluoroquinolones and/or tetracyclines are considered drugs of choice for the treatment of anthrax, plague, and tularemia. Although there may be some hesitation in using these antibiotics in pediatric patients, considerable recent experience has demonstrated their appropriateness in selected serious pediatric infections.³²⁻³⁴ Ciprofloxacin use in children had been questioned due to a theoretical risk of cartilage damage based on animal studies; however, this medication appears to be relatively free from this adverse effect. Doxycycline was also questioned due to its potential to stain teeth. However, this risk also appears to be low. Overall, the potential morbidity and mortality from these category A agents far outweighs the minor risks associated with the short-term use of these medications.³⁵

Chemical Agents

Chemical warfare dates back to antiquity. Chemical agents are classified into several broad classes as listed in Table 152-2. Many of these chemicals are used in industry and are transported on our roadways on a daily basis. For others, there are recipes readily available on the Internet and in published books. The toxic effect of these chemicals may occur through topical injury to skin, eyes, or mucous membranes, or through systemic absorption via dermal or respiratory means.²

When treating chemically contaminated patients, the initial crucial step is to determine what level of personal protective equipment (PPE) is required by health care workers. In previous chemical events, health care workers have been injured by chemical vapors from victim's clothing.³⁶ Before initiating treatment in these circumstances, proper PPE must be utilized. EMS crews must not be allowed to bring contaminated victims into the emergency department. Once the proper PPE is worn, resuscitation and decontamination efforts can begin. Removing clothing eliminates between 75% and 90% of contaminate.³⁷ This can then be followed by showering with warm water and soap. There is no proven benefit to the use of diluted bleach solution over soap and water, as bleach may act as a skin irritant.²⁶ It should not be used in civilian decontamination efforts.

To reduce the risk of hypothermia in children, warm water must be used in the decontamination process. In addition, there must be the ability to rapidly dry and warm pediatric victims if decontamination is occurring in a cold environment.

Contaminated clothing must be double-bagged and either placed outside or far away from the decontamination process.

Table 152–1 Potential Bioterrorism Agents**Category A**

The U.S. public health system and primary health care providers must be prepared to address varied biologic agents, including pathogens that are rarely seen in the United States. High-priority agents include organisms that pose a risk to national security because they:

- can be easily disseminated or transmitted person-to-person
- cause high mortality, with potential for major public health impact
- might cause public panic and social disruption
- require special action for public health preparedness

Category A agents include:

- Anthrax (*Bacillus anthracis*)
- Botulism (*Clostridium botulinum* toxin)
- Plague (*Yersinia pestis*)
- Smallpox (*variola major*)
- Tularemia (*Francisella tularensis*)
- Viral hemorrhagic fevers
- Filoviruses
 - Ebola hemorrhagic fever
 - Marburg hemorrhagic fever
- Arenaviruses
 - Lassa (Lassa fever)
 - Junin (Argentine hemorrhagic fever)
 - Machupo (Bolivian hemorrhagic fever)
 - Guanarito (Venezuelan hemorrhagic fever)
 - Sabia (Brazilian hemorrhagic fever)

Category B

Second highest priority agents include those that:

- are moderately easy to disseminate
- cause moderate morbidity and low mortality
- require specific enhancements of CDC's diagnostic capacity
- require enhanced disease surveillance

Category B agents include:

- Brucellosis (*Brucella* species)
- Epsilon toxin of *Clostridium perfringens*
- Glanders (*Burkholderia mallei*)
- Melioidosis (*Burkholderia pseudomallei*)
- Psittacosis (*Chlamydia psittaci*)
- Q fever (*Coxiella burnetii*)
- Ricin toxin from *Ricinus communis* (castor beans)
- Staphylococcal enterotoxin B
- Typhus fever (*Rickettsia prowazekii*)
- Viral encephalitis (alphaviruses)
 - Venezuelan encephalomyelitis
 - Eastern and Western equine encephalomyelitis

A subset of List B agents includes pathogens that are food- or waterborne. These pathogens include but are not limited to:

- *Salmonella* species
- *Shigella dysenteriae*
- *Escherichia coli* O157:H7
- *Vibrio cholerae*
- *Cryptosporidium parvum*

Category C

Third highest priority agents include emerging pathogens that could be engineered for mass dissemination in the future because of:

- availability
- ease of production and dissemination
- potential for high morbidity and mortality and major health impact

Category C agents include:

- Nipah virus
- Hantaviruses
- Multidrug-resistant tuberculosis
- Tickborne hemorrhagic fever viruses
- Tickborne encephalitis viruses
- Yellow fever

Preparedness for List C agents requires ongoing research to improve disease detection, diagnosis, treatment, and prevention.

Knowing in advance which newly emergent pathogens might be employed by terrorists is not possible; therefore, linking bioterrorism preparedness efforts with ongoing disease surveillance and outbreak response activities as defined in CDC's emerging infectious disease strategy is imperative.

Abbreviation: CDC, Centers for Disease Control and Prevention. Modified from Centers for Disease Control and Prevention: Bioterrorism Agents/Diseases. Available at <http://www.bt.cdc.gov/agent/agentlist-category.asp> (accessed September 2005).

These clothes may have trapped chemicals on them that could pose a continuing threat to health care workers.

The major classes of chemical agents that have been used or are likely to be used are listed in Table 152–2, which includes examples of each chemical and common antidotes. Although these chemicals are often listed as potential terrorist agents, there are many tons of equally harmful industrial chemicals in our communities that could be intentionally or accidentally released. Some of the largest chemical events in the past have resulted from the accidental release of industrial chemicals used in manufacturing (methylisocyanate in Bhopal, India; hydrofluoric acid release in Texas, etc.). In order to adequately assess risks in the community and plan for chemical disasters, it is important to perform an analysis of industry in the area. Companies are required to disclose the types and quantities of dangerous chemicals that are used. This information is available through the local Office of Emergency Management. By utilizing this information, the proper level of PPE can be selected, antidotes can be identified, and required resources can be determined.

One of the major categories of agents that has received much attention recently is nerve agents. These agents are organophosphate compounds that act as potent inhibitors of acetylcholinesterase, similar in action to organophosphate insecticides.¹⁶ Common cholinergic signs and symptoms are listed in Table 152–3. Overall treatment focuses on airway and ventilatory support, aggressive use of antidotes, prompt control of seizures, and decontamination. Treatment for nerve agents includes atropine, pralidoxime, and a benzodiazepine (for control of seizures in significant exposures). While there is a commonly discussed and widely stocked nerve agent antidote kit for adult exposure (MARK I kit), a similar kit for children is not available in the United States.

In 2003, the Food and Drug Administration (FDA) approved a pediatric atropine autoinjector.³⁸ The AtroPen now comes in three strengths: AtroPen 2 mg (green) for adults and children weighing over 90 pounds, AtroPen 1 mg (dark red) for children weighing 40 to 90 pounds (generally 4 to 10 years of age), and AtroPen 0.5 mg (blue) for children weighing 15 to 40 pounds (generally 6 months to 4 years).³⁹ Currently, there is no approved pediatric 2-PAM autoinjector. While it would be optimal to use the appropriate AtroPen for the size of the child, most EMS agencies in the United States only stock the adult MARK I kits, which contain the 2-mg AtroPen autoinjector. In dire circumstances, the use of adult MARK I kits (with 0.8-inch needles and 2 mg of atropine and 600 mg of pralidoxime) might be useful in children older than 2 to 3 years of age or weighing more than 13 kg.²⁶ During the Gulf War in 1991, 240 Israeli children, none of whom was exposed to nerve agents, were evaluated due to accidental atropine injection by an autoinjector. While some had systemic anticholinergic effects, there were no deaths, severe dysrhythmias, or seizures.⁴⁰ The use of adult MARK I kits in children during extreme emergencies is summarized in Table 152–4.

Although nerve agents are most often discussed and MARK I kits are stocked by first response agencies across the United States, there may be multiple other chemicals present in the community that pose a risk to the population. As treatment guidelines for chemical exposures continue to evolve, there are several sources of valuable information. The CDC

Table 152–2 Potential Chemical Agents for Use in Chemical Terrorism*

Class	Examples	Interventions [†]	Antidotes
Nerve agents	Tabun Sarin Soman VX	Respiratory support, skin decontamination	Atropine, pralidoxime, diazepam
Vesicants	Mustard gas Nitrogen mustard	Respiratory support, skin and eye decontamination Respiratory support, skin and eye decontamination	 Nebulized albuterol
Irritants/corrosives	Chlorine Bromine Ammonia		
Choking agents Cyanogens	Phosgene Hydrogen cyanide	Respiratory support Cardiorespiratory support	Amyl nitrate, sodium nitrite, sodium thiosulfate
Incapacitating agents CNS depressants	Cannabinoids Barbiturates	Respiratory support	
Anticholinergics Lacrimators	3-Quinuclidinyl benzilate (BZ) Capsaicin		Physostigmine

*Chemical agents that might be used by terrorists range from warfare agents to toxic chemicals commonly used in industry. Criteria for determining the high-priority chemical agents include chemical agents already known to be used as weaponry, agents that are available to potential terrorists, agents likely to cause major morbidity or mortality, agents with a high potential for causing public panic and social disruption, and agents that require special action for public health preparedness.

[†]Note: Decontamination includes rapid removal of clothing and washing with soap and warm water. Health care workers must protect themselves adequately from the chemical agent before initiating patient care.

maintains a 24-hour hot line for health care providers at 1-770-488-7100 and a website at <http://www.bt.cdc.gov>. In addition, one may consult the local poison control center at 1-800-222-1222 (same number everywhere in the United States).

Radiologic Agents

Radiologic exposure can be either accidental or intentional. Accidental exposures include nuclear power plant releases and unintentional exposure to radiologic sources. Intentional acts may result from terrorism or military conflict.

Radiologic disasters can be grouped into four categories:

Detonation of a nuclear weapon. While this is possible, it is considered unlikely due to the sophistication of such devices and the intrinsic difficulties in producing a successful nuclear fission explosion.

Damage to a facility that contains radioactive material (such as nuclear power plants, facilities that make radioactive materials for medical use, and nuclear waste reprocessing plants). This may result in the release of radioactive substances into the environment.

Explosion of a radiologic dispersal device (“dirty bomb”). These devices use conventional explosives to spread radioactive material over a large area. This is considered to be the most likely terrorist scenario involving radiologic materials.

Radiologic source left unshielded in a public place. Many highly radioactive materials are used in industry. For example, potent radiologic agents are used to examine pipe welds. There have been examples of the accidental loss of these agents with the subsequent radiologic exposure of unsuspecting people.

Proper management of a child with a radiologic injury depends on the type of exposure (whole body or partial), the amount of radiation exposure, and the presence of other associated injuries. An important early step in managing a radiologic exposure victim is determining whether the victim is simply exposed, or contaminated and exposed. An exposed victim is one who receives a dose of radiation without coming into physical contact with the source material. Once

Table 152–4 MARK I Autoinjector Usage

Note: Each MARK I kit contains 2 autoinjectors (0.8-inch needle insertion depth), one each of atropine 2 mg (0.7 ml) and pralidoxime 600 mg (2 ml). While not approved for pediatric use, they should be used as initial treatment in circumstances for children with severe, life-threatening nerve agent toxicity for whom intravenous treatment is not possible or available or for whom more precise intramuscular (mg/kg) dosing would be logistically impossible. Suggested dosing guidelines are offered below; note potential excess of initial atropine and pralidoxime dosage for age/weight, although within general guidelines for recommended total over first 60 to 90 minutes of therapy for severe exposures. Although this table describes usage of the MARK I kit for children 3 years and older based on adherence to recommended dosages for atropine and pralidoxime, following an actual nerve agent exposure if a MARK I kit is the only available source of atropine and pralidoxime, it should not be withheld from even the youngest child based on weight-based dosing guidelines.

Approximate Age (yr)	Approximate Weight (kg)	No. of Autoinjectors (Each Type)	Atropine Dosage Range (mg/kg)	Pralidoxime Dosage Range (mg/kg)
3–7	13–25	1	0.08–0.13	24–46
8–14	26–50	2	0.08–0.13	24–46
>14	>51	3	0.11 or less	35 or less

- Atropine: 0.05 mg/kg IV, IM (min. 0.1 mg, max. 5 mg), repeat q2–5min prn for marked secretions, bronchospasm
- Pralidoxime: 25 mg/kg IV, IM* (max. 1 g IV; 2 g IM), may repeat within 30–60 min prn, then again q1h for 1 or 2 doses; 0.2 mg/kg prn for persistent weakness, high atropine requirement
- Diazepam: 0.3 mg/kg (max. 10 mg) IV
- Lorazepam: 0.1 mg/kg IV, IM (max. 4 mg)
- Midazolam: 0.2 mg/kg (max. 10 mg) IM prn for seizures or severe exposure

*Pralidoxime is reconstituted to 50 mg/ml (1 g in 20 ml water) for IV administration, and the total dose is infused over 30 minutes, or may be given by continuous infusion (loading dose 25 mg/kg over 30 minutes, then 10 mg/kg/hr). For IM use, it might be diluted to a concentration of 300 mg/ml (1 g added to 3 ml water—by analogy to the U.S. Army's MARK I autoinjector concentration), to effect a reasonable volume for injection.

Adapted from Henretig FM, Cieslak TJ, Eitzen EM: Biological and chemical terrorism. *J Pediatr* 141:311–326, 2002.

this person is removed from the source of radiation, they are no longer subject to irradiation. A good example of this would be patients who have had a chest radiograph taken. While they are exposed to x-ray radiation, they are not contaminated, are not radioactive, and do not pose a threat to health care workers. These patients do not require decontamination as they do not have any radioactive material on them.

Contaminated victims, in contrast, actually have radioactive material on them and continue to be exposed to radiation even when removed from the event site. They may contaminate other surfaces or health care workers and must be decontaminated to reduce the risk to themselves and others. As with adults, the first step in decontamination of children is removing clothing. In many cases, this will eliminate up to 90% of contaminated particles. Contaminated clothing must be moved as far away from health care workers and victims as possible so as not to further expose individuals to radiation. It is important to remember that putting this clothing in a plastic bag is not an adequate shield from the radiation. In addition, it is important not to create a large pile of contaminated clothing as this will create a large irradiating source.

The initial care of the radiologically injured patient involves treating any associated trauma or medical problems. Caring for his or her radiation injuries is secondary to the other medical needs. One caveat to remember is that all necessary surgery must be completed within 48 hours of a large exposure before immunosuppression and wound healing impairment prevents surgical intervention for up to 3 months.⁴¹

Table 152–5 lists commonly used treatments for radiation injuries. Consultation in the care of radiologically injured patients can be obtained at any time from the Radiation Emergency Assistance Center/Training Site at the Oak Ridge Institute for Science and Education at 1-865-576-1005.

Table 152–5 Radionuclide Treatment Options

Radionuclide	Radioprotectant
Americium (²⁴¹ Am)	Diethylenetriamine pentaacetic acid (DTPA)
Californium (²⁵² Cf)	DTPA
Cesium (¹³⁷ Cs)	Prussian blue, sodium polystyrene sulfonate
Cobalt (⁶⁰ Co)	Laxatives*
Curium (²⁴⁴ Cm)	DTPA
Iodine (¹³¹ I)	Potassium iodide (KI)
Iridium (¹⁹² Ir)	Unknown
Plutonium (²³⁸ Pu; ²³⁹ Pu)	DTPA
Radium (²²⁶ Ra)	Common antacids, barium sulfate
Strontium (⁹⁰ Sr)	Common antacids, barium sulfate
Technetium (^{99m} Tc)	DTPA
Thallium (²⁰¹ Tl)	Prussian blue
Uranium (²³⁵ U; ²³⁸ U)	Common antacids
High radiation dose	Filgrastim, amifostine, antiemetics, Neumune, 5-AED
Gastrointestinal uptake of radionuclides	Laxatives, sodium polystyrene sulfonate

*Little information is available on treatment options. One should also consider EDTA, *N*-acetyl-L-cysteine, or penicillamine. From New Jersey Center for Public Health Preparedness: Radiological Countermeasures: Candidates for Inclusion in a State Stockpile. White paper, 2005.

There are some additional issues concerning potassium iodide (KI). Many people are under the misconception that KI is indicated as a general radiation antidote. There has been much press about this medication in the past few years. The only indication for this medication is in the prevention of thyroid cancer in releases of radioactive iodine (¹³¹I). Radioactive iodine is most likely to be released from a nuclear reactor accident. For this reason, the Nuclear Regulatory Commission has directed that KI be included in the

emergency planning for the residents in areas 10 miles around a nuclear plant.⁴² This is in order to facilitate the rapid administration of KI to affected residents. It is unlikely that radiologic dispersal devices or “dirty bombs” will contain ¹³¹I due to the difficulty in obtaining large quantities of radioactive iodine and the short half-life of the material. Therefore, in these exposures, KI is not indicated.

KI blocks the uptake of radioactive iodine by saturating the thyroid with nonradioactive iodine. In order for KI to be effective, the correct dose must be taken quickly, preferably within 2 hours of exposure. The protective effect of KI lasts approximately 24 hours, so additional doses may be required if continuing exposure to radioactive iodine is expected.

Current recommendations for the safe and effective use of KI to prevent the uptake of radioiodine by the thyroid are based on a review of data from the Chernobyl nuclear accident in 1986 where large amounts of ¹³¹I were released into the atmosphere. Following the event, thyroid cancers in Belarus, Ukraine, and the Russian Federation skyrocketed. In neighboring Poland, where KI was used in 10.5 million children less than 16 years old and in 7 million adults, there was a significant decrease in cancer rates. As the risk of thyroid cancer is inversely proportional to age, it is essential to make KI available to children.⁴³

Table 152–6 lists the current FDA recommendations for the use of KI during an emergency. The following caveats should be kept in mind:

1. Neonates who receive KI must be monitored for hypothyroidism by measuring thyroid-stimulating hormone

and free thyroxine. Thyroid hormone replacement must be initiated in cases in which hypothyroidism develops to protect critical neurologic development.

2. Pregnant females should be given KI for their own protection and for that of the fetus, as iodine readily crosses the placenta. However, because of the risk of blocking fetal thyroid function with excess stable iodine, repeat dosing with KI should be avoided. Lactating females should be given KI for their own protection and potentially to reduce the concentration of radioiodine in their breast milk, but not as a means to deliver KI to infants, who should get their KI directly. Iodine as a component of breast milk may also pose a risk of hypothyroidism in nursing neonates. Therefore, repeat dosing of KI should be avoided in lactating mothers, except during continuing severe contamination. If repeat dosing of the mother is necessary, the nursing neonate should be monitored for hypothyroidism as noted above.

Tables 152–7 and 152–8 outline methods for preparing KI solutions for children using the 130-mg tablets and the 65-mg tablets, respectively.⁴⁴ During an emergency, high accuracy in dosing is less important than rapidly administering KI to affected populations.

Solutions

Caring for children during a mass casualty event or disaster poses many challenges. Whether childhood casualties are the result of an accident, a natural phenomenon, or an inten-

Table 152–6 Threshold Thyroid Radioactive Exposures and Recommended Doses of KI for Different Risk Groups—U.S. Food and Drug Administration (FDA)

	Predicted Thyroid Exposure(cGy)	KI Dose (mg)	# of 130-mg Tablets	# of 65-mg Tablets
Adults >40 yr	≥500	130	1	2
Adults >18–40 yr	≥10	130	1	2
Pregnant or lactating women	≥5	130	1	2
Adolescents >12–18 yr*	≥5	65	1/2	1
Children >3–12 yr	≥5	65	1/2	1/4
Over 1 mo–3 yr	≥5	32	1/4	1/2
Birth–1 mo	≥5	16	1/8	1/4

*Adolescents approaching adult size (≥ 70 kg) should receive the full adult dose (130 mg).

The protective effect of KI lasts approximately 24 hours. For optimal prophylaxis, KI should therefore be dosed daily, until a risk of significant exposure to radioiodines by either inhalation or ingestion no longer exists. Individuals intolerant of KI at protective doses, and neonates and pregnant and lactating women (in whom repeat administration of KI raises particular safety issues; see below) should be given priority with regard to other protective measures (i.e., sheltering, evacuation, and control of the food supply).

Note that adults over 40 need to take KI only in the case of a projected large internal radiation dose to the thyroid (>500 cGy) to prevent hypothyroidism.

These recommendations are meant to provide states and local authorities as well as other agencies with the best current guidance on safe and effective use of KI to reduce thyroidal radioiodine exposure and thus the risk of thyroid cancer. FDA recognizes that, in the event of an emergency, some or all of the specific dosing recommendations may be very difficult to carry out given their complexity and the logistics of implementation of a program of KI distribution. The recommendations should therefore be interpreted with flexibility as necessary to allow optimally effective and safe dosing given the exigencies of any particular emergency situation. In this context, we offer the following critical general guidance: **across populations at risk for radioiodine exposure, the overall benefits of KI far exceed the risks of overdosing, especially in children, though we continue to emphasize particular attention to dose in infants.**

These FDA recommendations differ from those put forward in the World Health Organization (WHO) 1999 guidelines⁵ for iodine prophylaxis in two ways. WHO recommends a 130-mg dose of KI for adults and adolescents (over 12 years). For the sake of logistical simplicity in the dispensing and administration of KI to children, FDA recommends a 65-mg dose as standard for all school-age children while allowing for the adult dose (130 mg, 2 × 65-mg tablets) in adolescents approaching adult size. The other difference lies in the threshold for predicted exposure of those up to 18 years of age and of pregnant or lactating women that should trigger KI prophylaxis. WHO recommends a threshold of 1 cGy for these two groups. As stated earlier, FDA has concluded from the Chernobyl data that the most reliable evidence supports a significant increase in the risk of childhood thyroid cancer at exposures of 5 cGy or greater.

⁵World Health Organization: Guidelines for Prophylaxis Following Nuclear Accidents: Update. Geneva: World Health Organization, 1999. Modified from Food and Drug Administration, Center for Drug Evaluation and Research: Guidance: Potassium Iodide as a Thyroid Blocking Agent in Radiation Emergencies. Washington, DC: Food and Drug Administration, 2001.

Table 152–7 Preparation of Potassium Iodide Solution for Children**Preparation Using 130-mg Potassium Iodide Tablet**

1. Put **one** 130-mg potassium iodide tablet into a small bowl and grind it into a fine powder using the back of the metal teaspoon against the inside of the bowl. The powder should not have any large pieces.
2. Add four teaspoonfuls (20 ml) of water to the potassium iodide powder in the small bowl. Use a spoon to mix them together until the potassium iodide powder is dissolved in the water.
3. Add four teaspoonfuls of raspberry syrup, low-fat chocolate milk, juice, or flat soda* to the potassium iodide powder and water mixture described in Step 2.

The amount of potassium iodide in the drink is 16.25 mg per teaspoon (5 ml).

Dosing Guidelines

(This is the amount for **one** dose. Repeat daily doses may be indicated.)

Newborn–1 mo of age:	Give 1 teaspoon (5 ml)
2 mo–3 yr of age:	Give 2 teaspoons (10 ml)
4–17 yr of age:	Give 4 teaspoons (20 ml)

Children over 70 kg (154 pounds) should receive one 130-mg tablet or 8 teaspoons.

Notes

*To see what worked best to disguise the taste of potassium iodide, FDA asked adults to taste the following six mixtures of potassium iodide and drinks: water, low-fat white milk, low-fat chocolate milk, orange juice, flat soda (e.g., cola), and raspberry syrup. The mixture of potassium iodide with raspberry syrup disguised the taste of potassium iodide best. The mixtures of potassium iodide with low-fat chocolate milk, orange juice, and flat soda generally had an acceptable taste. Low-fat white milk and water did not hide the salty taste of potassium iodide.

Potassium iodide in any of the six drinks listed above and in infant formulas will keep for up to 7 days in the refrigerator. FDA recommends that the potassium iodide drink mixtures be prepared weekly; unused portions should be discarded.

Table 152–8 Preparation of Potassium Iodide Solution for Children**Preparation Using 65-mg Potassium Iodide Tablet**

1. Put **one** 65-mg potassium iodide tablet into a small bowl and grind it into a fine powder using the back of the metal teaspoon against the inside of the bowl. The powder should not have any large pieces.
2. Add four teaspoonfuls (20 ml) of water to the potassium iodide powder in the small bowl. Use a spoon to mix them together until the potassium iodide powder is dissolved in the water.
3. Add four teaspoonfuls of raspberry syrup, low-fat chocolate milk, juice, or flat soda* to the potassium iodide powder and water mixture described in Step 2.

The amount of potassium iodide in the drink is 8.125 mg per teaspoon (5 ml).

Dosing Guidelines

(This is the amount for **one** dose. Repeat daily doses may be indicated.)

Newborn–1 mo of age:	Give 2 teaspoons (10 ml)
2 mo–3 yr of age:	Give 4 teaspoons (20 ml)
4–17 yr of age:	Give 8 teaspoons (40 ml) or one 65-mg tablet

Children over 70 kg (154 pounds) should receive two 65-mg tablet or 16 teaspoons.

Notes

*To see what worked best to disguise the taste of potassium iodide, FDA asked adults to taste the following six mixtures of potassium iodide and drinks: water, low-fat white milk, low-fat chocolate milk, orange juice, flat soda (e.g., cola), and raspberry syrup. The mixture of potassium iodide with raspberry syrup disguised the taste of potassium iodide best. The mixtures of potassium iodide with low-fat chocolate milk, orange juice, and flat soda generally had an acceptable taste. Low-fat white milk and water did not hide the salty taste of potassium iodide.

Potassium iodide in any of the six drinks listed above and in infant formulas will keep for up to 7 days in the refrigerator. FDA recommends that the potassium iodide drink mixtures be prepared weekly; unused portions should be discarded.

tional attack, there are several general planning principles that must be addressed when preparing for pediatric mass casualties:

1. Understand how the facility fits into the overall emergency management plan for the community. Most communities in this country have a Local Emergency Planning Committee. This committee is responsible for developing the emergency management plans for the community. Assess whether there is adequate representation of medical professionals on this committee and, more specifically, medical professionals with pediatric expertise. In addition, have planning discussions with local industry. It is important to determine what community medical risks are posed by industry and what emergency plans exist. There have been occasions when

local hospitals have been included in industry emergency response plans without their knowing it. Finally, review the hospital disaster command structure to guarantee that it utilizes an ICS that is NIMS compliant, to seamlessly interface with local response agencies.

2. Review community plans to ensure that the needs of pediatric patients will be met. Unfortunately, for a variety of reasons, pediatric needs are often overlooked in government and community planning. It is vital that emergency physicians bring their expertise in caring for children to the planning table. In addition, children spend the majority of their days in school. It is vital that adequate plans are in place to address the care of children when they are not with their parents.

3. Review hospital plans to ensure that they address the needs of pediatric patients. Apply the plan to a fictitious influx of children during an exercise to assess how it functions. Train the staff so they are comfortable in mass casualty care of children. If the emergency department is segregated into adult and pediatrics sections, ensure that all staff are cross-trained to care for all patients. Finally, educate and drill the adult and pediatric emergency department staff in pediatric disaster triage.
4. Review antidotes for the most likely agents and plan how to administer them to pediatric patients. If premade kits are not available for children, develop plans to obtain necessary medications and devise ways to formulate them for administration to children. This may involve having the pharmacy mix antidotes into cherry syrup, and crush pills. Determine the hazards in the community and plan for any needed medications to treat victims of these hazards.
5. Develop community-wide transfer agreements and procedures to distribute injured or sick children across a region. Consider matching needed pediatric resources with the nature and severity of a child's injuries.
6. Work with day care centers and schools to ensure that they have adequate disaster management plans in place. Check that those plans integrate into the community's plans and the hospital's plan.
7. Encourage family disaster planning. Many resources are available to help families plan for disaster. These resources can be downloaded from ready.gov or obtained from the American Red Cross.

Summary

Children make up approximately 29% of our population and will invariably be involved in disasters. Many community disaster plans presently do not adequately address the needs of large numbers of critically injured or sick children. As discussed, there are distinctive characteristics and challenges involved in providing mass casualty care for children. It is imperative that emergency physicians share this information with local emergency planners to guarantee that community plans include policies and procedures to provide optimal care for childhood victims of disasters.

Chapter 153

Family Presence

Mirna M. Farah, MD

Key Points

Family presence during resuscitation and procedures meets the family's emotional needs of being informed, feeling accepted, and being able to provide comfort to the patient.

An organized and properly studied approach is essential to the success of a family presence program.

Written guidelines that balance staff's concerns about providing care and families' need to be present are among the crucial initial steps towards establishing a family presence curriculum.

A family support person is essential to assess and prepare family members prior to and after entering the treatment room.

Introduction and Background

The concept of family presence during resuscitation emerged in the mid-1980s when the emergency department staff at a Michigan hospital questioned a policy that excluded families from the resuscitation room.¹ Initially opinions about family presence were mixed; however, the trend of subsequent literature has moved toward acceptance of the process.² Currently, several organizations promote family presence, including the American Academy of Pediatrics, the American Heart Association, the Emergency Nurses Association, and the federally funded Emergency Medical Services for Children program.³⁻⁶

Parents play an integral role in the health and well-being of their child. Supporting and integrating the family into the emergency care process is vital to meeting the full spectrum of the patient's needs. The fear that family presence would hinder medical care can be eliminated by properly assessing and preparing families prior to entering the resuscitation room. The more experience health care providers (HCPs) have with family presence and dealing with distressed families, and the more comfort they have in their clinical skills, the higher the acceptance and success of family presence.

Issues

There are several compelling reasons to consider offering the option for family presence (Table 153-1). Including the family

in the care plan, promotes collaboration among medical providers, patients, and family members. Both pediatric patients and their parents are significantly less distressed when the parents are present during a procedure.⁷⁻⁹ Regardless of the patient's condition, parents seem to focus on their child comforting role rather than the logistics of medical care.¹⁰ The patient becomes less anxious, and therefore more compliant, so the procedure has the potential to go more smoothly.¹¹ Even if the parents decide not to be at their child's bedside, knowing that they have that option fosters trust and positive communication.

Even when the patient is likely to die, family presence remains extremely beneficial.¹¹ Family presence allows parents to be by their loved one until the last minute. Parents can touch their child, express their love, and say good-bye while there is still a chance that the patient can hear. Family presence brings a sense of reality to the treatment efforts and clinical status of the patient, avoiding a prolonged period of denial.¹² Parents can see for themselves the tremendous effort put into the resuscitation attempt, and this has far more meaning than being told: "Everything possible was done."¹¹ Family presence facilitates the grieving process, and may be one of the most powerful interventions that can be offered to a grieving family.¹³⁻¹⁶ The manner in which HCPs care for and respect the wishes of both the dying patient and their parents is crucial in helping the family accept the death and deal with the crisis.

There are many perceived barriers to family presence.¹⁷ It often represents breaking a tradition. Family presence challenges basic assumptions and long-standing practices. In the past, parents were routinely excluded from visitation and were never permitted to view resuscitations. The more informed HCPs are about the process of family presence, the higher the acceptance for family presence.^{12,18-20} There are concerns that family presence may increase staff anxiety or hinder performance. Patient care is always a top priority, and it may be harder for a resuscitation team to work with an audience.¹ Confidence in procedural and cardiopulmonary resuscitation (CPR) skills, and experience with family presence, quickly decrease the anxiety level.¹² The majority of HCPs who offer family presence do not report a change in their performance or a change in the outcome of the procedure or CPR.^{7-9,11,12}

Worries that family presence may distract staff or obstruct medical care are unfounded. Disruptions and occurrences of family members becoming physically involved in the resuscitation attempt have not been consistently reported.^{13,21} Most family members are awed by the activity in the resuscitation room and frequently have to be led to the bedside

Table 153–1 Rationale for Offering the Option for Family Presence

- Promotes collaboration and fosters trust between medical providers, patients, and family members
- Reduces anxiety and sense of helplessness
- Allows parents to comfort and support their child
- Meets the family's need of being informed and feeling accepted
- Facilitates the grieving process
- Allows families to be by their loved one until the last minute and be able to say good-bye
- Brings a sense of reality to the treatment efforts and clinical status of the patient

and encouraged to touch and speak with their loved ones.²¹ Regardless of their background, family members understand the need for appropriate behavior so that their presence does not impede the care of the person they are trying to help.

It may be harder to end an unsuccessful resuscitation when family members are expressing grief.²¹ Stressing that every possible intervention has been done, and allowing time for family members to say what they need to say before ending the resuscitation, may help them accept the death. Witnessing CPR helps family members understand how grave the patient's condition is, and allows them to feel confident that everything was done to save the patient.^{1,12,21}

Staff may be traumatized by witnessing the family grieving, bringing emotions to the surface and making it harder to forget and move on. However, this is unavoidable, and taking the time after a resuscitation to talk and vent these feelings can make the circumstances easier to deal with.²¹ Family presence may also be very traumatic for the family. No matter how often people see HCPs providing CPR on television, witnessing these procedures on a loved one is not the same. Family presence should be offered as a choice so parents can participate in the decision about their presence. Being present during invasive procedures or resuscitation is not something all families want. Patients who choose not to have family members present, or family members who desire not to participate, must be supported in their decision without judgment. Even though a parents' desire to stay decreases as procedures becomes more invasive, the majority still wish to be present.²² Even family members who have witnessed CPR say that they would participate again.^{12,13,15,23}

It may be difficult to teach trainees in the presence of family members. We must remain professional and careful with our choice of words in the presence of family. Family presence should be viewed as an opportunity to learn about how to address and support distressed parents. Family presence during resuscitation and procedures does not increase litigation.^{24,25} In fact, family presence may decrease disputes by improving communication, increasing openness, and decreasing doubt about the adequacy of care.^{26,27} Family presence should be presented as an option by letting parents know that they can leave the room any time if they wish to avoid further stress.

Solutions

Institutional/Systems Requirements

Family presence requires the availability of critical staff members and institutional resources to succeed. A family

presence program needs a family presence champion who will write guidelines that are institution specific, delineate roles and responsibilities, survey and educate staff members, and monitor progress and provide feedback. A family support person (FSP) is an individual who will provide most or all of the clinical support when family presence occurs. This individual must understand grief reactions, be competent at supporting distressed families, and have training in the explanation of medical care and in assessment and preparation of family members. The designated FSP can be a social worker, nurse, or chaplain who has no direct patient care responsibility, and is assigned exclusively to assist the family. Duties will include screening and preparing families prior to entering the treatment area, and remaining present with the family at all times in the resuscitation room.

Follow-up services, especially when death occurs, should be established. Staff can be defused or debriefed, informally or through a critical incident stress management program. Security personnel should be available at all times to prevent serious disruption by family members. A family room adjacent to the resuscitation room works well as a staging area, and there must be adequate space in the treatment room. Any family presence program should have dedicated resources and funding for staff education and a mechanism for feedback.

Setting Up a Family Presence Program

One or more family presence champions must first be identified. These are individuals who believe in the benefits of family presence and have good knowledge of the literature. They are committed to initiate and motivate change and act as the driving force behind the establishment of the family presence program. They help to increase awareness and role model family support interventions. A project team assists the family presence champion and should be assembled from a number of disciplines to assure consideration of all perspectives. Input is sought from a broad constituency, including nursing, medicine (emergency department, trauma, critical care, anesthesia, residents, fellows), transport personnel, social work, pastoral care, child life, administration, risk management, respiratory therapy, and technicians. Family member representation on the team should be encouraged. Team members meet regularly and help develop and implement the family presence program.

Next, barriers to family presence within the institution should be identified. The project team should assess institutional resources and identify root causes that prevent the practice of family presence. They should survey a broad group of colleagues for suggestions, concerns, and educational needs. Based on this information, guidelines that are institution specific can be written. These should help delineate staff roles and responsibilities during a family presence event. Support procedures must be addressed for all hours of the day. HCP involvement in both resuscitation situations and invasive procedures that vary in complexity and need for personnel should be specified. The guidelines should balance the staff's concerns about providing care and the families' need to be present in the treatment room. They also need to stress that family presence should remain an option both for the family and for the staff and that the decision to participate must be supported without judgment. A sample guideline is provided in Table 153–2.

Table 153–2 Guidelines for Family Presence during Invasive Procedures and Resuscitations**Family Support Person (FSP)****Prior to Patient's Arrival:**

- Inquire about patient's status and anticipated interventions
- Prepare the space where family members will stay

Patient and Family Assessment:

- Promptly communicate known information about the patient's status to the family.
- Assess the family's reaction:
 - Acceptable behaviors for family presence:
 - Quiet
 - Distressed, crying but consolable
 - Distracted but able to focus and answer questions
 - Anxious or angry but cooperative and follows instructions
 - Worrisome behaviors:
 - Uncooperative
 - Physically aggressive, combative
 - Threatening and argumentative
 - Extremely unstable emotionally, hysterical, loud, cannot be redirected or calmed
 - Altered mental status, intoxicated

A family member's ability to participate can progress or regress throughout their presence in the emergency department. Continuous assessment and intervention are critical for the success of family presence.

- Assess the patient's desire for family members to be present when applicable.
- Assess the family's desire/willingness to participate, and comfort with being present from previous experiences with similar situations (blood draws, procedures performed on a loved one, etc.).
- Inform the HCP of the family's arrival and request to be present in the treatment area.

Preparation of the Patient and Family:**Prior to entering the treatment room:**

- Families should be told:
 - How many family members may enter the room at one time
 - Where they will stand/sit initially and when they will be able to move to the bedside
 - That they may leave the room if they feel the need to step out, and that they are welcome to reenter
 - Why they may be **asked to step out of the room:**
 - At the request of the HCP
 - Obstruction of care: violent behavior, uncontrolled outbursts, etc. Security will join the FSP in moving the family out of the treatment area.
 - Need for medical assistance: fainting, chest pain, etc. In this case an HCP not involved in the care of their child will assist them.

In the treatment room:

- During resuscitations, an FSP must always remain with the family in the treatment area. During invasive procedures, the HCP will assign an FSP as needed.
- The family must be clearly informed of the status of their loved one and be prepared for the interventions that are in progress.
 - Explain the procedures being performed.
 - Potential responses the patient may exhibit.
 - Explain the patient's role during the procedure (i.e., holding still etc.).
 - Family members' role in providing comfort and reassurance.
 - Interpret medical jargon.
 - Provide opportunity to ask questions and clarify details: The FSP should mainly describe the procedures performed. The physicians will explain indications and outcomes.

Health Care Professional (HCP)**Attending Physician:**

- Communicates with the FSP known information about the patient's status and anticipated plan of care.
- Approves/disapproves family presence, indicates to the FSP when to bring the family in.
 - The attending physician and the trauma chief will retain the option to allow the family to enter the treatment room or be escorted away from the bedside and/or out of the room if deemed necessary.
- Notifies family of outcome of procedures and/or resuscitation as soon as practical.

Emergency Department Charge Nurse:

- Assures FSP is contacted for resuscitation situations.
- Designates a staff member to act in the FSP role until support staff arrives.
- Provides the FSP with clinical information and helps answering questions.

All Care Providers:

- Interact with the family as soon as practical.
- Address the patient by name.
- Offer and provide comfort measures: Assist the family in making phone calls, provide a place to sit down, water, tissues, etc.
- Use terminology appropriate to the person's level of understanding.
- Provide opportunities for the family to see and speak with the patient.
- Provide for patient and family privacy.
- Maintain professional behavior and language at all times.

Situational Constraints

- When space is critically limited, it may be necessary to limit the number of family members to one at a time, or ask the family to step out temporarily.
- When multiple patients need the resuscitation room simultaneously, family members may not be allowed in the room. Accommodations to bring the family to the bedside should be made as soon as practical, even if only briefly.

Educating staff is a large part of the creation of a family presence program. The purpose of this education is to provide the skills necessary to support distressed families, become familiar with grief reactions, and introduce the guidelines and respective roles of the staff. Support personnel need to have a strong psychosocial background and some understanding of common invasive procedures and CPR. Other personnel need to be comfortable assessing families' needs and initiating appropriate interventions and consultation. A variety of formats may be used, including lectures and workshops, role play exercises, videotaped presentations, self-study modules, and case reviews.

A date should be designated for the program to begin. Implementation of a family presence program will take time and will require a shift in the culture of the department. Assessing staff readiness and ensuring adequate resources are essential steps in changing practice and integrating a family-centered care approach. Once the program is in place, the project team should monitor progress, provide feedback, and customize the guidelines. Evaluation is an essential step to validate the efficacy of the strategies implemented. Input should be sought from HCPs, support staff, and families. This helps to identify further educational needs, problems, and potential revisions of the guidelines. The mechanisms for evaluation may include surveys, postevent questionnaires, interviews, and open forum discussions. The timing of the evaluation should take into consideration the clinical situation and outcome. Opinions from staff may be solicited within days of an event and after several weeks to months from families who lost a loved one. Knowledge of the program should be spread within and outside the institution among all parties, including prehospital care providers.

Summary

Due to perceptions, attitudes, previous exposures, and biases, many HCPs overlook the benefits of family presence. When planned properly, family presence helps meet the family's needs without disrupting medical care. However, this type of change requires great commitment, adequate resources, continuing education, careful planning, and time. The greater the depth of experience with family presence, the greater the likelihood of supporting the process. As patient advocates, HCPs should strive for widespread establishment of family presence.

Chapter 154

The Child-Friendly Emergency Department: Practices, Policies, and Procedures

Susan Fuchs, MD

Key Points

There are suggested minimum pediatric emergency department (ED) equipment, supplies, and medication.

There are many different staff training options.

Continuous quality improvement and creating a safe environment are essential for any pediatric ED.

Key pediatric policies, procedures and external agreements must be available 24 hours a day, 7 days a week in all pediatric EDs.

Introduction and Background

What is Emergency Department Preparedness?

Emergency department (ED) preparedness means that the “Emergency Department must have the staff and resources to evaluate all persons presenting to the ED.”¹ However, when it comes to pediatric patients, this is not always the case. A national survey concluded that only 10% of U.S. hospitals have a pediatric intensive care unit, 25% of hospitals without a pediatric trauma service admit critically injured children, and 7% of hospitals without a pediatric ward admit children.² A Canadian study of ED preparedness demonstrated deficiencies in equipment needed to resuscitate a critically ill pediatric patient.³

Not all children are, or need to be, seen in a pediatric ED. In fact, of the approximately 35 million pediatric ED visits per year, only 10% seek care initially in a children’s hospital/pediatric ED. What this means is that the other 31.5 million children seek care in general and community EDs, which have varying abilities to care for them. In most community EDs, pediatric patients account for 20% to 35% of the patient visits. This chapter reviews the issues involved in prepared-

ness, possible solutions, suggested policies and procedures, and additional information that may prove beneficial to create an ED appropriately prepared for infants, children, and adolescents.

Facility Categorization

While most physicians and nurses are familiar with terms such as a Level I trauma center or a burn center, the terminology for pediatric centers is new, and often varies from state to state, if it exists at all. “Categorization is the assessment of a facility based on its ability to manage certain categories of patients.”⁴ The levels of categorization are usually based upon state (e.g., Level I vs. II adult/pediatric trauma center) or national (e.g., burn center) standards. This can lead to a “designation,” or the assignment of responsibility for care of certain categories of patients to specific institutions based upon compliance with standards as well as on their catchment area.⁴ The designation is conferred by an outside agency once the facility has gone through a site survey or other process to verify that it meets the existing standards. A hospital can also voluntarily agree to adopt a set of standards as its own, without an outside agency involved, and can be “confirmed.”⁴

Another important distinction is the method by which states categorize hospitals and EDs. In many states there are comprehensive EDs. This is an ED with at least one physician available 24 hours a day, 7 days a week (24/7), with specialty services, and with ancillary services such as radiology, laboratory, and pharmacy staffed at all times.⁵ A basic ED has at least one physician 24/7, limited specialty services, and ancillary services staffed or “on call.” A standby ED has a registered nurse, nurse practitioner, or physician’s assistant available for emergency services 24/7, and a physician who is “on call.”⁵

Issues

In 1995, the American Academy of Pediatrics (AAP) issued guidelines for pediatric emergency care facilities. This document established four levels of care: standby, basic, general

emergency facilities, and comprehensive regional pediatric center.⁶ It included recommendations on personnel, medical specialist consultants, surgical specialists, equipment and supplies, and facilities for each level. It also covered topics such as access, triage, transfer and transport, education, training, research, quality assessment and improvement, administrative support and hospital commitment.⁶ This guideline added the requirement that the physician be competent in the care of pediatric emergencies. This could be demonstrated by the successful completion of Pediatric Advanced Life Support (PALS) or Advanced Pediatric Life Support (APLS) courses.⁶ This set the foundation for the development of a national policy statement in 2001 (see later).⁷

In February 1995, the American College of Emergency Physicians (ACEP) issued a policy statement on pediatric equipment guidelines. These were recommended for equipment of pediatric patients in a general ED. This list included monitoring devices, vascular access supplies and equipment, respiratory equipment and supplies, medications, related supplies/equipment, miscellaneous equipment, specialized pediatric trays, and fracture management devices.⁸ The equipment and medications listed in this document and the AAP 1995 document are similar.

In 1998, the Committee on Pediatric Equipment and Supplies for Emergency Departments of the National Emergency Medical Services for Children Resource Alliance developed a consensus statement regarding pediatric resuscitation medication and minimum equipment and supplies.⁹ They based their recommendations on previously published lists, including the two documents by the AAP and ACEP.^{6,8} The article mentioned that the ED may choose to modify this list, and that ED health care providers should be trained in the use of all equipment and supplies. The committee also took into account financial factors when recommending items, and occasionally provided some equipment options.

In 2001, the AAP and ACEP, along with the federal Emergency Medical Services for Children (EMSC) program, developed a joint policy statement: “Care of Children in the Emergency Department: Guidelines for Preparedness.”⁷ In addition to these organizations, this statement was supported by numerous national organizations and agencies. While this document does list medications, equipment, and supplies (adapted from the 1998 list⁹), its strength lies in the agreement on personnel staffing and training, administration and coordination for pediatric emergency care, quality improvement (QI), and ED policies, procedures, protocols, and support services. The information in this policy provides a framework for many of the areas to be discussed in the “Solutions” section later in this chapter.

State Guidelines

In 1994, the California Emergency Medical Services Authority compiled a list of recommended equipment, supplies, and medications for the care of pediatric patients in the ED.¹⁰ In 1999, the Los Angeles County Department of Health Services’ Emergency Medical Services (EMS) division published Emergency Department Approved for Pediatrics (EDAP) standards.^{4,11} These standards include administration, coordination, personnel, policies, procedures and protocols, QI, support services, equipment, supplies, and medications. Pediatric Critical Care Center (PCCC) was another category

designation that was added. This designation is achieved if a hospital meets requirements for an EDAP, has a trauma center, and has a California Children’s Services–approved pediatric intensive care unit.¹¹ In 2004, there were 57 EDAPs and 9 PCCCs in Los Angeles County.¹¹

In 2002, the State of Illinois added a section to the Emergency Medical Services and Trauma Center Code to include facility recognition criteria for EDAPs and the Standby Emergency Department Approved for Pediatrics (SEDP).^{12,13} Although this is a voluntary process, since these rules have been in effect the EMSC facility recognition process has recognized 114 (out of a possible 200) hospitals. These criteria cover topics similar to the Los Angeles County criteria, but include recommended equipment lists as well as professional staff (nurse, physician, nurse practitioner, physician assistant) qualifications, continuing medical education (CME) requirements, a multidisciplinary QI committee, and a pediatric continuous QI liaison.¹²⁻¹⁴ Another important part of this document was the development of interfacility pediatric trauma and critical care consultation and/or transfer guidelines.¹⁵

Solutions

Triage

When a child enters an ED with his or her parent(s), the first encounter they have with a health professional is at triage. It is important for that person to be comfortable assessing a child, to have the necessary equipment (e.g., scales, thermometer, appropriate-sized blood pressure cuffs, and pulse oximeter probes), as well as to have some criteria on which to base the child’s triage category assessment. Published criteria for children are based upon age-related norms, signs, and symptoms, and are divided into three or five categories.¹⁶⁻¹⁸ Triage criteria provide a guide as to the level of acuity of the patient, which in turn provide a time frame in which the patient should be seen (see Chapter 155, Triage).

Physical Space (Child Friendly)

While a designated pediatric care area is not feasible in many facilities, it may be possible to make the ED child friendly in several simple ways. Just separating pediatric patients from adult patients in the waiting room may protect them from some of the sights, language, and other inappropriate behavior of adults. It can also provide some separation between children who may have a contagious disease and elderly adults, who are very susceptible to these illnesses. It is important to childproof the waiting room by avoiding sharp corners on chairs and tables, locking cabinets, covering electrical outlets, and covering trash cans.¹⁹ If pediatric-size furniture is available, it is important to keep it clean after use. This is also true of any toys used in a play area. Some simple solutions are to provide coloring books and crayons, or books to read, all of which can be taken home.

If a separate pediatric room or care area is available, simple decorations can brighten the room and provide distractions for children. This can be a cheerful wall border, hanging pictures, or ceiling drawings. While one could argue that a teenager will not enjoy being in a room decorated with Mickey Mouse or Sesame Street characters, they can still provide distractions during an examination. This room

should also be childproofed by placing all medical equipment out of reach of a child, providing bed rails with child guards, and assuring that there are no sharp objects or corners at an infant or roaming child level. Another option is to provide a TV/VCR/DVD player in the room. The TV can have limited channels, and the VCR or DVD can be utilized to view cartoons, movies, or even educational tapes.¹⁹ As a convenience to parents, having diapers, skin wipes, and blankets in the room can help them provide care or comfort for their child while waiting to be seen.

Staffing

Creating a child-friendly environment should involve the staff. While many pediatric hospitals allow brightly colored shirts/blouses/scrub tops, these may not look professional to an adult entering the ED. Each hospital has dress code regulations that determine the use of scrubs outside of the operating room. The ability of clerical, ED, and ancillary staff to deal with patients of various ages cannot be overstressed. Education and training sessions on how to communicate and interact with pediatric patients should be available to all the staff involved in their care.

Many emergency nurses work in different hospital locations before they seek employment in the ED, but their exposure to pediatrics may have been limited to nursing school rotations. If there is a pediatrics ward in the hospital, having them spend some time with pediatric nurses (and vice versa) can be an invaluable experience. There are specific CME courses, including the Emergency Nurse Pediatric Course (ENPC) offered through the Emergency Nurses Association, APLS, and PALS, that can help them improve their assessment, technical, and treatment skills.²⁰ The specific number of staff is based upon the hospital designation (comprehensive vs. standby) as well as the usual census, but will include at least one nurse present 24/7.

Physician attitude and training are also crucial. Once again, depending upon the physician's specialty, his or her last exposure to pediatrics may have been in medical school. Residency-trained emergency physicians are trained in the acute and emergent care of pediatric patients. Additionally, each state may have additional CME requirements for physicians, some being specific for topics such as pain management, end-of-life issues (California), and child maltreatment (New York). Specific physician staffing is based upon hospital designation (e.g., for a standby hospital, the physician may be on call but promptly available, whereas a basic facility has an emergency physician present 24/7). The ACEP emergency care guidelines contains specific staffing and credentialing requirements for physicians and nurses.⁹

The availability of specialists (surgical and medical) varies based upon the hospital designation. The AAP guidelines for pediatric emergency care facilities include a table that lists these physicians, and whether they are essential in the hospital or promptly available, based on hospital designation.⁶

Competency

The issue of developing staff competency is difficult to define. Courses that do exist do not guarantee competency, but provide certification that one has completed the course. Becoming competent requires experience, ongoing training, practice, and education. There are no set number of times a

physician must suture a laceration, or a nurse must start an intravenous line, to prove he or she is competent. The requirements for board certification in all medical specialties are undergoing change to include the following: physicians must maintain active licensure, pass a written examination, read current literature, obtain CME credits, and receive an evaluation of their practice performance. While this does not prove competency either, it is a multilayered process that is more rigorous than previous requirements.

For those staff who do not have pediatric experience, available courses can help educate them about common pediatric illnesses and injuries, resuscitation skills, and procedural techniques. These classes include ENPC and APLS or PALS for nurses, and PALS or APLS for physicians.^{18,20,21}

Equipment/Supplies

Even with all of the expertise and training of the staff, an ill infant cannot be cared for appropriately if the right-size equipment is not present. This can include basic equipment such as a sphygmomanometer with an infant-sized blood pressure cuff, or a 22- or 24-gauge intravenous catheter, or a 10F chest tube. While there are several published equipment lists, the equipment/supply list published by the AAP and ACEP is based upon the consensus of many organizations⁷ (Table 154–1).

Medications

The majority of the medications required in the ED can be used in children.¹⁹ However, there are some unique concentrations for children, such as sodium bicarbonate (4.2%), and dextrose (10%, 25%).⁹ It is important to have frequently used medications readily available in the ED, and a process for obtaining those used less frequently in a short time frame (Table 154–2).

Quality Improvement

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) requires that hospitals improve patient safety and perform QI activities. Each year JCAHO establishes national patient safety goals and quality indicators.²² Common ED QI monitors include deaths, transfers, and ED returns visits within 48 or 72 hours. Additional pediatric QI indicators can include pediatric resuscitations, intubations, and patients admitted to the general pediatric ward who require transfer to a pediatric intensive care unit. More specific QI ideas can include timing to administration of antipyretics, or pain assessment and management.²³ It is important to include some out-of-hospital QI indicators such as appropriate airway management (airway adjunct or assisted ventilation), delivery of 100% oxygen to a child in respiratory distress, establishment of vascular access, appropriate immobilization for trauma, and appropriate sized equipment used. The Institute of Health Care Improvement has defined the four essential components of a high-performing quality program as follows: (1) focus on identifying appropriate indicators, developing a plan for improvement (plan); (2) implement this plan (do); (3) collect and analyze the data (study); and (4) reach conclusions and make recommendations (act). It is also important to have a multidisciplinary QI team, as different perspectives will be obtained and many lessons learned (see Chapter 149, Patient Safety, Medical Errors, and Quality of Care).

Table 154–1 Recommended Equipment and Supplies**Monitoring**

- Cardiorespiratory monitor with strip recorder
- Defibrillator (0–400 J) with pediatric (4.5-cm) and adult (8-cm) paddles or corresponding adhesive pads
- Pediatric and adult monitor electrodes
- Pulse oximeter with sensors for children
- Sphygmomanometer
- Doppler blood pressure device
- Blood pressure cuffs (neonatal, infant, child, adult arm and thigh cuffs)
- Stethoscope
- Thermometer (must be able to measure from 25° C to 44° C)
- Endotracheal tube placement monitor (disposable CO₂ detector, electronic waveform or measurement, or for children ≥ 20 kg or ≥ 5 yr, esophageal detector device)

Airway Management

- Portable oxygen regulators/canisters
- Oxygen masks
 - clear simple face masks—neonatal, infant, child, adult
 - Venturi masks—neonatal, infant, child, adult
 - partial non-rebreathing masks—neonatal, infant, child
 - rebreathing masks—child, adult
- Oropharyngeal airways (sizes 0–5)
- Nasopharyngeal airways (sizes 12F–30F)
- Bag-valve-mask resuscitator—self-inflating (450- and 1000-ml sizes)
- Nasal cannulae (infant, child, adult)
- Endotracheal tubes
 - uncuffed (sizes 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, and 6.0 mm)
 - cuffed (sizes 6.5, 7.0, 7.5, 8.0, and 9.0 mm)
- Stylets (pediatric and adult)
- Laryngoscope handle (pediatric and adult)
- Laryngoscope blades: straight/Miller (sizes 0, 1, 2, and 3) and curved/Macintosh (sizes 2 and 3)
- Magill forceps (pediatric and adult)
- Nasogastric/feeding tubes (sizes 5F–18F)
- Suction catheters—flexible (sizes 6F–16F)
- Yankauer suction tip
- Bulb syringe

Vascular Access

- Butterfly needles (sizes 19G–25G)
- Catheter-over-needle devices (sizes 14G–24G)
- Intraosseous needles (two sizes, between 13G and 18G)

- Intravenous fluids
- Rate-limiting infusing device and tubing
- Fluid/blood warmer

Fracture Management

- Cervical immobilization equipment (backboard with straps, and head immobilizer)
- Semi-rigid cervical collars (sizes to fit infant, child, and adolescent)

Miscellaneous Equipment

- Length-based resuscitation tape (precalculated drug or equipment list based on weight)
- Pediatric urinary catheters (sizes 5F–16F)
- Infant and standard scales
- Towel rolls, blanket rolls
- Resuscitation board
- Medical photography capability

Specialized Pediatric Trays

- Lumbar puncture
- Tube thoracotomy with water seal drainage capability
- Venous cutdown kit
- Needle cricothyrotomy tray

Essential Equipment That Can Be Shared (Nursery, Floor, Operating Room), but Is Readily Available to the Emergency Department

- Umbilical vein catheters (3.5F, 5F [but size 5F feeding tube can also be used])
- Chest tubes (sizes 8F–40F)
- Seldinger vascular access technique kit (3F, 5F, 8F)
- Extremity splints
- Femur splints (child and adult)
- Tracheostomy tubes (sizes 00–6)
- Obstetrics pack
- Newborn delivery kit
- Umbilical vessel cannulation supplies
- Surgical airway kit (tracheostomy or surgical cricothyrotomy kit)
- Infant formula and oral rehydrating solutions
- Heating source (infrared lamps or overhead warmer)
- Sterile linen

Equipment That Is Desirable

- Laryngeal mask airways (sizes 1, 1.5, 2, 2.5, 3, 4, and 5)

Adapted from American Academy of Pediatrics, Committee on Pediatric Emergency Medicine; and American College of Emergency Physicians, Pediatric Committee: Care of children in the emergency department: guidelines for preparedness. *Pediatrics* 107:777–781, 2001.

Table 154–2 Recommended Medications

Activated charcoal
 Adenosine
 Antibiotics (parenteral)
 Anticonvulsants
 Antidotes
 Antipyretics
 Atropine
 Bronchodilators
 Calcium chloride
 Corticosteroids
 Dextrose (25%, 50%)
 Epinephrine (1:1000, 1:10,000)
 Inotropic agents
 Lidocaine
 Naloxone hydrochloride
 Neuromuscular blocking agents
 Oxygen
 Sedatives
 Sodium bicarbonate (4.2%, 8.4%)

Transfer Criteria

While many ill and injured children can be cared for in local EDs and hospitals, some require transfer to a specialized care center. There are hospitals that offer specialized care for newborns, critical care services, pediatric trauma, and burns. They offer 24-hour consultation with the appropriate specialist, and may have their own interfacility transport service. The decision to transfer pediatric patients depends upon the ED and hospital capabilities, but guidelines have been developed to help physicians identify which patients would benefit from specialized care. It is important for the referring physician to consult with the receiving physician, so the appropriate method of transport and the required personnel can be determined. Transfer guidelines can be based upon physiologic criteria, anatomic criteria, burn criteria, or diagnostic criteria. An example of these guidelines has been developed for the Illinois EMSC program.²⁴

Policies and Procedures

Policies, procedures, and protocols that specifically deal with the emergency care of children should be developed for use in the ED and hospital. These include policies on child maltreatment and consent issues. Other protocols may be integrated into ED/hospital policies, procedures, and protocols, but pediatric-specific components should be included. This includes policies on death in the ED, do-not-resuscitate orders, injury and illness triage, sedation and analgesia, immunization status, mental health emergencies, physical or chemical restraint of patients, family issues (e.g., family presence during care), communication with the patient's primary care provider, and transfer policies.⁷

Restraints (Chemical and Physical)

JCAHO has behavioral health care restraint and seclusion standards that apply to patients in the ED who are being restrained or secluded for behavioral health reasons.²⁵ Restraint, whether chemical or physical, should be a method of last resort. It should never be used as a means of discipline, coercion, or retaliation or for convenience. Restraint is often considered when the patient's or another's safety is a concern. Included in this policy should be the use of seclusion. When restraint or seclusion is considered, the patient's caregivers should be involved in the treatment decision. If this is not possible, they should be notified.

Each use of restraint or seclusion must be based on the patient's needs, age, and past medical history. The restraint policy should cover definitions and exceptions to restraints (e.g., intravenous infusion armboards, temporary immobilization for procedures). When restraint or seclusion is utilized, there need to be written orders by a physician, time limits for the written orders, patient assessment parameters (constant visualization, vital signs, nutrition, hydration, and safety every 15 minutes), and a re-evaluation time for renewal of the restraint order.²⁵ During restraint or seclusion, documentation should include a physician order, completion of a nursing or trained staff form/flowsheet, notification of the patient's legal guardian, and documentation of monitoring/vital signs. All staff are required to have ongoing education in the proper use of restraint devices and seclusion techniques, as well as alternative methods for handling behaviors that may lead to the use of restraint or seclusion. The ED medical records of those patients who require restraint or seclusion should be reviewed as part of the department's QI plan.

Procedural Sedation and Analgesia

The use of sedation and analgesia for pediatric procedures should be standard in the ED. According to JCAHO and the American Society of Anesthesiologists (ASA), there are only two levels that are appropriate for the ED: minimal sedation (anxiolysis), and moderate sedation/analgesia ("procedural sedation").²⁶ The fact that two children may respond differently to the same dose of medication necessitates advanced planning on the part of the ED staff. The procedural sedation and analgesia policy should include the following: preparation (patient history and physical examination, information about allergies, prior sedation and analgesia procedures, last meal and liquids), monitoring parameters, "nothing by mouth" guidelines, appropriate candidates for sedation (ASA

Physical Status Classification classes I and II), parental consent, and discharge criteria.²⁶ Depending upon the level of sedation planned, the monitoring parameters may change, as will the equipment available in the room and the personnel present²⁶⁻²⁹ (see Chapter 159, Procedural Sedation and Analgesia).

Drug Testing

The use of drug testing for alcohol, drugs of abuse, controlled substance, or other toxins should be written in an ED policy. In some states, the state police can request that a physician perform this test, even without the patient's consent. In some states, the emergency physician is required to obtain drug testing if the physician believes the patient was given a controlled substance without his or her consent. If it is unclear that the patient was given a drug, then asking the patient for consent is appropriate. The consent form for a toxicology screen should be completed by the patient/legal guardian, and witnessed, timed, and dated. It may also be possible for the patient/legal guardian to sign the consent later, and to revoke the consent (both within 48 hours).

Health Care–Acquired Infection

One of the 2004 JCAHO safety parameters is to reduce the risk of health care–acquired infection.²² This can be accomplished by complying with the Centers for Disease Control and Prevention (CDC) hand hygiene guidelines.³⁰ Items in these guidelines include limiting the use of artificial nails, keeping natural nails short, and using alcohol-based hand cleaners.^{22,30} In addition, nosocomial infections that result in unanticipated death or major permanent loss of function should be managed as sentinel events.²²

Infectious Diseases

In the United States, state laws and regulations mandate which diseases are reportable, and this varies from state to state. Local and/or state departments of health collect this information. The CDC maintains a list of notifiable infectious diseases that is released every year that allows the CDC to follow trends in reportable disease across the United States during a given year, and from year to year. This list currently contains 60 diseases such as acquired immunodeficiency syndrome, anthrax, gonorrhea, hepatitis (types A, B, and C), Lyme disease, meningococcal disease, pertussis, salmonellosis, shigellosis, smallpox, syphilis, and tuberculosis.^{31,32} Recently, diseases such as ehrlichiosis, giardiasis, severe acute respiratory syndrome (SARS), smallpox, and vancomycin-intermediate and -resistant *Staphylococcus aureus* have been added.³¹

The use of standard precautions took on a heightened awareness during the early days of acquired immunodeficiency syndrome/human immunodeficiency virus infection, and this has continued. In order to reduce the number of needle sticks, there has been an increased use of needleless systems and retractable needles. With new and emerging infections such as SARS, this has progressed to include special respiratory masks (N-95), rather than simple paper/procedure masks.

The ED should have policies regarding the use of isolation rooms, negative pressure rooms (if available), and patient decontamination. There should also be a policy regarding

exposure to potential blood-borne pathogens, which includes reporting, testing, and prophylaxis.

EMTALA

The Emergency Medical Treatment and Labor Act (EMTALA) is a federal law that forbids a hospital, physician, dentist, or other health care provider to refuse to provide emergency care based upon a patient's inability to pay³³ (see Chapter 150, Emergency Medical Treatment and Labor Act [EMTALA]). This legislation, often referred to as the Comprehensive Omnibus Budget Reconciliation Act or “anti-dumping” legislation, is included in Title XVII of the Social Security Act. Any hospital that received Medicare funding must comply with these regulations, even for non-Medicare patients. A hospital can be fined up to \$50,000 per violation, and the hospital's or physicians' Medicare and Medicaid agreements may be terminated by the Centers for Medicare & Medicaid Services.^{33,34}

EMTALA applies when a person comes to a hospital with an ED and requests care for an emergency medical condition. It also applies if a parent is requesting care for his or her child. An emergency medical condition is an illness or injury that manifests itself by acute symptoms requiring immediate attention to avoid placing the health of the person in serious jeopardy.³³ In terms of a woman in labor, this constitutes inadequate time to transfer her prior to delivery. However, the existence of an “emergency medical condition” is based upon the definition of a prudent layperson, not a health care professional.³³

In order to fulfill the EMTALA obligation, a patient must be screened and, if necessary, stabilized. If a patient cannot be stabilized, he or she must be transferred to an appropriate facility, with the receiving facility aware of and accepting the transfer.³³

The ED and hospital should have an EMTALA policy that addresses items such as what constitutes a screening examination, who can perform the screening examination, which parts of the hospital/main campus qualify under EMTALA, and who responds to medical emergencies outside of the ED.^{33,34}

A revised aspect of EMTALA is the “on-call” requirement. Each hospital must have an on-call schedule and written policies related to the schedule, including response times. This policy applies to emergency physicians as well as medical and surgical specialists³⁴ (see Chapter 150, Emergency Medical Treatment and Labor Act [EMTALA]).

Transfer Policies and Procedures

A transfer policy should be in place for hospitals that do not have pediatric intensive care units, inpatient beds, or pediatric trauma capabilities/specialists, or when specialized pediatric care is not available. It is helpful to have a list of referral hospitals and contact numbers placed prominently in the ED. It is preferable to have transfer agreements with several hospitals in the region for similar or different categories of patients (e.g., trauma vs. medical). These agreements should be signed by the hospital chief executive officer and updated as needed. In some cases, these agreements are extremely important for reimbursement if the transfer involves crossing state lines. In rare cases, the receiving facility may have no available beds, but can assist the transferring hospital in finding another appropriate

facility. Before the patient is transferred, there should be physician-to-physician and nurse-to-nurse communication. Written documentation, including consent to transfer, method of transfer, and reason for transfer, should be included.³⁵

Hospital Overcrowding

In 2003, there were nearly 114 million ED visits, a 26% increase over the last 10 years.³⁶ Yet at the same time, the number of EDs decreased by 10%.³⁶ This is just one of the many causes of hospital overcrowding, a situation in which the identified need for emergency services exceeds the available resources in the ED.³⁷ This problem can affect child-friendly EDs and can result in ambulance diversion, where an ED does not have the capability to accept an EMS/ambulance patient, and prolonged ED stays after admission or transfer decisions are made due to a lack of inpatient beds (“ED boarders”).^{37,38} This may mean that an ill child will be transported by EMS to another ED that may be further away, and perhaps not child friendly. It can also mean that, even after an ill or injured child has been stabilized, there may be no available beds at the pediatric centers. While there are no easy solutions to this problem, utilizing QI indicators to track time on EMS diversion, ED boarding time, ED waiting room time, the number of patients who left without being seen, and the number of times when patients could not be transferred in a timely manner will help those outside the ED realize there is a problem, and help advocate for change.

Summary

The process of developing ED preparedness for children is not a new issue. Over the last 20 years, the goal of the EMSC program was to assure that children were included in the entire scope of care, including out-of-hospital care, the ED, and hospital care. Many of the policies and programs developed over the past 10 years were the result of this initiative.^{7,9,12-15} By being inclusive rather than exclusive, many national organizations have supported the idea of pediatric ED guidelines for preparedness. It is unrealistic to expect that a rural community hospital that lacks pediatric inpatient beds would have the same ED equipment and supplies as a large suburban community hospital with pediatric inpatient beds, or even an urban, freestanding children's hospital. The goal is to provide some ideas, solutions, and examples that will improve the care of children everywhere.

The Future: An ACEP/AAP Implementation Kit

The ACEP, through a grant from the federal EMSC program, is developing an implementation kit for ED preparedness.³⁹ This kit contains information such as a copy of the AAP/ACEP paper “Care of Children in Emergency Departments: Guidelines for Preparedness”⁷; 12 model emergency department policies for care of children, including child maltreatment, consent, and death in the ED; relevant ACEP and AAP pediatric clinical care guidelines and policies; a pediatric medication calculator; and a pediatric preparedness checklist. Prior to wide dissemination, the implementation kit is currently being evaluated, and will be refined based on evidence generated (Table 154–3).

Table 154–3 ACEP/AAP Implementation Kit for ED Preparedness

- A copy of “Care of Children in the Emergency Department: Guidelines for Preparedness.”⁷⁷
- 12 model ED policies for the care of children
- Pediatric Medication Calculator
- Pediatric Preparedness Checklist

Triage

Sharon E. Mace, MD and Thom A. Mayer, MD

Key Points

Triage is the prioritization of care based on illness/injury, severity, prognosis, and resource availability.

Triage identifies patients who cannot wait to be seen, prioritizes all patients, and initiates diagnostic and therapeutic measures.

Disaster triage differs from emergency department triage. During a disaster with limited resources, patients with little or no chance of survival are not resuscitated.

The disaster triage categories are red (most urgent, first priority), yellow (urgent, second priority), green (nonurgent, walking wounded, third priority), and black (dead or catastrophic).

Introduction and Background

Triage is the prioritization of patient care (or victims during a disaster) based on illness/injury, severity, prognosis, and resource availability. The purpose of triage is to identify patients needing immediate resuscitation; to assign patients to a predesignated patient care area, thereby prioritizing their care; and to initiate diagnostic/therapeutic measures as appropriate.

The term *triage* originated from the French verb *trier* which means to sort. During the time of Napoleon, the French military used triage to serve as a battlefield clearing hospital for wounded soldiers. The U.S. military's first use of triage was during the Civil War. Triage on the battlefield was a distribution center from which injured soldiers were sorted or distributed to various hospitals. For the military during World Wars I and II, triage was the procedure that determined which injured soldiers were able to be returned to the battlefield. Military triage continued to evolve during the Korean and Vietnam wars with the tenet of doing the "greatest good for the greatest number of wounded and injured."¹ Refinements in battlefield medicine and military triage have continued during more recent conflicts, including Iraq.

Other situations in which the triage process has been employed, in addition to the battlefield, are during disasters, following mass casualty incidents (MCI), and in emergency departments (EDs). Triage during a disaster involves field triage, which sorts disaster victims into categories ranging from the walking wounded to those with injuries who are salvageable to the unsalvageable and the dead.

Issues and Solutions

The Triage Process

The nurse assesses and determines priority of care (trages) based not only on the patient's physical, developmental, and psychosocial needs but also on parameters of patient flow in the emergency care system and of health care access. According to the Emergency Nurses Association (ENA), triage should be done by an experienced nurse with competency in triage.^{2,3} The nurse should accomplish the following during triage: take history appropriate to the severity of the complaint, obtain vital signs, ask predetermined ED/hospital-required screening questions, and assign patient priority. Triage may be either focused or comprehensive. Comprehensive triage refers to taking a complete history, checking vital signs, determining allergies, and, where appropriate, performing a physical examination. Focused triage is generally used for more minor illnesses or injuries and includes a more limited history and screening prior to assessing patient priority. Triage bypass, which is addressed more fully later in this chapter, refers to an approach that places patients directly into ED rooms at times when space and staffing allow, and triage is performed at the bedside.

The advantages of comprehensive triage include immediate identification of patients with life-threatening or emergent conditions and administration of basic first aid measures. In addition, the patient (and family) are met by an experienced nurse who can address the patient/family's physical, psychosocial, and emotional issues.

One criticism of a comprehensive triage system is that it takes too much time, thereby creating a "logjam" of patients backed up waiting to be seen by the triage nurse.⁴ This has led to a two-tier triage system with the triage nurse determining, from the chief complaint and an observation or "across the room" assessment, who is taken immediately to the patient care area versus waiting for additional assessment and registration. The two-tiered triage system includes a primary

nurse and a sorter nurse, and may be used to achieve comprehensive triage during high-volume periods.

Pediatric and geriatric patients take more time to triage than other patients. Comprehensive triage is said to take only 2 to 5 minutes, although one study found that this occurred only 22% of the time.⁵ A concern has been expressed that this 2- to 5-minute time frame for triage may be unrealistic.⁴ There have also been studies indicating inconsistency in triage assessment among experienced triage personnel and between nurses and physicians.⁶⁻¹⁰ Whether focused triage, comprehensive triage, or triage bypass is used, performance improvement data should be monitored to assess efficacy.

Triage Categories

Emergency department triage has several functions, including (1) identification of patients who should not wait to be seen, and (2) prioritization of incoming patients. This is accomplished by determining the patient's illness/injury severity or acuity. Acuity is the degree to which the patient's condition is life- or limb-threatening and whether immediate treatment is needed to alleviate symptoms.

There are various triage acuity systems ranging from two to five levels (Table 155-1). In the United States, a three-level triage system is most commonly used (69%), with 12% of EDs using a four-level system, 3% using a five-level model, and 16% using no acuity system or nonresponding according to an ENA survey done in 2001.¹¹ There is some evidence that a five-level triage system is more effective than a three-level triage system.¹²

Specific Triage Systems

Various triage systems have been used throughout the world: the Australian Triage Scale, the Manchester Triage Scale, the Canadian Triage and Acuity Scale, and the Emergency Sever-

ity Index (ESI)¹³⁻²¹ (Table 155-2). All four of these scales have been validated for reliability and validity in adults.¹⁴⁻¹⁷

Emergency Severity Index

The ESI is a five-level triage system developed in the United States that uses a flowchart-based triage algorithm.¹⁸⁻²¹ The ESI uses patient acuity (stability of vital signs, degree of distress), as well as expected resource intensity and timeliness (expected staff response, time to disposition), to define the five categories (Table 155-3).

Pediatric Triage

Of the approximately 110.2 million patients seen in EDs in the United States in 2002, about 30% were pediatric patients, with 85% of those seen in general EDs.²² Furthermore, there is some evidence that, in a general ED, adults may be "seen sooner than equally ill pediatric patients, resulting in unacceptable waiting times for seriously ill pediatric patients" unless triage criteria are modified for pediatric patients.²³ Improvement in pediatric patient flow with an increase in pediatric triage acuity levels (e.g., a significant increase in the emergent and urgent pediatric patients) resulted from incorporating specific pediatric acuity markers and from posting age-specific abnormal signs and symptoms.²³

Issues relevant to pediatric triage include inapplicability of adult triage criteria to pediatric patients; the often subtle and difficult-to-recognize signs and symptoms of illness/injury in young children and infants, especially those less than 1 to 2 years of age; the frequent unreliability of the clinical impression (even with experienced triage personnel); physiology and behavior in children and infants, particularly in infants, different from that in adults; greater morbidity and mortality in pediatric patients than in adults for similar diseases; and symptom variability during a given illness. Because

Table 155-1 Triage Acuity Systems by Level

2 Levels	3 Levels	4 Levels	5 Levels	5 Levels
Emergent Nonemergent	Emergent Urgent Nonurgent	Life threatening Emergent Urgent Nonurgent	Resuscitation Emergent Urgent Nonurgent Referred	Critical Emergent Urgent Nonurgent Fast track

Table 155-2 International Triage Systems

Australasian		Manchester (United Kingdom)		Canadian		Emergency Severity Index	
Level	Physician/ Staff Response Time (min)	Level	Physician/ Staff Response Time (min)	Level	Physician/ Staff Response Time (min)	Level	Physician/ Staff Response Time (min)
1 = Resuscitation	0 (Immediate)	1 = Immediate (Red)	0 (Immediate)	1 = Resuscitation	0 (Immediate)	1 = Unstable	0 (Immediate)
2 = Emergency	≤10	2 = Very Urgent (Orange)	≤10	2 = Emergent	≤15	2 = Threatened	Minutes
3 = Urgent	≤30	3 = Urgent (Yellow)	≤60	3 = Urgent	≤30	3 = Stable	≤60
4 = Semi-Urgent	≤60	4 = Standard (Green)	≤120	4 = Less Urgent	≤60	4 = Stable	Could be delayed
5 = Nonurgent	≤120	5 = Nonurgent (Blue)	≤240	5 = Nonurgent	≤120	5 = Stable	Could be delayed

Table 155–3 Emergency Severity Index (ESI)

	ESI-1	ESI-2	ESI-3	ESI-4	ESI-5
Stability of vital functions (ABCs)	Unstable	Threatened	Stable	Stable	Stable
Life threat or organ threat	Obvious	Reasonably likely	Unlikely (possible)	No	No
Requires resuscitation	Immediately	Sometimes	Seldom	No	No
Severe pain or severe distress	Yes	Yes (sufficient, but not necessary for this category)	No	No	No
Expected resource intensity	Maximum: staff at bedside continuously; mobilization of outside resources	High: multiple, often complex diagnostic studies; frequent consultation; continuous (remote) monitoring	Medium: multiple diagnostic studies; or brief period of observation; or complex procedure	Low: one simple diagnostic study; or one simple procedure	Low: examination only
Physician/staff response	Immediate team effort	Minutes	Up to 1 hr	Could be delayed	Could be delayed
Expected time to disposition	1.5 hr	4 hr	6 hr	2 hr	1 hr
Examples	Cardiac arrest, intubated trauma patient, severe drug overdose	Most chest pain, stable trauma (mechanism concerning), elderly pneumonia patient, altered mental status, behavioral disturbance (potential violence)	Most abdominal pain, dehydration, esophageal food impaction, hip fracture	Closed extremity trauma, simple laceration, cystitis, typical migraine	Sore throat, minor burn, recheck

of the difficulties in determining acuity for infants less than 6 months old, some have recommended that EDs that see relatively few pediatric patients assign all children less than 6 months old to the emergent category.²⁴

Triage Categories and Triage Systems for Pediatric Patients

Various acuity systems for specific diseases, illnesses, and injuries in pediatric patients have been developed. Multiple pediatric trauma scoring systems exist.²⁵ Scoring systems for specific respiratory diseases, such as “Croup Scores,” have also been developed.²⁶ Various scales for assessment of the young infant with fever, such as the Yale observational scale, have been used to specifically evaluate the febrile infant.²⁷ Unfortunately, a comprehensive pediatric triage assessment tool that applies to all types of pediatric illnesses and injuries throughout the entire range of pediatric age groups (newborns, infants, toddlers, preschool age, early school years, and adolescence) has yet to be developed and validated in extensive numbers of pediatric patients.²⁴ However, several pediatric triage and/or assessment tools are available.

A commonly used triage acuity classification for pediatric patients uses four levels²⁸:

- Class 1—critical: life- or limb-threatening illness/injury that needs immediate care
- Class 2—acute: significant alteration in physical or mental health that could potentially become life or limb threatening and needs intervention as soon as possible
- Class 3—urgent: significant physical or mental health problems that are not life threatening and need intervention in a timely fashion
- Class 4—nonurgent: may receive care when convenient

These are similar to the adult four-level acuity classifications. More recently, a five-level system has been suggested, again similar to the adult five-level acuity classifications: level 1 =

critical, level 2 = emergent, level 3 = urgent, level 4 = nonurgent, and level 5 = fast track²⁹ (see Table 155–1).

Several important caveats have also been suggested. All immunocompromised pediatric patients should be considered as being seriously ill even if their presenting symptoms are not critical.³⁰ Immunocompromised patients include those on corticosteroids or immunosuppressives; patients with chronic illnesses, malignancy, and sickle cell disease; and the very young (particularly young infants), who may not have the typical signs and symptoms of a serious or life-threatening illness early during the course of their illness. Such high-risk patients, including patients with a history of premature birth, chronic illness, and being immunocompromised, may initially “look well” and then rapidly deteriorate.

Child maltreatment should be considered in the differential diagnosis of all pediatric complaints. Key elements of the suspected child abuse or neglect (SCAN) triage interview include detailed documentation of a thorough history with quotes, and an exact description of findings and observations.^{28,31}

Many of the specific pediatric triage systems are based on the primary survey (airway, breathing, and circulation [ABCs]) and a secondary survey from the American College of Surgeons Committee on Trauma^{28,32,33} (Tables 155–4 and 155–5). A primary and secondary pediatric triage survey using an A-to-J alphabetized mnemonic is included in the Emergency Nursing Pediatric Course²⁸ (see Table 155–4).

All of these various triage systems, whether adult or pediatric, need to be validated for reliability and validity in large numbers of pediatric patients. There is evidence that application of the adult triage systems (see Table 155–2) may not be valid for pediatric patients without the addition of pediatric clinical observations and pediatric vital signs, which may lead to a more reliable triage of younger children.^{23,34–36}

Table 155–4 Primary and Secondary Pediatric Triage Survey

	Primary		Secondary
A = Airway	✓ Patency, positioning for air entry, audible sounds, airway obstruction (blood, mucus, edema, foreign body)	F = Find	Find out underlying history of current illness or injury
B = Breathing	✓ Increased or decreased work of respiration, quality of breath sounds; nasal flaring; use of accessory muscles; pattern; quality; rate	G = Get vital signs	Obtain vital signs, obtain orthostatic vital signs if condition warrants
C = Circulation	✓ Color and temperature of skin; capillary refill; strength and rate of peripheral pulses	H = Head-to-toe assessment	Perform a head-to-toe assessment for a complete and thorough examination
C = Cervical collar	Placement of a cervical collar when indicated	I = Initiate	Initiate the Triage Documentation Record
C = Consciousness	✓ Level of consciousness (Glasgow Coma Scale); response to environment; muscle tone; pupil response	I = Isolate	Assess patient for rashes, communicable diseases, or immunosuppression, and place in appropriate isolation
D = Dextrose	✓ Serum glucose level in patients with altered mental status	I = Intervention	Perform triage interventions (first aid, medication administration, diagnostic studies)
E = Expose	Expose patient by undressing to identify underlying injuries	J = Judgment	Make appropriate triage classification of patient acuity

Table 155–5 Triage Observation Tool

	Triage Observation Tool (No/Yes)
Airway	Obstructed airway (blood, vomit, foreign bodies, facial burn)
Breathing	Allergic reaction Increased respiratory effort Fatigue, nasal flaring Tachypnea Tracheal tug, chest recession Wheeze, stridor, grunting Bradypnea, hypoventilation O ₂ saturation higher than expected for degree of respiratory effort
Circulation	Tachycardia, bradycardia Capillary return >2 sec Pale, mottled, or cyanosed Peripheral pulses or perfusion Obvious bleeding out Sunken eyes, dry oral mucosa Decreased feeding, decreased urine output
Disability	Irritable or drowsy and hard to wake Responds only to pain High-pitched cry Obvious pain
Expose	Purpura Chickenpox or measles
Risk Factors	Oncology patient or immunosuppressed Cardiac history Infant <3 mo old Diabetic or metabolic illness Central line or Port-A-Cath

Training and pediatric experience may also play a role in nursing triage assessment of pediatric patients.^{37,38}

PEDIATRIC ASSESSMENT TRIANGLE

The pediatric assessment triangle refers to an “across-the-room” assessment or a quick “eyeball” assessment of the pediatric patient.³³ This is done while the triage nurse obtains the history and chief complaint. The assessment triangle includes evaluation of the infant or child’s overall appearance

(look, cry or speech, hygiene/dress), breathing (respiratory effort and rate), and skin circulation (color, appearance)³³ (see Chapter 10, General Approach to Poisoning).

SAVE-A-CHILD GUIDE

A pediatric triage mnemonic—“SAVE-a-CHILD”—was designed to aid in recognizing a seriously ill pediatric patient.²⁴ SAVE stands for the skin, activity, ventilation, and eye contact. SAVE is based on observations made before touching the child. The “CHILD” component stands for cry, heat, immune system, level of consciousness, and dehydration; this information is obtained from the parent (or caregiver) and a brief examination²⁴ (Fig. 155–1).

Pediatric Triage Assessment and Interventions

Pediatric assessment may use any one or a combination of techniques (e.g., pediatric assessment triangle, SAVE-a-CHILD, primary/secondary survey using ABCs). Important elements in the triage history include the chief complaint, history of present illness or injury, allergies, medications, immunizations, and past medical history.

Several mnemonics for the history have been suggested. CIAMPEDS stands for chief complaint, immunizations or isolation (communicable disease exposure), allergies, medications, past medical history, events surrounding the illness or injury, diet or diapers (bowel/bladder history), and symptoms associated with the illness/injury. Alternatively, the OLDCART mnemonic has also been used (onset of symptoms, location of problem, duration of symptoms, characteristics of symptoms, aggravating factors, relieving factors, and treatment before arrival). For patients in pain, PQRST has been used: precipitating factors, quality of pain, region/radiation of pain, severity, and time of pain onset.

A problem-oriented method, the SOAPIE format, has been recommended by the ENA for comprehensive triage documentation. SOAPIE follows the steps in the comprehensive triage process from obtaining the history and vital signs, to assigning a triage category, to determining and

Save-A-Child	
Recognition of the seriously ill pediatric patient	
Skin	Mottled? Cyanotic? Petechiae? Pallor?
Activity	Needs assistance/ Not ambulating? Responsive?
Ventilation	Retractions? Head bobbing? Drooling? Nasal flaring? Slow rate? Fast rate? Stridor? Wheezing?
Eye Contact	Glassy stare? Fails to engage/focus?
Abuse	Unexplained bruising/injuries? Inappropriate parent?
Cry	High pitched, cephalic? Irritable?
Heat	High fever (>41°)? Hypothermia (36°)?
Immune System	Sickle cell? AIDS? Corticosteroids?
Level of Consciousness	Irritable? Lethargic? Pain only? Convulsing? Unresponsive?
Dehydration	Hollow eyes? Capillary refill? Cold hands, feet? Voiding? Severe diarrhea? Vomiting: projectile, bilious, persistent? Dry mucous membranes?
SAVE: Observations made prior to touching the child CHILD: History from caretaker and brief exam	

FIGURE 155–1. SAVE-a-CHILD triage system for recognition of the seriously ill pediatric patient.

implementing diagnostic/therapeutic measures and reassessing the patient. SOAPIE stands for subjective data (chief complaint); objective data such as vital signs; analysis of data, leading to assigning acuity; plan, or what is to be done; initiating diagnostic/therapeutic interventions per protocols and nursing practice; and evaluation, which indicates that triage is a dynamic process with constant evaluation and re-evaluation.

Triage interventions range from beginning diagnostic studies, such as radiologic studies and an electrocardiogram, to initiating therapeutic measures, including giving oral pain medications and antipyretics and applying dressings. Other triage measures include applying topical anesthetics to

wounds (to be sutured later) and to potential intravenous sites for children and infants who will likely need intravenous fluids and/or medications. Such treatment interventions in triage have been shown to decrease ED turnaround time, thereby improving ED flow. Triage-initiated protocols can expedite care and improve patient/family satisfaction.

Customer Service at Triage

Customer service has become an increasingly emphasized aspect of the provision of emergency medical care, and is especially pertinent to the care of children. Virtually every hospital in the country has some patient satisfaction tool, which is used to assess the patient's and family's perception of the care that they received in the ED. While the axiom "You never get a second chance to make a first impression" was not meant to specifically describe ED triage, it might well have been. Nearly 75% of patients presenting to the ED undergo triage, which is their first contact with the medical care system. For that reason, triage nurses and other personnel assisting in the process should be trained in the importance of delivering customer service excellence at the earliest appropriate time. Mayer and Cates have suggested that this comprises three elements³⁹:

- Making the customer service diagnosis as well as the clinical diagnosis
- Negotiating agreement and resolution of expectations
- Building moments of truth into the clinical encounter

By way of simple example, one of the most common clinical presentations in the pediatric and general ED is the child with fever. While the clinical diagnosis is often apparent, even at triage, the customer service diagnosis comprises the fear of more serious illness on the part of the parents and perhaps even the child. Addressing those concerns at triage by providing reassurance at the earliest time is an extremely important part of maximizing patient satisfaction. Similarly, the parent's expectations are often dramatically different from those of experienced health care providers, since the parents often are concerned that the child may have seizures, meningitis, or another life-threatening illness, whereas an experienced clinician may understand from simple observation of the child that these diagnoses are not likely. In order to assure that the best customer service is provided, negotiating these expectations is important, and can also begin at triage.

Finally, the concept of "moments of truth" was originally described by Jan Carlzon in a book of that same name. Carlzon pointed out that customer perceptions are usually not based on technical aspects, but rather comprise what he described as "50,000 Moments of Truth per day, created by the service provider himself."⁴⁰ Thus the institution is not assessed so much on the detailed provision of clinical care, but on the moments of truth provided by the nurses, physicians, technicians, and other ED personnel. For example, simple statements ("scripts") can be made, such as, "I have three children of my own, and I remember how concerned I was the first time one of them developed a fever in the middle of the night." Delivering excellent customer service and assuring patient satisfaction require the same proactive approach that one would apply to clinical guidelines or protocols. The customer service aspects of triage should be discussed among the providers of clinical care, so that such scripts and procedures can be proactively developed.

Newer Concepts of Triage

Virtually all EDs encounter times when they are severely capacity constrained. A number of creative process improvements have been made to help assure that triage functions expeditiously, even at times when there are a large number of patients to be seen. These include advanced triage/advanced initiatives (AT/AI), Team Triage and Treatment, triage bypass, Triage Away, and secondary triage. Each of these is designed to be used in various ways and addresses the substantial capacity constraint issues faced by many EDs, including both general and pediatric EDs.

AT/AI consists of a set of medically approved standing orders and initiatives that may be implemented at the triage area at times when rooms are not available in the treatment area. These include protocols for minor extremity trauma, urinary tract infections, abdominal pain, neutropenic patients with fever, and pretreatment of lacerations with topical anesthetic agents. Each of these protocols is discussed in advance between the medical and nursing staff of the ED, approved jointly, and implemented after training of the triage nurses.

Triage bypass is utilized at times when several patients have presented to triage, but there are adequate numbers of physicians, nurses, and support personnel in the treatment area to care for such patients in a timely fashion. Since these patients will be seen by the same ED staff in the same treatment areas, they bypass triage, are registered in the room, and are triaged and treated by the same nurses and physicians who will be caring for them. Because of the nature of patient flow and the fact that most EDs become capacity constrained by the mid-morning or afternoon hours, triage bypass is predominantly utilized during the early to mid-morning hours.

Team Triage and Treatment is a unique and innovative approach to dealing with capacity constraints by assigning an emergency physician (or physician assistant/nurse practitioner), nurse, technician, and, in some cases, registrar to the triage area at times when there are predictable delays in patient care due to the number of treatment rooms available. Following initial triage by the triage nurse, acutely ill or injured patients are sent directly back to the treatment area. Similarly, patients with minor (fast track) problems are sent to such an area. The remainder of the patients are then evaluated at the triage area by the team triage members. In a busy level I trauma center that sees over 80,000 patients per year, team triage is utilized approximately 8 hours per day and substantially decompresses patient waiting times, improves patient satisfaction, improves patient safety, and offers better access to care for patients (T. Mayer, personal communication, May 2005). These data indicate that one third of such patients are evaluated, treated, and have their treatment completed at the triage area, including patients with sufficient severity of abdominal pain to warrant an abdominal computed tomography scan. While this program requires an investment in resources, the reduction in patients left without treatment and the capacity for increasing volume more than offset the cost of the investment in the program.

Triage Away is a program used in some EDs that have chosen to evaluate patients at triage and, when it is determined that they have a minor illness or injury, simply triage them away to other facilities. In some communities such

programs can be effective; however, it does require a clearly specified primary health clinic or public health facility to which the patients can be safely and efficiently triaged. Such Triage Away programs are unusual, precisely because the safety net capacity of the ED is not backed up by such primary care or public health facilities in most communities.

Secondary triage refers to the combined effort of the emergency physicians and nurses to re-triage patients who are already in treatment rooms either to alternate rooms or to hallway spaces at times when their workup and treatment have not been completed, but additional patients are in need of treatment areas in which they can be evaluated. Emergency physicians and nurses should prospectively design protocols and procedures to assure that such secondary triage is safe, efficient, and in the patient's best interest.

Legal Considerations

According to the Consolidated Omnibus Budget Reconciliation Act passed in 1985, hospitals receiving Medicare funds are mandated to evaluate all patients who arrive in the ED and treat anyone with an emergent medical problem or any woman in active labor. In addition, any transferred patients must be stabilized and the receiving institution must have agreed to accept the patient. Under the Emergency Medical Treatment and Labor Act (EMTALA), patients can be transferred only when they need a higher level of care (or a service not provided at the institution at which they present) and only after an appropriate "screening" evaluation and stabilization (see Chapter 150, Emergency Medical Treatment and Labor Act [EMTALA]). It is inappropriate for a nurse or any other medical personnel to arbitrarily triage a patient to another facility. After an appropriate medical screening examination, usually by the responsible physician, it is possible that triage nurses, while following written protocols, could redirect patients to predesignated areas such as an outpatient clinic. However, precise documentation and pre-established written protocols are mandatory. Indeed, many experts recommend that a chart be generated for any patient presenting to the ED regardless of whether or not they are evaluated and treated.

Prehospital Triage

Field triage by Emergency Medical Services (EMS) personnel is the assessment of individual patients with the purpose of determining the most appropriate receiving facility. The development of trauma systems led to trauma triage in pre-hospital care. This is based on the principle that patients with life-threatening or serious multisystem injuries from trauma have a better outcome when transported directly to a facility staffed and equipped to provide resuscitation and definitive treatment. The aim is to send all seriously injured patients to a trauma center without overwhelming the resources of the trauma center by over-triaging. Occasionally a trauma patient may bypass the closest hospital to be transported directly to the trauma center. System-wide prehospital EMS trauma protocols provide guidelines to prehospital care providers for differentiating which trauma patient is transported to the trauma center or to the closest hospital for treatment.

With the advent of more sophisticated therapies and specialized hospitals, such as chest pain centers with around-the-clock cardiac catheterization capabilities or stroke centers capable of delivering organ/region-specific thrombolytics,

the expansion and increased importance of “prehospital” or “field” triage are likely.

Disaster Triage

A disaster is an event that exceeds the capabilities of the response (e.g., the need is greater than the resources), resulting in disruption of normal function.^{41,42} In order to more concisely describe and reflect the degree (or stage) of disaster, the Potential Injury Causing Event (PICE) nomenclature has been developed.⁴³

Triage during a disaster is different from ED triage. The purpose of ED triage is to identify critically ill patients and assure that they receive immediate resuscitation, while the principle of disaster management is to “do the most good for the most people.”⁴¹ It is possible during a disaster with limited response resources that, in order to maximize care for the majority of victims, some patients who have little or no chance of survival will not be resuscitated.⁴⁴ It is often a difficult concept for health care providers to ration resources and not expend efforts to resuscitate patients who are considered near death in order to save others. Comfort care should be provided to the dying patients when resources become available.

As with ED triage, there is no universally accepted standardized system for disaster or MCI triage, although several

triage systems have been suggested. One MCI/disaster triage tool is the Simple Triage and Rapid Treatment (START) technique.⁴⁵ This is based on a rapid assessment of respiration, perfusion, and mental status (RPM). Casualties who are ambulatory are asked to move away from the immediate area of the incident. These “walking wounded” are categorized as “green” or minor. The remaining patients are sorted into unsalvageable, immediate, and delayed (Fig. 155–2). If the patient has a patent airway and is breathing, by assessing the respiratory rate (>30 per minute or <30 per minute), the radial pulse (present or absent), and the mental status (follows commands: yes or no), the patient can be categorized. Unsalvageable patients are patients who are not breathing even after positioning their airway and are classified “black” or deceased. “Red” (immediate) patients have an immediate threat to life or limb but, if given immediate care, will probably survive. Examples include a patient with altered mental status, labored respirations, or shock. “Yellow” (delayed) patients have significant injuries but can probably tolerate a 45- to 60-minute wait without undue risk.

This color-coded four-category system is probably the most common disaster/MCI triage system in the United States. “Red” casualties are the first priority and are “most urgent.” Patients classified “Yellow” are the second priority and are “urgent.” “Green” patients comprise the “walking

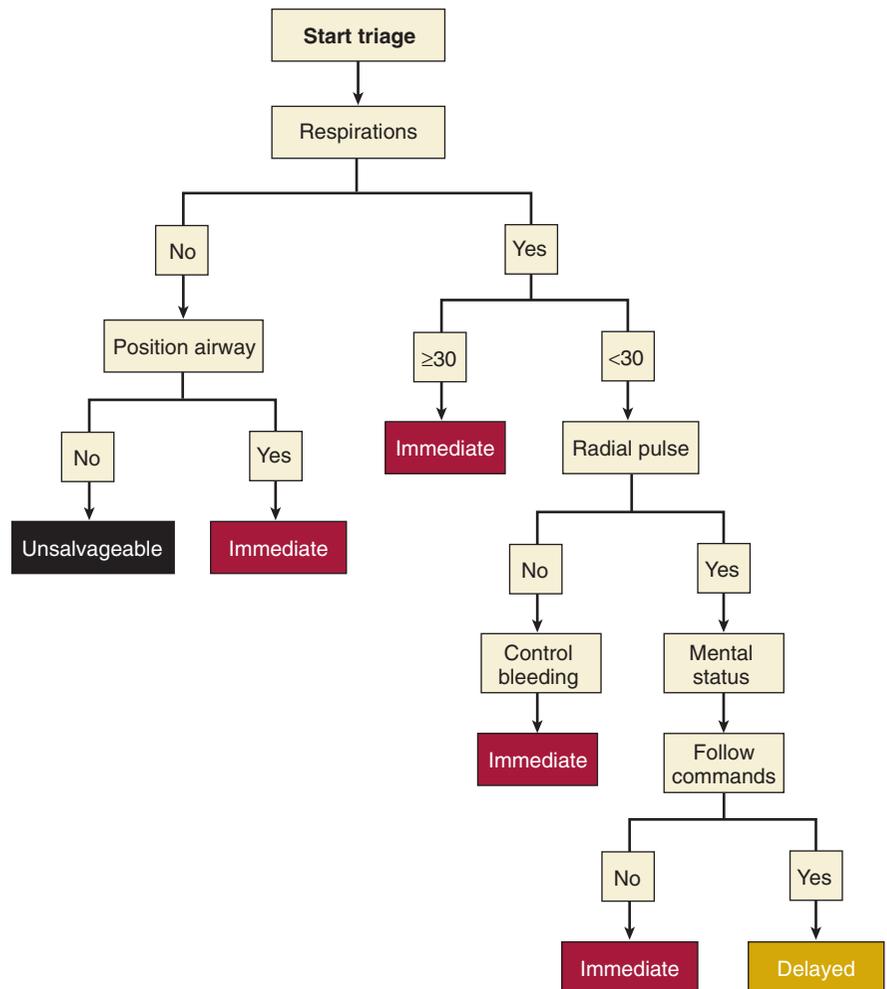

FIGURE 155–2. Simple Triage and Rapid Treatment (START) tool.

wounded” or “nonurgent” and are the third priority. Dead patients and catastrophically injured patients with a negligible chance of survival belong to the “Black” triage category.

The MASS triage model has been used by the U.S. military in order to quickly assign large numbers of casualties into treatment categories.⁴² MASS triage incorporates the processes of “move, access, sort, and send.” Patients are grouped into four categories based on the “ID-ME” mnemonic: “immediate, delayed, minimal, and expectant.”⁴² Minimal patients are stable patients with minor injuries, such as contusions and minor lacerations, whose medical care could be delayed for days without any untoward effect from the delay. At the disaster or MCI scene, the triage officer should request that “Everyone who can hear me [the triage officer] and needs medical attention should move to the area with the green flag.” This will separate out the ambulatory “minimal” group or walking wounded.

The “delayed” patients need definitive medical care but will quickly decompensate if their care is delayed initially. Patients with open fractures, deep lacerations with pulses/distal circulation, hemodynamically stable abdominal injuries, or stable head injuries belong to the “delayed” category. To sort this delayed group of patients after separating out the ambulatory walking wounded, the “MOVE” command is to ask the remaining casualties to raise a hand (or leg) so that they can be helped.

After separating out the “minimal” and “delayed” groups, the rescuers proceed immediately to those who are left. These patients are in the immediate or expectant categories. The immediate patients are patients with an obvious threat to life or limb. These casualties generally have a problem with the ABCs, such as shock, respiratory distress, altered mental status, or a severe abdominal, chest, or head injury. These patients often need immediate life-saving care. The expectant patients are patients near death who probably will not survive no matter what treatment is rendered. A patient in traumatic arrest, a patient with a penetrating chest wound in shock, or a trauma patient who is not breathing would be classified as “expectant” since they are near death and have a minimal chance of surviving.

The Secondary Assessment of Victim Endpoint (SAVE) triage system was developed to identify patients who have the greatest possibility of benefit from care delivered under austere field conditions.⁴⁶ SAVE is employed when patient transport to a definitive care facility is not available for days and treatment within the “golden hour” at a medical center is nonexistent.⁴⁵ The three patient groups according to the SAVE triage are: (1) patients who will die no matter what treatment is rendered, (2) patients destined to survive whether or not care is given, and (3) patients for whom significant benefit will be obtained from “austere field interventions.” Casualties who would benefit most from early evacuation (e.g., a patient with intra-abdominal hemorrhage) are designated as “first out.”

JumpSTART is a modification of the START disaster triage for pediatric patients ages 1 to 8 years⁴⁷ (Fig. 155–3) (see Chapter 152, Disaster Preparedness for Children).

Future of Triage

With the increasing ED volume and ED patient acuity in an era of diminishing resources, and the public’s demand for more rapid treatment along with governmental regulations

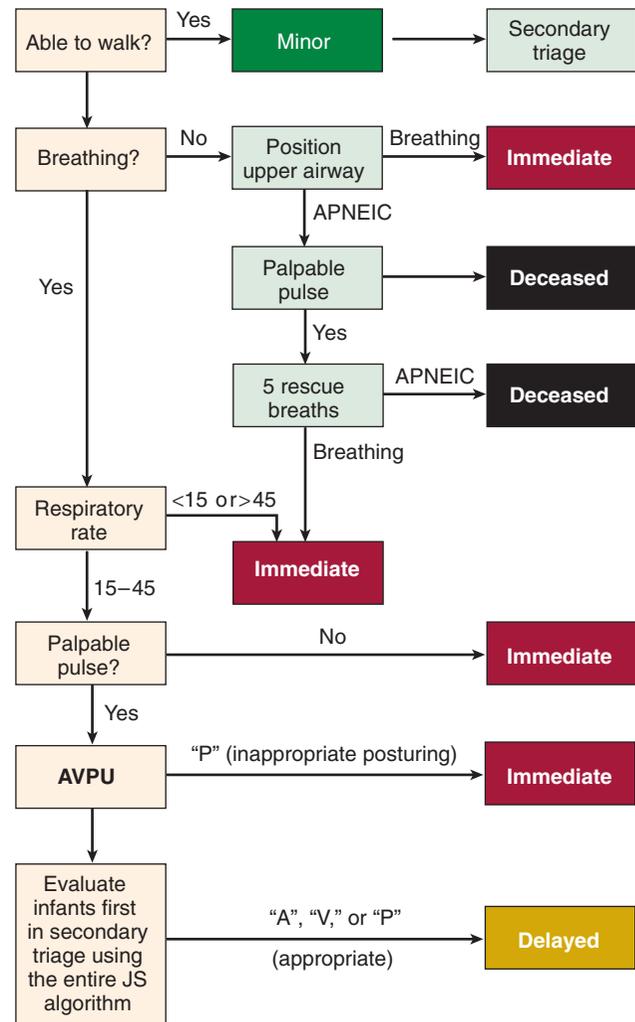

FIGURE 155–3. JumpSTART pediatric mass casualty incident triage. Abbreviations: AVPU, alert, responsive to voice, responsive to posturing, or unresponsive. (From Romig LE: Pediatric triage: a system to Jump START your triage of young patients at MCIs. *J Emerg Med Serv* 27(7):52–58, 60–63, 2002.)

and the focus on patient safety and quality, triage will be expected to perform an even more complex and important role in the future.^{48,49} Triage in the redesigned ED of the future will have new systems and processes and expanded technology to streamline patient flow. Current technology such as in-room registration and discharge by mobile patient registrars using laptop computers may be replaced by handheld devices. Registrars may not even need to be physically present in the room to interview patients but could use videoconferencing techniques. More elaborate instantaneous patient tracking systems are possible. Real-time communication via cell phones/walkie-talkies or microchip tracking technology will allow the triage nurse to instantly see and communicate with patients and families in the waiting room and other areas. Patient pagers can be distributed to patients and families (and to ED staff) to notify them of room availability, radiology, and other testing availability. Medical information, including medications, allergies, and past medical history, will be automatically available via computer, rather than manually entered, in a fashion that protects

patient confidentiality according to the Health Information Portability and Accountability Act. Individual patient data will be connected to patient data banks within and between hospitals so clinical information for purposes of research and new therapies as well as syndromic surveillance (for new diseases or bioterrorist threats) is available while maintaining individual patient confidentiality and patient rights.⁵⁰ The ED of the future will also incorporate the principles of family-centered care so that the ED provision of care occurs in a caring, comfortable environment attentive to the emotional, social, and cultural needs of patients and families. Such advances, however, are dependent on the necessary financial resources and continuing technological advances.

Summary

Triage is a critical and necessary component of ED care. Triage is essential for the early recognition of the seriously ill patient and rapid initiation of therapy, which reduces morbidity and mortality. Early initiation of therapy not only saves lives, but also decreases hospital and intensive care unit length of stay, and lowers morbidity, ultimately decreasing health care costs. An efficient triage can expedite patient care, improve ED flow, and increase patient and family satisfaction, thereby decreasing litigation, and, most importantly, improve patient care and outcome by rapidly initiating care to the seriously ill or injured.

Postexposure Prophylaxis

Esther H. Chen, MD

Key Points

Children and adolescents are most likely to acquire human immunodeficiency virus (HIV) through perinatal transmission, high-risk sexual contact, and needle sharing. Contact sports activities, human bites, or casual mucosal contacts generally have almost no risk of transmission.

Postexposure prophylaxis with a three-drug regimen (zidovudine, lamivudine, and nelfinavir) should be initiated for high-risk situations within 72 hours of the exposure and continued for 28 days, but only if counseling and follow-up with an infectious disease specialist can be ensured.

All health care providers are required to report new HIV seroconversions and acquired immunodeficiency syndrome cases.

Introduction and Background

Exposure to blood or body fluids prompts most people to seek immediate medical attention in an emergency department (ED). These exposures have an associated risk of hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV) transmission. However, because all children currently receive the HBV vaccine series (neonates born to hepatitis B surface antigen-positive mothers receive concurrent HBV immunoglobulin)¹ and prophylactic antiviral therapy has not been shown to be effective following HCV exposure,² postexposure prophylaxis (PEP) is reserved for secondary prevention against HIV. This chapter focuses primarily on the transmission risks of HIV in the pediatric population and discusses current available recommendations for pediatric PEP.

PEP is classified into occupational and nonoccupational exposures. Occupational exposures, defined as any percutaneous injury or contact of mucous membrane or nonintact skin with any blood, tissue, or body fluid that is potentially infectious, occur in health care workers (HCWs) and are managed using established public health guidelines.² In contrast, no established guidelines exist for nonoccupational

exposures (percutaneous penetration and mucous membrane and nonintact skin contact with potentially infectious body fluids, and sexual exposures [discrete penetrative acts involving vaginal, anal, penile, and/or oral contact]),³ although several states now have their own recommendations.^{4,5}

There are even fewer recommendations for adolescents and children except for the use of chemoprophylaxis to prevent perinatal and postnatal transmission.⁶ Antepartum use of zidovudine (ZDV) can decrease the HIV transmission rate from 25.5% (for infants receiving placebo) to 8.3%⁷; use of elective cesarean delivery further reduces the rate to 1.8%.⁸ Results from these clinical trials led to current recommendations that all pregnant HIV-infected women receive full clinical, immunologic, and virologic evaluation, with initiation of chemoprophylaxis after the first trimester.

Children and adolescents commonly present after non-occupational exposures, consisting of bite injuries, sexual assault, consensual unprotected sex, needle sharing, or unintentional needle sticks. In a recent study of PEP use in an urban ED, pediatric patients were more likely to present with a sexual exposure compared to adult non-HCWs (37% vs. 6%), with the majority caused by sexual abuse (71%).⁹ Rates of nonsexual exposures were similar in both pediatric and adult patients, with human bites occurring most frequently, followed by needle stick injuries and blood splashes. However, compared to adult non-HCWs, PEP was less likely to be initiated in adolescents and children for needle stick injuries (29% vs. 18%), blood and body fluid splashes (9% vs. 0%), and human bites (<1% vs. 0%).⁹

Issues

Determining the Risk of Transmission

A patient's risk of viral transmission depends on the probability that the source patient has HIV infection and that transmission of a sufficient amount of virus has occurred. The probability that the source patient has HIV may be determined directly from prior HIV testing or indirectly from assessing the patient's risk (i.e., medical history, intravenous drug use, sexual history). In contrast, the probability of viral transmission depends on the type and volume of source material, concentration and viability of virus in the source material, and mode of contact.

All body fluids are not equally infectious. Any blood or blood-contaminated body fluid from an HIV-infected person

Table 156–1 Transmission Risk by Exposure Type

Type of Exposure	Transmission Risk per Exposure	Exposure Risk Category	Suggested Approach
Perinatal exposure ⁷	25.5%	High	Recommend PEP
Cutaneous exposure: body fluid splash on intact skin ¹¹	Almost 0%	No risk	No PEP
Sexual contact			
Receptive anal intercourse ¹³	0.82%	High	Recommend PEP
Receptive vaginal intercourse ¹⁴	0.15%	Intermediate	Consider PEP
Insertive anal intercourse ¹³	0.06%	Intermediate	Consider PEP
Insertive vaginal intercourse ¹⁴	0.09%	Intermediate	Consider PEP
Mucous membrane exposure			
Kissing/oral-genital contact ¹¹	Almost 0%	No risk	No PEP
Breast-feeding ¹¹	0.004%	Low	Consider PEP
Percutaneous injury			
Scratch from discarded needle ¹¹	Almost 0%	No risk	No PEP
Needle sharing (injection drug use) ²¹	0.67%	High risk	Recommend PEP
Occupational needle stick injury ¹⁰	0.3%	Intermediate risk	Recommend PEP

has the highest risk of transmission. Less infectious materials include semen or vaginal secretions, body fluids (cerebrospinal, synovial, peritoneal, pericardial, amniotic), human milk, and unfixed body tissue. Least likely to be infectious are urine, feces, saliva, and vomitus.² Furthermore, exposure to a large volume of infectious material carries a greater risk of transmission than a small exposure. For example, the transmission risk of a percutaneous injury from a large hollow-bore needle is four times higher than from a solid suture needle.¹⁰

Another important determinant of transmission risk is the characteristic of the virus in the infected material, such as its concentration and viability. Percutaneous exposure to blood from a patient with a high viral load increases transmission risk by more than fivefold.¹⁰ Antiretroviral therapy use in these patients decreases their viral load, thereby decreasing their risk of transmission. This risk is further influenced by the viability of the virus in the infected fluid, which depends largely on its environment. HIV is susceptible to drying, so a needle immediately withdrawn from an infected patient would have a higher concentration of live virus than a contaminated syringe that had been discarded several hours earlier.¹⁰

A final consideration in determining transmission risk is the mode of contact. Blood transfusion carries the highest transmission risk, followed by perinatal transmission, breast-feeding, sexual exposure, percutaneous injury, and human bites¹¹ (Table 156–1).

Transmission Rates and Management by Type of Exposure

Cutaneous Exposure to Body Fluids

Cutaneous or mucous membrane exposure to body fluids usually carries a low risk of transmission. Kissing, body fluid splashes on intact skin, bites that causes no skin breaks, and close athletic contact in school are considered to have almost no risk of transmission.^{11,12} Oral-genital sex and body fluid splashes to the eye or mouth are also considered low-risk incidents. PEP is not recommended for these exposures.¹¹ Routine wound care should be administered, including flushing the exposed site with water or saline solution and administration of antibiotics and a tetanus booster.

Sexual Contact

Adolescents have the highest rate of HIV from sexual transmission of any group, particularly from sexual assault and rape (5 per 1000 adolescents annually).⁴ Even though there are established management guidelines for classic sexually transmitted illnesses (STIs) in sexual assault victims, they do not include use of PEP for HIV prevention.⁴ The risk of HIV transmission from sexual exposure varies significantly, according to the type and frequency of contact. In addition, the presence of a concurrent STI increases the risk of HIV acquisition. Receptive anal intercourse with a known HIV-infected partner has the highest per-contact risk of transmission (0.82%),¹³ followed by receptive vaginal intercourse (0.15%).^{13,14} Insertive vaginal and anal intercourse are lower risk activities, with transmission rates of 0.09%¹⁴ and 0.06%, respectively.¹³ Factors that increase transmission risk are local infection at the exposure site, presence of foreskin, use of an intrauterine device contraception, presence of cervical ectopy, genital tract trauma, active menstruation, and source patient's stage of HIV infection.¹⁵ Use of condoms and antiretroviral therapy significantly decreases infectivity.¹⁵

PEP use after sexual abuse is extrapolated from adult data, even though a pediatric exposure might result in a higher transmission rate because children often are repeatedly abused by the same person over a period of time. PEP should be considered for patients presenting within 72 hours of the exposure (although optimally within 4 hours), if the assailant has known HIV disease, and if the type of exposure is considered high risk (i.e., concurrent genital tissue injury, presence of STI, receptive anal intercourse).¹⁶ PEP is not recommended for patients participating in ongoing consensual sexual exposure to HIV.

Breast-feeding

Breast-feeding is a leading source of mother-to-child HIV transmission, with an overall risk of 16.2%, the majority of which (75%) occurs within 6 months of feeding.¹⁷ In addition, there is an associated increased risk of mortality in the mother.¹⁸ Assuming that an infant breast-feeds 6 to 10 times daily, his or her transmission risk is estimated to be 0.001% to 0.004% per episode.¹¹ Risk factors for transmission include longer duration of breast-feeding, maternal characteristics (e.g., higher parity, lower CD4⁺ count, higher blood viral

load, breast/nipple infections or lesions), infant characteristics (i.e., oral candidiasis), and milk characteristics (e.g., higher viral load).¹⁹ According to the American Academy of Pediatrics, HIV-infected mothers should avoid breast-feeding if replacement feeding is readily available.¹⁹ If replacement feedings are not available, interventions that decrease transmission include early weaning, decreasing viral load in the milk through antiretroviral therapy or breast milk pasteurization, treating breast infections, and treating infant oral candidiasis.¹⁹

The transmission risk after a single exposure to infected breast milk is magnitudes lower than that for other mucous membrane exposures, so PEP is not recommended (although it may be considered in high-risk situations).¹¹ Management after a single exposure includes flushing the infant's mucous membranes with water or saline solution.

Percutaneous Injury

Percutaneous exposures include not only accidental needle injuries, but also needle sharing and human bite wounds. HIV seroconversion from exposure to discarded needles has been reported in the pediatric population.¹² Adolescents, however, represent a unique group because new HIV cases are usually associated with injection drug use (including anabolic steroids) and associated risky sexual behavior. An estimated 14% of new HIV infections in teenage girls are caused by injection drug use.²⁰

The transmission risk is related to the severity of the injury, the initial concentration of HIV on the needle, and the time interval since the needle was in contact with the source patient. Factors associated with a higher risk of infectivity are deep wounds, presence of blood on the needle, hollow-bore needles, and needles recently in the source patient's vein or artery.¹¹ The risk of a puncture wound sustained from a discarded needle appears to be lower than that for an occupational needle stick injury, perinatal exposure, or blood transfusion.¹¹ However, needle sharing during injection drug use has a higher infection risk per injection compared to occupational percutaneous injury in HCWs (0.67%²¹ vs. 0.3%¹⁰).

The decision to initiate PEP depends on the risk of transmission through the wound. A superficial scratch with a discarded needle or body piercing is considered to have almost no risk, so PEP is not recommended. Injuries caused by discarded needles are also considered low risk, so PEP should not be initiated unless the needle or syringe has visible blood and the source is known to be HIV infected. Testing the syringe is low yield and not recommended. Cases of needle sharing during injection drug use should be treated with PEP, except for cases of repeated consensual contact.¹¹

Another percutaneous injury incurred by children is bite wounds. Although the HIV transmission risk of human bites is relatively low, cases of seroconversion have been reported in the literature, specifically in police officers and HCWs. A needle transmits 20 times more HIV-infected cells than a human bite.²² PEP is not recommended if blood is absent in the saliva and the bite wound. Even if there is potential blood exchange, transmission is still extremely rare. Large, deep, bloody wounds caused by an HIV-infected patient poses a greater risk, so PEP may be more strongly indicated.¹¹

All percutaneous exposure sites should also be thoroughly assessed for the presence of a potential foreign body or associated crush injury. Initial management includes washing thoroughly with soap and water, followed by irrigation with saline in the ED.²³

Mandatory Reporting for Seroconversion

Treatment of adolescents in the ED setting should follow state and local confidentiality laws.¹¹ Significant exposures (where PEP is initiated) used to be reported to the nonoccupational HIV PEP registry, which was completed and closed on October 31, 2004. All states require health care providers to report new cases of HIV infection and AIDS to the state health department. Although protocols vary by state, the majority place the responsibility on both the health care provider and the laboratory to report new cases.²⁴

Use of Antiretrovirals in Children

Because there are no studies to date that evaluate the effectiveness of PEP in reducing the transmission rate in nonoccupational exposures, the benefit of PEP is extrapolated from animal studies, PEP use in occupational settings, and perinatal studies.¹¹ A recent survey of ED health care providers showed that 68% have ever prescribed PEP, mostly for HCW needle stick injuries (92%), and only 19% have ever prescribed PEP for pediatric patients, mainly for sexual assault (69%) and needle stick injuries (31%).²⁵

PEP for perinatal exposure and occupational injury is now standard practice. There is growing evidence supporting PEP for sexual assault (with subsequent mucosal or cutaneous injury), significant needle stick injury with obvious mixing of blood, and needle sharing (during injection drug use). There are few contraindications. Absolute contraindications are known allergy to the medications and known HIV infection. Relative contraindications have been proposed in the literature, such as exposures with no likelihood of transmission and recurrent risky behavior.^{12,26}

Before treatment, draw baseline HIV, CBC, liver and renal function, β hCG and hepatitis B antibody titers. CBC, liver and renal tests will be repeated in 2 weeks and HIV in 6 and 12 weeks. If source patient is available, draw rapid HIV if such testing is available. Discontinue treatment of exposed individual if rapid HIV test is negative.

One approach to determine whether to initiate PEP in adolescents and children is shown in Figure 156–1. Once the decision to start PEP has been made, choosing the best regimen for nonoccupational exposures in children and adolescents may be difficult. Medications that might be considered are shown in Table 156–2. Even though monotherapy with ZDV has been extensively studied, triple therapy with ZDV, lamivudine, and nelfinavir is now thought to be more effective (although this is based primarily on the chemoprophylaxis guidelines for occupational exposures). Theoretically, using two nucleoside analogue reverse transcriptase inhibitors and a protease inhibitor should more effectively suppress viral replication than monotherapy or dual therapy.¹¹

PEP use in the pediatric group may be problematic for several reasons. Compliance with a three-drug combination therapy is very difficult. Recent data suggest that only 25% of patients were able to finish a 28-day regimen.²⁷ Reasons cited for this noncompliance were financial hardship, side

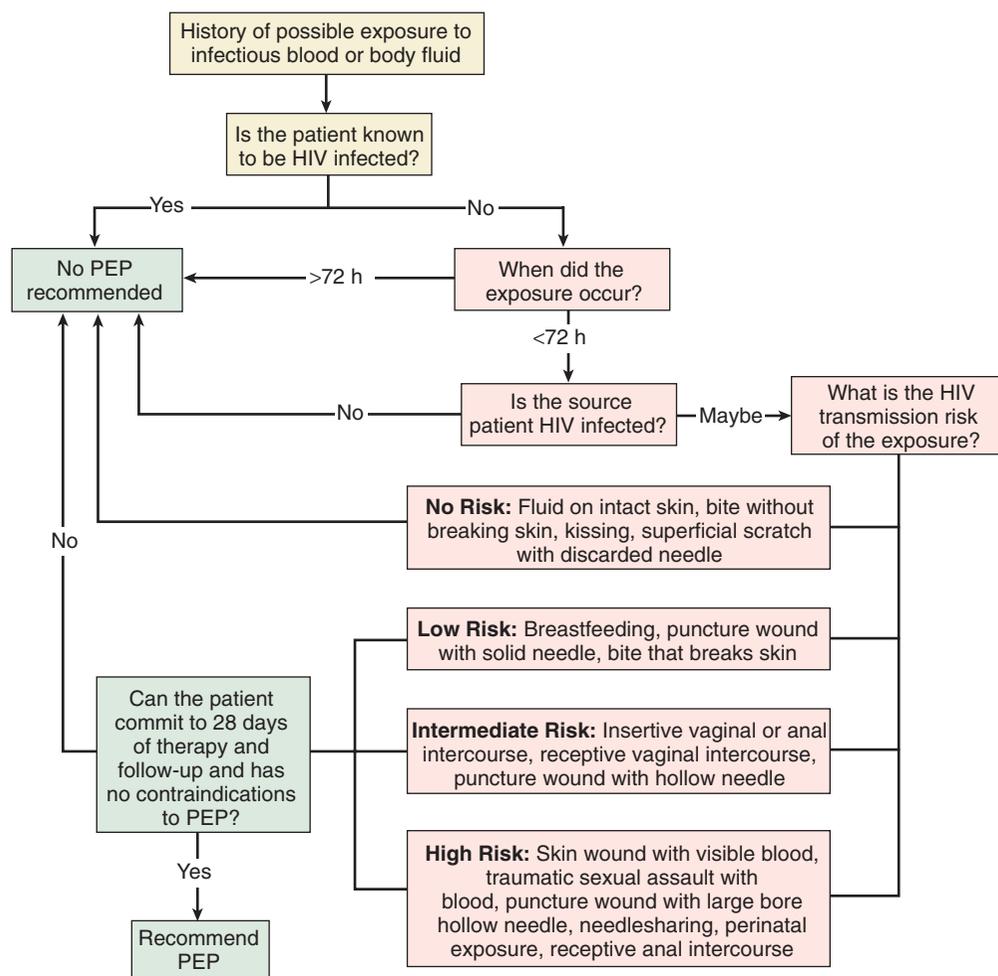

FIGURE 156-1. Decision algorithm: determining initiation of postexposure prophylaxis (PEP) for potential human immunodeficiency virus (HIV) exposures.^{11,12}

Table 156-2 Antiretroviral Medications Used for PEP^{11,12,28}

Medication	Pediatric Dosage	Major Side Effects
Nucleoside Reverse Transcriptase Inhibitors		
First-Line Therapy		
Zidovudine (ZDV, AZT, Retrovir)	Birth-4 wk: 1-2 mg/kg/dose IV q12h 4 wk-12 yr: 160 mg/m ² /dose PO q8h >13 yr-adult: 200 mg q8h or 300 mg PO q12h	Granulocytopenia, lactic acidosis, steatosis
Lamivudine (EpiVir, 3TC)	Birth-4 wk: 2 mg/kg/dose q12h <50 kg: 4 mg/kg/dose q12h ≥50 kg: 150 mg/dose q12h or 300 mg q24h	Pancreatitis, peripheral neuropathy, steatosis
Alternatives		
Abacavir (Ziagen, ABC)	Birth-3 mo: not recommended 3 mo-16 yr: 8 mg/kg/dose q12h >16 yr: 300 mg/dose q12h	Fatal hypersensitivity reaction
Didanosine (Videx, DDI, dideoxyinosine)	1-3 mo: 50 mg/m ² /dose q12h 3 mo-12 yr: 90-150 mg/m ² /dose q12h >13 yr: <60 kg, 125 mg q12h ≥60 kg, 200 mg q12h	Severe hepatomegaly
Stavudine (Zerit, d4T)	<30 kg: 1 mg/kg/dose q12h 30-60 kg: 30 mg q12h >60 kg: 40 mg q12h	Severe hepatomegaly
Protease Inhibitor		
Indinavir (Crixivan, IDV)	Neonates: not recommended Pediatric: 500 mg/m ² /dose q8h Adult: 800 mg/m ² /dose q8h	Hyperbilirubinemia, nephrolithiasis
Nelfinavir (Viracept, NPV)	1 mo-12 yr: 20-30 mg q8h ≥13 yr: 750-1250 mg q12h	Spontaneous bleeding, hypoglycemia, ketoacidosis
Ritonavir (Norvir, RTV)	3 mo-12 yr: 400 mg/m ² /dose q12h ≥13 yr: 600 mg q12h	Spontaneous bleeding, hypoglycemia, ketoacidosis

Combivir = ZDV 300 mg + EpiVir 150 mg.

Most cases will require a 2 drug regimen, seven cases may require 3 drugs; consult with pediatric infectious disease expert for specific recommendations.

Abbreviations: IV, intravenously; PO, orally.

effects, and admission or transfer to another health care facility.²⁷ Therefore, in patients for whom compliance might be an issue, a two-drug regimen might be a more reasonable option.¹³ Moreover, fewer medications may mean fewer associated side effects, which are commonly reported to be nausea, vomiting, and abdominal pain.²⁷ More serious side effects are listed in Table 156–2. Symptoms usually resolve after medications are discontinued.

The safety profile of these drugs has not been extensively studied in children. Abacavir sulfate potentially causes severe hypersensitivity reactions. Indinavir may be associated with nephrolithiasis, and therefore requires extra hydration and should be avoided in children. Liquid amprenavir contains propylene glycol in concentrations that might be toxic for infants and are not recommended for children under 4 years old. Nevirapine has been associated with life-threatening hepatotoxicity and should also be avoided.

Solutions

Health care professionals should not manage potentially exposed patients without consulting an infectious disease specialist familiar with using these medications in the pediatric population. EDs should have clear, easy-to-use protocols for PEP use in both adult and pediatric patients and provide “starter kits” of 3 days of medications for immediate initiation of therapy. Follow-up in these patients is especially important to ensure compliance, schedule repeated HIV testing, monitor toxicity, and provide psychological counseling. Referral to specialists in HIV care is paramount to ensuring adequate follow-up clinical care.

The dearth of standardized guidelines for PEP use in children has spawned a flurry of initiatives by the American Academy of Pediatrics and several states to make practical recommendations for clinicians. The University of California–San Francisco has a hotline (1-888-HIV-4911) supported by the Centers for Disease Control and Prevention that is staffed 24 hours a day to answer questions and provide guidance.¹² Data collected from the nonoccupational HIV PEP registry should lead to national guidelines in the near future.

Summary

Children and adolescents may be exposed to HIV-infected blood or body fluids through perinatal transmission, breastfeeding, sexual contact, injection drug use, and human bites. High-risk sexual behaviors are the leading cause of seroconversion in adolescents. PEP with dual or triple combination therapy may be initiated for high-risk exposures, such as perinatal exposure, sexual contact with mucosal injury or concurrent STI, and injection drug use, and continued for 28 days. Follow-up counseling and monitoring of side effects should be provided by infectious disease specialists. More studies on the efficacy and safety profiles of these medications in children will enable standardized guidelines to be developed and implemented.

Interpersonal and Intimate Partner Violence

Joel A. Fein, MD, MPH and Megan H. Bair-Merritt, MD, MSCE

Key Points

Children can be exposed to and be victims of violence in homes, in schools, and on the streets; many who experience violence in one setting also experience it in another.

The emergency department clinician should perform a safety and risk assessment of violently injured patients.

The American Academy of Pediatrics recommends that pediatric practitioners routinely screen for intimate partner violence (IPV).

Child abuse and IPV co-occur in 30% to 70% of families.

Introduction and Background

Youth violence is defined as any intentional assault on another person by one or more young people ages 12 to 19 years. Although the emergency practitioner is most often confronted with patients who have physical injuries after an assault, the broad definition of youth violence also includes emotional and psychological violence. Youth violence is unfortunately part of many American children's routine daily activities. Despite an overall decrease in firearm mortality in the past decade, the prevalence and severity of this problem in American adolescents remains high, especially in impoverished areas. Age-adjusted rates of assault-related trauma for 10- to 19-year-olds were 5 per 100,000 deaths and 1035 per 100,000 nonfatal injuries in 2002.¹ Although advances in trauma care may reduce mortality, the level of self-reported violent behaviors by adolescents and young adults has not declined.²

When faced with a patient who is injured through community violence, emergency physicians can either "treat or street," or can "screen and intervene." In order to accomplish the latter, the clinician must recognize the injury mecha-

nism, assess the youth's risk factors for violent injury, and implement interventions or referrals on his or her behalf.

Exposure to intimate partner violence (IPV) is an equally common and damaging life experience for children. Every year in the United States, between 2 and 4 million women are abused by an intimate partner.³ Children are overrepresented in homes in which this occurs. In particular, families with current IPV are significantly more likely than families without IPV to have children less than 5 years of age living in the home.⁴ Current literature cites that between 3.3 and 10 million children witness IPV each year.⁵⁻⁹ These numbers are extrapolated from population-based surveys,¹⁰ and are potentially an underestimate of the overall prevalence. One cross-sectional survey conducted with a convenience sample of mothers in an urban pediatric emergency department (ED) determined that 32% of women had been physically abused by a spouse or boyfriend over their lifetime, and 9% had been physically abused by a spouse or boyfriend within the past year.¹¹ The authors of this study theorized that abused women preferentially select ED care for their children secondary to the availability of 24-hour service and to the perceived anonymity of this environment.

Children who are exposed to IPV are at increased risk for poor mental, behavioral, and physical health outcomes. For example, children in homes with IPV are more likely than their peers to be depressed, to have anxiety disorders, to suffer from posttraumatic stress disorder, and to become involved in risky behaviors, such as alcohol and drug abuse, during adolescence.¹²⁻¹⁴ The physical health consequences have been somewhat less clearly delineated. However, a large, retrospective cohort study has suggested an independent association between childhood IPV exposure and a variety of poor physical health outcomes in adulthood.¹⁵⁻¹⁹ Additionally, multiple studies have cited a large overlap between child abuse and IPV, with the co-occurrence of both forms of violence 30% to 70% of the time.²⁰⁻²² Recognizing the scale and the impact of childhood exposure to IPV, the American Academy of Pediatrics (AAP) established guidelines in 1998 entitled "The Role of the Pediatrician in Recognizing and Intervening on Behalf of Abused Women." In these guidelines, the AAP stated, "identifying and intervening on behalf of battered women may be one of the most effective means

of preventing child abuse.²⁶ They recommend routine screening for IPV in the pediatric setting.

Issues

Most ED clinicians believe that they can recognize violent injury, and feel comfortable referring to a social worker, chaplain, or other external resource.^{23,24} However, many clinicians report that they do not fully assess safety and risk factors in violently injured patients.²⁴

Although male gender is a consistently reported single risk factor for violent injury, both genders are at risk for youth violence.²⁵ Males and females may, however, present to the ED with different stories and physical complaints. Girls who come to the ED with nonfatal injuries are more likely than males to suffer a contusion or human bite injury rather than a gunshot wound or laceration.²⁶ Younger girls (under 14) are more likely than boys to be injured in or around the home, and to have had a previous fight with the other person(s) involved.²⁷ Although most patients are forthcoming with the details of their violence-related injuries, some will not admit to the nature of their injuries. For example, one can assume that, if the patient is involved in illegal activities, or is in an intimate relationship with the offender, he or she could be less likely to disclose the full story. As discussed later, an appropriate safety assessment relies on the details of the actual injury-related events.

The violently injured patient may exhibit a range of emotional responses, such as anger, sadness, or apparent indifference. Younger children are often just as frightened about the impact of their injuries as they are about the manner in which they were incurred. It is known that violently injured youth are at risk for developing posttraumatic stress symptoms after the event, although there is significant variability in the expression of these symptoms.^{28,29} Traumatic stress symptoms include reexperiencing the event, avoidance, hyperarousal, and dissociation. Most patients experience relief of these symptoms over weeks to months.

Screening for IPV

Just as assessing safety and risk factors in violently injured patients can assist in recognizing traumatic stress symptoms and in providing comprehensive care, screening for IPV in the patient's caregiver may improve the ED provider's understanding of the child's current illness, home environment, and ability to follow physician recommendations. In addition to the AAP recommendations for routine IPV screening, the American College of Emergency Physicians, the Joint Commission on Accreditation of Healthcare Organizations, and the American Medical Association all have policies or statements advocating routine screening of women. However, in 2004, the United States Preventive Services Taskforce (USPSTF) published guidelines stating that insufficient evidence exists to recommend either for or against routine IPV screening.³⁰ Critiques of these guidelines include the following: 1) the concept of a "screening" test for IPV had been misapplied, and asking about IPV should instead be viewed as a routine behavioral health inquiry; 2) benefits of screening may extend beyond simply decreasing violent episodes, and these should be considered in evaluating the merits of screening; and 3) IPV is a complex issue, and qualitative research or studies outside of the traditional medical litera-

ture should be considered.³¹⁻³³ Benefits and risks for children related to screening mothers for IPV therefore remain uninvestigated.

With the neutral position on screening from the USPSTF, the evidence-based clinician is left in somewhat of a quandary. Alternatives to routine screening include not screening at all or performing targeted screening. In the pediatric setting, targeted screening would naturally include children in whom concern exists for child abuse and neglect. However, with a targeted approach, many female victims of IPV will not be identified. As a general rule, inquiring about IPV provides important data about behavioral risk factors. Importantly, women generally support routine IPV screening in the pediatric setting.⁵

In considering screening, decisions must be made by the institution and by the provider about what method will be used (face-to-face, pen and paper survey, computer/technology-assisted questionnaire), and what questions will be asked. Numerous methods have been tested and compared and each has advantages and disadvantages, with no clear consensus regarding which is preferred.³⁴⁻³⁶ With face-to-face screening, women appear to be equally comfortable with physician and nurse screening, but are less at ease when screening is performed in triage.³⁷

Numerous sets of screening questions have been studied for appropriateness and effectiveness in the adult ED setting.^{38,39} One of the more commonly used screens is the three-question Partner Violence Screen described by Feldhaus et al.⁴⁰ (Table 157-1). The efficacy of specific screening questions for female caregivers in a pediatric ED has not been studied.

In the pediatric setting, concern has been raised about performing direct screening in the presence of children over the age of 3.³⁴ In a qualitative study of former abuse victims, Zink and Jacobson detailed women's concern that screening in front of older children may lead the children to inadvertently relay the conversation to the abuser, thereby potentially increasing abuse.³⁴ When an older child is present, Zink and Jacobson suggested that providers attempt to separate the caregiver and child. If this cannot occur, they suggested that the provider ask general questions such as "Do you feel safe in your current relationship?" and "In general, how would you describe your relationship: a lot of tension, some tension, or no tension?" If there is continued concern based upon the response or the reaction to these questions, the provider should attempt to interview the woman alone to pursue more specific questions.

A second controversy relevant to screening for IPV in the pediatric ED setting is documentation. Unlike in the adult

Table 157-1 Partner Violence Screen

1. Have you been hit, kicked, punched, or otherwise hurt by someone within the past year? If so, by whom?
2. Do you feel safe in your current relationship?
3. Is there a partner from a previous relationship who is making you feel unsafe now?

Adapted from Feldhaus K, Koziol-McLain J, Amsbury H, et al: Accuracy of 3 brief screening questions for detecting partner violence in the emergency department. *JAMA* 277:1357-1361, 1997.

ED, where providers are directly screening their patients and the chart reflects care for the female adult patient, in the pediatric setting, the child is the patient and both legal guardians can access the medical record. If the perpetrator is the child's father, he has access to the chart and could become aware of the IPV conversation, thereby potentially increasing the risk of violence. In contrast, it may be legally beneficial to document the abuse in case the victim requires this information in court. While the risks of documentation are more theoretical than evidence based, it is important to discuss the risks and benefits of documentation with the victim, and abide by her wishes.

When a patient's caregiver discloses IPV in the ED setting, the response should entail the following: (1) a statement supporting the woman for her disclosure, and emphasizing that the abuse is not her fault and that she does not deserve to be treated that way; (2) an assessment of the woman's and child's current safety (including questions about escalation of violence and weapons) and comfort going home; (3) careful questioning and examination for child abuse and injury to the child or children; (4) the offer of social work and/or national and local IPV resources; and (5) safety planning, as needed.³⁹

Mandated Reporting

As evidenced by the aforementioned dilemmas about screening and documentation, screening for IPV in a pediatric setting poses unique challenges. One of the important issues to consider and to discuss is mandated reporting. Pediatric providers are obligated to report to child protective services any concern for child abuse or neglect, or concern that the child is in a situation of imminent danger (see Chapter 119, Physical Abuse and Child Neglect). With any disclosure of IPV, a careful assessment of the child's well-being and safety is essential. While adult health care providers may be mandated reporters of IPV, pediatric providers generally are not responsible for reporting injury to the child's mother when the practitioner is not actually providing medical care to the woman.³⁹

Currently, some states have mandated reporting laws for childhood exposure to IPV. Staying current with requirements for reporting is essential. If practicing in a state *with* mandated reporting laws for childhood exposure to IPV, your response should include the following: (1) inform the mother of your responsibility to report, (2) encourage the mother to also file a report herself (which often lessens later accusations of "failure to protect"), (3) provide child protective services with all relevant information, and (4) ensure that the safety needs of the mother are met.³⁹ If practicing in a state with less specific reporting laws, consider each situation individually to determine what is best for that child and mother.

While proponents of mandated reporting state that it is justified secondary to the negative sequelae of childhood exposure to IPV, many in the field of IPV are concerned about such requirements. Apprehension about mandated reporting for exposure stems from fear that reporting is punitive to the victim, implying that she failed to protect the child. Universal reporting also incorrectly assumes that all children are affected in the same way by IPV exposure, and may increase demands on an already overburdened child protective services system. There are also concerns that man-

dated reporting decreases women's likelihood of disclosing and seeking help.³⁹

Solutions

There are no easy solutions for preventing violence in the lives of children and adolescents. For the individual patient who presents to the ED, the standard of care is to address patient safety and emotional needs. It is crucial to recognize the mindset of some urban youth regarding the role of violence in settling conflicts and to understand what sociologic phenomena govern many inner-city interactions and behaviors.⁴¹

For the adolescent patient, the clinician should clarify any issues of confidentiality before interviewing the patient about sensitive topics, such as emotions, safety, and sexuality. Specifically, the practitioner could state: "Our conversation will remain private unless you tell me something that makes me believe that you or someone else will suffer serious harm." This short statement helps to establish trust on which the clinician can perform a brief risk assessment and develop a safety plan with the youth. At all costs, the clinician should avoid the perception that he or she is blaming the youth for his or her situation. This will invariably destroy the trust that is required to gather important information, and will sabotage potential interventions on the part of the health care system.

The ED clinician should assess the immediate safety issues related to the violent event, asking questions regarding the patient's safety concerns, his or her relationship with the other involved persons, and if the incident was reported to the police or other authorities. Intuitively, if the other involved person is a complete stranger, as in a robbery incident, the potential for retaliation seems less. Likewise, it seems unlikely that a juvenile who reports an incident to the police would incite a retaliation event. Mandatory reporting of gunshot wounds is a controversial topic and varies by jurisdiction; it is prudent to know the laws and regulations in your practice setting.⁴²⁻⁴⁴

If the patient knows the other involved person(s), the ED clinician should ask directly if he or she thinks that the argument or fight is over and will remain so. It is important to assess any ongoing rivalries that could lead to further injury. This line of questioning should include asking about friends or family members who may plan to retaliate. To assess overall safety concerns, the clinician can ask the simple question, "Will you feel safe when you leave today?" If needed, strategies for safety planning can then be made in conjunction with social workers, police, or other community resources. This may also be an opportune time to assess and counsel about weapon carrying and use.

Many violently injured patients will experience emotional and psychological ramifications, irrespective of injury severity. Family and patient education about the signs and symptoms of posttraumatic stress provide support to the patient. Information about posttraumatic stress disorder is available through various national organizations such as the National Child Traumatic Stress Network (<http://www.nctsn.net>), the International Society for Traumatic Stress Studies (<http://www.istss.org>), and the National Center for Post-Traumatic Stress Disorder (<http://www.ncptsd.org>).

Although a safety and risk analysis is within the domain of ED care, interventions for violence are often more aptly

situated in the patient's community. It may be helpful to share any concerns with the patient's primary care provider, and encourage the family to involve the patient's school counselors, if applicable. Hospital social workers may be helpful in linking the patient with school-based or community-based organizations that range from after-school programs, external support programs (such as Big Brother/Big Sister), or Rites of Passage programs. In some areas, community organizations such as the Police Athletic League and Boys' and Girls' Clubs have specific programs for troubled youth.⁴⁵ Older adolescents may benefit from job training and placement programs, General Education Development services, and alcohol or drug rehabilitation services. It is not possible, or even necessary, to link all violently injured patients with a community-based intervention. However, safety assessment, risk factor analysis, and intuition will identify the most concerning patients. A well-suited referral can alter the trajectory of a few youth who otherwise may present to the ED time and time again with violence-related injury.

Children who are not obviously injured may still have significant violence exposure risks, including exposure to IPV. Ideally, every ED should develop a protocol surrounding IPV identification, documentation, and management. Development of this protocol should include input from physicians, nurses, social workers, and IPV advocates. Potential solutions for issues about screening in front of children include providing a pen-and-paper or computer-based questionnaire, or starting with more general safety questions and pursuing more specific IPV questions with the woman alone if concerned. A code known by members of the department, but not otherwise obvious, can be created for IPV documentation. For management, each department should consider state laws as well as available resources. In the absence of a departmental protocol, providers must make a personal decision about when and how to screen for IPV in the pediatric ED. At a minimum, one should be aware of the high co-occurrence of IPV with child abuse. Additionally, ready access to IPV resources such as posters and numbers with IPV hotlines can provide an essential service for women in abusive relationships.

Additional information can be obtained through reading the AAP clinical guidelines, or through contact with the Family Violence Prevention Fund, whose publications include "Identifying and Responding to Domestic Violence: Consensus Recommendations for Child and Adolescent Health" (<http://www.endabuse.org>).^{6,39}

Summary

Consideration of both youth and family violence is essential when treating children. Youth violence is a public health problem that permeates most EDs. The multifactorial nature of violence should not dissuade ED practitioners from performing a safety and risk assessment for violently injured patients, or from attempting to link patients and families with social and emotional support resources. IPV is prevalent and is frequently comorbid with child abuse, and exposure to IPV may lead to poor mental, behavioral, and physical health outcomes in children. After IPV is disclosed, an empathetic response may be an intervention in and of itself. A careful assessment of the child's and the caregiver's safety and an offer of resources are of utmost importance. Practi-

tioners should be aware of state laws with regard to mandated reporting of IPV exposure.

Chapter 158

Approach to Pain Management

Kelly D. Young, MD, MS

Key Points

Pain management in the emergency department (ED) is increasingly recognized as an important topic: in clinical practice, in the research literature, and among accrediting organizations.

Pain needs to be assessed, managed, and reassessed routinely in the ED. Achieving this goal requires a multidisciplinary approach.

Successful pain management includes both pharmacologic and nonpharmacologic techniques, as well as modifications to the ED environment and “culture.”

Introduction and Background

Pain is often inadequately assessed and addressed in emergency departments (EDs), and this is especially true for pediatric patients.¹ As recently as a few decades ago, the myth that young children did not feel pain was widely believed. Since then, there has been a burst of literature on the pediatric pain experience, but a gap remains between knowledge and clinical practice.^{2,3} Nevertheless, improved pain management is increasingly recognized as an important goal. Congress has declared the current decade as the “Decade of Pain Control and Research” as of 2001.⁴ The Joint Commission, formally known as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has also set standards for pain assessment and management.⁵ Research has shown that, in addition to acute pain itself, other consequences of undertreated pain include decreased parent and patient satisfaction, adverse effects such as hypoxemia and poor healing, and possible long-term effects such as increased risk for chronic pain syndromes, decreased pain tolerance, and avoidance of medical care.^{1,6} Consequences to staff include stress and career dissatisfaction from having to inflict pain on children during procedures.

Issues and Barriers

Perpetuation of several myths regarding the pediatric pain experience and available treatments has been a barrier to

improved pain management.⁷ Young children cannot self-report their pain, and ED practitioners are often less comfortable with pediatric medication dosages, and may be more wary of potential adverse effects. Whereas adult patients who are dissatisfied with pain management can complain, and such complaints are likely to result in changes in practice, children require adult advocates. Parents focused on diagnosis and management of the primary condition (e.g., otitis media) may be satisfied with an antibiotic prescription, while the child’s related pain goes untreated. Parents recalling procedures performed on themselves when they were children may not realize that advances in procedural pain and anxiety management exist.

The ED environment is busy and chaotic and has a constantly changing staff. ED flow is an important factor in clinicians’ decision making and practice. Overcoming these barriers requires a multidisciplinary team, composed of physicians, nurses, child life specialists if available, pharmacists, and any other interested parties, to work together to educate health care workers, create pain management policies that do not significantly interfere with ED flow, perform quality improvement projects, and work toward a change in the “culture” of the ED to emphasize good pain management.^{1,8} Table 158–1 outlines some of the major barriers to adequate pain management in the pediatric ED.

Parental presence during pediatric procedures is an increasingly discussed topic (see Chapter 153: Family Presence). While evidence on whether parental presence actually results in lower child self-reported pain scores, pain behaviors, and anxiety is mixed, it is clear that children prefer to have their parents present.⁹ Health care workers are often uncomfortable with parental presence, citing concerns about interference and decreased procedural success. These concerns are not evidence based. Each unique situation should be assessed depending on the individual parent and child’s preference, but an overall policy of allowing parental presence is recommended.^{1,6}

Solutions

The greatest barriers to adequate pain management in health care systems are lack of support from administration, lack of coordination of improvement efforts, and lack of accountability.⁵ The Joint Commission has set standards related to pain management as of 2001 (Table 158–2).⁵ Increased regulatory scrutiny should provide the impetus for strong

Table 158–1 Ten Barriers to Adequate Pediatric Pain Management in the Emergency Department (ED)

1. Belief that children do not feel pain, or that pain is a beneficial “life lesson” of childhood
2. Difficulty in assessing pain in children
3. Myth that pain medication use (especially opiates) will result in addiction, or carries an exceptionally high risk of adverse effects in children
4. Concern that ED flow will be slowed considerably by using pain management methods
5. Lack of health care worker knowledge of effective pain management techniques, especially nonpharmacologic techniques
6. Belief that children prefer “one needle” to the two needles required for local anesthetic injection, and belief that rapid completion of the procedure, using forceful restraint if necessary, is less stressful than prolonging the procedure for use of pain management techniques
7. Staff and parents more focused on diagnosis and management of primary condition and/or believe that pain treatment will interfere with diagnosis
8. Staff uncomfortable with parental presence during pediatric procedures
9. Lack of coordination between various health care workers in efforts to reduce pain
10. Lack of health care provider accountability and feedback regarding pain management practices

Table 158–2 Joint Commission Standards

1. Recognize the right of patients to appropriate assessment and treatment of pain.
2. Assess the presence, intensity, and nature of pain in all patients.
3. Record the results of the assessment such that regular reassessment is promoted.
4. Evaluate and establish staff competency in pain assessment and management.
5. Establish policies that support appropriate prescription and recommendation of pain medications.
6. Ensure that pain does not interfere with patients’ ability to participate in rehabilitation.
7. Educate patients and their families about effective pain management and its significance.
8. Address patient needs for pain management in the discharge planning process.
9. Incorporate pain management into quality performance activities and assessments.

Adapted from National Pharmaceutical Council, Inc: Pain: Current Understanding of Assessment, Management, and Treatments [monograph]. Available at <http://www.jcaho.org/news+room/health+care+issues/pm+monographs.htm> (accessed January 19, 2005).

institutional commitment to focus on pain management. Thus the first step is to establish institutional pain management standards and to empower a pain management “czar” and/or multidisciplinary pain management team to work toward meeting these standards.

Education of health care workers to improve pain assessment is one important goal for the pain management team. Many methods for pediatric pain assessment exist, broadly categorized as self-report, behavioral measures, and physiologic measures^{6,10} (Table 158–3). Self-report is considered the “gold standard,” but children younger than 3 years are generally not able to differentiate levels of pain. Behavioral

measures, looking at such factors as facial expression, torso movements, resistance, and crying, may be used in young children and noncommunicating developmentally delayed children. Physiologic measures should be used as corroborative evidence only. The pain management team should review available measures, choose one appropriate measure for each age group or patient type, educate all health care workers on using the selected methods, and make the assessment tools widely available in the triage and patient care areas. Redesign of patient care triage forms and computer entry interfaces to include routine pain assessment may improve the frequency of pain assessment.⁸

Both pharmacologic and nonpharmacologic pain management methods exist. Health care providers may be unfamiliar with pediatric dosing for pain medications, or may be overly concerned about potential adverse effects. The pain management team can provide pocket card references of commonly used pain medications^{5,11,12} (Table 158–4); education regarding the incidence, prevention, and treatment of potential adverse effects; and follow-up data on the actual occurrence of any significant adverse effects seen in the ED. Nurse-driven standing-order protocols allowing pain medication administration in triage will improve the rapidity with which pain relief is provided.¹³

The World Health Organization developed a three-step Pain Relief Ladder for management of cancer pain; the concepts behind this ladder are also applicable in the ED setting.¹⁴ Using the ladder, a nonopiate is first given for mild to moderate pain. If pain persists, a weak opiate is added. If pain continues to persist, a stronger opiate is given. Adjunctives such as muscle relaxants, antianxiety agents, anticonvulsants or antidepressants for chronic neuropathic pain, and nonpharmacologic methods can be added. For severe pain, the clinician may choose to start higher on the ladder and give an opiate immediately. Treatment should be multimodal, given preemptively when pain is expected (e.g., for a procedure), and given around the clock rather than on an as-needed basis (to avoid a cycle of breakthrough pain due to undermedication, then overmedication, then breakthrough pain again).

Health care providers may be unfamiliar with the adjunctives, topical agents, and nonpharmacologic methods available (Table 158–5).¹⁶ The literature strongly supports decreased pain for minor needle procedures with use of topical anesthetics.^{15,16} Studies have demonstrated the efficacy of pretreatment of lacerations with topical anesthetics at triage,^{17–19} and the ability of triage nurses to predict the need for intravenous cannulation and thus place topical anesthetic at triage.²⁰ In this study, the majority of intravenous cannulations were performed more than 60 minutes after triage, allowing for full efficacy of topical anesthetics. Orally administered sucrose, 2 ml of a 24% to 30% solution given 2 minutes prior to the procedure and/or during the procedure, is an effective pain reducer in neonates.²¹ Commercial solutions are available, or the pharmacy may prepare them. One group reports mixing a standard packet of table sugar with 10 ml of water.²² Pain management teams should work with pharmacists to ensure availability of topical anesthetics and sucrose, and institute protocols for their routine use.

Distraction has been definitively shown to be effective in reducing procedural pain and distress.²³ Child life

Table 158–3 Pediatric Pain Assessment

Method	Examples	Validated Age Range	Comments
Self-report			
Faces scales	Bieri faces ³² Wong-Baker faces ³³	3 yr–adult	Gold standard Preferred by children, young children may tend to choose extremes, minimum clinically significant difference = 1 face
Visual analog scale	10-cm line labeled “no pain” at one end, “worst pain possible” at other end	7 yr–adult	Best validated for research purposes, minimally clinically significant difference 10–13 mm ^{34,35}
Oucher	Combination of 0–10 numeric scale for older children and faces scale for younger children	3–12 yr	African American, Hispanic, and white versions validated ^{36–38}
Others	Colored analog scale, pain ladder, poker chip tool, pain thermometer	Variable	
Behavioral			
Preverbal children	Children’s Hospital of Eastern Ontario Pain Scale (CHEOPS), ³⁹ Faces, Legs, Activity, Cry, Consolability (FLACC) ^{40,41}	1–7 yr	For preverbal and noncommunicating children Based on pain behaviors such as facial expression, torso movements, kicking, verbal protest, need for restraint
Developmentally delayed children	Noncommunicating Children’s Pain Checklist, ^{42,43} University of Wisconsin Children’s Hospital Pain Scale for Preverbal and Nonverbal Children ⁴⁴	0–7 yr 3–18 yr All ages	
Neonates	Neonatal Facial Coding System (NCFS) ⁴⁵ CRIES ⁴⁶ Modified Behavioral Pain Scale ⁴⁷	Neonates Neonates Birth–6 mo	Facial expressions most valid indicator of neonatal pain
Physiologic			
Heart rate Blood pressure Salivary cortisol		All ages All ages All ages	Least reliable, should be used as corroborative data only Increases 20 min after painful procedures ⁴⁸

Table 158–4 Pharmacologic Pediatric Pain Management Methods^{5,11,12}

Medication	Indication	Dosage Guidelines and Comments
Nonopioid Analgesics	Mild to moderate pain	Potential adverse effects include gastric upset, renal insufficiency, hypersensitivity reaction, platelet dysfunction.
Acetaminophen	Mild to moderate pain	15 mg/kg (max 650 mg per dose or 4 g/day, whichever is less) PO or PR q4–6h; antipyretic also.
Ibuprofen	Mild to moderate pain	10 mg/kg (max 800 mg per dose or 2400 mg/day) PO q6–8h; anti-inflammatory and antipyretic also.
Naproxen	Mild to moderate pain	5–7 mg/kg PO q8–12h for children 2 yr or older, max 1250 mg/day; anti-inflammatory also.
Ketorolac	Moderate pain, short-term use (<5 days)	0.5 mg/kg IV or IM (max 30 mg per dose or 90 mg/day) q6h; anti-inflammatory, particularly effective for renal colic.
Opiates	Moderate to severe pain	Potential adverse effects include nausea, constipation, pruritis, respiratory depression, sedation, and hypotension. Tolerance and dependence are very unlikely with acute use and appropriate doses in children. Naloxone 0.1 mg/kg (max 2 mg) IV, IM, subQ, or ET may reverse adverse effects. If one opiate is ineffective, switching to another may be effective.
Morphine	Severe pain	0.1 mg/kg IV or IM (max 15 mg) q1–2h; 0.5 mg/kg PO (max 30 mg for adult size) q4–6h
Fentanyl	Severe pain	1 mcg/kg IV or IM (max 100 mcg) q30–60 min; shorter duration of action.
Hydromorphone	Severe pain	0.015 mg/kg IV (max 1 mg) q4–6h; 0.05 mg/kg PO (max 5 mg) q4–6h; less pruritis than morphine.
Meperidine	Severe pain	1 mg/kg IV or IM (max 100 mg) q3–4h; high incidence of dysphoria, agitation; not preferred.
Codeine	Moderate pain	1 mg/kg PO (max 60 mg) q4–6h. Often given with acetaminophen in premixed preparations: elixir, 12 mg codeine and 120 mg acetaminophen in 5 ml; Tylenol #2, 325 mg acetaminophen/15 mg codeine; Tylenol #3, 325/30; Tylenol #4, 325/60. Must be metabolized to be effective; 10% or more of patients may not be able to metabolize to effective metabolite.
Oxycodone	Moderate pain	0.1 mg/kg PO (max 5 mg) q4–6h. Often given with acetaminophen in premixed preparations: 325 mg acetaminophen + 5 mg oxycodone (Percocet) most common form.
Hydrocodone	Moderate pain	0.15 mg/kg PO (max 10 mg) q4–6h. Often given with acetaminophen in premixed preparation of 500 mg acetaminophen + 5 mg hydrocodone (Vicodin) or 7.5 mg hydrocodone (Vicodin ES), or premixed with ibuprofen 200 mg + 7.5 mg hydrocodone (Vicoprofen).

Abbreviations: ET, endotracheally; IM, intramuscularly; IV, intravenously; PO, orally; PR, rectally; subQ, subcutaneously.

Table 158–5 Adjunctive and Nonpharmacologic Pediatric Pain Management Methods^{6,12}

Antianxiety Agent		
Midazolam	Adjunctive	0.05–0.1 mg/kg IV (max 2 mg) q3–5 min for up to three doses, titrated to effect; 0.5–0.75 mg/kg PO (max 10 mg). Antianxiety and amnesic only; no analgesia. Flumazenil may reverse respiratory depression: 0.01 mg/kg IV (max 0.2 mg) q1min to max of 1 mg, then q20min to max of 3 mg.
Topical Agents		
Eutectic mixture of local anesthetics (EMLA)	Procedural pain	1–2 g topical cream per 10-cm ² area of intact skin; cover with occlusive dressing; gives 4- to 5-mm depth of anesthesia after 45–60 min on skin. Maximum doses: Birth–3 mo: 1 g 3–12 mo: 2 g 1–6 yr: 10 g 7–12 yr: 20 g
4% Liposomal lidocaine (LMX4)	Procedural pain	Apply as for EMLA; no occlusive dressing needed; anesthesia within 20–30 min; available without a prescription.
Vapocoolants (ethyl chloride, flouromethane)	Procedural (injection) pain	Spray onto area of injection immediately prior to injection; cold sensation may be unpleasant to some children.
Lidocaine iontophoresis (Numby Stuff, LidoSite)	Procedural (injection) pain	Uses iontophoresis of lidocaine to provide 5- to 7-mm depth of anesthesia within 10 min. Requires initial investment in equipment.
Lidocaine 4%, epinephrine 1 : 2000, and tetracaine 0.5% gel (LET)	Laceration repair	Apply 3 ml directly into wound using a cotton ball (not gauze) for 15–30 min prior to laceration repair with sutures, staples, tissue adhesive, or prior to additional local anesthetic infiltration if needed. Not for areas where epinephrine is contraindicated.
Lidocaine jelly 2%	Urethral catheterization, ⁴⁹ nasogastric tube insertion ⁵⁰	Instill 0.5–2 ml into urethra 2 mins before procedure (may instill up to three times). Use 5 ml in an adult for lubricant when inserting nasogastric tube.
Nonpharmacologic Methods		
Distraction	Procedural pain	Age appropriate selection: pacifier/non-nutritive sucking, bubbles, toys, songs, pop-up books, party blower, kaleidoscope, videos, video games, puzzles, stories, jokes, counting, music, nonprocedural conversation
Sucrose	Procedural pain	Effective for young infants <6 mo; 2 ml of 30% sucrose or glucose solution, half 2 min prior to procedure and half during the procedure.
Counter-irritation	Injection pain	Rub on the surrounding skin during local anesthetic infiltration or injections; Shot Blocker device (http://www.bionix.com) stimulates surrounding skin, leaving a center hole for inserting the needle.
Tissue adhesives	Laceration repair	Dermabond or Indermil can be used to painlessly repair simple lacerations
Blowing, deep breathing	Procedural pain	Have child blow out imaginary candles, “blow away the pain,” or use a party blower. Have child take slow deep breaths.
Suggestion	Procedural pain, visceral or headache pain	Suggest the child place a “magic glove” or “magic invisible cream” that removes the pain of a procedure, or turn a “pain switch” to off position. Works best with suggestible preschool-age children.
Heat or cold	Muscular pain, visceral or ear or headache pain	Apply cold in the first 24 hr after a muscular injury; apply warm compresses to other sources of pain.

specialists can work with health care providers to ensure that distraction items are available and used. Health care providers can always use nonprocedural conversation, such as asking the child questions about school, sports, or favorite television shows, or even allowing demonstration of math skills, to distract the child without the need for special equipment.⁶

Table 158–5 lists other effective yet uncommonly used nonpharmacologic methods to reduce pain in the ED. Pain management teams can provide education, demonstration, and encouragement to use these methods. They can ensure, for example, that sucrose for use with young infants undergoing painful procedures,^{21,24} and tissue adhesives for laceration repairs,²⁵ are available in the ED, and that health care providers are comfortable with their use. A “train-the-trainer” approach, utilizing shift leaders who undergo educational sessions and then teach the rest of the health care workers on their shift, may be used. Similarly, one physician or nurse in

a group may attend a continuing education presentation or undergo training, and then teach the technique to others in the group.

Table 158–6 lists pain management approaches to several common pediatric procedural and medical situations seen in the ED^{1,26} (see Chapter 159, Procedural Sedation and Analgesia). Because clinicians tend to concentrate on diagnosis and management of the primary condition, rather than the associated pain, the pain management team must emphasize pain control. Education of health care providers, inclusion of pain management in patient aftercare handouts, and inclusion of pain assessment and management in clinical practice guidelines for specific complaints will improve attention to pain management.⁸ Patients and parents may inadequately treat children’s pain due to false beliefs about the importance of being stoic, fears of addiction or side effects from pain medications, and lack of education on medication dosing and alternative therapies.⁵ Discharge instructions should empha-

Table 158–6 Management of Specific Emergency Department Pediatric Pain Situations

Situation	Management Options
Mildly painful procedure (e.g., venipuncture)	Distraction + topical or local anesthesia
Moderately painful procedure (e.g., laceration repair, lumbar puncture, nail avulsion)	Distraction + topical or local anesthesia Distraction + topical or local anesthesia + midazolam Nitrous oxide Procedural sedation and analgesia
Moderately to severely painful procedure (e.g., abscess incision and drainage, fracture reduction, chest thoracostomy)	Procedural sedation and analgesia (most commonly fentanyl + midazolam or ketamine) ^{51,52}
Injections	Topical anesthetic cream, counter-irritation
Intravenous catheter placement	Topical anesthetic cream
Urethral catheterization	Viscous lidocaine placed in urethral opening 2 min prior to catheterization, with additional viscous lidocaine used as lubricant for the catheter ⁴⁹
Nasogastric tube placement	Lidocaine jelly placed in nasopharynx and used as lubricant; vasoconstrictor (phenylephrine) adjuvant; lidocaine solution in nasopharynx and oropharynx and/or cetacaine spray in oropharynx, or nebulized lidocaine ⁵⁰
Laceration repair	Topical anesthetic, evaluation for tissue adhesive. Inject local anesthetic that is warmed and buffered; inject slowly with smallest gauge needle available
Infant lumbar puncture	Topical anesthetic cream, infiltrated local anesthetic
Burns	Depending on severity of pain, nonopiate analgesics or opiates. For dressing changes, procedural sedation and analgesia may be necessary
Otitis media pain	Nonopiate analgesics, weak opiate oral analgesics, topical anesthetic otic solution, warm compresses
Pharyngitis pain	Nonopiate analgesics, weak opiate oral analgesics, anesthetic sprays and lozenges, salt water gargles, dexamethasone
Viral stomatitis pain	Nonopiate analgesics, “magic mouthwash” with topical anesthetic, sucralfate, bland diet
Musculoskeletal pain	Rest, ice, compression, elevation, nonopiate analgesics (especially nonsteroidal anti-inflammatory drugs)
Chest pain	If musculoskeletal (e.g., costochondritis): nonopiate analgesic (especially nonsteroidal anti-inflammatory drugs). If due to gastroesophageal reflux: antacid therapy
Mild abdominal pain	Nonopiate analgesics; relieve any constipation present
Acute abdominal pain	Short-acting opiate (fentanyl); no reason to delay pain treatment for consulting specialist examination ⁵³
Renal colic	Ketorolac, opiate for severe pain
Fracture pain	Acutely: strong opiate parenterally may be required, then nonopiate analgesic or weak opiate oral analgesic, immobilization
Headache	Nonopiate analgesics, opiates, migraine therapies if indicated

size the importance of pain management to the healing process, appropriate medication dosing and around-the-clock administration, and the need for the patient to return if pain is inadequately controlled.

Overcoming myths regarding pediatric pain is an important educational goal. For example, generations of clinicians have been previously taught that use of local anesthetics for infant lumbar puncture actually increases pain due to the use of a “second needle,” and that it may interfere with the success of the procedure. A recent study confirms that 68% of pediatric ED physicians still do not use routine analgesia for neonatal lumbar punctures.²⁷ The literature does not support these myths; use of local anesthesia results in decreased pain behaviors and has no effect on the success of the procedure.^{28,29} There are no physiologic data to support a different standard of care for infants versus older children and adults—that is to say, if the myth were true, why wouldn’t adults also prefer just one needle? For clinicians still concerned about procedural success, use of topical anesthetic cream offers an alternative, although the depth of anesthesia is less.³⁰ These and other myths will expire only when the next generation of emergency physicians, pediatricians, and family practitioners are no longer exposed to them by the current generation.

An important barrier to overcome is the overall “culture” of the ED.⁶ Because the ED is a busy and often hectic environ-

ment, health care providers may feel that changes are impossible, and that patients must accept the ED as it is. However, the pain management team can use education, newsletters, positive feedback, examples, policies, and even rewards to promote change.⁸ Change will not be instantaneous, and the team must be patient and persistent. Table 158–7 lists changes to the ED environment to improve children’s experiences with procedures.⁶ Table 158–8 summarizes policies and projects that can be used to provide solutions to barriers in improving pediatric pain management in the ED.^{1,8,31}

Summary

Adequate pain management is increasingly recognized as a significant factor in patient well-being and satisfaction. Inadequate pain management has both short-term (suffering, decreased healing, dissatisfaction with care, possible decreased compliance with other treatments) and long-term (chronic pain syndromes, increased pain sensitivity, avoidance of medical care) consequences. Regulatory agencies are emphasizing pain management, and research advances are rapidly occurring. EDs need multidisciplinary pain management teams to collect, assimilate, and then disseminate information on pain assessment and management to health care providers. The “culture” of the ED must promote

Table 158–7

Emergency Department Cultural Characteristics that Promote Reduction of Pediatric Procedural Pain⁶

Providing Information and Preparing the Parent and Child

- Give step-by-step information as to what will occur during the procedure.
- Give sensory information about what the child will see, hear, and feel.
- Use age-appropriate language and terminology and avoid medical jargon.
- Avoid high-anxiety words such as pain, hurt, cut, and shot. Use words such as poking, freezing, squeezing, bothering, or bugging you instead.
- Do not insinuate that the procedure will definitely hurt.
- Be aware of possible misinterpretations of words and phrases such as “dye” or “put to sleep.”
- Address children’s concerns (e.g., “taking all my blood”).
- Consider using books describing the procedure that the child can read with the parents.
- Give information both before and during the procedure.
- Be honest.

Parental Involvement

- Ask the parents how much distress they expect from the child.
- Allow parents to remain present.
- Do not ask the parent to help restrain the child.
- Instruct the parent not to threaten the child (e.g., with additional shots).
- Instruct the parent on coping-promoting behaviors (e.g., distraction) and to avoid distress-promoting behaviors (e.g., reassurance).

Health Care Worker Behavior

- Be calm, confident, and in control.
- Avoid reassurance, apology, and criticism.

- Avoid conversation with other health care workers and parents that may be distressing (e.g., describing possible adverse events) in front of the child.
- Teach students how to perform the procedure outside the room to minimize discussion in front of the child.

Health Care Setting

- Maintain a quiet, calm environment.
- Avoid stressors such as beeping monitors.
- Avoid long delays between informing the child of the procedure and performing it.
- Avoid situations in which children can see or hear procedures performed on other children.

Procedural Details

- Allow comfort items such as favorite stuffed animals or blankets.
- For venipunctures and intravenous cannulation in thumb-sucking children, avoid the arm of the preferred thumb.
- Don’t force the child to lay down if he or she doesn’t want to and isn’t required to.
- Consider giving the child a “job” (e.g., holding a gauze).
- Give the child choices to increase the perception of control (e.g., right arm or left).
- For long procedures (e.g., burn dressing changes), allow the child “time-outs” of a predetermined number and duration (e.g., three 20-second time-outs).
- Allow the child to “count down” from 10 to 1 before a brief procedure.
- Use automatic lancets for fingersticks.
- Venipuncture, when feasible, may be less painful than heel lance.
- Do not allow the child to see the larger needle used to draw up local anesthetic.

Table 158–8

Solutions to Barriers in Reducing Pediatric Pain in the Emergency Department (ED)

Barrier	Solution
Lack of organization in approach to pain, lack of coordination and education of health care workers, failure of health care system to make pain relief a priority	Appointment of a “pain czar” and/or a multidisciplinary “pain management team” to establish standards and target goals for improvement, provide health care worker education, devise policies and procedures to improve pain management, perform ongoing quality assessments, and test interventions
Need for health care worker education, need to stop perpetuation of myths regarding pediatric pain	Variety of educational methods, including lectures, workshops, in-services, continuing medical education meetings, journal clubs to review particular pain management solutions, distribution of review articles, periodic newsletters from the pain management team, and appointment of shift leaders who disseminate and teach new policies and procedures
Lack of assessment of pain	Multidisciplinary team reviews existing pain assessment methods, chooses a few methods that cover all ages and situations to use, educates all health care providers in using these methods, posts the methods in the triage and patient care areas
Delay in pain medication due to time spent in triage, registration, and waiting to be seen	Nurse-driven protocols allowing standing orders for nonopiate analgesic administration for moderate pain, and automatic contact of physicians to prescribe analgesics in triage for severe pain
Analgesics not used effectively	Educate health care workers and encourage use of preemptive analgesia, multimodal analgesia (World Health Organization Pain Relief Ladder), around-the-clock dosing rather than PRN dosing.
Disruption to ED flow when topical anesthetics requiring 20–60 min for effect are applied	Nurse-driven protocols allowing placement of topical anesthetics in triage for lacerations judged by nurses to require repair, or patients judged by nurses likely to require phlebotomy, intravenous catheterization, lumbar puncture, or other needle procedure. Placement of topical anesthetic cream by physician or registered nurse at time of placing order for phlebotomy, intravenous access, or lumbar puncture setup.
Lack of availability of items for distraction; health care provider discomfort with parental presence	Put together “distraction baskets” for each room, with items appropriate for all ages. Put together a preprinted brief instruction booklet for parents on how to help their child through a procedure, and how to use the distraction items.
Busy health care providers concentrating on diagnosis and management of primary condition	Redesign patient care forms and charts to include preprinted spaces for pain assessment, reassessment, and pain management recommendations at discharge. Redesign computer interfaces to include automatic prompts for pain assessment and treatment.
Health care providers’ lack of knowledge regarding pain medication doses and nonpharmacologic methods available	Multidisciplinary team to formulate a pocket reference card for all health care providers with medication doses, equianalgesic doses for opiates, protocols for nonpharmacologic methods
Patients and health care providers concentrating on primary condition and not knowledgeable about importance of managing pain	Revise patient aftercare handouts to emphasize the importance of pain management to adequate healing and of appropriate and around-the-clock medication dosing, or formulate separate handouts.
Lack of accountability for pain management practices	Conduct quality assessment projects, and give both positive feedback and suggestions for improvement to health care providers. Consider periodic rewards to individual health care workers demonstrating superior pain management practices.
Lack of availability of literature-supported pain management methods	Pain management team to include pharmacist representative, with goals of making available topical anesthetics, oral sucrose solutions for use with infants, etc. Pain management team to conduct in-services and educational workshops to educate health care providers on the use of these methods.

an environment conducive to good pain management practices.

Procedural Sedation and Analgesia

PART 1 ■ PRINCIPLES AND PRACTICE

Steven M. Green, MD and Baruch Krauss, MD, EdM

Key Points

Successful and safe application of procedural sedation and analgesia requires careful patient selection, customization of therapy to the type of procedure and the specific needs of the patient, and careful patient monitoring for prevention of adverse events.

The most important element of procedural sedation and analgesia monitoring is close and continuous patient observation by an individual capable of recognizing adverse events prior to the development of complications.

Current sedation state terminology includes moderate sedation, deep sedation, and dissociative sedation. Although historically popular, the widely misinterpreted and misused term *conscious sedation* has fallen into disfavor and has been replaced with the term *moderate sedation*.

For nondissociative agents, intravenous titration to patient response is the most effective method of obtaining rapid and safe analgesia and/or sedation.

Recent food intake is not a contraindication for administering procedural sedation and analgesia, but should be considered in choosing the depth and sedation end point.

requires careful patient selection, customization of therapy to the specific needs of the patient, and continuous patient monitoring for adverse events. Emergency physicians must ensure that all patients receive pain relief and sedation commensurate with their individual needs during any procedure.

The most common pediatric PSA indications include diagnostic imaging, fracture reduction, and laceration repair, as well as a variety of other painful and/or anxiety-producing procedures. There are two absolute PSA contraindications: severe clinical instability requiring immediate attention, and refusal by a competent patient or his or her parents or guardians. Relative contraindications include hemodynamic or respiratory compromise, abnormal airway, altered sensorium, or inability to monitor side effects. However, even in many of these circumstances, appropriate agents can be given to provide analgesia and sedation while minimizing the chances for further deterioration. Although safely sedating infants and young children is challenging and requires additional care, age is not a contraindication to PSA.

In all but the most emergent situations, a directed history and physical examination should precede PSA. If this evaluation suggests additional risk, the advisability of PSA should be reconsidered. High-risk cases may be better managed in the more controlled environment of an operating room. The decision to proceed with PSA should be a thoughtful process in which the urgency of the procedure is considered together with the associated risks identified by the pre-sedation evaluation. PSA is contraindicated when the risks outweigh the expected benefits.

Indications and Contraindications

Procedural sedation and analgesia (PSA), is the use of analgesic, dissociative, and sedative agents to relieve the pain and anxiety associated with diagnostic and therapeutic procedures. Successful and safe application of PSA

Portions of this chapter were adapted from Green SM, Krauss B: Procedural sedation and analgesia. In Roberts JR, Hedges JR (eds): Clinical Procedures in Emergency Medicine, 4th ed. Philadelphia: W.B. Saunders, 2004, pp 596–620.

Preparation and Consent

The practice of PSA has four sequential phases: the pre-sedation evaluation; medication administration, and where appropriate, titration to a specific sedation end point; maintenance of appropriate level of sedation during the procedure; and postprocedure recovery and patient discharge from the emergency department (ED). Pre-sedation assessments are a requirement of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO),¹ and most hospitals have developed specific forms to facilitate consistent

documentation of the involved items. Except in emergency situations, the risks, benefits, and limitations of any PSA should be discussed with the parents or guardians in advance and verbal agreement obtained. Written consent is not required (unless it is a local institutional requirement), though documentation, as discussed, is essential.

General

Physicians should assess the type and severity of any underlying medical problems. A common tool used for this purpose is the American Society of Anesthesiologists' physical status classification, which is used for preoperative risk stratification (Table 159–1).² Current medications and allergies should be verified. It is advisable to inquire regarding prior adverse experiences with PSA or anesthesia.

Airway

The airway should be inspected to determine if there are abnormalities that might impair airway management (e.g., severe obesity, short neck, small mandible, large tongue, trismus).

Cardiovascular

Cardiac auscultation should be performed to assess for rhythm disturbance or other abnormality. In patients with known cardiovascular disease, their degree of reserve should be evaluated, as most PSA agents can cause vasodilation and hypotension.

Respiratory

Lung auscultation should be performed to assess for active pulmonary disease, especially obstructive lung disease and active upper respiratory infections that may predispose to airway reactivity.

Gastrointestinal

Although pulmonary aspiration of gastric contents is a serious complication of vomiting when protective airway reflexes are impaired, there is no evidence that a specific fasting duration is necessary prior to PSA.^{3,4} Two large, prospective ED series have failed to show any association between fasting and adverse effects.^{5,6} However, aspiration is not an acceptable PSA outcome, and clinicians must remain consistently and aggressively vigilant in its prevention. A case-by-case risk:benefit assessment is more consistent with the current literature than setting an arbitrary fasting period,

and clinicians should avoid sedation depth where protective airway reflexes might be impaired unless the expected benefits outweigh the additional risk. Great care should be taken to avoid inducing respiratory depression necessitating assisted ventilation, because such ventilation insufflates the stomach and may induce emesis.^{3,4}

Hepatic/Renal

The implications of delayed metabolism or excretion of PSA agents in infants less than 6 months of age, in the elderly, and in the presence of hepatic or renal abnormality should be carefully evaluated.

Equipment and Monitoring

Personnel and Interactive Monitoring

The most important element of PSA monitoring is close and continuous patient observation by an individual capable of recognizing adverse events during PSA. This person must be able to continuously observe the patient's face, mouth, and chest wall motion, and equipment or sterile drapes must not interfere with such visualization. This careful observation will allow prompt detection of adverse events such as respiratory depression, apnea, upper airway obstruction, laryngospasm, emesis, and hypersalivation.

PSA personnel should understand the pharmacology of analgesic and sedative agents and their respective reversal agents, and be proficient at maintaining airway patency and assisting ventilation if needed. PSA requires a minimum of two experienced individuals, most frequently one physician and one nurse or respiratory therapist. The physician typically oversees drug administration and performs the procedure, while the nurse or respiratory therapist continuously monitors the patient for potential adverse events and documents administration of medication, response to sedation, and periodic vital signs. The nurse or respiratory therapist may assist with minor, interruptible tasks; however, their ability to remain focused on the patient's cardiopulmonary status must not be impaired. An individual with advanced life-support skills should be immediately available, a requisite easy to fulfill in the ED setting.

During deep sedation (Table 159–2), the individual dedicated to patient monitoring should be experienced with this depth of sedation and have no other responsibilities that would interfere with the advanced level of monitoring and documentation appropriate for this sedation level.⁷ Individual

Table 159–1 American Society of Anesthesiologists' (ASA) Physical Status Classification

ASA Class	Description	Examples	Suitability for Sedation
1	A normally healthy patient	Unremarkable past medical history	Excellent
2	A patient with mild systemic disease—no functional limitation	Mild asthma, controlled seizure disorder, anemia, controlled diabetes mellitus	Generally good
3	A patient with severe systemic disease—definite functional limitation	Moderate to severe asthma, poorly controlled seizure disorder, pneumonia, poorly controlled diabetes mellitus, moderate obesity	Intermediate to poor; consider benefits relative to risks
4	A patient with severe systemic disease that is a constant threat to life	Severe bronchopulmonary dysplasia, sepsis; advanced degrees of pulmonary, cardiac, hepatic, renal, or endocrine insufficiency	Poor, benefits rarely outweigh risks
5	A moribund patient who is not expected to survive without the operation	Septic shock, severe trauma	Extremely poor

From Krauss B, Green SM: Sedation and analgesia for procedures in children. *N Engl J Med* 342:938–945, 2000.

Table 159–2 PSA Terminology and Definitions**General**

- **Analgesia:** Relief of pain without intentional production of an altered mental state such as sedation. An altered mental state may be a secondary effect of medications administered for this purpose.¹⁴
- **Anxiolysis:** A state of decreased apprehension concerning a particular situation in which there is no change in a patient's level of awareness.¹⁴
- **Procedural Sedation and Analgesia (PSA):** A technique of administering sedatives, analgesics, and/or dissociative agents to induce a state that allows the patient to tolerate unpleasant procedures while maintaining cardiorespiratory function. PSA is intended to result in a depressed level of consciousness but one that allows the patient to maintain airway control independently and continuously. Specifically, the drugs, doses, and techniques used are not likely to produce a loss of protective airway reflexes.¹⁵

Specific Sedation States

- **Minimal sedation (anxiolysis):** A drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.¹
- **Moderate sedation** (formerly “conscious sedation”): A drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. Reflex withdrawal from a painful stimulus is not considered a purposeful response. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.¹
- **Dissociative Sedation:** A trancelike cataleptic state induced by the dissociative agent ketamine, characterized by profound analgesia and amnesia, with retention of protective airway reflexes, spontaneous respirations, and cardiopulmonary stability.¹⁶
- **Deep sedation:** A drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.¹
- **General anesthesia:** A drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.¹

hospital-wide sedation policies may have additional requirements for how and when deep sedation is administered, based upon their specific needs and available expertise.

For situations in which sedation is initiated by the intramuscular (IM), oral, nasal, inhalational, or rectal routes, it is not mandatory to have intravenous (IV) access, although this may be preferred based upon anticipated depth of sedation and on comorbidity, or for the convenience of additional drug titration. When sedation is performed without IV access, an individual skilled in initiating such access should be immediately available.

Mechanical Monitoring

The routine use of mechanical monitoring has greatly enhanced the safety of PSA. With current technology, oxygenation (pulse oximetry), ventilation (capnography), and hemodynamics (blood pressure and electrocardiography [ECG]) can all be monitored noninvasively in spontaneously breathing patients. Although continuous ECG monitoring cannot be considered mandatory in the absence of cardiovascular disease, such monitoring is simple, inexpensive, and readily available. PSA mechanical monitoring should include continuous pulse oximetry with an audible signal (if available). Pulse oximetry measures the percentage of hemoglobin that is bound to oxygen and is not a substitute for monitoring ventilation, as there is a variable lag time between the onset of hypoventilation or apnea and a change in oxygen saturation of hemoglobin molecules.

Capnography provides a continuous, breath-by-breath measure of respiratory rate and CO₂ exchange and provides the earliest detection of respiratory failure.⁸ Hypoventilation and respiratory depression result in a progressive decrease in respiratory rate, an increase in the end-tidal CO₂, and a change in the shape of the CO₂ waveform. Apnea, upper airway obstruction, and laryngospasm result in an almost instantaneous loss of the CO₂ waveform. Early detection of respiratory compromise is especially important in infants

and toddlers, who have smaller functional residual capacity and greater oxygen consumption relative to older children and adults.^{9,10} In the ED setting, capnography has been shown to identify respiratory depression undetectable by pulse oximetry.⁸ Capnography should be added where available, as it can alert practitioners to respiratory depression and apnea before hypoxemia develops, especially if the patient is on supplemental oxygen.

The sedation area should include all necessary age-appropriate equipment for airway management and resuscitation, including oxygen, a bag-valve mask, suction, and drug reversal agents. A defibrillator should be available for subjects with significant cardiovascular disease.

The need for supplemental oxygen during PSA, and its benefits, have not been studied. Although this intervention will decrease the incidence and severity of hypoxemia due to airway complications, it will also delay the detection of apnea with pulse oximetry.^{11,12} If oxygen is administered and capnography is not available, continual visual inspection of chest-wall motion and air movement is especially important. Supplemental oxygen cannot be considered mandatory at this time and remains an option best left to the physician's preference.

Vital signs should be periodically measured at individualized intervals, in most cases including measurements at baseline, after drug administration, on completion of the procedure, during early recovery, and at completion of recovery. During deep sedation, it is advisable to assess vital signs every 5 minutes. Patients are at highest risk of complications 5 to 10 minutes following IV medications and during the immediate postprocedure period when external stimuli are discontinued.

Standards and Guidelines**Terminology**

The progression from minimal sedation to general anesthesia represents a continuum. Low doses of opioids or

benzodiazepines induce mild analgesia or sedation, respectively, with little danger of adverse events. If clinicians continue administering additional medication beyond this initial level, progressively altered consciousness ensues with a proportionately increased risk of respiratory and airway complications. At a certain point on the continuum, protective airway reflexes are lost and general anesthesia is ultimately reached. This sedation continuum is not drug specific, as varying states from mild sedation to general anesthesia can be achieved with virtually all nondissociative PSA agents (e.g., opioids, sedative-hypnotics).

A key recent development in the field of PSA has been the revision of the original 1985 sedation-state terminology and the adoption of clearer descriptions of varying types and degrees of sedation (see Table 159–2).^{1,13–16} Although historically popular, the widely misinterpreted and misused term *conscious sedation* is an inaccurate descriptor¹³ and has been replaced with the term *moderate sedation*.¹ Despite improvements in PSA terminology, there is still not an objective method for assessing sedation depth. Levels of responsiveness are crude surrogate markers of respiratory drive and retention of protective airway reflexes. This is especially true for all levels of sedation in young children who do not understand or who cannot reliably follow verbal commands. Although respiratory depression and respiratory arrest can be quickly detected using standard interactive and mechanical monitoring, there is no safe and practical method to assess the status of protective airway reflexes.

PSA Standards and Guidelines

There are numerous sets of PSA guidelines created by various specialty societies, with the intent of better standardizing the manner in which PSA is performed in order to enhance patient safety. Those most pertinent to emergency physicians are those from the American College of Emergency Physicians,^{15,17} the American Academy of Pediatrics,^{7,18} and the American Society of Anesthesiologists.^{11,12} In the early 1990s, the JCAHO took a special interest in PSA, with the central theme that the standard of sedation care provided should be comparable throughout a given hospital.¹ Thus patients sedated in the ED should not receive a significantly different level of attention or monitoring than those sedated for a similar-level procedure in the operating room. To ensure this, the JCAHO requires specific PSA protocols that apply consistently throughout each institution. These hospital-wide sedation policies will vary from site to site based upon the specific needs and expertise available within each institution.¹

At each hospital accreditation survey, the JCAHO will look to see if practitioners practice PSA consistent with their hospital-wide sedation policy, and whether they provide sufficient documentation of such compliance. Physicians must be familiar with their hospital's sedation policies, and should work with their medical staff to ensure that such policies are suitably detailed, yet reasonable and realistic. Unduly restrictive policies do a disservice to patients by discouraging appropriate use of analgesia and anxiolysis. Most hospitals pattern their sedation policies after JCAHO standards and definitions. It is important to note that the unique ketamine dissociative state is incompatible with existing JCAHO definitions of sedation and anesthesia.¹⁶ A ready solution adopted

by some hospitals is the assignment of a distinct definition for “dissociative sedation” (see Table 159–2).

The JCAHO requires that PSA practitioners who are permitted to administer deep sedation must be qualified to rescue patients from general anesthesia,¹ a standard readily met by emergency physicians. Emergency physicians will typically perform all levels of sedation except general anesthesia. Moderate sedation suffices for the majority of procedures in cooperative children, although it will not be adequate for painful procedures (e.g., fracture reduction, cardioversion). Deep sedation can facilitate these, but at greater risk of cardiorespiratory depression than moderate sedation. Moderate sedation is frequently insufficient for effective anxiolysis and immobilization in younger, frightened children. In this instance, deep and dissociative sedation are possible alternatives.

Techniques

Therapeutic mistakes resulting in inadequate analgesia and sedation include using the wrong agent, the wrong dose, and the wrong route and frequency of administration, and poor use of adjunctive agents. With proper training and technique, adequate PSA can be provided under almost any circumstance. Understanding titration principles is critical to providing safe and effective PSA. Physicians must have a thorough knowledge of the pharmacokinetics, dosing, administration, and potential complications of the PSA agents that they use. Onset time from injection to initial observed effect must be appreciated, especially when using drugs in combination, to avoid stacking of drug doses resulting in oversedation.

The correct agent (or combination of agents) and the route and timing of administration depend on the following factors: How long will the procedure last? Will it be seconds (e.g., simple relocation of a dislocated joint, incision and drainage of a small abscess, cardioversion), minutes (e.g., complex fracture manipulation for reduction, breaking up loculations in a large abscess and then packing it), or prolonged (e.g., complex facial laceration repair)? How likely is it that the procedure will need to be repeated (e.g., fracture reduction)? Can topical, local, or regional anesthesia be used as an adjunct? Does the patient only require sedation for a noninvasive diagnostic imaging study?

Prior to drug administration, every effort should be made, pharmacologically and nonpharmacologically, to minimize a child's anxiety and distress. The emotional state of a patient on induction strongly correlates with the degree of distress on emergence and in the immediate days following the procedure.^{19–22}

Emergency physicians must avoid being pressured by consultants to cut corners or rush PSA. During the presedation preparation, discuss the sedation plan and length of time required to safely prepare and sedate the patient with the consultant to avoid risks associated with a hurried sedation.

Routes of Administration

For nondissociative agents, IV titration to patient response is the best method to obtain rapid and safe analgesia and/or sedation. When using opioids, doses administered in 2- to 3-minute increments, while observing for side effects such as miosis, somnolence, decreased responsiveness to verbal

stimuli, minimally impaired speech, and diminished pain on questioning, are appropriate initial end points. For sedative-hypnotics, similar end points such as ptosis (rather than miosis), somnolence, slurred speech, and gaze alteration should be sought. Repeated doses may be given in a titrated fashion based on the patient’s response during the procedure.

Oral, transmucosal (i.e., nasal, rectal), and IM routes are convenient means of administration when IV access is not necessary. However, they cannot be titrated to a desired response. The efficacy of intranasal drug administration in particular is operator dependent. The main advantage of these other routes is their usefulness for children in whom IV access may be problematic, for procedures that may require only minimal sedation in conjunction with the use of local anesthetics, and for diagnostic imaging.

With the exception of ketamine, agents administered IM have erratic absorption and a variable onset of action. As such, prolonged preprocedural and postprocedural observation may be necessary. When required because of limitations in obtaining IV access, the IM route offers little advantage over oral or transmucosal administration.

Another PSA route is via inhalation using nitrous oxide. This gas can either be delivered by a demand-flow system using a handheld mask, or delivered to young children by a continuous-flow system under close physician supervision using a nose mask.

Because individual needs may vary widely, application of arbitrary ceiling doses of analgesic and sedative regimens is unwarranted. The true ceiling dose of an agent is that dose that provides adequate pain relief or sedation without major cardiopulmonary side effects such as respiratory depression, apnea, bradycardia, or hypotension.

Alternatives

Many ED nonpainful, or minimally painful, procedures in older children and cooperative young children can be performed without PSA. Skilled practitioners can frequently combine a calm, reassuring bedside manner with distraction techniques and careful local or regional anesthesia.^{23,24} Should such techniques fail, then PSA can be used. The traditional alternative of performing painful and/or anxiety-provoking ED procedures in children using forcible restraint alone is strongly discouraged.

Complications

The principal adverse effect of most PSA agents is cardiopulmonary depression, and this can be identified through inter-active and mechanical monitoring practices as described earlier. Other drug-specific adverse effects are discussed in the second part of this chapter.

Postprocedure Care and Disposition

All children receiving PSA should be monitored until they are no longer at risk for cardiorespiratory depression. To be discharged, they should be alert and oriented (or returned to age-appropriate baseline), and vital signs should be stable. Many hospitals have chosen to use standardized recovery-scoring systems similar to those used in their surgical post-

anesthesia recovery areas (Table 159–3). A reliable adult must be available to observe these children for postprocedure complications after discharge. Instructions should be given regarding appropriate diet, medications, and level of activity (Table 159–4). To be eligible for safe discharge, children are not required to demonstrate that they can tolerate an oral

Table 159–4 Sample Pediatric Disposition Instructions after PSA

Your child has been given medicine for sedation and/or pain control. These medicines may cause your child to be sleepy and less aware of his or her surroundings, making it easier for accidents to happen as he or she walks or crawls. Because of these side effects, your child should be watched closely for the next few hours. We suggest the following:

1. No eating or drinking for the next 2 hours. If your child is an infant, you may resume half normal feedings when they are hungry.
2. No playing for the next day that requires normal coordination, such as bike riding or jungle gym activities.
3. No playing without an adult to watch and supervise.
4. No baths, showers, cooking, or use of potentially dangerous electrical appliances unless supervised by an adult.

If you notice anything unusual about your child, please consider returning to the emergency department for re-evaluation.

challenge (most PSA agents are emetogenic, and forcing fluids postsedation can lead to emesis pre- and/or postdischarge), nor are they required to walk unaided. The American Academy of Pediatrics guidelines only stipulate that “the patient can talk (if age-appropriate)” and “the patient can sit up unaided (if age-appropriate).”⁷ A recent study has demonstrated that primary adverse events did not occur 30 minutes beyond final drug administration in children sedated with either ketamine or midazolam.²⁵

PART 2 ■ DRUG SELECTION

Steven M. Green, MD and Baruch Krauss, MD, EdM

Key Points

Emergency physicians should tailor their drug selection strategies to the specific needs of the procedure at hand (i.e., analgesia, anxiolysis, and/or immobilization).

Intravenous pentobarbital appears to be the most effective agent to facilitate nonpainful diagnostic imaging studies such as computed tomography or magnetic resonance imaging scanning, although many centers use oral chloral hydrate, particularly in children less than 18 months of age.

Midazolam can be effectively used for moderate and deep sedation through careful intravenous (IV) titration to effect, typically together with fentanyl.

When administered IV, the ultra-short-acting sedatives propofol, etomidate, thiopental, and methohexital can rapidly induce potent sedation followed by relatively rapid awakening, but with a greater risk of respiratory depression.

Ketamine produces a unique state of cortical dissociation that permits painful procedures to be performed more consistently and effectively than with other agents.

Nitrous oxide can be administered via a self-administered demand mask in cooperative children, or by a continuous-flow face mask in the uncooperative child.

Drug Selection Strategies

The majority of emergency department (ED) procedures in older children can be performed without procedural sedation and analgesia (PSA). Skilled practitioners can frequently combine a calm, reassuring bedside manner with distraction techniques and/or careful local or regional anesthesia.^{1,2} Many procedures, however, cannot be technically or humanely performed without PSA, especially in younger children. These situations can be divided into three categories:

Insufficient Analgesia—Regardless of the level of cooperation, for some procedures it is impossible to achieve effective pain control with local or regional anesthesia. Examples of procedures requiring systemic PSA include fracture reductions, dislocation reductions, large loculated abscess incision and drainage, wounds that require

scrubbing (e.g., “road rash”), bone marrow aspiration/biopsy, and extensive burn débridement.

Insufficient Anxiolysis—Some patients will be so frightened despite effective local or regional anesthesia that procedures cannot be technically or humanely performed without PSA. Young children requiring laceration repair are frequently terrified, and older children may be highly anxious in anticipation of laceration repairs in sensitive and/or personal regions (e.g., face, genitalia, perineum).

Insufficient Immobilization—Despite effective local or regional anesthesia and anxiolysis, PSA may be indicated to prevent excessive motion during procedures that require substantial immobilization (e.g., repair of complex facial lacerations). Immobilization is most commonly an issue with young or mentally disabled children.

Clinicians must therefore customize their drug selection based upon the unique needs of the patient (i.e., anxiolysis, analgesia, immobilization) and their individual level of experience with specific agents. A risk:benefit analysis should be performed prior to every administration of sedation and analgesia. The benefits of reducing anxiety and controlling pain should be carefully weighed against the risks of respiratory depression and airway compromise.

Cooperative Older Children

Minor procedures can usually be managed with topical, local, or regional anesthesia. Systemic PSA is typically unnecessary, although mild anxiolysis (nitrous oxide, oral midazolam) can make some of these patients more comfortable.

For longer procedures, supplementation of topical, local, or regional anesthesia with either nitrous oxide, or intravenous (IV) midazolam and fentanyl permits customization of sedation depth and pain relief to the specific needs of each patient.

Uncooperative Children

Minor procedures (e.g., small lacerations, IV cannulation, venipuncture, superficial foreign body removal) in uncooperative children can frequently be managed by skilled practitioners using a combination of nonpharmacologic techniques (e.g., distraction, guided imagery, hypnosis, comforting, breathing techniques; see Chapter 158, Approach to Pain Management) in conjunction with topical anesthesia, careful local anesthesia, and—when necessary—brief physical restraint (by personnel or by a restraining device). In other cases, supplementing nonpharmacologic techniques with topical or local anesthesia and anxiolysis with oral midazolam may be sufficient. Although oral midazolam administration is most popular and least invasive, the nasal or rectal routes can also be used depending upon operator experience and preference.

Major painful procedures (fracture reduction, large loculated abscess incision and drainage, arthrocentesis of a major

joint) require systemic PSA, as do essentially all procedures in uncooperative children in whom satisfactory immobilization cannot be achieved. Options include IV fentanyl/midazolam, intramuscular (IM) or IV ketamine, or an ultra-short-acting sedative such as IV propofol.

Selection Strategies and Dosing Recommendations

Drug selection strategies are summarized in Table 159–5, and dosing recommendations for PSA drugs are shown in Table 159–6. Specialized protocols for midazolam/fentanyl and ketamine are shown later in Tables 159–7 and 159–8, respectively. Individual agents are discussed in the following sections.

Sedative-Hypnotic Agents

Chloral Hydrate

Pharmacology

Chloral hydrate is a pure sedative-hypnotic agent without analgesic properties. When administered orally, the average

time to peak sedation is approximately 30 minutes, with a recovery time of an additional 1 to 2 hours.^{3,4} Residual motor imbalance and agitation may persist for several hours beyond this.⁵ Rectal administration is erratically absorbed and therefore not recommended.

Pediatric Use

Chloral hydrate is widely used as a sedative to facilitate non-painful diagnostic procedures such as electroencephalography³ and computed tomography (CT) or magnetic resonance imaging (MRI).^{6–10} Pentobarbital IV appears to be more effective for the latter indication than chloral hydrate,¹¹ although many centers prefer chloral hydrate in younger children (e.g., <18 months) simply to avoid the need for IV access.^{7,8,11}

Adverse Effects

Despite a wide margin of safety, chloral hydrate can cause airway obstruction and respiratory depression, especially at higher doses (75 to 100 mg/kg).^{3,5,7,9,10,12} The incidence was 0.6% in one large series.³ There is not a known dosage threshold of chloral hydrate below which this potential

*This table is intended as a general overview. Sedation strategies should be individualized. Although the pharmacopeia is large, clinicians should familiarize themselves with a few agents that are flexible enough to be used for the majority of procedures. In all cases it is assumed that practitioners are fully trained in the technique, appropriate personnel and monitoring are used as detailed in this chapter, and specific drug contraindications are absent.

Abbreviations: IM, intramuscular; IN, intranasal; IV, intravenous; PO, oral; PR, rectal.

Modified from Krauss B, Green SM: Sedation and analgesia for procedures in children. *N Engl J Med* 342:938–945, 2000.

Table 159-6 PSA Drug Dosing Recommendations*

Drug	Clinical Effects	Indications	Pediatric Dose	Onset (min)	Duration (min)	Comments
Sedative-Hypnotics						
Choral hydrate	Sedation, motion control, anxiolysis. No analgesia. Not reversible.	Diagnostic imaging (age <3 yr)	PO: 25–100 mg/kg, after 30 min may repeat 25–50 mg/kg. Max total dose: 2 g or 100 mg/kg (whichever is less). Single use only in neonates.	PO: 15–30	PO: 60–120	Effects unreliable if age > 3 yr. Avoid in patients with significant cardiac, hepatic, or renal disease. Rectal absorption erratic. May produce paradoxical excitement. Since drugs cannot be titrated with the oral route, monitor closely for oversedation.
Etomidate (Amidate)	Sedation, motion control, anxiolysis. No analgesia. Not reversible.	Procedures requiring sedation and/or anxiolysis	IV (caution, limited research): 0.15–0.2 mg/kg	IV: <1	IV: 5–15	See warnings in text. Adverse effects include respiratory depression, myoclonus, nausea, and vomiting. Adrenocortical suppression occurs, but is rarely of clinical significance. Not FDA approved in children. Reduce dose when used in combination with opioids.
Midazolam† (Versed)	Sedation, motion control, anxiolysis. No analgesia. Reversible with flumazenil.	Procedures requiring sedation and/or anxiolysis	IV (0.5–5 yr): Initial 0.05–0.1 mg/kg, then titrated to max 0.6 mg/kg IV (6–12 yr): Initial 0.025–0.05 mg/kg, then titrated to max 0.4 mg/kg IM: 0.1–0.15 mg/kg PO: 0.5–0.75 mg/kg IN: 0.2–0.5 mg/kg PR: 0.25–0.5 mg/kg	IV: 2–3 IM: 10–20 PO: 15–30 IN: 10–15 PR: 10–30	IV: 45–60 IM: 60–120 PO: 60–90 IN: 60 PR: 60–90	May produce paradoxical excitement. Since drugs cannot be titrated with the oral/rectal/intranasal routes, monitor closely for oversedation.
Methohexital (Brevital)	Sedation, motion control, anxiolysis. No analgesia. Not reversible.	Diagnostic imaging	IV (caution, limited research): 0.5–1 mg/kg	PR: 10–15	PR: 60	See warnings for IV use in text. Avoid in patients with temporal lobe epilepsy or porphyria. Since drugs cannot be titrated with the rectal route, monitor closely for oversedation.
Pentobarbital (Nembutal)	Sedation, motion control, anxiolysis. No analgesia. Not reversible.	Diagnostic imaging	IV: 1–6 mg/kg, titrated in increments of 1–2 mg/kg to desired effect IM: 2–6 mg/kg; max 100 mg PO/PR (<4 yr): 3–6 mg/kg, max 100 mg PO/PR (>4 yr): 1.5–3 mg/kg, max 100 mg	IV: 3–5 IM: 10–15 PO/PR: 15–60	IV: 1–45 IM: 60–120 PO/PR: 60–240	May produce paradoxical excitement. Avoid in patients with porphyria. Since drugs cannot be titrated with the oral/rectal routes, monitor closely for oversedation.
Propofol (Diprivan)	Sedation, motion control, anxiolysis. No analgesia. Not reversible.	Procedures requiring sedation and/or anxiolysis	IV: 1 mg/kg over 20–30 sec, followed with similar repeat 0.5 mg/kg doses PR to maintain sedation.	IV: <1	IV: 5–15	See warnings in text. Frequent respiratory depression and hypotension. Avoid with egg or soy allergies.
Thiopental (Pentothal)	Sedation, motion control, anxiolysis. No analgesia. Not reversible.	Diagnostic imaging	PR: 25 mg/kg	PR: 10–15	PR: 60–120	Avoid in patients with porphyria. Since drugs cannot be titrated with the rectal route, monitor closely for oversedation.

Table continued on following page

Table 159–6 PSA Drug Dosing Recommendations* (Continued)

Drug	Clinical Effects	Indications	Pediatric Dose	Onset (min)	Duration (min)	Comments
Analgesic†						
Fentanyl (Sublimaze)	Analgesia. Reversible with naloxone.	Procedures of moderate to severe pain	IV: 1.0 mcg/kg/dose, may repeat q3–10min, titrate to effect	IV: 3–5	IV: 30–60	Reduce dosing when combined with midazolam.
Dissociative Agent						
Ketamine (Ketalar)	Analgesia, dissociation, amnesia, motion control. Not reversible.	Procedures of moderate to severe pain or requiring immobilization	IV: 1–1.5 mg/kg slowly over 1–2 min, may repeat 1/2 dose q10min PRN IM: 4–5 mg/kg, may repeat after 10 min (full or 1/2 dose without additional atropine)	IV: 1 IM: 3–5	IV: dissociation 15; recovery 60 IM: dissociation 15–30; recovery 90–150	Multiple contraindications (see Table 159–8). Risk of unpleasant hallucinations and dreams if age > 15 yr (rare if younger) that may be blunted with midazolam. No apparent advantage to routine coadministration of midazolam in children. Hypersalivation can be minimized with concurrent atropine 0.01 mg/kg IM/IV (min 0.1 mg, max 0.5 mg), although such coadministration does not appear mandatory.
Inhalational Agent						
Nitrous oxide (Nitronox)	Anxiolysis, analgesia, sedation, amnesia (all mild).	Procedures requiring mild analgesia or sedation (age > 4 yr)	Pre-set mixture with minimum 40% O ₂ self-administered by demand-valve mask for cooperative child; continuous-flow nasal mask in uncooperative child with close monitoring.	<5	<5 min following discontinuation	Requires specialized apparatus and gas scavenger capability. Several contraindications. [§] Synergistic effect with recent opioids or sedative-hypnotics—use with caution in this setting.
Reversal Agents (Antagonists)						
Naloxone (Narcan)	Opioid reversal	Opioid toxicity	IV: 0.01 mg/kg, may repeat 0.1 mg/kg if inadequate response, may use IM/SC/ET route if IV unavailable	IV: 2	IV: 20–40 IM: 60–90	If shorter acting than the reversed drug, serial doses may be required.
Flumazenil (Romazicon)	Benzodiazepine reversal	Benzodiazepine toxicity	IV: 0.02 mg/kg/dose, may repeat q1min up to 1 mg	IV: 1–2	IV: 30–60	If shorter acting than the reversed drug, serial doses may be required. Do not use in patients receiving chronic benzodiazepines, cyclosporine, isoniazid, lithium, propoxyphene, theophylline, tricyclic antidepressants.

*Alterations in dosing may be indicated based upon the clinical situation and the practitioner's experience with these agents. Individual dosages may vary when used in combination with other agents, especially when benzodiazepines are combined with opioids.
 †Midazolam is preferred to other benzodiazepines (e.g., diazepam, lorazepam) for PSA due to its shorter duration of action and multiple routes of administration.
 ‡Fentanyl is preferred to other opioids (e.g., morphine, meperidine) for PSA due to its faster onset, shorter recovery, and lack of histamine release.
 §Generally accepted contraindications to nitrous oxide: pregnancy (patient or personnel); preexisting nausea/vomiting; trapped gas pockets (e.g., middle ear infection, pneumothorax, bowel obstruction).
 Abbreviations: FDA, Food and Drug Administration; IM, intramuscular; IN, intranasal; IV, intravenous; PRN, as needed; PO, oral; PR, rectal.
 Adapted from Krauss B, Green SM: Sedation and analgesia for procedures in children. N Engl J Med 342:938–945, 2000.

Table 159–7 Procedure for Moderate to Deep Sedation with Intravenous Midazolam and Fentanyl**Caveats**

- Do not consider this procedure if you do not have experience with the drugs or the time to perform it properly. Do not attempt the procedure if the pulse oximeter, suction, oxygen, or bag-valve-mask is not working, the intravenous (IV) access is not secured, or the room is too small or not set up for procedural sedation and analgesia.
- This is a two-person procedure, one to monitor the patient and one to perform the procedure.
- Individual response to the drugs is variable and dependent upon the patient's underlying physiologic state and the presence of concomitant drugs/medication.
- Maximum drug effect occurs 2–3 minutes following administration. Proceed slowly and patiently, allowing the medication to take full effect before giving the next dose.
- Have naloxone and flumazenil immediately available for oversedation and/or respiratory depression.
- If the patient seems overly sedated, begin the procedure. The pain of the procedure often stimulates respiration and lessens sedation.

Contraindications—Absolute (Risks Essentially Always Outweigh Benefits)

- Active hemodynamic instability
- Active respiratory distress or hypoxemia

Contraindications—Relative (Risks May Outweigh Benefits)

- Respiratory depression or altered level of consciousness
- Anticipated difficulty if ventilatory assistance should become necessary (e.g., facial deformity or trauma, small mandible, large tongue, trismus)

Protocol

- Establish IV access.
- Connect appropriate monitoring equipment to the patient.
- Pulse, respiratory rate, blood pressure, and level of consciousness should all be recorded initially, and periodically throughout the procedure depending on the depth of sedation.
- Suction equipment, oxygen, a bag-valve-mask, and reversal agents should be immediately available. An age-appropriate resuscitation cart with oral and nasal airways, endotracheal tubes, and a functioning laryngoscope must be nearby.
- The order of the drugs is one of personal preference. The ratio of analgesia to sedation is determined by the nature of the procedure. Some procedures require primary analgesia and secondary anxiolysis/sedation (e.g., abscess incision and drainage, bone marrow aspiration, arthrocentesis, burn débridement, central catheter placement), while others require primary anxiolysis/sedation with secondary analgesia (e.g., lumbar puncture, simple foreign body removal).
- Administer local anesthesia if indicated (this often serves to help gauge effectiveness of systemic analgesia).
- Perform the procedure. Additional doses of fentanyl or midazolam may be required if further pain or anxiety is noted based on the response and length of the procedure.
- If hypoxemia, oversedation, or slowed respirations are seen during or after procedure, the patient should be first stimulated while oxygen is applied and the airway repositioned. If the patient's response is insufficient, assist ventilations with a bag-valve-mask. Reversal agents should be considered if there is not a prompt response to assisted ventilation.
- Continue close observation until the patient is awake and alert, and release the patient with a friend, parent, or relative only after a sufficient discharge score has been attained.

complication can be consistently avoided,^{9,12} and accordingly standard interactive and mechanical monitoring precautions apply to chloral hydrate as they do to other PSA agents.

Despite reports of potential carcinogenicity, the American Academy of Pediatrics has judged that the evidence is currently insufficient to avoid single doses of chloral hydrate for this reason alone.¹³

Midazolam**Pharmacology**

Benzodiazepines are a group of highly lipophilic agents that possess anxiolytic, amnestic, sedative, hypnotic, muscle relaxant, and anticonvulsant properties. They lack direct analgesic properties, and thus are commonly coadministered with opioids. Caution must be exercised when using benzodiazepines and opioids together, since the risks of hypoxia and apnea are significantly greater than when either is used alone.¹⁴

Midazolam is by far the most common benzodiazepine used for PSA, and is preferred over the longer acting lorazepam and diazepam unless unavailable. The time to peak effect for midazolam is approximately 2 to 3 minutes when given IV. Unlike diazepam, midazolam and lorazepam are water soluble, making parenteral administration less painful and mucosal absorption more rapid.

Pediatric Use

Midazolam can be effectively used for moderate and deep sedation through careful IV titration to effect, typically together with fentanyl (Table 159–7). The advantage of midazolam over other benzodiazepines is its availability in multiple routes of administration. Some children require larger doses than would be typical for adults on a milligram-per-kilogram basis,¹⁵ and paradoxical responses (e.g., hyperexcitability) are not infrequent.^{5,16,17}

To avoid the need for IV access in frightened or uncooperative children, midazolam has been alternatively administered via the IM,¹⁸ oral,^{17,19–23} intranasal,^{23–27} and rectal^{28,29} routes. However, the inability to effectively titrate using these routes dictates that a reliable depth of sedation cannot be predictably or regularly achieved. Thus these routes are primarily reserved for pure anxiolysis and/or minimally painful procedures. Respiratory depression can also occur via these routes.²¹

Adverse Effects

When administered by skilled practitioners using standard precautions (see Table 159–7), the safety profile for midazolam is excellent.^{30–33} However, when administering benzodiazepines, one must maintain continuous vigilance for respiratory depression.^{5,12,14,32} Such respiratory depression is

dose dependent and greatly enhanced in the presence of ethanol or other depressive drugs, especially opioids. Deaths from undetected apnea have occurred in non-ED settings,¹⁴ underscoring the critical role for continuous interactive and mechanical monitoring.

Benzodiazepines induce mild cardiovascular depression. Although hypotension can occur, it is rare when the agents are carefully titrated.

Pentobarbital

Pharmacology

Pentobarbital is a barbiturate capable of profound sedation, hypnosis, amnesia, and anticonvulsant activity in a dose-dependent fashion. It has no inherent analgesic properties. When carefully titrated IV, sedation is evident within 5 minutes with a duration of approximately 30 to 40 minutes.³⁴

Pediatric Use

Pentobarbital is the IV sedative of choice in many centers for diagnostic imaging in children.^{8,11,34-37} It is regarded as superior to midazolam^{11,34,35} or chloral hydrate¹¹ for this indication. Pentobarbital, like midazolam, is available in multiple routes of administration.

Adverse Effects

Like other barbiturates, pentobarbital can lead to respiratory depression and hypotension, as it is a negative inotrope.^{8,11,34,35}

Ultra-Short-Acting Sedatives

The current ultra-short-acting sedatives used in ED PSA are propofol, etomidate, thiopental, and methohexital. When administered IV, all can rapidly produce potent sedation and result in rapid awakening (<5 minutes) following drug discontinuation. As described later, rectal thiopental and methohexital also have established safety and efficacy for pediatric neuroimaging.

Substantial controversy surrounds the IV administration of these agents for ED PSA.³⁸ Proponents cite their extremely rapid onset and recovery as advantages over other sedatives. Critics cite the need for continuous vigilance required to achieve a desired effect while simultaneously avoiding significant respiratory depression as a distinct disadvantage. Patients receiving these agents can exhibit rapid swings in level of consciousness. An additional dedicated physician (separate from the individual performing the procedure) is widely believed to be required to oversee medication administration and patient monitoring; however, oversedation may not be reliably avoided despite this precaution. Currently, data from case series do not sufficiently quantify depth of sedation, and it is unclear whether some subjects experienced periods of general anesthesia. Although profound obtundation creates superlative procedural conditions, it also presents a greater aspiration risk than traditional sedatives.^{38,39}

Propofol

Pharmacology

Propofol exhibits numerous exceptionally desirable characteristics of a PSA agent. First, its clinical effect is essentially immediate following IV administration (“one arm-brain

circulatory time”). Second, its marked potency reliably produces effective PSA conditions, even for very painful procedures. Third, recovery following sedation is extremely short, typically 5 to 15 minutes. Finally, patient satisfaction is high, as propofol has antiemetic and euphoric properties.³⁸

Pediatric Use

Two large ED series^{40,41} and several smaller ones^{36,42-46} demonstrated that propofol can be administered to children in the ED with a high level of efficacy, with apparent safety, and with rapid recovery. The depth of sedation achieved in these reports is not well described, but frequently appears to be at or past levels consistent with deep sedation.

If it is ultimately shown that emergency physicians can consistently administer this drug in a manner that avoids oversedation and respiratory depression, propofol could potentially become the IV PSA sedative agent of choice.

Adverse Effects

The most serious adverse effect of propofol is potent respiratory depression, and apnea can occur suddenly and without warning. Rates of respiratory depression range widely by study (8% to 30%)³⁸ and thus the technique appears more operator dependent than does sedation with longer acting agents.

Propofol can also produce hypotension (by direct negative inotropy as well as arterial and venodilation), although this adverse effect is typically so transient as to be of little clinical importance in healthy patients.³⁸

Etomidate

Pharmacology

Etomidate produces sedation, anxiolysis, and amnesia equal to that of barbiturates, but with significantly fewer adverse hemodynamic effects. Its onset of action and recovery are similar to those of thiopental and methohexital.

Pediatric Use

Etomidate is widely administered as the induction agent of choice for rapid sequence intubation in both children and adults, especially for patients with head trauma or marginal blood pressure. As with the other ultra-short-acting agents, preliminary reports describe rapid recovery and a high level of efficacy using IV etomidate for pediatric PSA.⁴⁷⁻⁴⁹ Similarly, the depth of sedation achieved in these reports is not well described, but appears to frequently be at or past levels consistent with deep sedation.

Adverse Effects

The primary adverse effects of etomidate are respiratory depression, myoclonus, nausea, and vomiting.⁴⁷⁻⁵⁰ Etomidate appears to be a less desirable PSA choice than propofol, given that it induces myoclonus and emesis. Transient adrenal suppression occurs with etomidate, but appears to lack clinical significance when used in single doses.⁵¹

Thiopental and Methohexital

Pharmacology

When given IV, both thiopental and methohexital produce sedation within 1 minute. Clinical recovery is rapid

(approximately 15 minutes) and reflects the rapid redistribution of these agents from the central nervous system to the periphery. Because of their lipid solubility, barbiturates are rapidly absorbed rectally.

Pediatric Use

When administered rectally, thiopental and methohexital can reliably produce anxiolysis and sedation suitable for CT or MRI scanning.⁵²⁻⁵⁷ IV methohexital has been administered for brief PSA in children with excellent procedural success.^{58,59} The depth of sedation achieved in these small series is not well described, but appears to be at or past levels consistent with deep sedation.

Adverse Effects

Although respiratory depression is unusual when using rectal thiopental or methohexital in typical doses (see Table 159–6), it can rarely occur.⁵²⁻⁵⁶ Standard interactive and mechanical monitoring are warranted as with any PSA.

When these agents are administered IV, they exhibit potent respiratory depression in the same manner as propofol and etomidate.⁵⁸⁻⁶⁰ Barbiturates frequently can cause hypotension at typical IV doses, so their use should be avoided whenever possible in patients with volume depletion or cardiovascular compromise.

Analgesic Agents

Fentanyl

Fentanyl is the most common opioid used for PSA due to its rapid onset, brief duration of action, and lack of histamine release.⁶¹ Morphine and meperidine are instead preferred for pure pain control due to their longer duration of action. Children in the ED frequently receive morphine or meperidine initially for acute analgesia, and then later are administered shorter acting agents to facilitate a needed procedure. Although longer acting opioids can be readily used for analgesia during PSA, they will be associated with longer recovery times. Fentanyl is preferred unless unavailable.

Pharmacology

Fentanyl is 75 to 125 times more potent than morphine and has no intrinsic anxiolytic or amnestic properties. A single dose given IV has rapid onset (<30 seconds), with a peak at 2 to 3 minutes and brief clinical duration (20 to 40 minutes). This increase in potency and onset of action is in part related to its greater lipid solubility, which facilitates its passage across the blood-brain barrier. The effects of fentanyl can be reversed with opioid antagonists (i.e., naloxone, nalmefene).

Pediatric Use

Because of its pharmacokinetics, IV fentanyl is an ideal agent when analgesia is required for painful procedures, because it can be easily and rapidly titrated.⁶¹ As anxiolysis and sedation do not occur at low doses of fentanyl (1 to 2 mcg/kg), the concurrent administration of a pure sedative, most commonly midazolam, is advisable (see Table 159–7). The combination of fentanyl and midazolam remains a popular PSA sedation regimen in children, with a strong safety and efficacy profile when both drugs are carefully titrated to effect.^{31-33,62,63} Any level of mild, moderate, or deep sedation can be achieved using these agents.

Fentanyl is also available in an oral transmucosal preparation. Although this novel and noninvasive delivery route obviates the need for IV access, titration is difficult and efficacy is variable.⁶⁴ Furthermore, the incidence of emesis is high (31% to 45%),^{64,65} and this formulation has never become popular for PSA.

Adverse Effects

Like all opioids, fentanyl can cause respiratory depression.^{31-33,61-63} When used for PSA, standard interactive and mechanical monitoring are required. As the opioid effect is most pronounced on the central nervous system respiratory centers, apnea can precede loss of consciousness. If apnea should occur, verbal or tactile stimulation should be attempted prior to administration of opioid antagonists. As discussed earlier, caution must be exercised when using benzodiazepines and opioids together, since the risks of hypoxia and apnea are significantly greater than when either is used alone.^{14,30}

In the absence of significant ethanol intoxication, hypovolemia, or concomitant drug ingestion, hypotension is rare. Because of its safe hemodynamic profile, fentanyl is an ideal analgesic agent for use in critically ill or injured patients. Additionally, nausea and vomiting are rare compared to morphine and meperidine. A commonly observed reaction to fentanyl is facial pruritus, with patients frequently scratching their nose.⁶¹

A rare side effect of fentanyl that has the potential to cause respiratory compromise is chest wall rigidity. This complication is related to higher doses (>5 mcg/kg as a bolus dose) than those used for PSA, and has not been reported in ED series.^{31,61-63} If chest wall rigidity occurs, it usually can be reversed with opioid antagonists and/or positive pressure ventilation. Equipment for urgent pharmacologic paralysis should be available in case antagonist reversal and positive pressure ventilation are unsuccessful.

Other Short-Acting Opioids

Sufentanil, alfentanil, and remifentanil are other short-acting opioids that have a potential role in PSA in the future. However, currently there is insufficient published experience to warrant their routine use. Although intranasal sufentanil 0.75 mcg/kg appeared promising when combined with midazolam in one small pediatric trial,⁶⁶ in another study doses of 1.5 mcg/kg resulted in oxygen desaturation in 8 of 10 children studied.²⁶ This low toxic:therapeutic ratio and inability to titrate limit the utility of intranasal sufentanil. In the one published report of IV remifentanil with midazolam for PSA, there was an unacceptably high incidence of hypoxemia.⁶⁷ Currently there does not appear to be a clinically important advantage to these drugs compared to fentanyl.

Ketamine

Pharmacology

Ketamine produces a unique state of cortical dissociation that permits painful procedures to be performed more consistently and effectively than with other PSA agents. This state of “dissociative sedation” is characterized by profound analgesia, sedation, amnesia, and immobilization, and can be rapidly and reliably produced with IV or IM administration. Ketamine has been widely used worldwide since its

introduction in 1970 and has demonstrated a remarkable safety profile in a variety of settings.^{31,68-72} In 1999, the Joint Commission on Accreditation of Healthcare Organizations confirmed that ED ketamine administration is fully compliant with their standards when administered according to protocol.⁷³ Clinicians administering ketamine must be especially knowledgeable about the unique actions of this drug and the numerous contraindications to its use (Table 159–8).

Ketamine differs from all other PSA agents in several important ways. First, it uniquely preserves cardiopulmonary stability. Upper airway muscular tone and protective airway reflexes are maintained. Spontaneous respiration is preserved, although, when administered IV, ketamine must be given slowly (over 1 to 2 minutes) to prevent respiratory depression. Second, it differs from other agents in that it lacks the characteristic dose-response continuum to progressive titration. At doses below a certain threshold, ketamine produces analgesia and sedation. However, once a critical dosage threshold (approximately 1 to 1.5 mg/kg IV or 3 to 4 mg/kg IM) is achieved, the characteristic dissociative state abruptly appears. This dissociation has no observable levels of depth, and thus the only value of ketamine “titration” is to maintain the presence of the state over time. Finally, the dissociative state is not consistent with formal definitions of moderate sedation, deep sedation, or general anesthesia, and therefore must be considered from a different perspective than agents that exhibit the classical sedation continuum.^{68,74}

Ketamine is most effective and reliable when given IV or IM. Ketamine has a one arm-brain circulation time when given IV, with onset of dissociation noted within 1 minute and effective procedural conditions lasting for about 10 to 15 minutes. When given IM, the same effect is achieved within 5 minutes, with effective procedural conditions lasting 15 to 30 minutes. The typical duration from dosing until dischargeable recovery is 50 to 110 minutes when given IV, and 60 to 140 minutes when given IM.^{69,71,75}

Like benzodiazepines, ketamine undergoes substantial first-pass hepatic metabolism. Therefore, oral and rectal administration results in less predictable effectiveness and requires substantially higher doses. Clinical onset and recovery are substantially longer than when given parenterally, and thus these routes are rarely used in the ED.^{28,29,76}

Ketamine can induce salivation, and anticholinergics have traditionally been routinely coadministered to prevent this effect. Atropine is most commonly chosen in emergency medicine due to its ready familiarity to physicians and nurses, although glycopyrrolate is an equally acceptable but not superior alternative. However, a recent trial noted similar hypersalivation scores between children who did and did not receive concurrent atropine,⁷⁷ indicating that anticholinergics may not be considered mandatory with ketamine. Another author anecdotally described no difficulty with administration of ketamine without an anticholinergic to approximately 1100 children.⁷⁸

Pediatric Use

Ketamine is an ideal agent to facilitate short, painful procedures in children. The safety and efficacy of ketamine for this indication have been widely documented.^{30,31,68,69,71,75} The IM route is simple and effective. Venous access is unnecessary, and atropine can be concurrently administered in the same

syringe.⁶⁹ Intravenous administration is attractive because a lower cumulative dose can be used, and recovery is more rapid than with the IM route. The primary caution is that, with this route, ketamine must be administered slowly (each dose over 1 to 2 minutes) or respiratory depression and transient apnea can occur.⁷⁵

Unpleasant recovery reactions are uncommon in children and teenagers, and are typically mild.^{68,79,80} There is no evidence of any benefit from the prophylactic administration of concurrent benzodiazepines in children,^{79,80} and their role should be confined to treating unpleasant reactions if they occur.

Adverse Effects

In the largest published ED series (1022 patients), the following adverse airway events were noted: airway malalignment (0.7%), transient laryngospasm (0.4%), and transient apnea or respiratory depression (0.3%). All were quickly identified and treated, and there were no sequelae.⁶⁹

Vomiting was noted in 6.7% of patients from the same series, and in most cases it occurred well into recovery.⁶⁹ The incidence was age related, occurring in 12.1% of children age 5 years or older, and 3.5% in those younger than 5 years.⁷⁰ There was no evidence of aspiration⁶⁹; indeed, in 30 years of regular use there have been no documented reports of clinically significant ketamine-associated aspiration in patients without established contraindications. Because of its unique preservation of protective airway reflexes, ketamine may be preferred over other agents for urgent or emergent procedures when fasting is not assured.^{30,69,71}

Mild agitation during recovery (whimpering or crying) was noted in 17.6% of children from the same series, with more pronounced agitation in 1.6%. The incidence was age related, with agitation occurring in 12.1% of children age 5 years or older, and 22.5% in those younger than 5 years.⁷⁰ Only 2 of 1022 children had reactions that treating physicians judged severe enough to require treatment, and both children responded promptly to small doses of midazolam.⁶⁹ Another study quantified the degree of recovery agitation using a 0 to 100-millimeter visual analog scale; the median rating of recovery agitation was a 5, likely below the threshold of clinical importance.⁷⁹

Nitrous Oxide

Pharmacology

Inhaled nitrous oxide provides anxiolysis and mild analgesia. It is commonly dispensed at concentrations between 30% and 50%, with oxygen composing the remainder of the mixture. Nitrous oxide quickly diffuses across biologic membranes and accordingly has a rapid onset of action (30 to 60 seconds). Maximum effect occurs after about 5 minutes, and the clinical effect wears off quickly upon discontinuation. At typical PSA concentrations there is preservation of hemodynamic status, spontaneous respirations, and protective airway reflexes.⁸¹⁻⁸⁴ Nitrous oxide is widely used in dentistry at higher concentrations.⁸⁵

Nitrous oxide has an excellent safety profile; however, as a sole agent it cannot reliably produce adequate procedural conditions.⁸¹⁻⁸⁴ Given its relatively weak analgesic properties, in many cases nitrous oxide will need to be supplemented with an IV opioid and/or local anesthesia.

Table 159–8 Procedure for Dissociative Sedation with Ketamine**Purpose**

- To define the guidelines for patient selection, administration, monitoring, and recovery for emergency department dissociative sedation.

Definition of Dissociative Sedation

- A trancelike cataleptic state induced by the dissociative agent ketamine, characterized by profound analgesia and amnesia, with retention of protective airway reflexes, spontaneous respirations, and cardiopulmonary stability.

Characteristics of the Ketamine “Dissociative State”

- *Dissociation*—Following administration of ketamine, the patient passes into a fugue state or trance. The eyes may remain open but the patient does not respond (“the lights are on, but no one’s home”).
- *Catalepsy*—Normal or slightly enhanced muscle tone is maintained. On occasion the patient may move or be moved into a position that is self-maintaining. Occasional muscular clonus may be noted.
- *Analgesia*—Analgesia is typically substantial or complete.
- *Amnesia*—Total amnesia is typical.
- *Maintenance of Airway Reflexes*—Upper airway reflexes remain intact and may be slightly exaggerated. Intubation is unnecessary, but occasional repositioning of the head may be necessary for optimal airway patency. Suctioning of hypersalivation may occasionally be necessary.
- *Cardiovascular Stability*—Blood pressure and heart rate are not decreased, and typically are mildly increased.
- *Nystagmus*—Nystagmus is typical.

Indications

- Short, painful procedures, especially those requiring immobilization (e.g., facial laceration, burn débridement, fracture reduction, abscess incision and drainage, central line placement, tube thoracostomy).
- Examinations judged likely to produce excessive emotional disturbance (e.g., pediatric sexual assault examination).

Contraindications—Absolute (Risks Essentially Always Outweigh Benefits)

- Age less than 3 months (higher risk of airway complications)
- Known or suspected psychosis, even if currently stable or controlled with medications (can exacerbate condition)

Contraindications—Relative (Risks May Outweigh Benefits)

- Age 3 to 12 months (higher risk of airway complications)
- Procedures involving stimulation of the posterior pharynx (higher risk of laryngospasm)
- History of airway instability, tracheal surgery, or tracheal stenosis (presumed higher risk of airway complications)
- Active pulmonary infection or disease, including upper respiratory infection or asthma (higher risk of laryngospasm)
- Known or suspected cardiovascular disease, including angina, heart failure, or hypertension (exacerbation due to sympathomimetic properties of ketamine). Avoid ketamine in patients who are already hypertensive, and in older adults with risk factors for coronary artery disease.
- Head injury associated with loss of consciousness, altered mental status, or emesis (elevated intracranial pressure with ketamine)
- Central nervous system masses, abnormalities, or hydrocephalus (elevated intracranial pressure with ketamine)
- Glaucoma or acute globe injury (elevated intraocular pressure with ketamine)
- Porphyria, thyroid disorder, or thyroid medication (enhanced sympathomimetic effect)

Personnel

- Dissociative sedation is a two-person procedure, one (e.g., nurse) to monitor the patient and one (e.g., physician) to perform the procedure. Both must be knowledgeable regarding the unique characteristics of ketamine.
- Avoid dissociative sedation when personnel are not experienced with ketamine or may not have time to perform such sedation properly.

Preparation (See Part 1 of Chapter)

- Perform a standard preparation assessment.
- Educate accompanying family regarding the unique characteristics of the dissociative state, especially if they will be present during the procedure and/or recovery.
- Frame the dissociative encounter as a positive experience. Consider encouraging older children to “plan” specific, pleasant dream topics in advance of sedation (believed to decrease unpleasant recovery reactions). Emphasize, especially to school-age children and teenagers, that ketamine delivers sufficient analgesia so there will be no pain.

Ketamine Administration—General

- If a consultant physician is performing the procedure, discuss with him or her in advance the goal and anticipated depth of sedation and ensure that he or she is aware of the unique features of dissociative sedation.
- Ketamine is not administered until the physician is ready to begin the procedure, as onset of dissociation typically occurs within 5 min.
- Ketamine is initially administered as a single intramuscular (IM) injection or IV loading dose. There is no benefit from attempts to titrate to effect.
- The IM route is especially useful in those settings in which IV access cannot be consistently obtained with minimal upset to the child and for patients who are uncooperative and/or combative (e.g., the mentally disabled).
- IV access is unnecessary in children receiving IM ketamine. Since unpleasant recovery reactions are more common in adults, IV access is desirable in older teenagers to permit rapid treatment of these reactions should they occur.

Ketamine Administration—IM Route

- Administer ketamine 4–5 mg/kg IM.
- Repeat ketamine dose (full or half dose IM) if sedation is inadequate after 5–10 minutes (unusual) or if additional doses are required.

Ketamine Administration—IV Route

- Administer a loading dose of 1.5 mg/kg IV over 60 sec; 100 mg is a typical adult dose. More rapid administration produces high central nervous system levels and has been associated with respiratory depression.
- Additional incremental doses of ketamine may be given (0.5–1.0 mg/kg) if initial sedation is inadequate, or if repeated doses are necessary to accomplish a longer procedure.

Table continued on following page

Table 159–8 Procedure for Dissociative Sedation with Ketamine (Continued)

Route of Administration	IM	IV
Advantages	No IV access necessary	Ease of repeat dosing Slightly faster recovery
Peak concentrations and clinical onset	5 min	1 min
Typical duration of effective dissociation	20–30 min	5–10 min
Typical time from dose to discharge	60–140 min	50–110 min

Coadministered Medications

- Concurrent anticholinergics have been traditionally administered with the intent of minimizing ketamine-associated hypersalivation, although recent evidence suggests that this recommendation has been overstated.
- If atropine is used, the typically recommended dose is 0.01 mg/kg (minimum 0.1 mg, maximum 0.5 mg). Atropine can either be given IV just prior to ketamine, or mixed with ketamine in the same syringe for IM injection.
- Glycopyrrolate is an acceptable alternative to atropine at equipotent doses; however, there is no evidence that it is more effective or in any way advantageous.
- In children, benzodiazepine coadministration does not appear to decrease unpleasant recovery reactions. However, a benzodiazepine should be readily available to treat such rare reactions should they occur.

Procedure

- Adjunctive physical immobilization may be needed occasionally to control random motion.
- Adjunctive local anesthetic is usually unnecessary when using dissociative dose.

Interactive Monitoring

- Mandatory close observation of airway and respirations by an experienced health care professional is maintained until recovery is well established. THE PATIENT IS NEVER LEFT ALONE.
- Drapes should be positioned such that airway and chest motion can be visualized at all times.
- Occasional repositioning of the head may be indicated for optimal airway patency.
- Occasional suctioning of the anterior pharynx may be necessary.

Mechanical Monitoring

- Suction equipment, oxygen, a bag-valve-mask, and age-appropriate equipment for advanced airway management should be immediately available.
- Maintain continuous pulse oximetry until recovery is well established.
- Maintain continuous cardiac monitoring until recovery is well established.
- Maintain continuous capnography, if available, until recovery is well established.
- Pulse and respiratory rate should all be recorded periodically throughout the procedure. Blood pressure measurements following the initial value are generally unnecessary, as ketamine stimulates catecholamine release and does not depress the cardiovascular system in healthy patients.

Potential Side Effects

- Airway misalignment requiring repositioning of head (0.7%)
- Transient laryngospasm (0.4%)
- Transient apnea or respiratory depression (0.3%)
- Hypersalivation (1.7%)
- Emesis while sedated (0.8%)
- Emesis well into recovery (5.9%)
- Recovery agitation (mild in 17.6%, moderate or severe in 1.6%)
- Muscular hypertonicity and random, purposeless movements are common.
- Clonus, hiccupping, and/or rash may occur.

Recovery

- Maintain minimal physical contact or other sensory disturbance.
- Maintain a quiet area with dim lighting if possible.
- Advise parents or caregivers not to stimulate patient prematurely.

Discharge Criteria

- Return to pretreatment level of verbalization and awareness
- Return to pretreatment level of purposeful neuromuscular activity
- A pre-discharge requirement of tolerating oral fluids is not necessary or recommended after dissociative sedation.

Discharge Instructions

- Nothing by mouth for approximately 2 hr
- Careful family observation and no independent ambulation for approximately 2 hr

From Green SM, Krauss B: Clinical practice guideline for emergency department ketamine dissociative sedation in children. *Ann Emerg Med* 44:460–471, 2004.

Cooperative Child Use

The safest method of nitrous oxide administration is via a self-administered demand-valve mask.⁸²⁻⁸⁴ The patient must generate a negative pressure of 3 to 5 cm H₂O within the handheld mask or mouthpiece to activate the flow of gas. Patients can thus self-titrate by inhaling at will through the mask. This will only be effective when the patient is cooperative. This technique provides a built-in fail-safe mechanism. If the patient becomes somnolent, the mask will fall from the face and gas delivery will cease.

Nitrous oxide can be used as an adjunctive anxiolytic during mildly painful procedures, or during local or regional anesthesia administration for other procedures. Administration may also be useful during difficult pelvic examinations, attempts at difficult IV access, and the like.

A double-tank system is commonly used to deliver the nitrous oxide–O₂ mixture. The system relies on a mixing valve preset to deliver a fixed ratio that will only deliver gas when O₂ is flowing. The double-tank system contains a fail-safe device that automatically stops the flow of nitrous oxide when the O₂ supply is depleted.

Uncooperative Child Use

The primary limitation of self-administration is that it is ineffective in uncooperative patients, including most frightened young children. Continuous-flow nitrous oxide has been used in this population using a mask strapped over the nose, or over the nose and mouth.⁸⁶⁻⁸⁹ Nitrous oxide can effectively produce moderate or deep sedation when administered in this manner; however, this technique necessitates an additional physician dedicated to continuous gas titration to avoid oversedation. Additionally, the continuous-flow technique is associated with more frequent emesis (10%)^{86,88,89} than self-administration (0% to 4%),⁸¹⁻⁸⁴ posing a potential hazard when a mask is strapped over the child's mouth. Finally, the requirement of a mask hinders procedures involving parts of the face that are covered.⁸⁹

Adverse Effects and Precautions

A number of generally minor adverse effects may be seen, including nausea, dizziness, voice change, euphoria, and laughter.⁸¹⁻⁸⁴ Nitrous oxide should be avoided in patients with potential closed-space diseases such as bowel obstruction, middle ear disease, pneumothorax, or pneumocephaly. Because it is highly diffusible, nitrous oxide has the potential to increase the size of the closed space. This should be clinically unimportant for most short-term uses in typical PSA concentrations.

A scavenging system must be in place to collect exhaled nitrous oxide, and care must be taken to ensure compliance with occupational safety regulations. Care should also be taken to avoid nitrous oxide exposure in pregnant ED staff members as nitrous oxide is a known teratogen and mutagen.

Although the potential for abuse by ED staff exists, such abuse should be rare if simple steps are taken. As with other agents, a strict protocol of accountability should be in place. A simple locking device can be added to the cylinders of gas. In addition, the delivery valve or mouthpiece may be locked in the same location as controlled substances.

Other PSA Agents

Historically a popular PSA cocktail was the IM combination of meperidine, promethazine, and chlorpromazine (“DPT,” “Dem compound”). However, this regimen cannot be titrated, is frequently ineffective, and is associated with prolonged recovery times.^{90,91} Its use can no longer be recommended.

Antagonists

Reversal agents should not be routinely administered following administration of opioids or benzodiazepines for PSA, but rather should be reserved for rare situations of oversedation or respiratory depression. When administered, caution should be taken to avoid resedation after discharge by continuing to monitor patients until the effects of the PSA agents (which may last longer than the antagonist) wear off.

Naloxone

Naloxone is an antagonist that competitively displaces opioids from opiate receptors. It rapidly reverses the analgesic and respiratory depressant effects of opioids. It may be administered IV, IM, subcutaneously, or even sublingually if needed,⁹² and dosing has been standardized for infants and children.⁹³ Naloxone will not induce systemic opioid withdrawal symptoms in a patient without preexisting physiologic dependence. However, some patients will experience nausea with opioid reversal, and those patients with persistent pain following their procedure will be quite uncomfortable. Rapid reversal also may lead to return of anxiety and sympathetic stimulation. If the situation permits, careful titration of small amounts of naloxone may permit partial rather than complete reversal. The only absolute contraindication to the use of naloxone is administration to a neonate born to an opioid-dependent mother due to the risk of precipitating life-threatening opioid withdrawal.

Flumazenil

Flumazenil is a benzodiazepine antagonist that can promptly reverse benzodiazepine-induced sedation and respiratory depression.^{12,61,94} Flumazenil lowers the seizure threshold and may lead to life-threatening seizures. It should be avoided or used with extreme caution in settings of benzodiazepine dependence, seizure disorder, cyclic antidepressant overdose, and elevated intracranial pressure.⁹⁵ It should also be given cautiously to patients who are on medications known to lower the seizure threshold (cyclosporine, tricyclic antidepressants, propoxyphene, theophylline, isoniazid, lithium).⁹⁵ Rapid reversal also may lead to return of anxiety and sympathetic stimulation. If the situation permits, careful titration of small amounts of flumazenil may permit partial rather than complete reversal.

Chapter 160

Wound Management

Jason E. Bernad, MD and James M. Callahan, MD

Key Points

Providing proper anesthesia will allow for a complete evaluation, thorough irrigation, and meticulous repair of wounds.

Thorough cleaning and careful examination will identify and prevent most complications associated with wounds.

Proper lighting, adequate hemostasis, and examining the injured area through a complete range of motion will aid in identifying deep tissue trauma (e.g., tendon, joint injury).

Removal of nonviable tissue and foreign bodies is vital to ensure infection does not develop.

Indications

In 2002, there were 110 million emergency department (ED) visits in the United States. Of these, 39.2 million were injury related, with patients under 18 years of age accounting for approximately 3.5 million.¹ Over the last 10 years, there has been a significant decline in open wound–related visits in the pediatric population.¹ Still, the number of pediatric patients with open wound injuries is quite large, and clinicians must have a solid foundation regarding wound types and their proper management.

Wounds are sustained after a mechanical force has been applied to the skin; the types of forces that can produce injury are compression, shear, and tension type forces. These forces, whether alone or in combination, act to produce one of six types of wounds:

- *Abrasions*: loss of epidermis due to forces acting in different directions (e.g., “road rash”)
- *Lacerations*: tearing of the tissue secondary to shear forces (e.g., a knife cut)
- *Crush wounds*: result of an object impacting tissue, notably over a bone surface, which compresses the overlying tissue

- *Avulsions*: tissue is completely separated, and will be either in a flap configuration with a small base or completely lost
- *Puncture*: small area whose depth is unknown
- Any combination of abrasion, laceration, crush, avulsion, and puncture

Proper wound management revolves around five fundamental principles:

- Providing proper anesthesia
- Cleaning and careful examination for associated tendon, bone, or neurovascular injury
- Removal of nonviable tissue and foreign bodies
- Closure
- Protection

Equipment

The equipment that should be available for wound management is shown in Figure 160–1.

Wound Preparation

Preparation for wound exploration and closure begins with a history that includes the mechanism of injury and the patient’s tetanus immunization status and allergies. Important points to address include any factors that may put the patient at risk for infection or impaired wound healing. This includes, but is not limited to, end-stage renal disease, diabetes mellitus, malnutrition, and compromised immune status. Subsequently, a thorough examination is performed to evaluate tendons, neurovascular status, and bone or joint involvement. Then, a sterile field is established and local anesthesia provided. At that time, a more meticulous examination of the wound is undertaken.

Adequate anesthesia is paramount to obtaining a good examination, and allowing proper irrigation and exploration. Local anesthetics comprise two major classes: the esters and the amides. Lidocaine is one of the most popular of the amides. Prior to infiltration, it is necessary to ascertain whether your patient is allergic to the anesthetic you plan to use. There is little to no cross-reactivity between the two classes. However, patients may also be allergic to the preservative methylparaben, which is used in multidose vials. This preservative is similar in structure to one of the degradation products of the ester anesthetics and may cause problems.² In patients with allergies to both classes of local anesthetics,

FIGURE 160-1. Equipment used during wound management.

Table 160-1 Maximum Dose of Local Anesthetics (with) and Without Epinephrine

Lidocaine (Xylocaine)*	4 mg/kg (7 mg/kg)
Bupivacaine (Marcaine, Sensorcaine) [†]	2.5 mg/kg (3 mg/kg)
Mepivacaine (Carbocaine)	4 mg/kg (7 mg/kg)
Prilocaine (never use in patient < 3-6 mo old)	5.5 mg/kg (8.5 mg/kg)

*The maximum dose is 3 mg/kg for intravenous (IV) regional anesthesia (Bier blocks), and even less for a mini-Bier block. Preservative-free lidocaine without epinephrine should be used for Bier or hematoma blocks.

[†]Due to cardiac toxicity, never use for IV regional anesthesia or hematoma block, do not use <12 years old.

alternatives include the use of cardiac lidocaine (which does not contain a preservative) or the injection of diphenhydramine (which must be injected in a 1% solution to avoid tissue necrosis and has been shown to be more painful than injection of lidocaine).²⁻⁵ Once an agent is chosen, the maximum safe dose is calculated (Table 160-1).

The pain associated with local infiltration of anesthetic is often thought of as a “necessary evil” in wound management, but many options exist for easing this discomfort. These include the use of topical anesthetic prior to infiltration, buffering the lidocaine with sodium bicarbonate in a 1 : 10 solution, warming the lidocaine, infiltration of anesthetic into wound edges instead of outside the wound, use of small needles, and slow infiltration.²⁻⁶

LET gel (a combination of lidocaine, epinephrine, and tetracaine) has been shown to be effective and equivalent to the infiltration of lidocaine when applied to the face and scalp. If it is applied upon presentation to triage, use of this agent can reduce ED wait times and improve patient (and parent) satisfaction.^{7,8} When administering LET, the gel is applied directly into the wound and the wound is covered with cotton for 20 to 30 minutes. Gauze should not be used to cover the wound, since this material will absorb the gel and diminish the amount of LET present within the wound. After 20 to 30 minutes, wound edges that are blanched are likely to have good local anesthesia. At this time, the wound edges are re-evaluated for any missed areas that do not blanch. Some authors have recommended additional infiltration of local

anesthetic, citing the fact that any interruption during the repair process would lead to lost time and decreased patient satisfaction.⁷ As with any epinephrine-containing compound, LET gel should not be applied to any area containing an end artery (fingers, nose, toes, ears, and the tip of the penis) or devitalized tissue.

Following achievement of good local anesthesia, the wound is copiously irrigated. The goal of irrigation is to decrease the potential bacterial concentration so that it can be handled by host defenses.⁹⁻¹³ Normal saline is the irrigating fluid of choice in this situation, although studies have shown no difference in infection rates between saline and tap water irrigation.^{12,13} A syringe (preferably 30 to 60 ml) with an attached 18- to 19-gauge angiocatheter or splash guard (to avoid splatter and exposure to bodily fluids) is used for irrigation. Use of constant steady pressure will ensure proper irrigation; very high pressures have been shown to cause trauma to the tissue. The amount of fluid necessary for proper irrigation is tailored to the patient, location of the wound, amount of contamination, and underlying cause of the wound. Wounds should be irrigated with at least 50 to 100 ml of fluid per centimeter of wound.⁴ Wounds of the face and scalp (highly vascularized areas with low incidence rates of infection) deserve special mention in this regard. Infection rates and cosmetic appearance do not differ whether these wounds are irrigated or washed with normal saline and gauze if they are noncontaminated and nondevitalized, and patients present within 6 hours of injury.¹⁰

The use of antiseptic solutions, such as povidone-iodine and hydrogen peroxide, on wounds continues to be an area of controversy. Multiple studies have shown them to be effective at controlling the growth of microorganisms in wounds when used at low concentrations. However, at high concentrations they are cytotoxic and may actually hinder the healing process.¹⁴ Cell death and necrotic tissue left from this process may actually lead to infection. They are primarily useful for cleansing the skin surrounding the wound in preparation for further wound management, but should not routinely be used to irrigate wounds. If used to clean the inside of a wound, the solution needs to be diluted with saline and thoroughly rinsed out of the wound before further wound management and closure.

Techniques

Once a sterile field is established, the clinician should provide local anesthesia and irrigate and thoroughly examine the wound. Proper lighting should always be used to perform the examination. Achieving hemostasis will help maintain a dry field. Techniques that can be employed to ensure hemostasis include direct pressure or a blood pressure cuff placed proximal to the wound and inflated to 20 to 30 mm Hg above the patient’s systolic blood pressure. If the wound is on a digit, the clinician can place a sterile glove over the hand, cut off the tip of the glove on the corresponding digit, and roll the glove to the base of the digit.^{3,5}

Careful examination of the wound includes putting the area in question through a full range of motion, paying careful attention to those wounds overlying joints and tendons. Any suspected tendon injury or joint involvement will require orthopedic consultation and possibly operative intervention. Clinicians must always exclude a retained

foreign body by directly examining wounds and obtaining radiographic studies if there is any suspicion of a retained foreign body (see Chapter 162, Foreign Body Removal).

Hair in the area of the wound should be removed as this has been shown to be a source of contamination.^{3,5} Hair should be clipped or cut, since shaving injures the hair follicles and allows greater access to bacteria, increasing infection rates. The eyebrows should never be clipped or shaved as they may not grow back.

During the examination, the clinician should determine if there is any nonviable tissue. This tissue should be excised since nonviable tissue impairs resistance to bacterial infection.^{2,4,15} No more tissue should be removed than is necessary. This is especially important in areas with high tension (joints, digits) and areas where cosmetic outcome is significant (e.g., the face). If an extensive area is contaminated, crushed, or devitalized, high-pressure irrigation should be used initially and the tissue then re-evaluated. The option always exists for operative débridement, depending again on the wound's size, location, and degree of contamination. For wounds with jagged edges, conversion to a straight line may improve cosmetic outcome.¹⁵

Primary closure of wounds can be performed on most patients who present to the ED. While there is a direct

relation between the time from injury to wound closure and infection rate, that precise time beyond which wounds should not be closed is controversial.^{2,3,5,15-17} Each wound should be considered on an individual basis depending on time of injury, location, contamination, infection risk, and importance of cosmetic appearance.^{2,5} For wounds that are highly contaminated, in areas of poor vascular supply, or if the patient is immunocompromised, primary closure should be performed within 6 hours.³ Clean facial and scalp wounds can be closed up to 24 hours after injury.

Sutures are the most universally used wound closure material. They provide the greatest tensile strength and lowest risk of dehiscence.⁵ The proper choice of suture material is dependent on the type of wound, location, depth, and cosmetic goals. While evaluating the wound, the clinician should make note of the depth as well as the tension at the wound edges. Deep sutures should be considered to close deep wounds, diminish dead space and hematoma formation, and decrease tension at the surface of wounds. Deep sutures should be avoided in highly contaminated wounds and in fat due to increased risk of infection.^{2,3,5,15} Suture size and timing of suture removal varies with location of wounds (Table 160–2).

Choice of suture material is highly wound dependent (Table 160–3). In general, monofilament and synthetic

Table 160–2 Suture Size and Location

	Face	Scalp	Torso	Extremities	Joints	Oral
Suture size	6-0 to 7-0	3-0 to 5-0	3-0 to 4-0	4-0 to 5-0	3-0 to 4-0	3-0 to 5-0
Suture removal*	3–5 days	7 days	10 days	7–10 days	10–14 days	Absorbable

*Sutures under high tension may need to stay in place longer than the specified time.

Table 160–3 Properties of Various Suture Materials

Suture Material (s)	Absorbable	Synthetic	Properties
Surgical gut (chromic or not)	Yes	No	Plain gut is used for rapidly healing tissues and suturing subcutaneous fatty tissue, fast-absorbing gut is for epidermal use only, and chromic has tensile strength for 10–14 days with a slower absorption rate (due to chromium) and may be used in the presence of infection.
Polyglactin 910 (Vicryl)	Yes	Yes	Multifilament and coated with lactide to slow loss of tensile strength and calcium stearate to permit easy tissue passage and precise knots and tying. Tensile strength is $\frac{2}{3}$ by 14 days after use. Causes only minimal tissue reaction; may be used if infection is present, and for soft tissue approximation and vessel ligation. Dexon II has similar properties.
Poliglecaprone 25 (Monocryl)	Yes	Yes	Monofilament with good pliability and handling. Used for subcuticular closure, soft tissue approximation and ligations.
Polydioxanone (PDS II)	Yes	Yes	Monofilament polyester suture with only slight tissue reaction with wound support up to 6 wk. It is used for soft tissue approximations.
Surgical silk, cotton, and steel	No	No	These are rarely used in ED wounds.
Nylon			
Monofilament (Ethilon/Dermalon)	No	Yes	Pliable, elastic, and good for skin closures. Stronger than silk and minimal tissue inflammatory reaction.
Braided (Nurolon/Surgilon)	No	Yes	Pliable, elastic, and good for skin closures. Stronger than silk and minimal tissue inflammatory reaction.
Polybutester (Novofil)	No	Yes	Very elastic and low coefficient of friction, allowing for surface closure while permitting tissue edema and detumescence.
Polyester fiber			
Uncoated (Mersilene/Dacron)	No	Yes	Polybutylate coating or silicone coating reduces friction for easy tissue passage and tying. Only minimal tissue reaction. Mostly used for vessel closure and tying prosthesis.
Coated (Ethibond/Ti-cron)	No	Yes	Polybutylate coating or silicone coating reduces friction for easy tissue passage and tying. Only minimal tissue reaction. Mostly used for vessel closure and tying prosthesis.
Polypropylene (Prolene)	No	Yes	Monofilament suture that does not adhere to tissues and is easy to pull out/remove. It also holds knots better than other monofilament materials. Can be used in contaminated and infected wounds.

materials are preferable to braided and natural materials because they result in lower infection rates. The optimal suture material is easy to work with and has good tensile strength, minimal tissue reactivity, and excellent knot security. Based on the wound, the clinician must decide whether deep sutures will be placed. If so, an absorbable material should be used. In general, synthetic absorbable materials carry lower infection rates, less tissue reactivity, and more tensile strength than natural material. Polyglactin (Vicryl) is an example of a synthetic absorbable suture, and surgical or chromic gut are examples of natural material. The use of absorbable material need not be limited to the deep structures, as using them for superficial wound closure in children will avoid the traumatic experience of having those sutures removed. Fast-absorbing plain gut sutures are rapidly broken down and are even acceptable for use on the face in children. Cosmetic outcome is excellent as long as families are instructed in the care of the wound and they comply with these instructions. The wound should be gently cleansed with hydrogen peroxide two to three times per day using a cotton-tipped applicator and then bacitracin ointment applied to the wound. This leads to rapid breakdown of the absorbable sutures and decreased scar formation.

Nonabsorbable material (e.g., nylon and polypropylene) is often used for skin closure. This material maintains its tensile

strength for more than 60 days and is relatively nonreactive. These sutures require removal.

Suture Technique

Wound closure requires attention to good cosmetic outcome. Simple interrupted sutures can be used for wounds with minimal tension. A suturing technique that allows for a slight eversion of wound edges should be used. This can be accomplished by taking a slightly wider bite at the depth of the wound compared to the surface (Fig. 160–2). During healing and skin remodeling, the wound will flatten out as the tissue below it contracts. Without eversion, the patient will be left with a depressed scar. Also, the suture should be tied in such a way as to approximate the edges, but not so tightly as to cause necrosis due to swelling. When tying deep sutures, the knots should be buried to avoid any further tissue reactivity (Fig. 160–3).

Running sutures can be used to quickly close long wounds that are already well approximated (Fig. 160–4). Running locked sutures can be used for wounds with tension and minimal to moderate bleeding (Fig. 160–5). Since they can impair circulation, they are best suited for areas where cosmesis is less important (e.g., scalp, torso, extremities).

Corner sutures are used to approximate a laceration with a flap. The initial bite begins on the side of the wound on

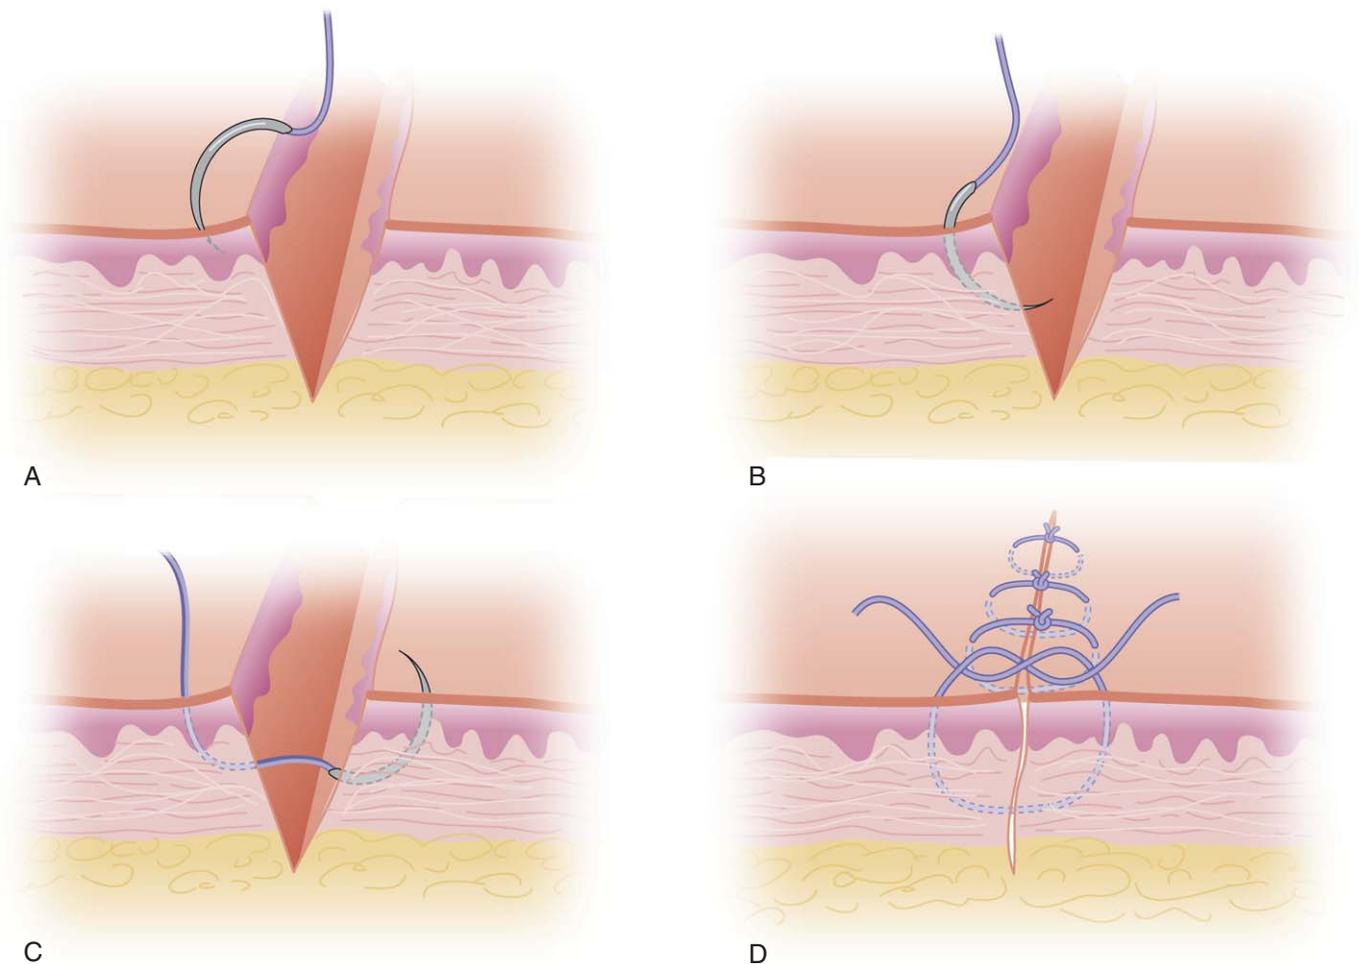

FIGURE 160-2. Simple interrupted sutures.

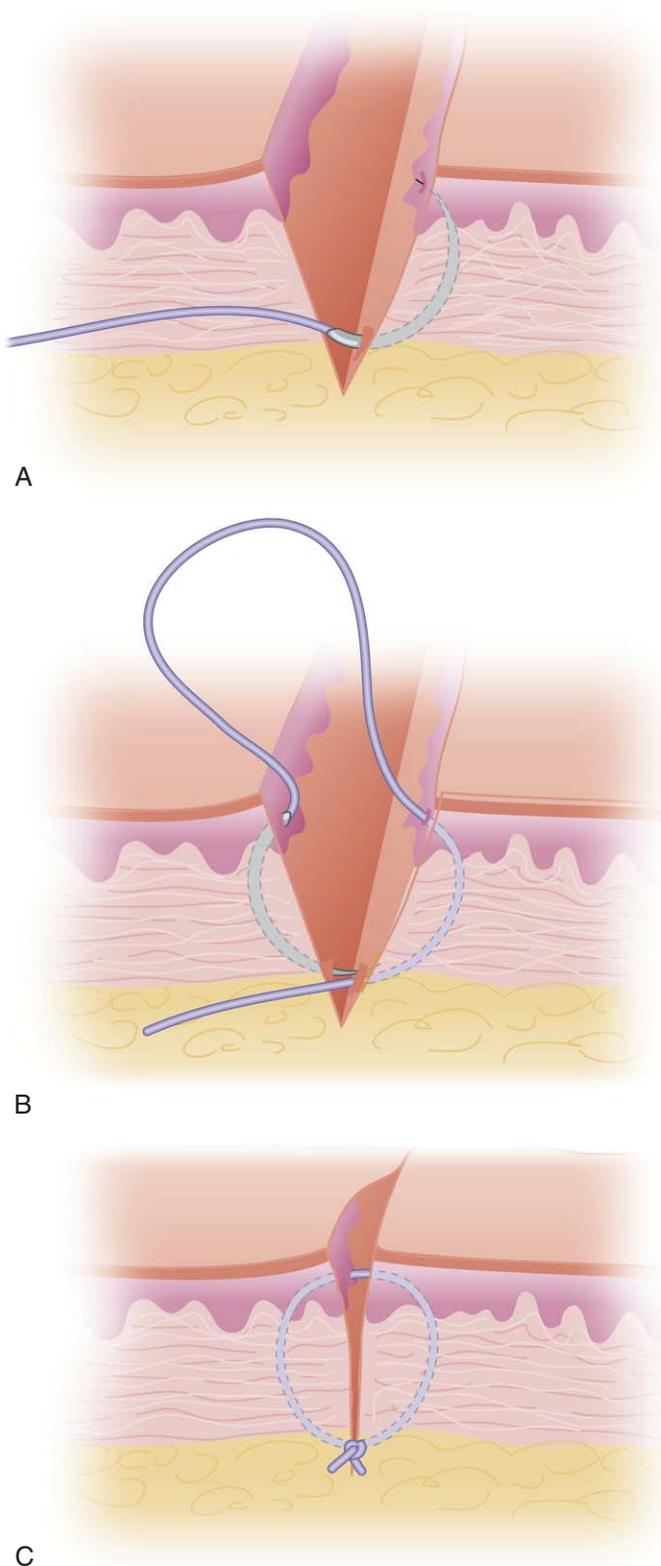

FIGURE 160-3. Deep absorbable sutures with buried knot.

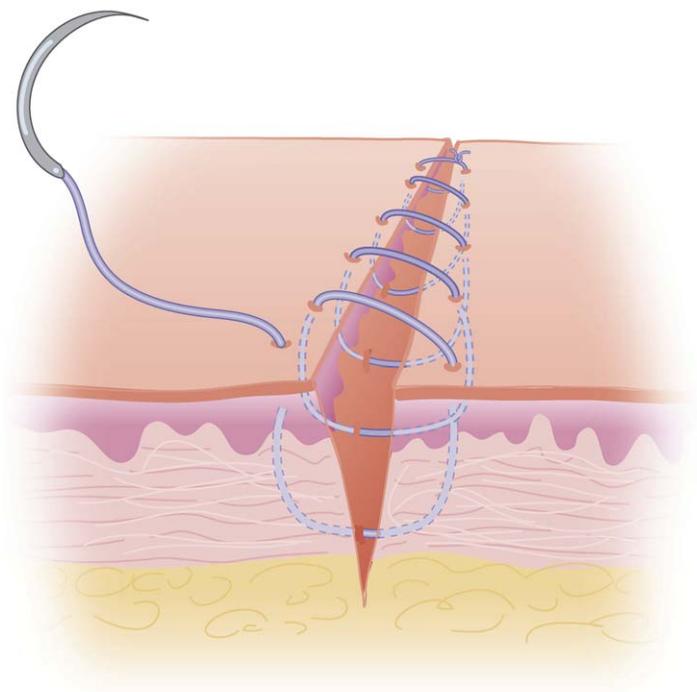

FIGURE 160-4. Running sutures.

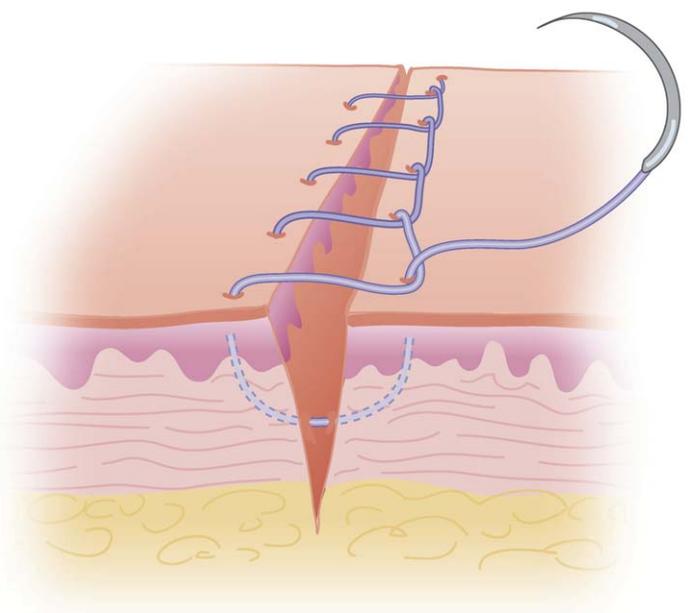

FIGURE 160-5. Running locked sutures.

which the flap is to be attached. The suture is placed through the dermis of the wound edge to the dermis of the flap tip, then passed through the flap to reenter the skin where the flap will be attached (Fig. 160-6).

Horizontal or vertical mattress sutures are helpful in areas with high tension across the wound edges. Mattress sutures are also helpful in everting the wound edges and reducing the dead space across a wound (Figs. 160-7 and 160-8). The running subcuticular suture is a buried horizontal mattress suture. It is placed by taking bites through the dermis on alternating sides of the wound (Fig. 160-9). This technique

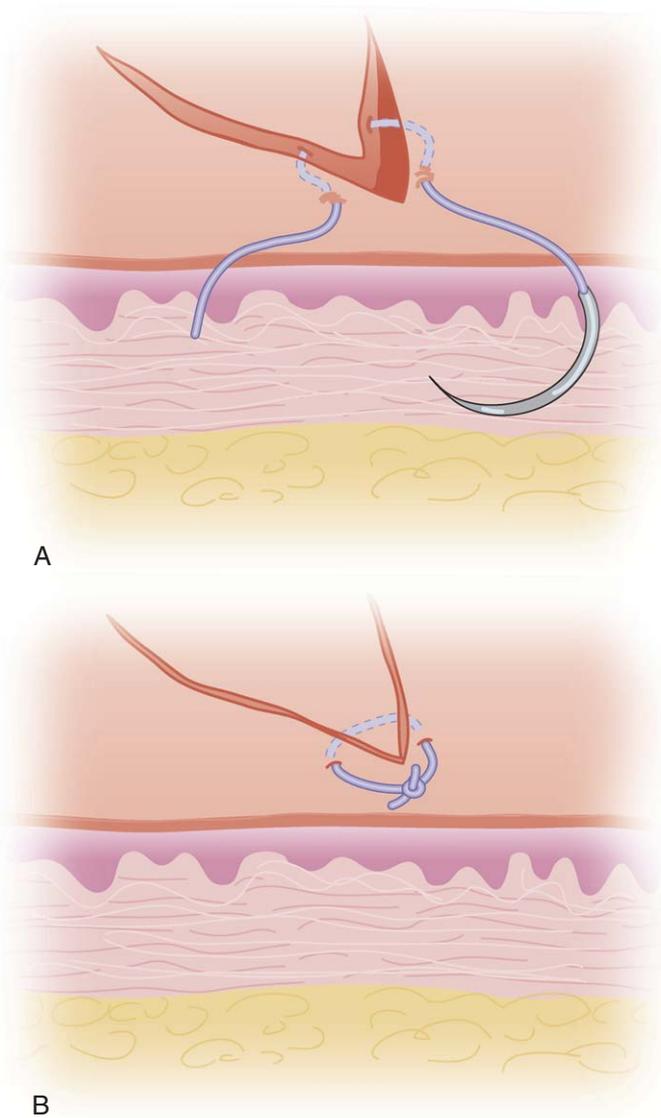

FIGURE 160-6. Corner sutures.

leaves no suture marks, and the suture may be left in place for several weeks.

Alternatives

Staples are an alternative to closure with sutures that offer a more rapid application time and are associated with decreased foreign body reactions and infection rates. This method is useful for wounds of the scalp, trunk, and extremities; they are also useful for very long wounds and situations in which a mass casualty incident may require triage-type wound management until definitive treatment can take place. Their placement is not as esthetically pleasing, and they are not suited for the hands, feet, or face.

Tissue adhesives are cost effective, and allow decreased ED wait times and improved patient and parent satisfaction. They are low risk as no sharp instruments are used, and they require no dressing, have antimicrobial properties against gram-positive organisms, and offer a cosmetic outcome as good as or better than suturing. In addition, there is no need

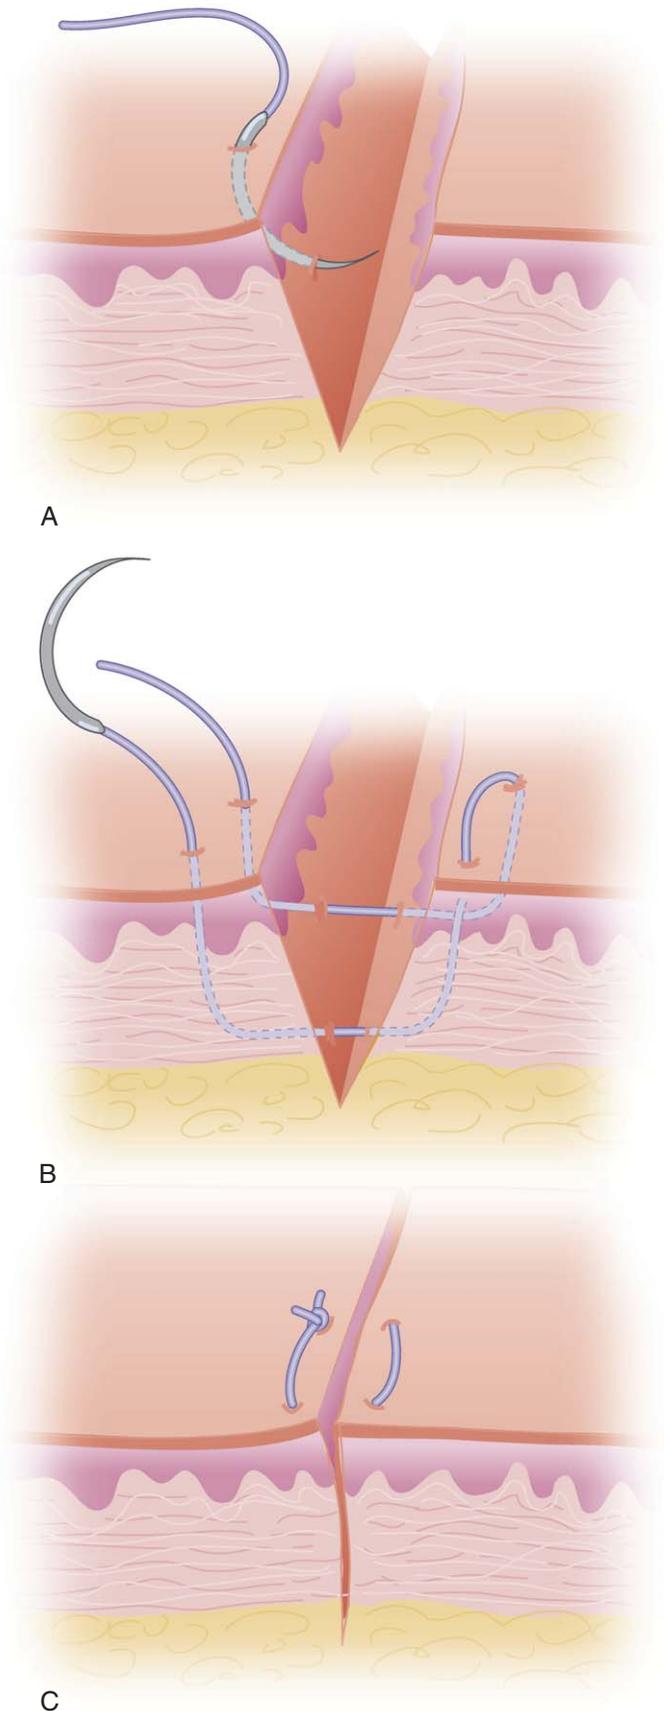

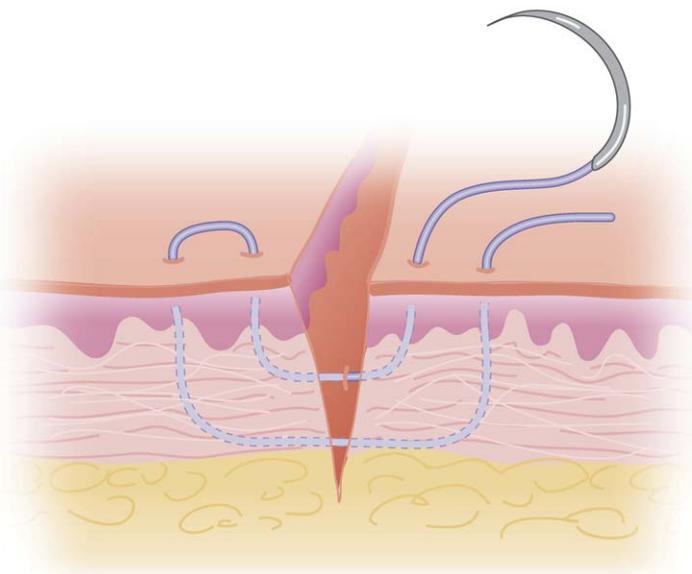

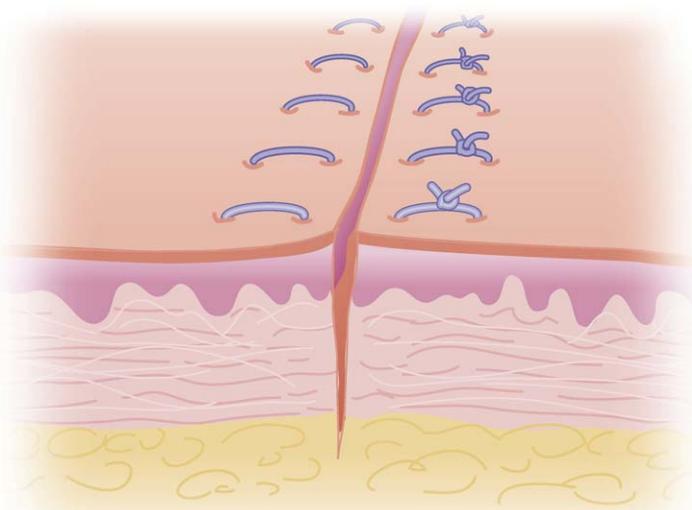

FIGURE 160-7. Horizontal mattress sutures.

A

B

FIGURE 160-8. Vertical mattress sutures.

for suture removal as the adhesive usually sloughs off after 7 to 10 days.^{3,18-22}

The tissue adhesive most widely used is 2-octylcyanoacrylate (Dermabond; Ethicon). This adhesive is less toxic and provides greater strength than previous adhesives. 2-Octylcyanoacrylate reaches maximum strength 2½ minutes after application, and its strength is equivalent to healed tissue 7 days postrepair. The adhesive is a monomer that is transformed into a polymer when it contacts the skin's moisture. This polymer forms a link between the two wound edges and allows healing to occur below. The change from monomer to polymer is exothermic and may be felt by patients. It is best to warn patients that the adhesive will feel warm and may be uncomfortable for young children.

Tissue adhesives are best used for wounds on the face, extremities, or trunk. Wounds that are short (<6 cm) and

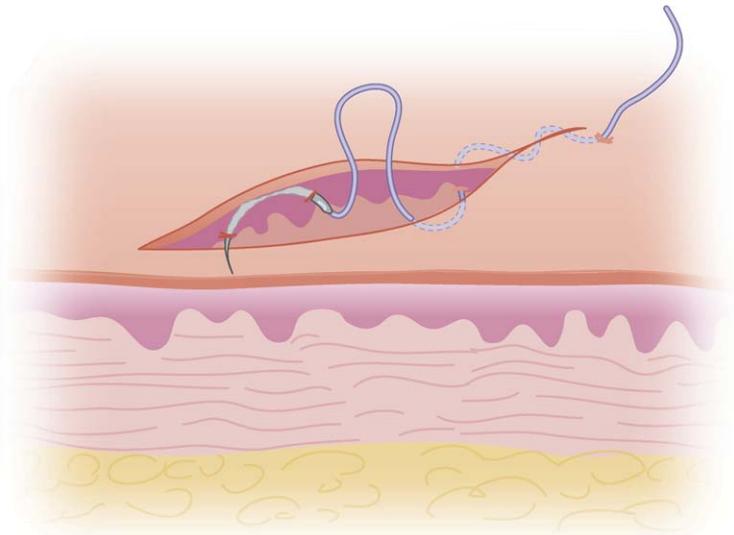

FIGURE 160-9. Running subcuticular sutures.

low tension (<0.5-cm gap between wound edges) are best.²³ Tissue adhesives should be avoided in jagged or stellate wounds, mucosal surfaces, and the axilla or groin. Patients with wounds that overlie the hands, joints, or other areas of repetitive motion are not good candidates as the epidermis will slough prior to proper healing. If used in these areas, immobilization is indicated to ensure proper healing. Tissue adhesives may also be appropriate for deep wounds as long as deep sutures have been placed to reduce skin tension.

As with suture placement, application requires special attention to detail. It is still recommended that a topical anesthetic be used for any wound. This serves several purposes. Local anesthesia will facilitate adequate cleansing and exploration of the wound, may minimize the sensation of heat release from the polymerization of the adhesive, and also may provide hemostasis. The wound must be clean and dry for the adhesive to work properly. After anesthesia and hemostasis, the wound is cleaned and evaluated. The area around the wound is dried, and the tissue edges are carefully aligned. Tissue adhesives are not bioabsorbable—the body will not break them down. Therefore, any adhesive that makes its way into the wound not only will prevent epithelialization, but can provoke foreign body reactions (inflammation, necrosis, and infection).^{18,24,25} After good tissue approximation, the plastic vial is cracked and the applicator tip is saturated. New devices have recently become available that are basically a pen with a needle-tipped applicator, which allows for a more precise application. The adhesive is applied in even strokes along the length of the wound in a layered manner, allowing 15 seconds between layers. Four layers are suitable for proper healing. When complete, the wound edges are held together for 30 to 60 seconds for drying.⁴ The skill of applying adhesive in a smooth, even manner without extensive runoff or dripping is attained with practice. All drips and runoff should be wiped up immediately. The clinician should pay careful attention when applying tissue adhesive to the forehead, protecting the eyes with gauze pads or applying a Tegaderm dressing over the eye for protection during application.

A wound dressing is unnecessary at this time. Patients and caregivers should be instructed to keep the area clean and dry. Petroleum jelly or antibiotic ointment should not be applied to the wound as either will advance breakdown of the adhesive. Importantly, these agents can be used to remove errantly placed adhesive. After application, the adhesive will slough off in 7 to 10 days with the top layer of skin. An adhesive bandage over the wound may prevent younger children from picking at the tissue adhesive and increase the time until it sloughs off. When placing a bandage over the wound, ensure that the tissue adhesive has completely dried and that only the gauze portion of the bandage comes in contact with the tissue adhesive.

An alternative to complete wound closure is open management. Wounds left to heal on their own will develop more inflammation and edge contraction than wound with edges that are approximated with sutures or tissue adhesives. This may lead to worse cosmetic outcome and possibly loss of function. This is especially true in areas with less vascular supply than the face or scalp. Also, the healing process may be unable to adequately heal an area that has little mobile tissue (i.e., the scalp). One small study found that hand lacerations (<2 cm in length) treated openly had cosmetic outcome at 3 months equivalent to suturing, had less pain during the procedure, and experienced no loss of function.²³ Open management may be considered in situations in which, after adequate irrigation and exploration, the wound is still considered to be highly contaminated and at risk for infection if closed. Puncture wounds, wounds more than 24 hours old, and wounds exposed to organic matter, soil, or feces are often appropriately left open. Wound that are left open can remain open until healing takes place, or they may be closed in a delayed fashion (delayed primary closure). In this instance, the clinician should administer oral antibiotics, cleanse the wound daily, and close the wound 2 to 5 days after the injury.

Finally, wounds that require extensive débridement, prolonged suturing times (e.g., >30 minutes), or meticulous alignment of involved structures (e.g., eyelids, philtrum) or that cover extensive areas may require plastic surgery consultation and possible management under general anesthesia.

Complications

Despite the large number of wounds treated in EDs every year, the rate of infection is extremely low (<1%). Most wound infections are due to poor cleansing and exploration, improper sterile technique, noncompliance with discharge instructions, or selection of dirty wounds that required delayed primary closure or healing by secondary intention. Potentially infected wounds in patients who return to the ED require gentle compression and the removal of enough sutures to allow for drainage. If purulent material is expressed from the wound, more extensive exploration, irrigation, and hospital admission may be required. The sutures may remain in place with one end of the wound remaining open to allow for further drainage. For deep or obviously tense wounds, the clinician should remove sutures and incise the wound (after proper local anesthesia), irrigate it, and pack it with gauze. The gauze is removed in 2 to 3 days and the wound left to heal by secondary intention.²⁶

Based on the anatomic location and extent of infection, an intravenous (IV) dose of antibiotics effective against suspected organisms should be administered. The decision to admit or discharge the patient will be based on many factors. These include anatomic location and the extent of infection: whether the infection is localized to the wound area, whether there is significant erythema or purulent drainage, and whether the patient is immunocompromised or is febrile, which may indicate systemic seeding. For localized infections, a single dose of IV antibiotics is administered followed by a course of oral antibiotics. Then, the wound is properly dressed and treated by delayed primary closure. In this case, the patient should return for a wound check and dressing change in 24 hours. If systemic signs of infection develop, the clinician should administer IV antibiotics and admit the patient to the hospital.

Wound dehiscence is usually caused by wounds closed under tension, formation of a hematoma or abscess, or placement of an inadequate number or size of sutures. If dehiscence is noted, the original sutures should be left in place. At the time of standard removal, alternating sutures are removed, leaving the others in place for an additional few days.²⁶ If dehiscence is noted when the remaining sutures are finally removed, skin tape can be placed until the wound heals. Resuturing is not recommended.

When patients return to the ED for reevaluation, the clinician should always consider the possibility of a missed foreign body, tendon injury, or bone injury. Radiographic examination may be required as well as reexploration of the wound if there is a high suspicion that a foreign body is present.

If there is any question of tendon injury after examination and exploration, the clinician should consider closing the wound, splinting the site and adjacent joints, and arranging orthopedic follow-up. Acute repair of tendon injuries in the ED setting may be associated with an increased complication rate. Repair of tendon or vascular injuries is often safely delayed for 1 to 3 days after closure. The use of microscopic instruments by an experienced operator in the operative setting is often associated with better outcomes and decreased rates of unintentional injuries to nearby nerves or other structures.

Postprocedure Care and Disposition

For all wounds, the clinician must consider whether the patient will need tetanus immunization (see Chapter 103, Tetanus Prophylaxis) or prophylactic antibiotics. Fortunately, less than 1% of all wounds become infected. For this reason, antibiotic use is not routinely recommended.²⁷ The decision to administer antibiotics is based on the mechanism and extent of injury, as well as the extent of contamination and the patient's immune status. Antibiotics are indicated for human, dog, and cat bites, open fractures, intraoral lacerations, and devitalized or severely contaminated wounds (see Chapter 120, Skin and Soft Tissue Infection).

Following wound repair, placement of a dressing is indicated in all but facial wounds. Optimal dressings will protect the wound from bacteria and foreign material, absorb exudate from the wound, prevent heat and fluid loss from the wound; in addition, they are nonadherent and provide a warm, moist, occluded environment to maximize epithelialization and minimize pain.²⁸ The patient should be instructed to

keep the initial bandage in place for the first 24 to 48 hours to allow for epithelialization of the initial skin layer.⁵ After 72 hours, wounds are resistant to infection from external contamination and dressings are not necessary.⁴ The patient may gently wash the wound after the first 72 hours, but should be instructed not to scrub it, as this may disrupt the healing process. Application of antibiotic ointment will help to keep the wound moist and may decrease the likelihood of infection.^{3,4} Topical antibiotics should be avoided if tissue adhesives are applied. Sutures on the face may be removed in 3 to 5 days, and those on extremities and most other areas of the body in 7 to 10 days (see Table 160–2).

Areas with high tension and mobility (i.e., joints and digits) should be immobilized. This will allow for proper healing without tension on the wound edges. Extremities should be splinted in their position of function. Sutures in these high stress areas may be removed in 10 to 14 days.

Patients are instructed to return for pain, erythema, drainage, or any evidence that the wound may have become infected. Following suture removal, patients should be instructed to apply sunblock to the healed area whenever they are outside for the next 6 to 12 months, as this will prevent the healed area from becoming hyperpigmented.

Summary

All wounds require anesthesia to allow for careful and thorough cleaning and examination. Foreign bodies, tendon, bone, and neurovascular injury should always be excluded before closing any wound. Choosing the most appropriate technique for closure and then appropriately protecting the wound during the healing process will lead to decreased rates of infection, decreased scarring, and increased patient comfort and satisfaction.

Vascular Access

Frances M. Nadel, MD, MSCE

Key Points

Vascular access should not delay or interfere with airway management in a critically ill child.

During an emergency, the provider who is most practiced and experienced in access should be primarily responsible for vascular access.

The site that is most quickly accessed and does not interfere with the resuscitation should be used.

Intraosseous lines can be used in children of any age.

Selected Procedures

- Peripheral intravenous line placement
- Intraosseous needle placement
- Central venous access
- Umbilical vessel cannulation

Discussion of Individual Procedures

Peripheral Intravenous Line Placement

Peripheral intravenous (PIV) access is a rapid, safe method of delivering medications, fluids, and blood products to the circulating blood system. In children, resuscitation medications given through PIVs have an onset of action and concentration similar to those delivered centrally. The volume of flush following a medication appears to be more important than the type of access.¹

Venous access should be avoided in areas distal to an injury, such as a fractured limb, because of the possibility of disrupted vasculature and difficulty monitoring for complications associated with extravasated infusions. When possible, areas with edema, overlying burns, or cellulitis should also be avoided. A vein that is scarred from frequent use may be difficult to access.

Families and children are often very anxious about PIV insertion. If time is available, the clinician should explain the procedure prior to insertion as well as during each step. Children should be informed honestly about the painfulness of

the insertion to prevent future mistrust. Separating a child from the guardian during a painful procedure may increase the child's anxiety. Instructing parents who are willing to stay for the procedure on how to convey support may be particularly helpful. Families of chronically ill children may have helpful hints regarding access.

Anatomy and Physiology

The smaller vessel diameter and pudginess of infants and young children can make vascular access challenging. In young infants, vessels are more superficial than in adults. PIVs can be inserted in the forearm, hands, feet, scalp, and external jugular veins. On the forearm, the medially located cephalic vein and proximal basilic veins and their branches on the dorsum of the hand are the vessels most commonly used. The cephalic vein that courses over the proximal radius is often overlooked. Since it is firmly fixed to the underlying fascia, it is a reliable site. The radial and ulnar arteries should not be punctured if the veins on the ventral aspect of the wrist are used. The antecubital veins are useful sites when emergency access is required or there is a suspicion of intra-abdominal injury. On the foot, the saphenous vein is another site that is firmly affixed to the underlying tissue. This vessel predictably is located along the anterior aspect of the medial malleolus and can be accessed blindly. On the dorsum of the foot, the lateral and medial median and dorsal arch vessels can be accessed as well.

In infants less than 9 months old, the scalp veins can be used. The superficial temporal vein and frontal veins are easily located and relatively large. The superficial temporal vein courses down from the midparietal region to anterior to the ear. The frontal vein is found in the midline of the forehead. Scalp arteries can be differentiated from veins by their tortuosity, presence of a pulse, and flow away from the heart. Fluids or medications injected into an artery will also cause blanching and require removal.

The physician may choose to peripherally access the external jugular vein when other sites have been unsuccessful. It is a large vessel that is easily visible as it passes posteriorly over the sternomastoid muscle from the angle of the jaw. This vessel is harder to cannulate because of its loose affixation to the underlying fascia and the presence of valves. The patient should be placed in Trendelenburg position with lateral neck rotation. Such positioning is contraindicated in a patient with a known or suspected cervical spine injury or in a patient in whom it would interfere with airway management.

Finally, the femoral vein can be accessed via peripheral and central techniques.

There are many commercially available topical anesthetics, such as ELA-max (liposomal lidocaine) and EMLA (lidocaine/prilocaine), that can be used to decrease the pain associated with PIV insertion in the nonemergent setting.² The major drawback is that these agents can take up to 30 to 60 minutes to work, though newer products are being developed that may have a quicker onset of action.³ Additionally, a triage nurse or family member of chronically ill children can be trained to apply the cream when it is suspected that a PIV will be inserted. The cream should be placed on the dorsa of both hands in case the first attempt fails. Injecting buffered lidocaine with sodium bicarbonate in a 9:1 ratio at the proposed puncture site can provide immediate anesthesia. However, this requires two punctures, which may be less preferable to families and may serve to obscure the vessel. The use of topical anesthetic or lidocaine is contraindicated in children allergic to any of the components of the medications. Other methods such as iontophoresis, nitrous oxide, and distraction are currently under investigation.^{4,5}

Equipment for PIV Insertion

- Retractable needle catheters (14 to 26 gauge)
- Topical antiseptic
- Alcohol swabs
- Tourniquet, rubber band
- Normal saline flush
- Gloves (nonsterile)
- T connectors
- Transparent tape
- Transparent occlusive dressing
- Arm board
- Warm packs, handheld illuminators
- Sharps disposal unit

The operator should have all the equipment easily available prior to starting the procedure. The tape should be cut to the appropriate size and the occlusive dressing removed from the package before beginning insertion. Two health care providers are usually necessary, especially for the young child who will likely need restraint.

Site Identification and Procedure

If the patient is in extremis, the physician should use the largest vessel than can be most easily accessed without interfering with other life-saving procedures.⁶ Patients undergoing less emergent access should be placed in a comfortable position and possible sites identified. Normal venous flow distal to the site should be assessed, and, if time permits, topical anesthetic should be applied to likely sites. Warm packs on the distal extremities, tapping the vein, placing the vein in a dependent position, rubbing the site with alcohol, light illumination under the vein, and having older children open and close the hand can help increase peripheral vasodilation and identification of sites.

A tourniquet is applied proximal to the intended site, making sure that the tourniquet does not impede arterial flow. For scalp veins, a rubber band placed around the baby's head can serve as a tourniquet. This scalp tourniquet is easier to remove if two pieces of tape are wrapped around the rubber band to form two pull tabs.

Universal precautions and antiseptic technique must be followed to prevent blood-borne pathogen exposure and catheter-related infections.⁷ Gloves do not need to be sterile.⁷ Antiseptic is applied in a circular fashion over the proposed site and surrounding area. Chlorhexidine, povidone-iodine, or 70% alcohol can be used for site preparation,⁷ waiting 20 to 30 seconds for the area to dry. Wiping away the povidone with an alcohol swab may help visualization.

With an assistant restraining the extremity proximally, and using the nondominant hand, the extremity is held distal to the site. It is best to select the most distal site so that, if necessary, more proximal sites can still be used. With the bevel side of the needle facing upwards, the skin is punctured just below the vessel at a 30- to 45-degree angle. The needle is advanced with catheter until a flashback of blood is seen. Once there is flashback, the needle and catheter are advanced only slightly to make sure the catheter is in the vein. The catheter is angled parallel to the skin and slowly advanced into the vessel, while withdrawing the metal stylet. The plastic portion should slide easily into the vein. Placing a finger just proximal to the catheter tip will help staunch blood return. In infants, young children, and severely hypovolemic patients, there may not be blood return after the initial flashback. In this case, the tourniquet is loosened and the catheter slowly flushed with a small amount of saline. If the PIV flushes easily and no extravasation of fluid is evident, the line is useable. A T connector is attached to the hub of the catheter. A Vacutainer or syringe attached to the T connector can be used to collect blood. For smaller catheters, it may be easiest to allow the blood to drip directly into the specimen tube from the catheter hub. The use of a needleless cap placed on the T connector can reduce further needle exposure. If the first attempt is unsuccessful, the needle portion should not be placed back in the catheter for repositioning as this may cause shearing of the catheter. A new PIV catheter should be used with every attempt.

A semipermeable polyurethane dressing or gauze is used to secure the line.⁷ Though the risk of infection is equivalent, the transparent dressing offers better visualization of the site. Before applying the dressing, blood should be cleaned from the area and the skin around the catheter dried to reduce the risk of infection. A tincture of iodine or chlorhexidine may be helpful as well. One method of stabilizing the PIV is taping the hub of the catheter using a chevron configuration (Fig. 161-1).

If the PIV stops flushing after it is taped, gentle traction should be applied to the PIV to locate a functional position, and the PIV retaped. The T connector tubing should be taped separately from the catheter to prevent accidental dislodgement. The PIV can be further protected by placing a soft splint on the extremity on the side opposite the PIV, taped above and below the insertion site, with the limb in a comfortable, functional position. A small limb restraint that encircles the site can further serve to protect the PIV.

Complications

Serious complications are rare.⁸ Dislodgement, hematomas, and intravenous infiltrates are common complications. Compression of a hematoma may help decrease swelling, and if associated with a lot of swelling, distal extremity perfusion should be monitored. The volume and type of infiltrate will determine necessary interventions. Small infiltrates of non-

FIGURE 161-1. Peripheral intravenous catheter with a chevron anchor, tape, and board.

sclerotic medications usually require compression and elevation alone. Some specific infiltrates may be toxic to the underlying tissue (e.g., vasopressors, promethazine, phenytoin), and specific antidotes may diminish damage. A pharmacist should be consulted for specific medications that may require such therapy (e.g., phentolamine for vasopressors). Arterial puncture, phlebitis, cellulitis, thrombus formation, tendon injury, and nerve injury are less common problems. If infection is suspected, the physician should remove the PIV and administer antibiotics directed at the suspected organism.

Intraosseous Needle Placement

Intraosseous (IO) needle placement is an excellent method for rapidly obtaining vascular access in children with cardiac collapse or arrest.⁶ Intraosseous access should be considered in other critically ill or injured children if access is needed emergently and other routes were unsuccessful or would delay therapy. An IO line can be used in any age group, though it may be more difficult to penetrate the thicker cortex of older children and adults. During resuscitation, the onset of action and peak concentrations of medications through the IO route are comparable to the vascular route.⁶ Though IO access has been shown to be useful in the neonate and older infant, it is not commonly used in newly born infants because the umbilical vein is more accessible, the small bones are fragile, and the intraosseous space is small in a premature infant.^{9,10} Intraosseous access can be used as an alternative route for medications and volume expansion if umbilical or other direct venous access is not readily attainable.⁷ For those physicians who infrequently perform neonatal resuscitation, the IO route may be a more rapid method of access than the umbilical route.¹¹

Intraosseous lines should not be placed in children with osteogenesis imperfecta or osteopetrosis, and bones that are fractured or infected should not be used. An overlying cellulitis or burn is a relative contraindication. If cannulation was unsuccessful in a bone because the needle went through both cortices, subsequent attempts should not be made in that same location.

FIGURE 161-2. Jamshidi and Cook catheters. The trocars have been removed.

Anatomy and Physiology

Blood in the marrow cavity reaches the central circulation through a rich venous network that drains from the central venous sinus into the emissary and nutrient vessels. The rigid marrow cavity is noncollapsible so that it can be accessed even with circulatory failure or hypovolemia. Though the marrow vasculature in the young child is much richer than in older children and adults, IO lines have been used successfully in all age groups. Blood obtained from IO aspiration can be used to assess serum pH, hemoglobin, and blood glucose, and sent for type and crossmatch. As with a central line, an IO line can be used for any medication or blood product.

Equipment for IO Needle Placement

- Antiseptic swabs
- Gloves (sterile if time permits)
- Needle with a trocar: IO/bone aspiration needles (16 to 18 gauge), 20-gauge spinal needle
- Syringe (5 to 10 ml)
- Saline flush
- Tubing
- Hemostat
- Tape
- 1% Lidocaine
- 25- to 27-gauge needle and syringe

The Jamshidi and Cook catheters are two of the most commonly used IO needles (Fig. 161-2). Both have distinct advantages, and individual preference is the primary reason for selection of one system over another. Threaded IO needles offer little advantage over straight needles and may make it difficult to feel the bone give when the marrow space is entered.¹³ There are newer IO needles that use a spring-loaded device that injects the needle into bone.¹⁴ This may be particularly helpful in thicker bones, although spring-loaded needles have not been extensively studied in children.

Site Selection and Procedure

Site selection is based primarily on the age of the patient as an estimate of cortical thickness of the bone. In infants less

than 2 months of age, the distal femur is preferred as the proximal tibia is often too thin. The proximal tibia is an excellent site until about 3 to 4 years of age, when the cortex becomes more difficult to penetrate. For older child and adults, the area just proximal to the medial malleolus or the anterior iliac spine is thin enough to use for an IO access site. Though the sternum in adults has been successfully used, this location is dangerous in children and not recommended. For the distal femur site, the IO catheter is inserted midline, 2 to 3 cm above the femoral epicondyles. The proximal tibial site is medial and 1 to 2 cm distal to the tibial tuberosity, on the flat part of the tibia.¹⁵ The distal tibial site is entered approximately 1 cm superior to the medial malleolus, on the flat part of the tibia (Fig. 161-3).

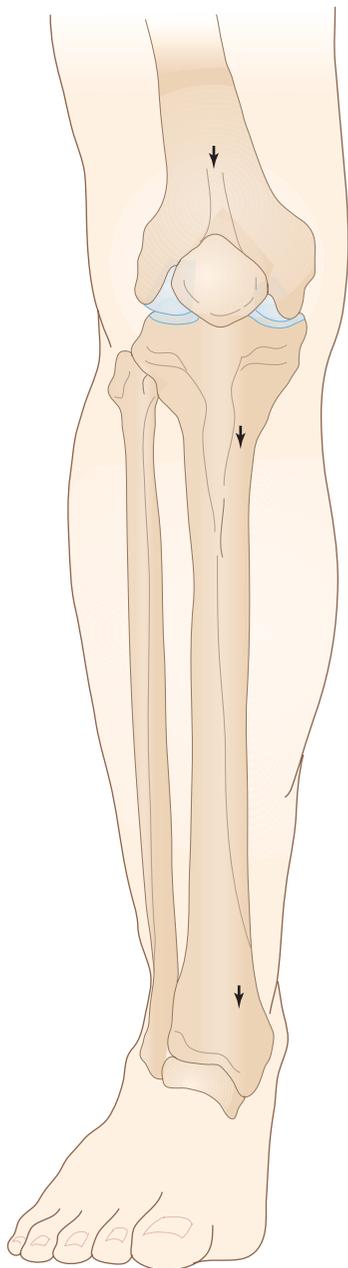

FIGURE 161-3. Common intraosseous needle sites.

If time permits, the physician should glove and sterilely prepare the site. In the conscious or semiconscious child, the skin and periosteum are locally anesthetized with 1% lidocaine using a 25- to 27-gauge needle and syringe. Before inserting the IO needle, the physician should make sure that the trocar is easily removed from the needle and then replaced. Placing the knob of the needle into the palm of the hand, using the dominant hand, the needle is held approximately 1 to 2 cm above the tip using the thumb and index finger. The extremity is grasped with the other hand, making sure the hand is not behind the insertion site. The needle is placed over the desired spot, either at an angle pointed away from the joint/growth plate or perpendicular to the bone. With a gentle clockwise-and-counterclockwise twisting motion, the needle is drilled into the bone until a sudden release of resistance is felt, indicating access into the marrow. Insertion is stopped immediately, the Luer-Lok connector of the needle is held in the nondominant hand, and the trocar is removed by unscrewing it. Confirmation of proper placement includes (1) a needle that stands firmly without moving, (2) aspiration of bone marrow, and (3) easy flushing with saline. Bone marrow can only be aspirated from a properly inserted IO about half of the time. Aspirated marrow can be sent for all the usual laboratory tests except a complete blood count.¹⁶ Though a properly placed IO will stand on its own, it should be secured to avoid accidental dislodgement. One method is to place a hemostat around the needle where it enters the skin and taped as depicted in Figure 161-4.

FIGURE 161-4. Securing an intraosseous line with a hemostat on a mannequin model. Note the tubing is taped separately.

Complications

The most immediate complication is the inability to place an IO line because the needle cannot penetrate the bone or the needle went into and through the bone. Subcutaneous infiltration of a large volume of fluid or medications in an improperly placed IO catheter may cause compartment syndrome. The area around and posterior to the IO site should be carefully monitored for swelling that may indicate fluid extravasation. Later complications may include osteomyelitis and cellulitis. The risk of infection is directly related to the duration of IO use. For this reason, the needle should be removed promptly when more definitive access is obtained. Fat embolism and growth plate injury are theoretical risks of the procedure of unknown clinical significance.

Central Venous Access

Central venous access should be considered in critically ill or injured children who require large-volume resuscitation or multiple infusions, medications, or hypertonic solutions that can only be delivered centrally, or who require central venous monitoring. Central venous access is also used in children who require immediate intervention due to critical illness and in whom peripheral access cannot be obtained.

Central venous lines should not be placed in abnormal vasculature such as a scarred or thrombosed vessel, or if perfusion distal to the proposed site is compromised. Relative contraindications to femoral access include an ipsilateral femoral hernia, abdominal trauma, or an abdominal tumor. In general, known or suspected injury to a limb or vasculature proximal to the proposed site, as well as overlying burns, cellulitis, or edema, are relative contraindications. Acquired and congenital bleeding disorders are relative contraindications, especially in the internal jugular and subclavian veins where hemostasis may be difficult to obtain or may result in airway obstruction.

Anatomy

In children, the femoral site offers many advantages over subclavian or jugular veins, including the high rate of success for relatively inexperienced physicians, visible/palpable landmarks, the low risk of serious complications, and the lack of interference with airway management and chest compressions.^{17,18} The femoral vein is located in the femoral sheath medial to the femoral artery and nerve. It becomes the external iliac vein as it passes under the inguinal ligament.

The smaller neck area and difficulty in identifying landmarks make the jugular veins difficult to use in children. The internal jugular vein lies in the carotid sheath, alongside the carotid artery and vagus nerve. It courses vertically down the neck and empties into the subclavian vein behind the sternoclavicular joint. The right internal jugular is easier to cannulate because it follows a straight course to the subclavian vein, whereas the left joins at a more acute angle. The subclavian vein lies behind the middle third of the clavicle in the lower part of the supraclavicular triangle. It lies medial to the posterior sternocleidomastoid (SCM) muscle and lateral to the anterior border of the trapezius muscle. It begins at the outer border of the first rib, extending to the sternal border of the clavicle, where it joins the internal jugular vein.

The subclavian approach is made more difficult because the chest shape in small children may make them more sus-

ceptible to a pneumothorax and the subclavian vein is smaller in diameter compared to the internal jugular vein.¹⁹ If subclavian lines are attempted, the right side of the neck is preferred because of the lower right pleural dome and the smaller right thoracic duct. However, under the age of 1 year, the right subclavian vein angles more acutely than in older children, first arching superiorly (cephalad) before coursing centrally and caudally into the superior vena cava.¹⁹ This acute angle may make placement of a right subclavian central catheter into the superior vena cava difficult in infants less than 1 year old, and the left side may be easier to cannulate at this age.

Procedural sedation should be considered in awake or semiconscious patients. Specific medications will depend on the physician's preference and the patient's condition.

Equipment for Central Venous Access

It is important that all the equipment is ready before the procedure starts. Prepackaged, commercially available central line kits simplify the gathering of equipment. Many emergency departments have designed additional trays with the necessary equipment not included in the commercially available kits:

- Antiseptic solution
- Sterile gloves, gowns, and masks
- Sterile drapes, gauze
- Lidocaine 1%, syringe, and 23- to 27-gauge needle
- Central line catheter
- Guidewire
- Introducer needle and syringe
- Heparinized saline
- Suture material (3-0 or 4-0 silk)
- Needle driver
- Scalpel
- Dressing material
- Blood sample collection tubes

A child's age, weight, or height can be used to guide selection of appropriate catheter sizes and depth (Tables 161-1 and 161-2).

Pulse oximetry and cardiorespiratory and blood pressure monitoring are required for all patients undergoing central venous line placement. Additional monitoring may be necessary based on the patient's condition and whether or not procedural sedation is being used. If attempting subclavian or internal jugular vein access, equipment necessary to decompress a pneumothorax should be readily accessible.

Procedure

The methods below describe central line insertion using the Seldinger technique, in which the catheter is passed over a guidewire. This technique is a safe, rapid means of central venous access in the emergency department.

In appropriate patients, the physician should obtain consent and consider procedural sedation. All necessary equipment is placed nearby to minimize contamination by the operator, assistants, or patient. An appropriate catheter size is chosen based on the patient's age and weight. The kit is opened, all lines are flushed with saline, and the dressing material is placed nearby. Universal precautions are used throughout the procedure. A sterile gown, gloves, and mask should be used when possible, though there is no evidence that this decreases the risk of infection.⁷

>7–15 yr	26–60	125–175	5.0–8.0

POSITIONING

For femoral access, the child's hip is abducted and externally rotated. To improve exposure and create a firmer surface, a rolled towel can be placed under the ipsilateral hip. For the jugular and subclavian veins, the patient should be positioned supine, arms at the side, with the head down at about a 15-degree angle and rotated away from the proposed site. The head-down, or Trendelenburg, position is used to decrease the risk of air embolus as well as distend the vessels. Over-rotation of the head past 30 degrees may cause the internal jugular vein to be compressed. For subclavian access, there is some controversy on optimal positioning in children. Though the cross-sectional area of the vein appears to be largest with the child's head in a neutral position with the chin midline, tilting the head toward the puncture site may improve the success rate of right subclavian access.^{20,21}

SITE IDENTIFICATION

The femoral vein is the preferred central venous access site in children, while either the internal jugular, subclavian, or femoral veins are appropriate for adolescents. Unlike in adults, use of the femoral vein is not associated with an increased rate of catheter-related infections compared to other central venous sites.²¹

The femoral vein is located 1 to 2 cm medial to the femoral arterial pulse. When there is a weak or absent pulse, the femoral vein can be assumed to be located halfway between the pubic tubercle and the anterior iliac spine. The entry

needle is inserted at a 10- to 20-degree angle for infants and a 30- to 45-degree angle for children. Needle entry should be 1 to 2 cm below the inguinal ligament to prevent inadvertent peritoneal perforation.

The median portion of the internal jugular vein is located lateral to the carotid artery, at the apex of the triangle formed by the sternal and clavicular heads of the SCM muscle (Fig. 161-5). More precise localization can be accomplished by using a vascular probe (within a sterile glove) during bedside ultrasonography. Moreover, needle insertion and advancement relative to the internal jugular vein can be monitored if bedside ultrasonography is available. Using the middle internal jugular approach, the child's head is rotated to the contralateral side. The needle is inserted just below this apex, at a 30-degree angle, directed toward the ipsilateral nipple. Using the posterior internal jugular approach, the needle is inserted just superior to the external jugular vein as it crosses the posterior border of the sternomastoid (see Fig. 161-5). The needle is directed caudally and medially toward the sternal notch under the lateral border of the sternomastoid. Using this approach, the internal jugular vein will be punctured before the carotid artery and the pleural dome will be avoided.

The external jugular vein (EJV) is used only when it can be visualized directly or by ultrasound. The EJV is accessed as it crosses over the SCM muscle. Because it is not firmly fixed to the underlying fascia, it is helpful to apply tension above the puncture site to stabilize the vessel. Using an angiocatheter instead of an entry needle may prevent through-and-through EJV perforation. The angiocatheter is inserted at a 10- to 20-degree angle, and when flashback is obtained, the needle is withdrawn and the guidewire inserted through the plastic catheter. Prior to insertion, the operator should check that the guidewire will pass through the plastic catheter.

An infraclavicular or supraclavicular approach can be used to access the subclavian vein. Use of the patient's right side is preferred due to the lower pleural dome, because there is a more direct route to the superior vena cava, and because the thoracic duct will not be injured since it is on the left side. In the infraclavicular approach, the needle is inserted infe-

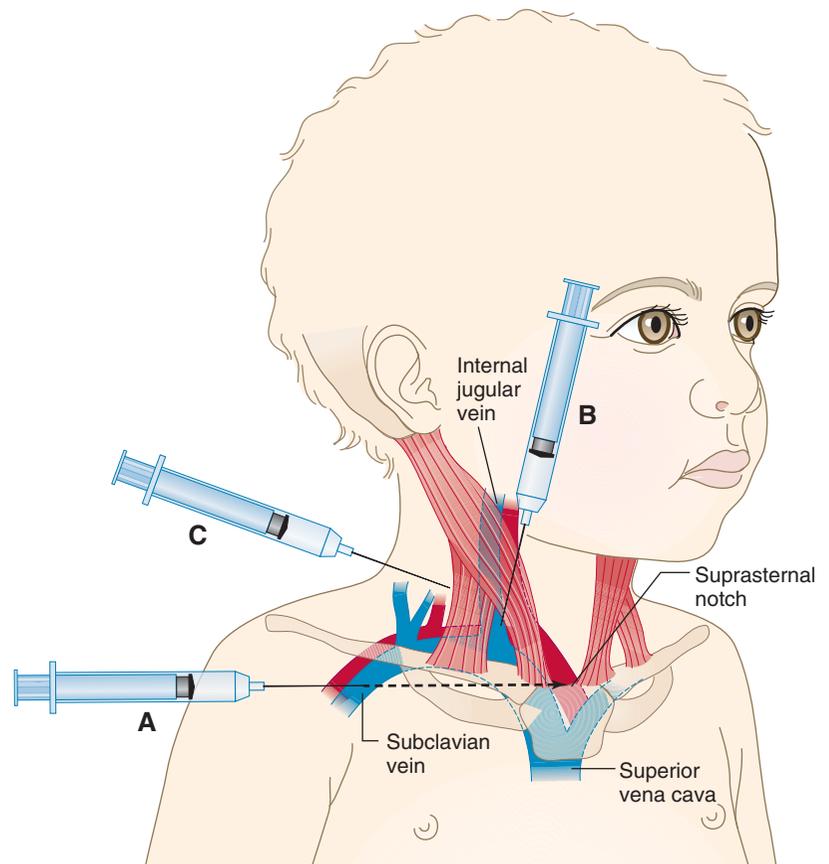

FIGURE 161-5. Insertion sites for (A) subclavian vein infraclavicular approach, (B) middle internal jugular vein approach, and (C) posterior internal jugular vein approach.

rior to the midclavicle (see Fig. 161-5). The needle should be maintained in the horizontal plane, and directed toward the sternal notch. In the supraclavicular approach, the needle is inserted superior to the clavicle at the point where the lateral border of the clavicular head of the SCM muscle joins the clavicle. The bevel of the needle should be directed medially and the needle advanced toward the contralateral nipple, parallel to the clavicle.

Technique

For internal jugular and subclavian approaches, the patient is placed in Trendelenburg position and the head is turned to the contralateral side. In awake or semiconscious patients, the skin and subcutaneous area are locally anesthetized with lidocaine. If desired, a small-gauge (23- or 25-gauge) finder needle and syringe can be used to locate the vessel. This needle can be left in place to guide the path of the entry needle or removed and the same path cannulated with the entry needle. Prior to use, the entry needle should be flushed with heparinized saline. The needle and syringe are slowly advanced while gently aspirating until there is blood return, continuing to advance the needle just slightly while maintaining negative pressure. If blood return stops, this may mean the posterior wall of the vessel was perforated. The needle is gently withdrawn while aspirating until there is free-flowing blood again. If no blood return is obtained, the physician should withdraw the needle to just below the skin entry site, reconfirm landmarks, and reattempt cannulation.

Once there is good blood return, the syringe is removed from the entry needle, placing a thumb over the hub to

prevent excessive blood loss or air embolus. If the blood is bright red or pulsating, it is likely that the artery has been cannulated, and the needle should be removed and pressure applied over the site. If it is difficult to determine if the vein or artery has been accessed, an arterial blood gas analysis may be helpful.

Next, the guidewire is inserted. The wire may be straight or have a flexible curved proximal end that is encased in a plastic sheath. Curved wires, or J wires, are particularly helpful in negotiating more tortuous vessels such as the EJV. The sheath is inserted into the hub, slowly advancing the wire. If resistance is met, it suggests that the vessel has not been properly cannulated or the wire is frayed. If this occurs, the wire should be removed and inspected. If there is no fraying, the physician should make sure blood flow is easily aspirated.

The distal end of the wire should always be visible to prevent its full insertion into the vessel. The wire is advanced to an appropriate depth, a little more than one half to three fourths of its total length. Then the index finger of the non-dominant hand is placed at the entry site while the dominant hand removes the entry needle and sheath together. The physician should press down on the wire at the entry site during this process to ensure that it is not removed as well.

To allow easy passage of the more fragile plastic catheter, the entry site is enlarged with a scalpel. The blade is inserted over the wire and, with the sharp side pointed away from the patient, a 0.5-cm line is incised up through the subcutaneous tissue and skin. Next, a single-lumen dilator is inserted over the wire to enlarge the tract for the catheter. Then the plastic

catheter is inserted over the wire, making sure the distal end of the wire protrudes through the catheter before advancing the catheter into the skin. The catheter is advanced into the vessel while holding onto the distal wire segment. Gently twisting the catheter can help pass it through the subcutaneous tissue. The catheter is advanced to an appropriate depth (see Table 161–1) and the wire removed. In catheters without slide clamps, the hub should be covered with the thumb until it has been attached to intravenous tubing that has been primed. If side clamps are present, they are moved into position to occlude blood flow. The line is sutured in place and a sterile dressing applied. Confirmation of short femoral line placement requires only direct visualization of blood return and, if desired, a blood gas analysis to assure venous blood. Jugular and subclavian line position is confirmed by chest radiography.

Complications

Serious complications are rare in pediatric femoral lines and are more frequent with subclavian lines.¹⁷ Peritoneal perforation or formation of a retroperitoneal hematoma has been reported due to a femoral central venous line that was placed above the inguinal ligament. This complication requires surgical consultation with possible surgical repair. All methods of central venous access can be complicated by an air or catheter embolus, surrounding nerve injury, or arterial puncture. Arterial puncture during internal jugular vein cannulation may be particularly dangerous because of its proximity to the carotid artery, difficulty obtaining hemostasis, and risk of airway compromise. Subclavian lines may be also be complicated by pneumothoraces, thoracic duct injury, dysrhythmias, and cardiac tamponade. Vessel wall perforation and erosion are rare complications; proper catheter positioning and appropriate sizing decreases these risks.

Thrombosis and catheter-related infections are delayed complications. Thrombosis may be prevented by use of heparinized solutions or flushes and rapid removal of the catheter. Recent studies have not shown an increase risk of clinically significant thrombosis with femoral lines.^{17,18} Aseptic technique in placement and caring for the catheter may decrease the risk of infection. Unlike in adults, pediatric femoral lines are not more likely to become infected than lines at other sites.^{7,22} There is growing evidence that an antiseptic sponge dressing and catheters impregnated or coated with antimicrobial or antiseptic agents may decrease the risk of catheter-related infection.⁷ It is unclear if an antimicrobial ointment applied at the insertion site prevents infection, and it may cause emergence of bacterial resistance. Some ointments may cause breakdown of the catheter, and compatibility should be assessed before using them.

Umbilical Vessel Cannulation

Umbilical vessel cannulation can be a rapid means of obtaining vascular access in the critical ill newly born infant in the emergency department. Umbilical venous catheterization (UVC) should be considered in newborns up to 2 weeks of age who are critically ill and require intravenous fluids, medications, or blood products when alternative means of access are not readily obtainable. In the neonate who has not responded to tracheally administered epinephrine, or who requires volume expansion, UVC is the next recommended

route.⁹ Umbilical arterial catheterization is indicated for critically ill neonates who require frequent arterial blood gas analysis or blood pressure monitoring. It can also be used for the administration of fluids and medications, or for exchange transfusions. Oxygen causes the umbilical artery to spasm and close, so insertion is best accomplished in the first 24 hours of life. Umbilical access is associated with serious complications and requires considerable experience and advanced skills.

Umbilical cannulation must not be attempted in neonates with an omphalocele, omphalitis, suspicion of necrotizing enterocolitis, inadequate bowel perfusion, or peritonitis. An umbilical arterial catheter must not be placed if there is a suspicion of vascular compromise of the lower extremities.

Anatomy and Physiology

Prenatally, the umbilical vessels serve as a blood exchange conduit between the fetus and placenta. Most infants have two umbilical arteries and one umbilical vein. The arteries are usually located above the vein and have a thicker wall and smaller lumen. The artery enters the abdominal aorta through the internal iliac artery. The umbilical vein is approximately 2 to 3 cm in length and joins the central circulation through the portal vein.

Equipment for Umbilical Vessel Catheterization

A great deal of specialized equipment is required for umbilical cannulation. Emergency departments planning to perform such a procedure should have prepackaged kits with all the required materials available. In addition, this procedure should be done under a radiant heater with temperature monitoring since the critically ill neonate is especially vulnerable to hypothermia.

- Radiant warmer
- Sterile gown, gloves, mask, cap
- Antiseptic solution
- Sterile drapes and gauze
- Umbilical tape
- Scalpel
- Curved, smooth iris forceps
- Two curved mosquito hemostats
- Straight Crile forceps
- Iris scissors
- Needle holder
- Umbilical catheters (3.5, 4, and 8 French)
- 3-0 and 4-0 silk suture on a needle, or with a needle driver
- 10-ml syringe
- Saline flush
- Intravenous tubing, pump
- Three-way stopcock
- Needle (20 to 22 gauge)
- Cardiac monitor, pulse oximeter
- Tape measure

Patients undergoing umbilical catheterization require constant cardiorespiratory monitoring. Often it is helpful to have a second person responsible for monitoring since the physician may be primarily focused on the procedure. Besides visually assessment, continuous electrocardiography, pulse oximetry, and patient temperature should be monitored. Other monitoring will depend on the patient's specific condition.

Procedure

The procedure varies slightly depending on the urgency of access needs. For emergent access, the umbilical vein is catheterized first. A stopcock is attached to the catheter and flushed with (heparinized) saline, making sure there is no air in the system and the stopcock is in the off position to the patient. The procedure should be performed as sterilely as possible and, at a minimum, the stump and abdomen cleaned with povidone-iodine solution. If time permits or there is a lot of bleeding from the stump, the stump base should be encircled with the umbilical tape and the tape tied with a single knot. The tape should be placed around the skin and not the actual cord, and the knot should not be tied so tight as to impede passage of a catheter or so loose as to allow constant blood oozing. The stump is grasped and the distal part cut off horizontally about 1 to 2 cm above the base. The umbilical catheter is inserted until there is free flow of blood, usually about 1 to 2 cm below the skin. If no blood returns at this depth, the catheter is flushed and aspirated back. This lower position assures that the catheter is not in the liver, and it can be used immediately without need for radiologic confirmation of position.

In the stabilized, critically ill patient, the umbilical artery often is accessed first. The patient is placed supine under a radiant warmer in a frog leg position. The necessary equipment should be in an easily accessible place that minimizes cross contamination. The physician should don a mask and gown and sterilely prepare the stump and abdomen. An eyelet drape may be particularly helpful. Umbilical tape is used and the cord incised as described for umbilical vein catheterization.

For arterial catheterization, the edges of the stump are grasped near the artery with the two curved hemostats, or a single hemostat is used to grasp a single edge to further expose the artery, being sure not to crush the artery. Using

the curved iris forceps, the artery is dilated by gently opening and closing the forceps until the tip easily passes to about a depth of 1 cm. Keeping the forceps open and in the artery, the catheter is inserted. Resistance encountered before passing beyond the abdominal wall may indicate that the umbilical tape is too tight and should be loosened. Resistance may also occur at the abdominal wall where the vessel turns caudally. Gently pulling the stump up and toward the infant's head may help. Resistance may also be felt at about 5 to 6 cm of insertion depth. Gently twisting the catheter may help bypass this junction of the umbilical artery to the internal iliac artery. The catheter is inserted to the predetermined length (see later) and aspirated for blood. Lack of blood flow may indicate a false track, and the line should be removed.

To secure this line, the stump is encircled with a purse-string suture and tied tightly around the catheter at the entry site. A bridge can then be constructed from tape to further stabilize the line (Fig. 161–6).

For UVC the procedure is similar, though the vessel often does not need to be dilated. The umbilical vein is larger than the arteries and is often collapsed on itself. Visible clots should be removed. A 5.0 catheter is usually sufficient for most infants, but for large infants an 8.0 French catheter may be needed.

UMBILICAL LINE POSITION

Umbilical arterial lines can be placed above or below the diaphragm (high or low positions). High umbilical arterial lines have less clinically obvious ischemic complications, a reduced incidence of aortic thrombosis, and a longer duration of catheter usability without an increase in serious complications.²³ To estimate insertion depth, the distance from the patient's umbilicus to the shoulder is measured. A quick approximation of a high umbilical arterial position is adding 1 cm to the umbilical stump-to-shoulder distance. The low

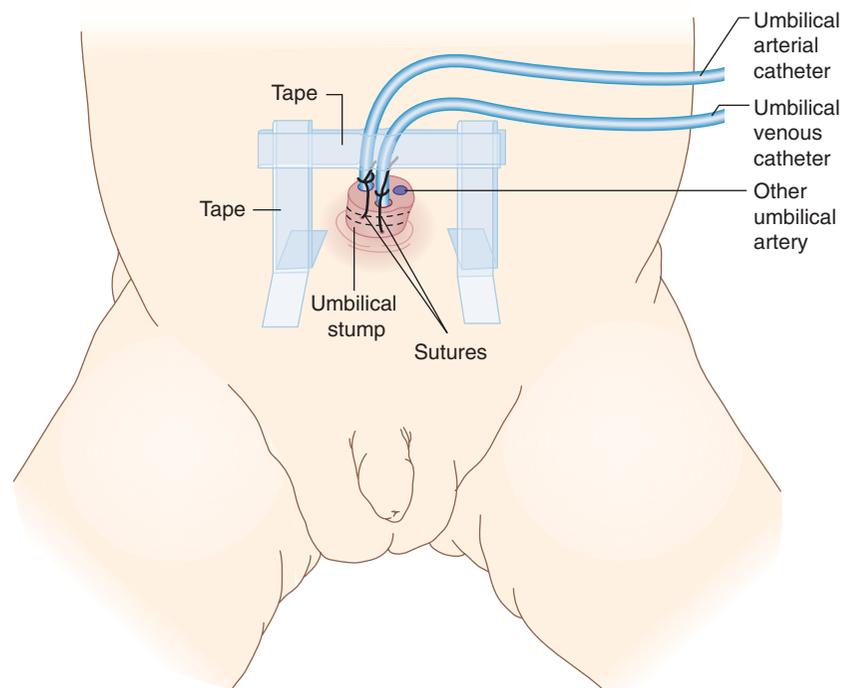

FIGURE 161–6. Umbilical vessel cannulation.

position can be approximated by advancing the catheter 1 cm beyond the point where blood is first obtained. UVC insertion depth is approximately two thirds of the shoulder-to-umbilicus distance, not including the stump length.

Though subject to error, line position should initially be assessed with radiographs.^{24,25} Often an anteroposterior radiograph is sufficient, but a lateral radiograph may be helpful when it is difficult to establish position. The umbilical artery enters at the umbilicus and courses caudally in the internal iliac artery before ascending in the aorta, posterior to the vein. The umbilical vein line enters at the umbilicus and travels cephalad. The catheter tip of a “high” arterial is above the diaphragm, between the sixth and ninth thoracic vertebral bodies on a radiograph. A low arterial line lies between the third and fifth vertebral bodies on a radiograph. The umbilical vein line should be at the right atrium–inferior vena cava junction, which corresponds to the eighth and ninth thoracic vertebral bodies on a radiograph. A catheter that is in the portal system should be removed. If a catheter is too low, it should be removed rather than pushing the nonsterile distal portion into the patient. Echocardiography may provide a more accurate assessment of line position.²⁵

Complications

Insertion may result in false tract formation, or perforation of a vessel or the pericardium or peritoneum. Gentle pressure with insertion and use of the correct catheter size and location can help prevent these complications. Sterile procedure in placement and use of the lines may help prevent infectious complications such as bacteremia, line sepsis, and omphalitis. Catheter hemorrhage can occur if the connections are not secure or the stopcock is left open when not in use. Dysrhythmias may occur if the catheter tip is inserted too high. Blanching and cyanosis of an extremity can occur soon after line placement and is usually due to either vasospasm or vessel obstruction from an oversized catheter. If the perfusion does not improve after 15 minutes of warming the contralateral extremity, the line should be removed to prevent limb loss. A UVC line that is in the portal system can lead to hepatic necrosis, portal hypertension, and necrotizing enterocolitis. To prevent air embolus, the catheter should be filled with fluid and the stopcock turned in the off position to the patient during insertion and use. Hypertension, hematuria, and thrombus formation are late complications.

Foreign Body Removal

Ruth Ann Pannell, MD and Joe Pagane, MD

Key Points

Batteries and foreign bodies with associated infection require immediate removal regardless of location.

A persistent malodorous nasal discharge is a retained foreign body until otherwise ruled out.

Imaging (plain films, ultrasound, computed tomography, or magnetic resonance imaging) should be considered for suspected foreign bodies that cannot be localized.

The physician must meticulously search for foreign bodies in all cutaneous wounds and document the patient's tendon, nerve, and vascular examination before and after any wound or foreign body manipulation.

Selected Procedures

- Ear foreign body removal
- Nose foreign body removal
- Fishhook removal
- Piercing removal
- Ring removal
- Subcutaneous foreign body removal

Discussion of Individual Procedures

Ear Foreign Body Removal

Parents and children with otic foreign bodies are often unaware that the foreign body is the cause of the symptoms. Sometimes, only a thorough physical examination will elicit the cause of the problem because many patients will not freely offer the examiner an adequate history. Presenting symptoms may include ear pain, increased cerumin, purulent drainage, hearing loss, and external inflammation.¹

Anatomy

The external auditory canal has an oval cylindrical shape, is approximately 2.5 cm long in adults, is short and straight

in infancy, and forms an “S” shape as one matures to adulthood. Sensitive epithelium lines the canal. Two narrowings in the canal, one in the osseous portion close to the tympanic membrane and another at the medial end of the cartilaginous area of the canal, are areas where objects frequently lodge.²

Common foreign bodies removed from the ear include beads, paper, popcorn kernels, insects, and small toys. The object's size, shape, material, and location present different challenges regarding removal.^{1,3,4} Tissue damage may occur from the foreign body itself, prior removal attempts, or the removal process. The presence of any tissue damage before manipulation should be documented. If there is concern regarding hearing damage, a pre-removal assessment should be performed prior to manipulation.¹

Few foreign bodies require immediate removal except those associated with significant infection and alkaline (button/disk) batteries. Alkaline batteries should be removed immediately because of the risk of tissue destruction due to pressure necrosis, liquefaction necrosis, and tissue electrolysis.^{5,6} Patients with previous unsuccessful removal attempts who meet certain criteria (Table 162–1) are less likely to have successful removal under direct visualization in the ED. Further manipulation in the ED is often unsuccessful and unnecessary. These patients usually require referral to otolaryngologists.^{4,7}

Evaluation

Imaging is rarely necessary in the evaluation of patients with an otic foreign body. Computed tomography (CT) or magnetic resonance imaging (MRI) may be indicated in order to characterize significant associated infection (e.g., mastoiditis) or erosive damage, or if other serious complications are suspected. MRI should be avoided if metallic foreign bodies are suspected.

Some children with foreign bodies require sedation or general anesthesia for removal because of location. The medial portion of the canal is narrow, and even minor manipulation can cause intense pain.⁷ Topical anesthetics inadequately anesthetize the canal due to their poor absorption at this site. Local injection of anesthetics is painful and difficult to perform in uncooperative patients. Frequently, successful removal requires immobilization with restraint by assistants or wrapping a sheet around the child.¹ Procedural sedation allows for a high (84%) success rate for foreign body removal by emergency physicians.⁸

Equipment

Useful tools for removing foreign bodies include^{1,7,9-11}

- Otoscope
- Forceps
- Curettes
- Hooks
- Hemostats
- Dental pick
- Baron suction
- Fogarty or Foley catheters
- Cyanoacrylate glue (Superglue)
- Saline
- 10- to 20-ml syringe
- Plastic catheter
- Mineral oil
- Lidocaine 2%, 4%
- Acetone

Table 162-1 Indications for Direct Referral for Otomicroscopic Removal

Object type	Spherical, sharp-edged, disk battery, vegetable matter
History	In canal greater than 24 hr Prior removal attempt(s)
Location	Adjacent to tympanic membrane
Patient	Age < 4 yr, agitated, and/or difficulty with visualization

Depending on what technique is used to immobilize or sedate the patient, cardiac telemetry and oxygen saturation monitoring may be required.

Techniques

Emergency physicians should be acquainted with several techniques and use the most appropriate approach based on equipment available, personal skill, cooperation of the patient, and the location, size, shape, and material of the foreign object.¹ For direct visualization, an otoscope is the instrument of choice for optimal magnification and lighting. In order to straighten the canal and inspect the foreign body, the pinna is grasped and retracted in a superior and posterior direction to provide good visualization.¹² The tympanic membrane should be inspected for any signs of rupture. The hand holding the otoscope should be stabilized against the patient's head to prevent injury if the patient moves unexpectedly.

Alligator forceps, hooks, a hemostat, or a dental pick may be used to manually remove foreign bodies. Objects with a leading edge or small rounded objects can be removed with alligator forceps or a hemostat if forceps are unavailable (Fig. 162-1A). Hooks, loops, or suction can be used to remove larger spherical objects or objects without a leading edge. A hook or loop can be placed behind the object, rotated 90 degrees, and used to pull the object outward (Fig. 162-1B). For soft foreign bodies, a stout hook can be used to spear the foreign body and withdraw it (Fig. 162-1C). For spherical, round, or light mobile objects, suction may be successful

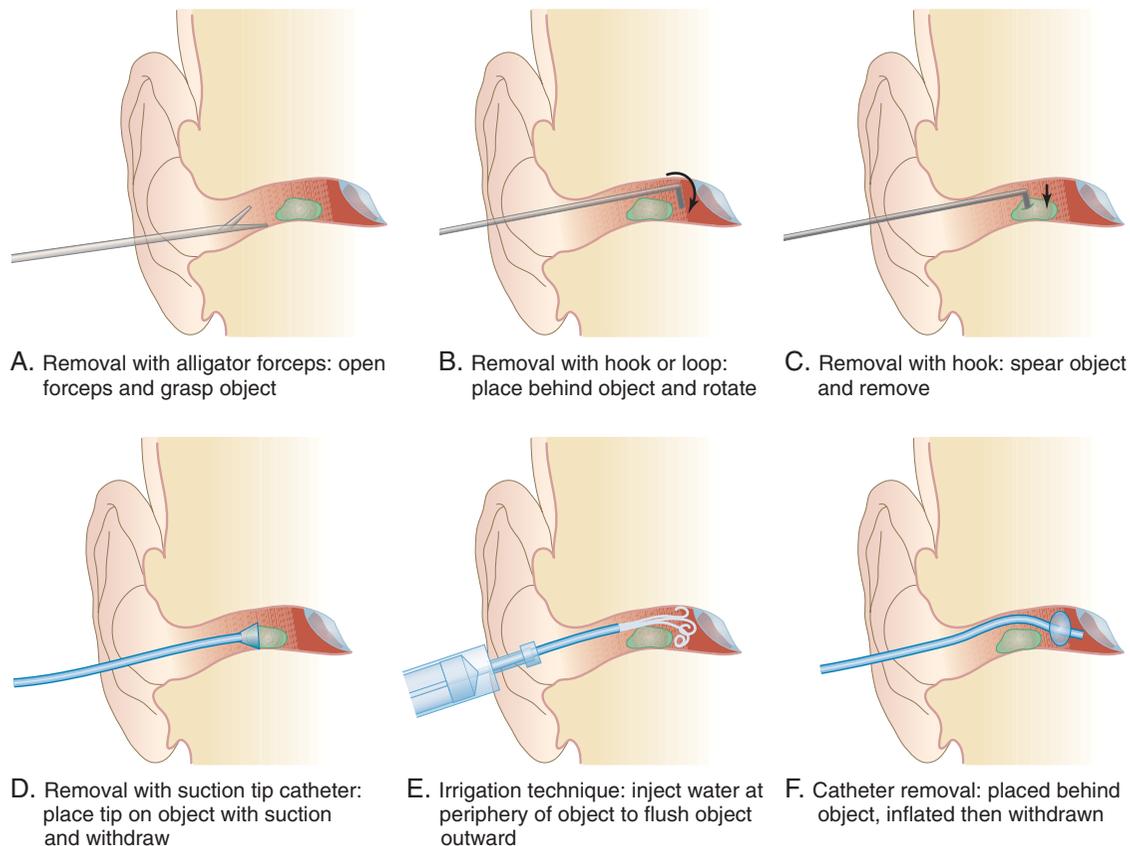

FIGURE 162-1. Techniques for removing foreign bodies from the ear.

alone. A suction-tip catheter is placed against the object, suction is turned on, then the catheter and object are slowly removed (Fig. 162–1D).

Irrigation can be a safe technique for removing certain otic foreign bodies. However, irrigation should never be used with vegetable matter that can expand, with button batteries, or if there is a possibility of tympanic membrane perforation.⁴ Warm water is instilled using a 10- to 20-ml syringe attached to the plastic tubing of a catheter. The water is gently injected toward the periphery of the object so that the water will go past the object, hit the tympanic membrane, and flush the object outward via posterior pressure¹³ (Fig. 162–1E).

The tip of a small Fogarty or Foley catheter can be placed carefully behind the object. Then, the balloon is inflated distal to the object in the canal. The foreign body is removed as the catheter balloon is pulled from the external auditory canal (Fig. 162–1F).

Another approach includes the application of cyanoacrylate glue (Superglue) to the end of a paperclip or swab. A small amount of rapidly drying glue is placed against the foreign body, the glue is given a few seconds to dry, and the bonded object is withdrawn from the canal. This method is effective but imposes the risk of contaminating the canal with glue that is difficult to remove.^{13,14}

A Styrofoam impaction was successfully removed in one case by direct application of 0.1 ml of pure acetone via a 22-gauge catheter and 1-ml syringe. This caused the Styrofoam to shrink in, allowing for easy extraction. To minimize the possibility of ototoxicity, a minimal amount of acetone should be instilled, and the ear canal should be irrigated after the procedure.¹¹

Insects in the external auditory canal can cause great discomfort and distress. It is important to kill the insect to provide relief from its movement and to aid with extraction. Mineral oil and 2% or 4% lidocaine kill insects within 1 minute.^{9,10} Lidocaine should not be used if the tympanic membrane is perforated since it can cause vertigo.¹⁵ When the insect stops moving, it may be mechanically extracted with forceps or suction.¹³

Before beginning manipulation of an external auditory canal foreign body, the physician must decide how many attempts are reasonable before stopping and referring to an otolaryngologist. In general, not more than two to three attempts should be made, and efforts should be discontinued if external auditory canal damage occurs or sedation and immobilization are inadequate. This will prevent frustration from causing unnecessary attempts and avoid iatrogenic damage. It is important to appropriately refer patients at risk for local complications (e.g., perforation, alkaline injury) if the object is not easily removable (see Table 162–1). In most cases, allowing foreign bodies to stay in the external auditory canal while the patient waits for referral is safe. Exceptions to this are foreign bodies associated with infection and presence of a button/disk battery.¹

Complications

Complications of foreign body extraction can occur from the removal procedure or from the foreign body. These include tympanic membrane perforation, canal wall laceration, bleeding or canal abrasions, hematomas, otitis externa, and otitis media.^{1,4,7}

Postprocedure Care and Disposition

In patients in whom cutaneous damage is present, a topical antibiotic is prescribed and the parents and patient are instructed to keep the canal clean and dry. Treatment of any associated infection or complication (e.g., otitis media) is initiated, and follow-up for unremovable foreign bodies is arranged. No follow-up is warranted following removal of uncomplicated foreign bodies. A complete examination of the nose and the opposite ear is essential prior to discharge.

Nose Foreign Body Removal

Nasal foreign bodies can be difficult to identify since children rarely relay a history of placing the foreign body in their nose.⁴ Children often present with a unilateral malodorous nasal discharge. Children with nasal objects also can present with symptoms consistent with sinusitis, the common cold, allergic rhinitis, tumor, or halitosis, as well as recurrent epistaxis.¹⁶

Anatomy

The nose consists of the nares, nasal septum, vestibule, and lateral walls.² On the lateral walls lie the superior, middle, and inferior nasal conchae with corresponding meatuses. Nasal foreign bodies are frequently found on the floor of the nose just below the inferior turbinate or immediately anterior to the middle turbinate.¹⁷ The types of foreign bodies that have been found in children's noses include rubber erasers, paper, pebbles, beads, beans, peanuts, marbles, sponges, small toys, and chalk.^{18–21}

Damage to the nose may occur from the foreign body, inflammation, or the removal process. Complications include pressure necrosis, mucosal erosion, epistaxis, formation of rhinoliths, and the promotion of infections in the surrounding structures, including sinusitis and otitis media.^{5,17,19}

Few foreign bodies of the nasal canal require emergent removal, and some have remained for years without significant complications.¹⁷ Exceptions to this include foreign bodies with any associated infection and alkaline batteries (button/disk) within the nose.²⁰ Foreign bodies adjacent to the cribriform plate (superior and medial to the middle turbinate) require otolaryngology removal.

Structures contiguous to an intranasal foreign body are not as easily damaged and are not as sensitive as the ear canal. Therefore, the need for consultation for removal is less likely. If necessary, procedural sedation is used to assist with nasal foreign body removal (see Chapter 159, Procedural Sedation and Analgesia).⁸ If there is concern for posterior displacement into the airway, removal under general anesthesia may be necessary.^{17,19}

Evaluation

Imaging is rarely necessary in the evaluation of children with a nasal foreign body. CT or MRI may be indicated to characterize associated infections, erosive damage, or other associated serious complications.

Proper examination of the nares involves placing the patient in the “sniffing” position while he or she is sitting upright. It may be helpful to tilt the head back slightly. A nasal head speculum is used to spread the naris in an inferior-to-superior direction.¹⁷ Any nasal damage should be documented prior to manipulation.

In many cases, mucosal edema may obstruct viewing and hinder removal of nasal foreign bodies. Prior to removal, the nasal mucosa may be sprayed with an available vasoconstrictor such as phenylephrine or oxymetazoline to shrink the mucosa, and a local anesthetic agent such as benzocaine spray.^{17,21}

Equipment

Removal tools and agents include²¹⁻²³

- Nasal speculum
- Topical vasoconstrictor
- Topical anesthetic
- Right-angle forceps
- Right-angle probe
- Suction catheter
- Alligator forceps
- Fogarty/Foley catheter
- Ambu bag

Depending on what technique is used to immobilize the patient, oxygen saturation and cardiac monitoring and airway rescue devices may be required.

Technique

Many nasal foreign bodies can be removed with manual instrumentation (Table 162–2). Alligator forceps or bayonet forceps can retrieve anteriorly lodged foreign bodies if they have edges that can be grasped. Wire loops and right-angle hooks can be carefully passed by the object and rotated 90 degrees, then used to easily spoon out the object.²² Number 4 or 5 Fogarty catheters or 5F to 6F Foley catheters can be used by inserting them carefully beyond the object, slowly inflating the balloon, and gently pulling the object outward.²¹

For suctioning spherical or smooth objects, a suction-tip catheter is placed in the nose until the tip is in contact with

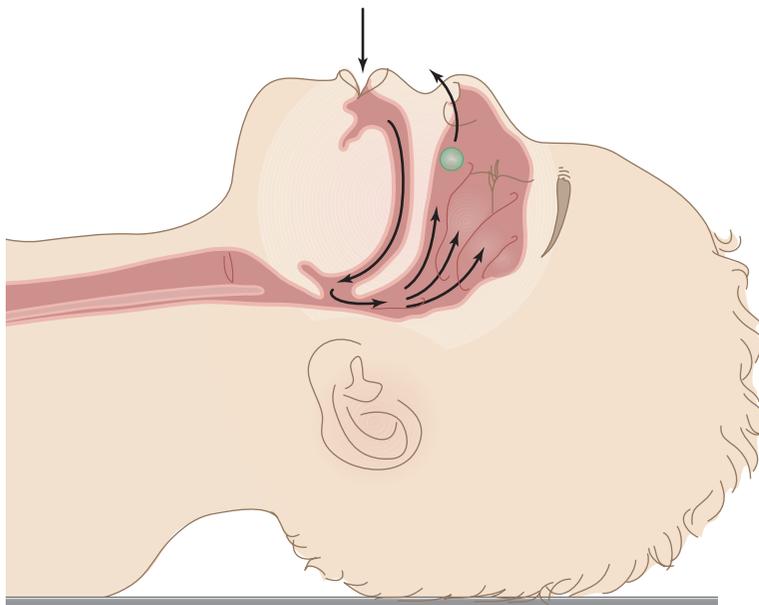

the object. Suction is turned on and the object retrieved while the catheter removed.²¹

A positive air pressure technique, similar to mouth-to-mouth resuscitation, is a safe and effective method for nasal foreign body removal. While digitally obstructing the nasal canal opposite the foreign body, air is exhaled through a child's mouth until resistance is felt (closing of the epiglottis). Air is then exhaled briskly into the child's mouth, producing an outward pressure that repositions the foreign object so it can be grasped or is dislodged. A modified version involves placing an Ambu bag over the child's mouth that is then squeezed forcefully^{18,23} (Fig. 162–2). Alternately, cooperative patients can be instructed to take a deep breath and exhale through the nose while the unobstructed nostril is occluded.¹⁷

Otolaryngology consultation is required if the foreign body cannot be removed in the ED. Button batteries or foreign bodies with significant mucosal damage, prolonged impaction, or infection warrant quick removal and consultation in the ED.²⁰

Table 162–2 Best Techniques for Removing Nasal Foreign Bodies With Respect to Object Position and Properties

Technique	Position	Object Properties
Forceps	Anteriorly lodged	Objects with leading edges
Wire loops and right-angle hoops	Anteriorly lodged	Any type, texture
Fogarty/Foley catheter	Posteriorly lodged	Any type, texture
Suction	Anteriorly lodged	Spherical, smooth, round
Positive air pressure	Posteriorly lodged	Any type, texture

Air is exhaled through mouth until resistance is felt. Then air is exhaled briskly into child's mouth which forces air into patient's posterior nares. Outward pressure then drives the foreign object into a new anterior position or out of the nares.

FIGURE 162–2. Use of positive pressure ventilation to dislodge nasal foreign bodies.

Complications

Complications from nasal foreign body removal include epistaxis from direct mucosal trauma and infection.¹⁷ With the air pressure technique, overzealous blowing theoretically can result in barotrauma to the tympanic membrane.¹⁸ Importantly, superiorly located foreign bodies can be lodged next to the cribriform plate, placing the patient at risk for intracranial trauma from removal attempts or intracranial extension of infection. Otolaryngology consultation is required for removal of these foreign bodies.

The most significant complication with nasal foreign bodies is the potential for posterior displacement leading to aspiration or airway obstruction. This complication can be avoided by using familiar removal techniques, appropriate equipment, lighting, and adequate visualization. Removal should be attempted only in children who are cooperative, adequately immobilized, or sedated. A small percentage of nasal foreign bodies may require removal under general anesthesia with the patient intubated to protect the airway.²⁰

Postprocedure Care and Disposition

Most patients will not require follow-up after removal of a nasal foreign body. Associated infection or complications (e.g., otitis media) require treatment and follow-up. If significant epistaxis or mucosal trauma is present, the patient should avoid nose blowing. The physician should always perform an examination of other orifices prior to discharging the patient.

Fishhook Removal

The choice of method to remove a fishhook will depend on the type of fishhook, location of the injury, and depth of penetration. Three main types of fishhooks exist: simple single-barbed, multiple-barbed, and treble-barbed fishhooks. Fishhooks should be left in place if they penetrate the orbital area, involve the eye, or place the eye at risk for injury during removal. In these cases, ophthalmology consultation is indicated.^{24,25}

Evaluation

Before attempting to remove a fishhook, any neurologic deficits or tissue damage should be recorded. Involvement of the bone, tendon, and vessels should be evaluated, and radiographs should be considered to evaluate the depth of penetration and the location of the barb, and to determine the type of fishhook involved.²⁴ CT scan should be considered for precise identification, localization, and determination of associated tissue injury in cases of orbital fishhooks. A local anesthetic or a nerve block can be used for pain control if needed.²⁶

Equipment

Equipment for removal may include

- Antiseptic solution
- Tape
- String or suture
- Scissors
- 18-gauge or larger needle
- Scalpel
- Needle driver
- Pliers

Removal is initiated by cleaning the site with povidone-iodine or hexachlorophene and removing debris by irrigating with saline. Fishhooks with more than one uninvolved point (hook) should be covered with tape prior to removal.^{24,26}

Technique

Occasionally, more than one removal technique may be required for fishhook removal. There are four standard techniques for removal of fishhooks: the retrograde, string-yank, needle cover, and advance-and-cut procedures (Table 162–3). The retrograde technique is simple, causes minimal tissue damage, and works best for barbless and superficial hooks.^{24,27} Gentle downward pressure is applied to the shank of the hook in order to disengage the barb while backing the hook out along the entry path (Fig. 162–3A). If resistance is met, an alternate technique should be considered.

The string-yank technique works well with small to medium fishhooks and with fishhooks that are deeply embedded. Material such as fishing line or silk suture is tied around the midpoint of the fishhook bend. The area is stabilized with the hook against a flat surface. The shank of the fishhook is depressed while holding the string tightly several inches away. As the shank is depressed, a firm quick jerk is then applied to the string while holding the string parallel to the shank (Fig. 162–3B). If the fishhook disengages, it may come out rapidly, placing the physician and bystanders at risk for trauma from the fishhook.²⁸

The needle cover technique works well with single barbs and large hooks, especially when the barb is superficially embedded and can be easily reached by a needle. An 18-gauge or larger needle is inserted along the entry pathway and used to cover and disengage the barb. The fishhook and needle covering the barb are removed as a unit simultaneously (Fig. 162–3C). A modification of this technique involves incising with a no. 11 blade along the wound to the point of the fishhook. This incision allows the fishhook to be backed out by creating room for the point and barb.^{24,27}

The advance-and-cut technique is usually successful, although it may produce tissue trauma. Using pliers or a needle driver, the tip of the hook is advanced through the skin. The sharp point is anchored with a clamp to avoid injury and then cut with pliers or another cutting tool. Then, the rest of the fishhook is backed out (Fig. 162–3D). If the fishhook has multiple barbs, the eye of the fishhook should be removed, then the shank and barbs advanced^{26,29} (Fig. 162–3E).

Table 162–3 Standard Techniques for Fishhook Removal

Technique	Location	Hook Size	Barb Number
Retrograde	Superficial	Any	Single
String-yank	Embedded	Small to medium	Single
Needle cover	Superficial	Large	Single
Advance-and-cut barb	Embedded	Any	Single
Advance-and-cut eye	Embedded	Any	Multiple

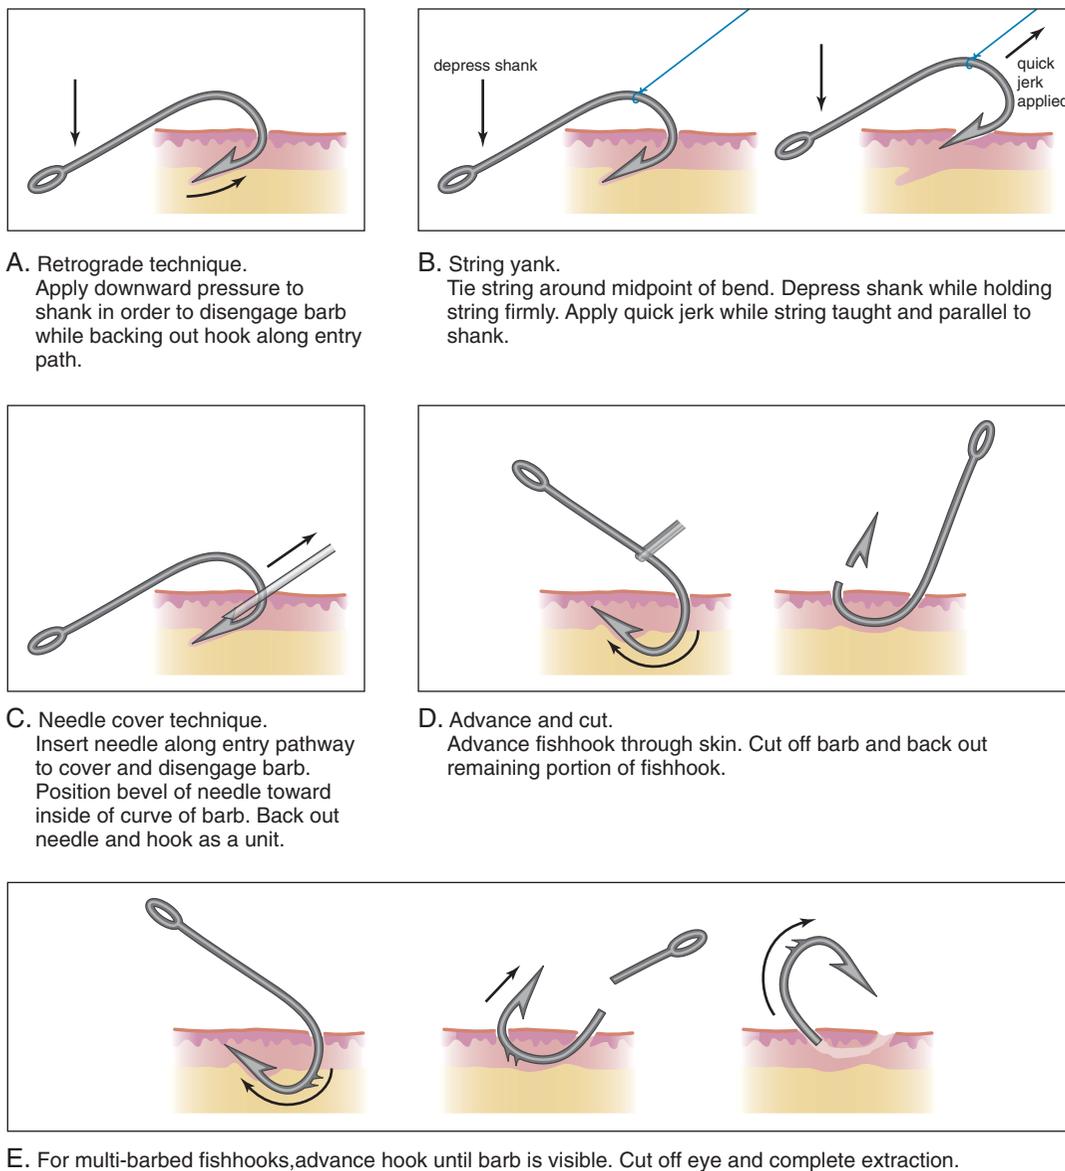

FIGURE 162-3. Techniques for removing embedded fishhooks.

Consultation is necessary for fishhooks that involve the orbit or orbital area, where removal may damage the eye. Consultation for removal may also be warranted for fishhooks associated with infection or if they involve bone, tendons, blood vessels, and nerves. Complications of fishhook removal include infection, abscess formation, scarring, and injury to surrounding structures.²⁴

Postprocedure Care and Disposition

Tetanus prophylaxis should be administered if needed. The wound should be explored for any foreign bodies. The wound can be left open and treated with antibiotic ointment and a simple dressing. Systemic antibiotics are generally not indicated, but prophylactic antibiotic therapy should be considered for patients with immunosuppression, poor wound healing (i.e., diabetes, peripheral vascular disease), or involvement of deep structures.²⁶ Follow-up care is generally not required except in complicated cases to ensure proper healing and absence of infection.

Piercing Removal

Jewelry may need to be removed in order to perform a procedure (e.g., Foley catheter insertion, intubation, electrocautery), to prevent damage to nearby structures, and to avoid interference with reading plain radiographs, CT scans, and MRI images.^{23,30} A complete examination of the site should be performed and preexisting infection, trauma, and neurological deficits documented prior to manipulation. Radiography is indicated if swelling or infection obstructs viewing of the ornament.³¹ To remove some piercings, a local anesthetic block of the pierced area may be necessary for pain control.³²

There are numerous types of body jewelry, including barbells, capture bar rings, labrets, rubes, flared eyelet flesh funnels, safety pins, and studs. The barbell is either straight or curved, and the ball on the barbell can be internally or externally threaded. The capture ball rings are circular rings that contain spheres that are held in place by tension. Labret-type jewelry has a threaded ball or cone on one side and a flat

surface on the other. Tubes and flared eyelet flesh tunnels are used to enlarge a pierced hold. Studs have a removable back that slides off.¹⁹

Ear piercing frequently uses capture ball jewelry or studs and can be placed in any portion of the ear or ear lobe. The nose may be pierced at the septum, nostril, or bridge using curved barbells, studs, or capture ball jewelry. Labret-type jewelry is used in lip piercing, with the flat surface of the jewelry resting inside the mouth. The tongue, navel, nipple, and genitalia can be pierced horizontally or vertically using barbell or capture ball ring jewelry.³⁰

Equipment

Specific tools available for removing jewelry include ring-closing and ring-opening pliers, which are available from commercial suppliers. If unavailable, hemostats, needle drivers, or surgical clamps may be used.³⁰ Use of a wire cutter for removal should be avoided since this instrument can create sharp edges and cause soft tissue trauma.

Technique

Barbell jewelry can be removed by unscrewing the removable ball attached to one end using pliers, clamps, or a hemostat. The removable ball is grasped while holding the opposite side still and turned counter clockwise to loosen it. When the ball is detached, the straight end of the bar can be pulled toward the stationary ball and removed.³⁰ Capture ball rings can be removed by inserting ring-opening pliers or clamps into the middle of the ring and prying the ring open. This will allow the ball to drop out, and the ring can be removed.³³

One newly described method for removing navel piercing involves opening the jewelry and placing the tip of a close-fitting intravenous catheter (14 or 16 gauge), without the needle, over the threaded tip of the bar. Advancing the catheter will push the jewelry out of the skin tract. The jewelry is then removed while leaving the catheter in place.³³

Studs are removed by grasping the stationary stud with clamps and pulling the removable back in an opposite direction, which may also warrant the use of clamps for a tight grasp. Flared eyelet flesh tunnels may be removed by holding the tissue stationary while either pushing or pulling the jewelry through the piercing to remove it.

Depending on piercing location, consultation with surgical subspecialists may be warranted if piercing is associated with infection or swelling that obstructs visualization and removal. Patients with serious associated infections may require hospital admission, surgical débridement, and treatment with intravenous antibiotics.³¹

Complications

Short-term complications of removal include closure of the subcutaneous tissue tract, which could cause emotional stress to the patient.³⁰ If jewelry is associated with local infection, it is important to consider gauze or wick placement within the tract after jewelry removal to avoid abscess formation. Any complication associated with the piercing or removal requires prompt follow-up (e.g., in 1 to 2 days) to ensure adequate healing and response to treatment.^{35,36}

Ring Removal

Injuries to the fingers, such as sprains, fracture, or bee sting, can cause significant edema, and rings can impair circulation

and cause ischemia if swelling is significant.^{37,38} Prior to ring removal, a neurologic, vascular, and tendon examination of the digit should be documented. Radiographs may be warranted if bony injury is suspected.³⁷ Occasionally a digital block may be necessary before ring removal.

Equipment

Necessary equipment for ring removal may include³⁸⁻⁴⁰

- Ice
- Water-soluble lubricant
- 0 or 1-0 silk
- Manual ring cutter
- Battery-operated ring cutter
- Surgical gloves
- Ear curette
- Scissors
- Hemostats or a ring spreader

Technique

Before resorting to more involved techniques for ring removal, simple methods such as elevating the patient's arm above the heart and application of ice to the finger should be considered. Next, the physician can lubricate the finger and attempt manual ring removal. If the ring does not slip off, it will be necessary to employ another technique.³⁸

The string wrap method is initiated by wrapping a wide tourniquet around the finger, distal to the ring. The tourniquet is left in place for approximately 5 minutes and then removed. Then, 20 to 25 inches of umbilical tape, 0 or 1-0 silk, or another type of atraumatic thread is fed under the ring using a forceps, hemostat, or metal ear curette. The string's proximal end is tightly grasped and the distal end wrapped clockwise around the finger, avoiding gaps. The string is unwrapped by pulling on the proximal end slowly, and the ring will be removed as the string is unwrapped^{40,41} (Fig. 162-4A).

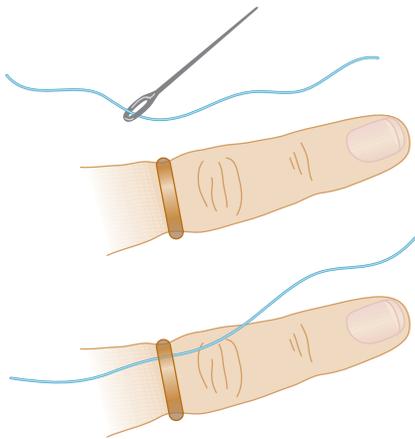

Another method involving the finger of a surgical glove can be used with burned, traumatized, or fractured fingers, for which the string wrap method may be too painful or traumatic. The glove finger can be cut off cylindrically and the cut end passed between the patient's finger and the ring using small forceps. The segment of the rubber behind the ring is then pulled toward the fingertip with a twisting motion on the ring³⁹ (Fig. 162-4B).

If the ring cannot be removed with these methods, it must be cut off. Manual cutters work best with thin to moderately thick rings. The least ornate part of the ring should be selected and the manual ring cutter guard placed under the ring. The thumbscrew is then turned clockwise. This technique may take several attempts in order to saw through the ring. If the ring is thick or cannot be cut manually, a battery-powered cutting device can be used, following the manufacturer's instructions. Once the ring is cut, hemostat or a ring spreader is used to open and remove the ring.³⁸

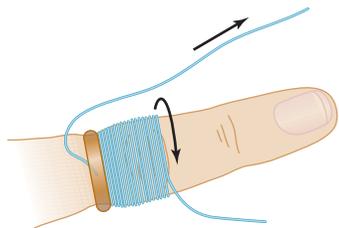

Complications

If rings are not removed from entrapped digits expeditiously, permanent, irreversible tendon, nerve, or vascular compromise can occur. Complications from ring removal include soft tissue (vascular, nerve, or tendon) and bony injury with resulting infection and loss of function.³⁷ Patients with entrapped rings require close monitoring to ensure that

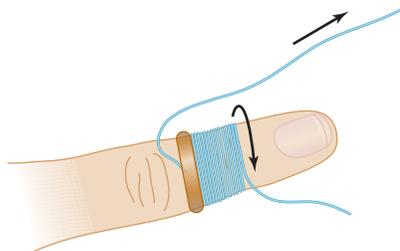

A. String wrap method for ring removal.

Wrap a wide tourniquet around the distal end of the finger and leave in place for five minutes before beginning technique. Umbilical tape or atraumatic thread should be fed under the ring using forceps, hemostat, or metal ear curotic.

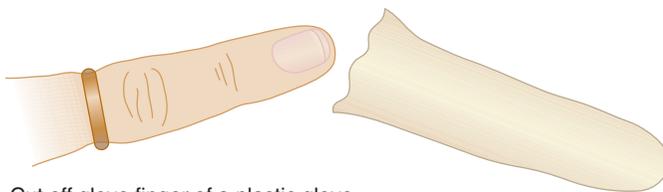

Tightly grasp the string's proximal end and wrap the distal end clockwise around the finger.

Unwrap by pulling on the proximal end slowly and the ring will be removed as the string is unwrapped.

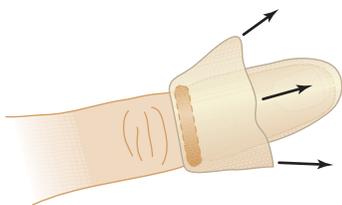

B. Glove method for ring removal.

Cut off glove finger of a plastic glove.

Pass the cut ends between the patient's finger and ring using small forceps.

Pull segment of rubber behind the ring forward toward the fingertip with a twisting motion on the ring for removal.

FIGURE 162-4. Techniques for removing rings from fingers.

vascular flow returns and infection does not develop. In general, antibiotics are not indicated unless significant tissue damage has occurred.

Subcutaneous Foreign Body Removal

A significant percentage of wounds treated in pediatric emergency departments involve retained foreign bodies.⁴²⁻⁴⁴ The presence of these foreign bodies places patients at risk for many complications, including infection, neurologic compromise, and increased scarring. In addition, retained foreign bodies continue to be a major source of malpractice claims against emergency physicians.

Anatomy and Physiology

The variability of a foreign body's reactivity with the host immune system can result in destruction and extrusion of the foreign body or chronic inflammation with granuloma formation. The presence of a foreign body can be relatively asymptomatic or can cause chronic inflammation depending on the retained foreign body material or its reactivity.⁴³⁻⁴⁷ Eighty percent of all foreign bodies are glass, wood, or metal.⁴³⁻⁴⁷ Wood and vegetable material produce more of an immune response than do metallic or glass foreign bodies. Vegetable matter foreign bodies can also introduce fungal organisms.^{45,47} The rubber in the sole of a sneaker or tennis

shoe is a good medium for *Pseudomonas* growth leading to perichondritis and osteomyelitis. Some anatomic areas, including the hand and foot, are associated with a higher complication rate and more technically difficult foreign body removal. Their complex anatomy, with proximity of tendon, bone, muscle, and neurovascular structures, places these areas at increased risk of tissue injury, infection, and missed foreign body. Small radiopaque foreign bodies in these areas may not be visualized because of proximity to bone.^{45,46,48} One of the most difficult steps in managing wounds is to determine if a foreign body is present. Historical clues to the presence of a foreign body include a puncture mechanism; scalp, face, or foot wounds; and involvement in a motor vehicle collision.⁴⁹

Particulate matter (e.g., dirt, rust, skin, sock, vegetable matter) can be tracked into a wound if a shoe is penetrated by a sharp object such as a nail. This is especially true if the penetrating object is 4.5 mm or greater.⁵⁰ A history of prior attempts at removal of wood foreign body or a nonhealing foot infection is highly suggestive of a retained foreign body.

Evaluation

Lacerations less than 0.5 mm in depth have been shown to very rarely contain glass foreign body.⁵¹ Physical examination findings suggestive of retained foreign body include excessive wound pain, tenderness to palpation over the wound, pain with passive movement, or a painful mass. A preverbal or apprehensive child can make these examination findings very difficult to uncover. Therefore, a slowly resolving or recurrent cellulitis, chronic drainage, culture-negative abscess, or any radiographic evidence of infection (lytic lesion, periosteal reaction, joint destruction) may require further evaluation, CT or MRI, or consultation with a surgical subspecialist for evaluation of a retained foreign body.

Plain radiographs can identify most metal and glass foreign bodies.⁴⁸ Embedded aluminum is also usually seen; however, ingested aluminum is usually not seen on plain radiographs.⁵² Plain radiographs may not identify glass or metal foreign body less than 2 mm in diameter in certain projections.⁴⁹ Wood, plastic, and vegetable foreign bodies are typically not visualized with plain films. Air within wood may be visible on plain films up to 48 hours, at which time body fluids absorbed into the wood make it the same density as soft tissue on radiographs.^{46,50} Ultrasound can be helpful in identifying foreign bodies and is especially helpful for identifying nonradiographic foreign bodies. CT and MRI can be extremely helpful to identify foreign bodies when a more exact anatomic location is needed.⁵³

Technique

First, the foreign body must be identified and localized. If foreign bodies cannot be directly visualized, radiologic studies must be used to localize the foreign body's anatomic location. Before any manipulation or exploration is performed, nerve and tendon function as well as vascular status are examined and documented. This examination should be performed throughout a complete range of motion of to identify all possible entry points and wound tracts, and to identify associated neurovascular or tendon injuries. To gain optimal visualization, complete immobilization, adequate

anesthesia or sedation, and proper lighting are needed. If a tourniquet is needed, a blood pressure cuff inflated to 20 mm Hg above systolic blood pressure will provide needed hemostasis.

Once a foreign body is identified and the area is properly prepped and draped, the removal procedure can begin. If the foreign body is not visualized, extension of the wound with a small scalpel (no. 15 blade) should be considered. The risk of damaging underlying structures will be minimized if only the superficial skin layers (epidermis and dermis) are incised. When possible, the wound should be extended parallel to Langer's lines, the natural skin creases. In small children, vital structures are close to one another and to the skin surface, placing them at an increased risk of injury during extension and manipulation. Therefore, all explorations should be performed by gentle spreading of the tissues with a hemostat, avoiding blind probing. When the foreign body is located, its proximity to other structures and its anatomic position are noted. The foreign body can then be grasped with a hemostat and removed.

After removal of the foreign body, the wound is reexplored to check for retained foreign bodies or damage to nearby structures. If no remaining foreign body is identified, and the wound appears clean and is less than 24 hours old, primary closure after irrigation can be performed. If the wound contains particulate matter, identifiable injured structures, or devitalized tissue, further management such as delayed primary closure, placement of a drain, and antibiotic therapy should be planned in consultation with a surgical subspecialist.

Long, thin foreign bodies, such as needles or glass, embedded parallel to the skin surface and superficial to deep structures can be removed by a slightly different technique. An incision is made in the skin perpendicular to the midpoint of the foreign body's long axis. Then, the tissue is gently spread with a hemostat until the foreign body is identified. The foreign body is grasped with the hemostat and pushed out through the original entrance wound or a wound created along the foreign body's initial tract. The wound should be examined for retained foreign body, and primary closure considered. Antibiotics should be administered for contaminated or infected wounds, wounds with retained foreign body, and wounds over 24 hours old.^{43,47,50,54}

Deciding whether or not to remove a retained foreign body can be difficult. Generally, foreign bodies with the following features should be removed: those that contain reactive materials, are likely to cause inflammation or infection, have heavy bacterial contamination, are toxic (spines with venom), impinge on or can damage tendons/vessels/nerves, impair mechanical function, are intra-articular, are proximate to fractured bone, can potentially migrate toward important anatomic structures, are intravascular, cause persistent pain, have established inflammation or infection, cause an allergic reaction, alter cosmesis, or cause psychological distress.⁵⁰ If the decision is made to leave a foreign body in place, the treating physician should explain the reasoning to the patient and the family. Then, the patient should be referred to a surgical subspecialist for further management. Discharge instructions should include this referral as well as aftercare instructions for wound care.

Contraindications to removal of a foreign body in the ED include an abnormal location. Foreign bodies in the chest,

abdomen, and neck require surgical consultation as removal of foreign bodies in these locations could result in excessive bleeding from a previously tamponaded blood vessel, or damage to the plural space or abdominal cavity. Time constraints for exploration and removal should also prompt the emergency physician to consult a surgical subspecialist. In general, an attempt in the ED should not exceed 30 minutes; further exploration and tourniquet time place nerves and vessels at greater risk.

Complications

Complications of a retained foreign body as well as of foreign body removal after exploration include wound infection, cellulitis, abscess formation, septic arthritis, osteomyelitis, and chronically draining wounds.^{43,48,50,54} Wound exploration and foreign body removal can injure adjacent structures or cause scarring. Complications associated with hemostasis, whether by tourniquets or by the use of vasoactive agents, include vascular damage, neurapraxia, and thrombosis. These complications can be greatly reduced by keeping tourniquet time to 20 to 30 minutes and by not using vasoactive agents on devitalized tissue or at end-organ sites.^{50,54,55}

Summary

The ability to assess, manage, identify, and remove foreign bodies is an important skill. Proper preparation, patient selection, technique selection, antibiotic use, and hemostasis and appropriate consultation with surgical subspecialists will improve outcome, while reducing complication rates.

Chapter 163

Enterostomy Tubes

Andrew D. Mason, MD and Kelly A. Keogh, MD

Key Points

Most problems with enterostomy tubes can be managed by emergency physicians.

Prior to removing and replacing a clogged enterostomy tube, the clinician should attempt to unclog the tube by flushing it with warm water or a carbonated beverage.

One should never attempt to place an enterostomy tube into an immature tract.

Maintaining patency of the fistula is a priority if the tube is dislodged. If replacement tubes are unavailable and the tract is mature, placement of a Foley catheter should be considered to maintain tract patency.

Indications and Contraindications

The use of enteral feeding tubes has become common in the management of children with medical and surgical problems who require long-term enteral feeding.¹ Children who require short-term enteral feeding (<2 to 3 months) are frequently managed with a feeding tube passed through the nose, with the tip of the tube being placed in the stomach (nasogastric tube) or the jejunum (nasojejunal tube). Complications of prolonged nasal tube use include sinusitis, reflux, aspiration, and esophageal strictures.²

Enterostomy tubes are placed if prolonged enteral feeding is required. A feeding catheter is placed through the abdominal wall into the stomach (gastrostomy tube, or G tube), or further down the gastrointestinal (GI) tract (gastrojejunostomy tube, or GJ tube, and jejunostomy tube, or J tube). GJ tubes and J tubes have the advantage of a lower incidence of reflux, aspiration, and GI bleeding compared to G tubes. However, GJ tubes and J tubes have a higher rate of obstruction, migration, and intussusception than G tubes.

Several different types of feeding catheters are in use today (Fig. 163–1). Most are made of silicone. A pigtail/loop, balloon, button, or collapsible wing is used to keep the distal end of the tube in place. A bumper or disk may be attached

to the tube at the skin surface in order to prevent the tube from migrating inward. After 8 weeks, when the fistula tract matures, the tube may be replaced by a low-profile “button,” which is cosmetically superior and eliminates the potential complication of inward migration of the catheter. Options for placement of enterostomy tubes include surgically placed G tubes; tubes placed using percutaneous endoscopy, or percutaneous endoscopic gastrostomy (PEG) tubes; and tubes placed by percutaneous insertion under fluoroscopy without endoscopy, or percutaneous radiologic gastrostomy (PRG) tubes. In patients who are candidates for PEG tube placement, this method of insertion is safer and more cost effective than surgical placement.³

Children with existing enterostomy tubes commonly develop problems requiring replacement of the tube. Indications for replacement include tubes that are dislodged, malpositioned, damaged, or occluded (if the occlusion cannot be corrected). Contraindications to replacing enterostomy tubes include recently placed tubes with an immature fistula tract (within 8 weeks of initial operative procedure), a fistula tract that is no longer freely patent, and the presence of peritoneal signs. In these cases, the surgeon, gastroenterologist, or interventional radiologist who originally placed the tube is consulted. Surgery consultation is always required if peritoneal signs are present. If the appropriate consultant is not immediately available, intravenous access is obtained to administer fluids and medication. Enterostomy tubes distal to the stomach (GJ and J tubes) must be replaced endoscopically.

Preparation and Consent

If the tube is dislodged, it must be expeditiously replaced to prevent the fistula tract from closing. Dislodged tubes should be replaced with the same type of tube, and often parents will carry an “extra” with them. If there is no replacement tube immediately available, a Foley catheter can be inserted to preserve fistula patency.

A thorough history should be obtained, including the original date of enterostomy tube placement and prior enterostomy tube complications. Physical examination is performed to ensure that there are no peritoneal signs and that there is no localized infection. The procedure is explained to the patient and family, and informed consent is obtained.

Several types of catheters are currently in use, and each comes with instructions for replacement. Equipment must be

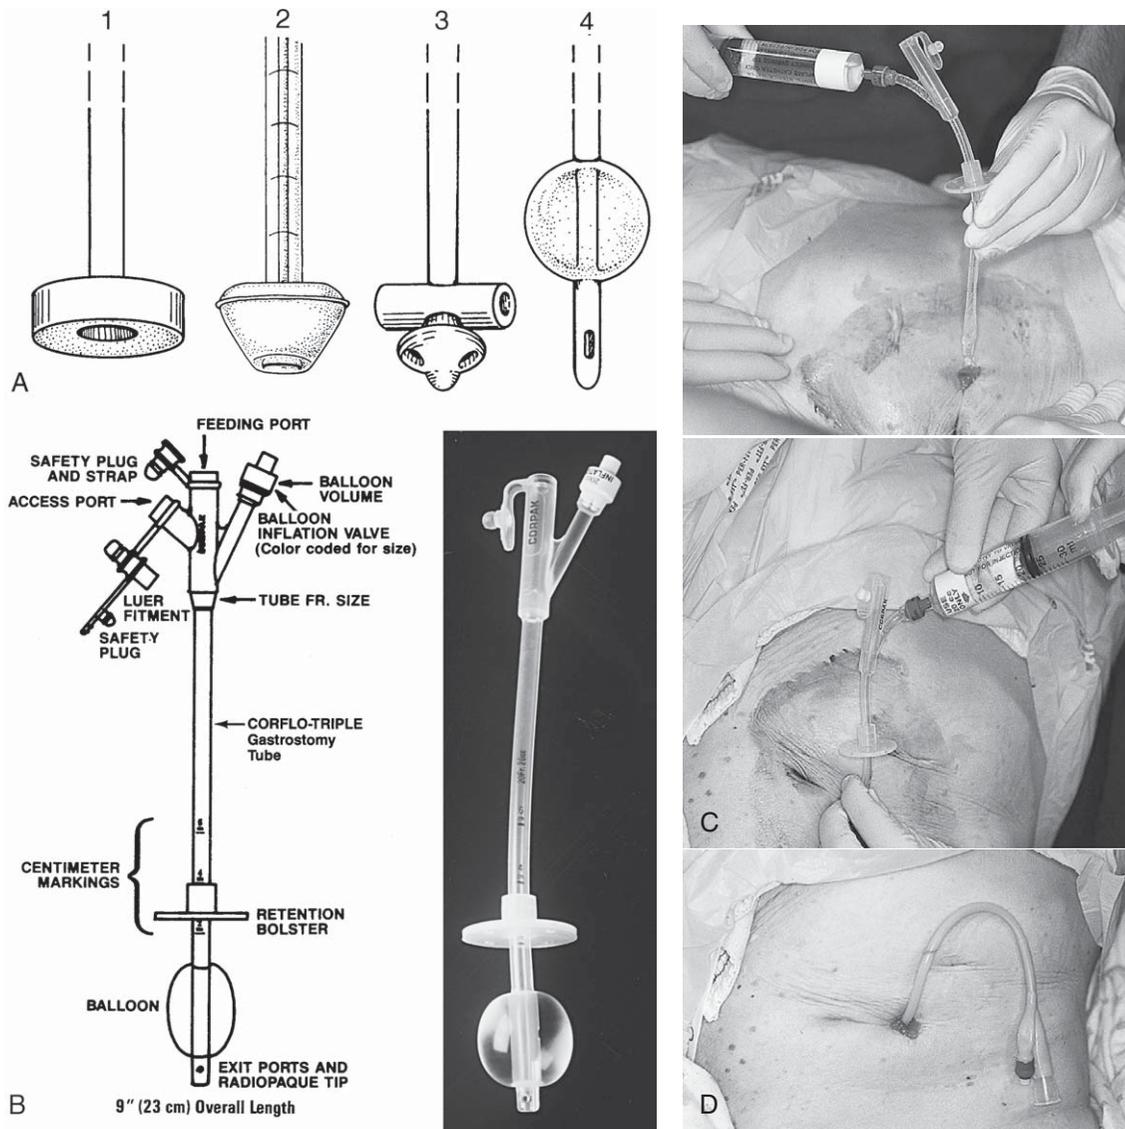

FIGURE 163-1. Various types of gastrostomy tubes. From left to right: coil loop gastrostomy tube (Cook Mac-Loc); balloon gastrostomy tube with a sliding retention disk (MIC, Kimberly Clark); and MIC-Key low-profile gastrostomy feeding tube with antireflux valve.

checked prior to the procedure. For balloon catheters that will be removed, an adaptable syringe (i.e., Luer-Lok) is checked to ensure that it fits the balloon port of the old gastrostomy tube. The integrity of the new balloon is checked. For collapsible wing or mushroom catheters, the clinician should ensure that the stylet or obturator fully distends the distal tip and allows narrowing for passage through the stoma. The child will need to be placed supine and restrained or sedated if unable to cooperate (see Chapter 159, Procedural Sedation and Analgesia).

Equipment

- Replacement tube of the same size as the old tube, or
- Temporizing balloon-tipped Foley catheter (one size smaller than the existing enterostomy tube)
- 5-ml syringe for balloon
- Lubricant (i.e., viscous lidocaine or K-Y Jelly)

- 20 ml normal saline
- Stethoscope
- Waterproof tape
- Adaptable syringe or Luer-Lok syringe (for balloon port of old enterostomy tube)
- Benzoin
- Gauze
- Absorbent dressing
- Obturator for stylet of dysfunctional tube (depending on type of tube used)
- Dilators (e.g., Hegar uterine dilators)

Monitoring

Monitoring devices are not necessary for a child simply requiring tube removal or replacement, unless the child is sedated (see Chapter 159, Procedural Sedation and Analgesia).

Techniques

Unblocking an Obstructed Enterostomy Tube

Tubes may become blocked when occluded with formula or undissolved medication. If the tube is blocked, an attempt should be made to unblock it. Warm water is gently instilled into the tube while pushing and pulling on the plunger of the syringe, allowing the water to flow in and out of the feeding tube repeatedly until patency is reestablished. It has been reported anecdotally that carbonated drinks are more effective than noncarbonated fluids for clearing tubes. If the tube remains blocked, then it must be replaced. Techniques to prevent future obstruction should be reviewed with the family, such as avoiding thick suspensions and fully crushing and dissolving tablets in warm water. Medications known to have a high incidence of tube obstruction include corn starch, lactulose, cholestyramine, kayexalate, magnesium oxide, ciprofloxacin, and clarithromycin. The tube should be flushed with at least 10 ml of sterile water after each use, and every 4 hours when the patient is receiving continuous feeds.

Removal of Dysfunctional G Tubes With a Mature Fistula Tract

First, the stoma site is liberally lubricated with water-soluble lubricant or lidocaine gel. If the old tube is balloon tipped, an adaptable syringe is attached to the balloon port of the old tube and the balloon contents are withdrawn. If the old tube has a loop, there is a suture at the skin surface that allowed the distal aspect of the tube to coil, preventing expulsion. This suture should be cut prior to removal. If the old tube is a collapsible wing or mushroom type, a stylet or obturator (which came with the catheter) is inserted to extend and collapse the distal tip within the stomach wall. A cooperative child can be asked to take a deep breath and hold it. As the child takes a breath, the tube is removed by gentle, constant traction.

Replacement of G Tubes With a Mature Fistula Tract

Several types of catheters are currently in use, and each comes with specific instructions for replacement. The stoma site is liberally lubricated prior to introducing the new catheter. The catheter is inserted into the stoma perpendicular to the abdominal wall. Holding the tip of the catheter between the thumb and index finger and placing the heel of the hand on the abdominal wall will stabilize it. The tip of the catheter is passed into the stoma with steady, firm pressure directed posteriorly, perpendicular to the abdominal wall. It may take 30 to 45 seconds of this steady pressure to stretch the site enough to permit entry. Intermittent or jerky movements should be avoided. Constant gentle, firm pressure directed posteriorly will maximize success. When the stomach is entered, the resistance suddenly decreases. The catheter should be advanced further to ensure placement in the stomach.

If a *balloon-tipped catheter* is used, the balloon is inflated with saline or water, and then pulled gently outward until the balloon contacts the stomach wall. If a *mushroom or collapsible wing type of catheter* is used, the obturator or stylet is now fully removed. The collapsible wing tube is gently pulled outward until the wings contact the stomach wall. If a *loop*

catheter is used, the suture is now pulled and tied to allow coiling of the distal end.

Once the replacement tube is inserted, the position should be confirmed. If the tube is in the stomach, it will move freely. The clinician should auscultate for borborygmi. A syringe should be attached to the tube and gastric contents aspirated. If no gastric contents can be aspirated, the tube is flushed with sterile water, and aspiration is attempted again. Failure to easily instill and aspirate from the tube suggests incorrect placement. Alternately, the tube's position can be confirmed by instilling Gastrografin into the tube and obtaining a plain abdominal radiograph. Once the lumen of the tube has been capped to prevent leakage of gastric contents, the tube may be freely exposed to the air. Alternatively, a dressing with waterproof tape can be placed over a temporizing Foley catheter. External dressings are optional.

Alternatives

If removal of the current but malfunctioning tube is not possible by gentle traction, the tube may be cut at the abdominal wall surface and the internal portion allowed to pass through the GI tract, or removed later endoscopically.

If the replacement tube does not insert successfully, an attempt can be made to gently enlarge the mature tract with dilators (e.g., Hegar dilators). For this purpose, the clinician should first gently insert the smallest blunt dilator that easily fits completely into the tract. The dilator is then gently rotated to gradually increase the tract size. Progressively larger dilators are inserted into the tract until the tract is an appropriate size for the replacement enterostomy tube. During dilation, clinicians must be sure that the dilators are in the correct tract and that trauma to the site is minimal. Alternately, a temporizing Foley catheter can be inserted into the tract. If the fit is not snug, the patency of the fistula will be maintained, although excessive leakage around the tube may limit the catheter's use for feeds or medications.

Complications

Complications are divided into those that occur soon after an enterostomy tube is manipulated or replaced, and delayed complications of enterostomy tube placement and utilization (Table 163–1).

Immediate Complications

Unsuccessful Replacement

In the event that the catheter will not advance into the stoma, or if the child is in extreme distress, the clinician should assume that the fistula is no longer patent. In this case, endoscopic or surgical placement of a new tube may be necessary. Intravenous access is obtained to administer fluids and medications pending definitive management.

Peritonitis

Peritonitis is an uncommon but serious complication after initial radiologic placement of a G tube, with an estimated incidence of up to 3%.⁴ When replacing a G tube, the fistula can become disrupted, creating a false lumen into the peritoneum. This complication is more common with immature fistulas. If excessive force is used, perforation of the stomach or bowel may occur. Instillation of formula into an improperly positioned tube or perforated viscus can cause chemical

Table 163–1 Enterostomy Tube Complications and Management

Complication	Possibility	Management
Tube dislodged < 8 wk after placement	If tube < 8 wk old, an immature fistula is present.	Do not replace tube percutaneously. Endoscopic or surgical replacement may be needed.
Tube dislodged > 8 wk after placement	Mature fistula is likely.	Replace tube or insert Foley catheter (one size smaller if needed). Dilators (e.g., Hegar cervical dilators) may be needed to gently enlarge tract. Confirm position by aspirating gastric contents. If unable, consider contrast confirmation.
Tube cannot be used for medicine or feeds	Tube is blocked from medications or inadequate postuse flushing.	Flush tube with warm water or carbonated beverage using small syringe under high pressure. Push and pull on the plunger of the syringe, allowing the water to flow in and out of the feeding tube repeatedly until patency is reestablished.
Tube leakage	Tube may be broken, or tube may be intact and leakage may be from around tube.	If tube is leaking, replace with similar-size tube. If unable to replace, seal tube with tape. If tube is intact and leakage is around site, see below.
Tube site redness, discharge, or irritation	Tube may be too mobile or loose, gastric contents may be leaking, infection may be present, granulation tissue may be forming, or tape allergy may be present.	Tube mobility—secure tube with tape Leaking gastric contents—apply antacids or barrier cream to site Infection—cleanse, administer antimicrobials Granulation tissue—soak with saline or apply silver nitrate sticks as needed
Tube migration	Tube is too mobile.	Tape allergy—use hypoallergenic tape. Secure tube to skin and consider disk to stabilize if needed. Measure tube length and reposition or pull back.
Vomiting with gastrostomy tube	Balloon migration to duodenum with obstruction.	
Vomiting with gastrojejunostomy tube	Gastric coil leak Migration into stomach Intussusception	Diagnose with contrast study (via tube). Ultrasound may diagnose intussusception. Removal is required if coil leak or migration is present, with air contrast enema for intussusception.
Formula-like diarrhea	Enterocolonic fistula	Diagnose with contrast study. Surgery may be required.

or bacterial peritonitis. Patients with peritonitis may present with vomiting, fever, and abdominal pain and distention. Management includes discontinuation of tube use, empirical antibiotic administration, and surgical consultation.

Malpositioned Enterostomy Tube

If the new tube is not advanced far enough, the distal tip will be in the fistula tract rather than the stomach. Pain and leakage will occur during instillation of materials through the tube. If this occurs, the tube should be advanced further.

Gastric Outlet Obstruction

If the catheter is not properly secured, it can migrate proximally or distally in the GI tract, resulting in esophageal migration, gastric outlet obstruction, or intestinal obstruction. Management consists of withdrawing the G tube to the appropriate position.

Delayed Complications

Major Complications

Major complications include aspiration of feeds with resulting pneumonia, peritonitis, or GI hemorrhage, and fistula formation, requiring discontinuation of enterostomy tube use and administration of intravenous hydration and medications as required.

Aspiration of feeds is a common problem in children whose oromotor pathology predisposes them to aspiration and pneumonia. Patients present with respiratory distress. Acute treatment may include antibiotics, bronchodilators, and steroids. Preventative measures include medications to reduce gastroesophageal reflux, and positioning of the tube distal to the pylorus (J tube).

Gastrointestinal hemorrhage is relatively uncommon but may be secondary to ulceration at the enterostomy site and gastritis. Following acute resuscitation, treatment may include discontinuation of tube use, administration of medications to reduce gastric acid production, and removal of the tube.

Fistulas may develop in patients with enteral feeding tubes. Fistulas may connect to the skin (enterocutaneous) or to the bowel (enterocolonic). Children with enterocolonic fistulas may present with liquid stools. Contrast studies may be helpful to delineate the fistula tract.

Vomiting (bilious or nonbilious) in patients with enterostomy tubes may indicate partial or complete bowel obstruction. Often a radiographic contrast study is helpful. Common causes include

- Inward migration of the balloon into the pylorus. This may be relieved by applying traction to pull the balloon back against the gastric wall, and securing it in place.
- Development of intussusception around GJ tubes. This requires radiologic evaluation. Shortening the length of the tube or replacing it entirely will usually relieve the intussusception. This procedure is usually performed by interventional radiology.

Other common causes of vomiting include gastritis, ulcers, and systemic infection.

Buried bumper syndrome occurs in patients whose internal bumper erodes through the gastric mucosa. As the erosion re-epithelializes over the bumper, it becomes “buried.” Patient’s symptoms frequently begin several months after placement of the tube, and include pain with feeding, resistance to flow, and irritability with movement or rotation of the tube. Replacement of the tube is curative.

Minor Complications

Minor complications of enterostomy tube use are common, and are often considered “routine maintenance problems.” These include blocked tubes (see Techniques section), dislodged tubes, and stoma site problems.

DISLODGED TUBE

Dislodged enteral tubes require expeditious attention since the fistula tract between the skin and stomach may close within hours. If it has been less than 8 weeks since insertion of the enterostomy tube, the fistula tract is immature, and the tube is NOT replaced in the emergency department. The clinician who inserted the tube is consulted. With a mature fistula tract, however, the enterostomy tube may be replaced, or a Foley catheter may be used to maintain fistula patency. For J tubes, a Foley catheter is inserted to maintain fistula patency until the tube can be replaced by an interventional radiologist.

STOMA SITE PROBLEMS

Stoma erythema must be differentiated into infectious and noninfectious causes. *Stoma site infection* may cause erythema, induration, tenderness, and local discharge. Infections are usually polymicrobial, predominately staphylococcal and streptococcal organisms. Minor infections often respond to topical antimicrobial ointment. Cellulitis is treated with systemic antibiotics. Yeast superinfection may present with typical “satellite” lesions. Wound cultures may be helpful for definitive diagnosis, especially in patients who are unresponsive to initial therapy or who are at risk for infection with resistant microorganisms (e.g., methicillin-resistant *Staphylococcus aureus*).

Noninfectious causes of stoma site erythema include irritation from leakage of gastric contents around the tube, mechanical irritation due to friction from movement of the tube, allergy to tape, and formation of granulation tissue. Many skin problems respond to saline-soaked dressings changed three times a day, barrier creams, hypoallergenic tape, and tighter affixing of the tube to the skin to prevent excessive movement. If these techniques are ineffective,

definitive treatment may require shortening of the tube or conversion to another type of enterostomy tube.

Dermatitis from leakage of gastric contents may occur if there is excessive space between the fistula tract and the catheter. Barrier cream is applied to protect the abdominal wall. Medications to decrease gastric acid production and local application of antacids may be beneficial. Persistent leakage of gastric contents may respond to discontinuation of tube use and connection to low suction for a time. If unsuccessful, the tube may require endoscopic replacement with a larger tube.

Granuloma formation at the enterostomy tube site appears as a pink or red cauliflower-like protuberance. This may regress with measures to decrease local irritation, such as saline-soaked dressings, and minimizing excessive movement of the tube. Bleeding is treated with the application of direct pressure, or cauterization with silver nitrate.

Postprocedure Care and Disposition

Patients are advised to return to the emergency department for potential complications of enterostomy tube placement, including abdominal pain, vomiting, fever, GI bleeding, and respiratory distress. Parents are advised that the best way to avoid tube obstruction is with proper flushing of the tube before and after each use. Parents should also be reassured that blockage, malpositioned tubes, cellulitis, and granuloma formation are not necessarily the result of incorrect technique, but rather are common and often unavoidable complications of enteral feeding tubes.

Replacing a Tracheostomy Tube

Jill C. Posner, MD, MSCE

Key Points

Respiratory distress in a patient with a tracheostomy indicates tube obstruction until proven otherwise.

It is important to ascertain and understand the indication for patient's tracheostomy.

All equipment (including rescue devices) should be prepared prior to initiating the procedure.

Parents and/or home care nurses are excellent sources for information and assistance.

The clinician should recognize when help is needed and call for assistance and/or backup (otorhinolaryngology, anesthesia).

Indications and Contraindications

In children, tracheostomies are indicated for respiratory insufficiency due to a variety of disorders, most commonly bronchopulmonary dysplasia and airway anomalies, including congenital anomalies and subglottic stenosis. Relatively common indications are neuromuscular or central diseases such as a brain tumor or Chiari malformation.¹⁻³ A child with a tracheostomy may or may not require additional ventilatory assistance.

Routine care for the child with an artificial airway includes periodic replacement of the tracheostomy tube. Commonly, trained family members or skilled home care nurses carry out this procedure in the child's home. However, in crisis situations or when acute medical issues arise, families will seek assistance from an emergency department or other health care personnel. The indications for tracheostomy tube replacement are *cannula obstruction* and *cannula dislodgement*. A child with a tracheostomy and respiratory distress is assumed to have airway compromise until proven otherwise.⁴

Patients may present with bleeding from the tracheostomy tube. Intratracheal bleeding most commonly results from drying and friability of the tracheal mucosa due to

inadequate humidification. However, even a small amount of bleeding from the tracheostomy tube may indicate a rare but life-threatening condition: erosion of the distal aspect of the tube into an innominate vessel. Large amounts of bleeding may ensue, making it difficult to secure the airway if the tracheostomy tube is removed. For this reason, tracheostomy tube change is relatively contraindicated in patients with bleeding depending upon the suspicion of arterial erosion and the severity of the patient's symptoms.

Preparation and Consent

Ideally, there should be at least two people available for the procedure, one to secure the patient and remove the old cannula and a second person who is responsible for placing the new tube. All the equipment necessary to complete a cannula replacement should be on hand, as should airway adjuncts, suction devices, and other rescue devices. Formal informed consent procedures are not necessary when managing an airway emergency; however, it is important to keep patients, caregivers, and nurses informed about management plans.

Equipment

Many caregivers of children with tracheostomy tubes are taught to carry "go-bags" or "emergency boards" containing all of the equipment required to perform an emergent tracheostomy tube change with them at all times. This includes a bag-mask ventilation device, oxygen source, replacement cannula, endotracheal tubes of the same diameter and smaller, lubricant, scissors, securing ties, and padding.⁵ If such a bag/board is not available, all the necessary equipment should be gathered prior to initiating the procedure.

Tracheostomy Tube Features

Some characteristics of a patient's tracheostomy tube of importance in the emergent setting are its size, whether it is cuffed or uncuffed, if it has an inner cannula, and if it is fenestrated. Tracheostomy tubes are *sized* according to three dimensions: the inner diameter, the outer diameter, and the length. The inner diameter is standardized among the many manufacturers of tracheostomy tubes, whereas the other dimensions may vary considerably among manufacturers. All or some of the dimensions of an individual tube are generally imprinted on that tube's flanges. In addition,

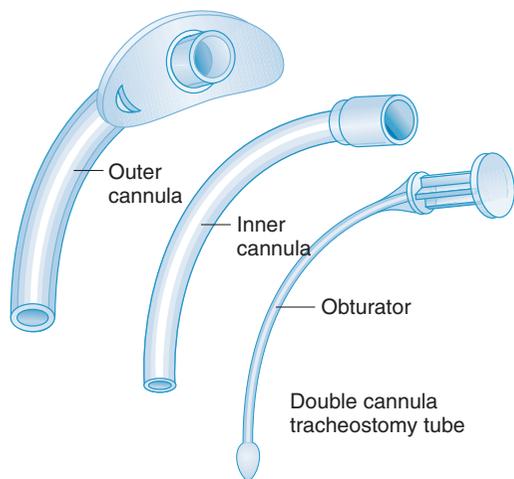

FIGURE 164–1. Use of double-cannula tracheostomy tube. Insertion of a double-cannula tracheostomy tube requires an outer cannula, an inner cannula, and an obturator.

tracheostomy tubes may be *cuffed* or *uncuffed*. The general guideline that the use of a cuffed tube is reserved for children over 8 years old does *not* hold true for children with tracheostomy tubes. Younger children, and even infants, may have a cuffed tracheostomy tube in place (e.g., if there is an airway anomaly); therefore, it is always important to look for the presence of a cuff for any age child and be sure to deflate it prior to removal of the tracheostomy tube.

Some tubes have a single cannula with a removable obturator, while others have a double cannula with an outer and an *inner cannula* (Fig. 164–1). This type of tube commonly is used for children with especially precarious airways, for whom routine tracheostomy tube changes could prove particularly threatening. With this type of tube, the inner cannula can be removed and cleaned while the outer cannula remains in place, providing a secure airway at all times. Importantly, the manual resuscitator bag cannot be attached directly to the outer cannula, and the inner cannula must be in place for hand ventilation. Finally, a *fenestrated* tube has a hole in the posterior aspect of the tube that allows the child to vocalize by forcing air retrograde through the vocal cords.^{4,6,7}

Monitoring

The monitoring of patients undergoing tracheostomy tube replacement parallels that which is routinely performed for other airway emergencies. Careful observation of cardiorespiratory function and gas exchange is performed noninvasively via cardiorespiratory and pulse oximetry monitoring. The detection of end-tidal carbon dioxide (ETCO₂) by colorimetric (yellow = yes, blue = bad) or capnography devices assists in the assessment of proper tube position.

Techniques

Assessment of Tube Position and Patency

The immediate management of patients presenting in respiratory distress with a tracheostomy tube seemingly in place is

to assess tube position and patency. The clinician should keep in mind that a tracheostomy tube positioned in the stoma does not necessarily indicate that it is positioned in the trachea, as false passage into the paratracheal soft tissues may have resulted in prior replacement attempts either at home or en route to the hospital. High-flow humidified oxygen should be supplied while rapidly evaluating tube positioning by physical examination and noninvasive monitoring techniques.

Clearing an Obstructed Tracheostomy Tube

Removal of obstructing secretions by careful suctioning may negate the need for emergent tracheostomy tube replacement. One to 2 ml of normal saline is placed into the tube to loosen secretions. The largest size suction catheter that will fit is inserted into the tube 2 to 3 inches into the cannula. If the child starts to cough, the catheter is in deep enough. Suction is applied for 3 to 5 seconds—and never for more than 10 seconds—with a portable machine set to 100 mm Hg or less. Heart rate and pulse oximetry should always be monitored,^{6,8} and suctioning should be stopped if the patient develops bradycardia or cyanosis. If suctioning equipment is not available, the clinician may try clearing the tube of secretions by inserting the obturator or a smaller sized endotracheal tube. If the tube cannot be cleared and respiratory distress continues, the tracheostomy tube should be changed.

Replacing a Tracheostomy Tube

Positioning the Patient

The patient should be lying supine with the neck in slight extension, fully exposing the tracheostomy tube and stoma. A rolled towel can be placed under the patient's shoulders to further optimize the view of the tracheal stoma. At least two people should be available to execute the tracheostomy tube change. One has the responsibility of securing the patient's head and removing the old tube, while the other's focus is on placing the new tube.

Removing the Old Tube

Before removing the existing tube, it is necessary to check for a balloon, indicating the tube has a cuff, and deflate it by aspirating until the balloon is flat (cutting the balloon will *not* deflate the cuff). Securing tape or ties are unfastened or cut. The tube is removed by withdrawing it out and down in an arclike motion.

Inserting the New Tube

After lubricating the tube and with the obturator in place, the tip of the cannula is gently placed into the stoma, pushing it posteriorly and down (again, in an arclike motion) using gentle pressure. The clinician should avoid scraping the posterior aspect of the trachea. The tube is pushed in until the flanges are flush against the patient's neck. The obturator is removed, and the inner cannula inserted and connected to the bag-valve circuit (Fig. 164–2). The cuff is then inflated if used.

Confirmation of Tube Positioning

Physical examination clues (e.g., improvement in respiratory distress, equal breath sounds over the anterior and lateral

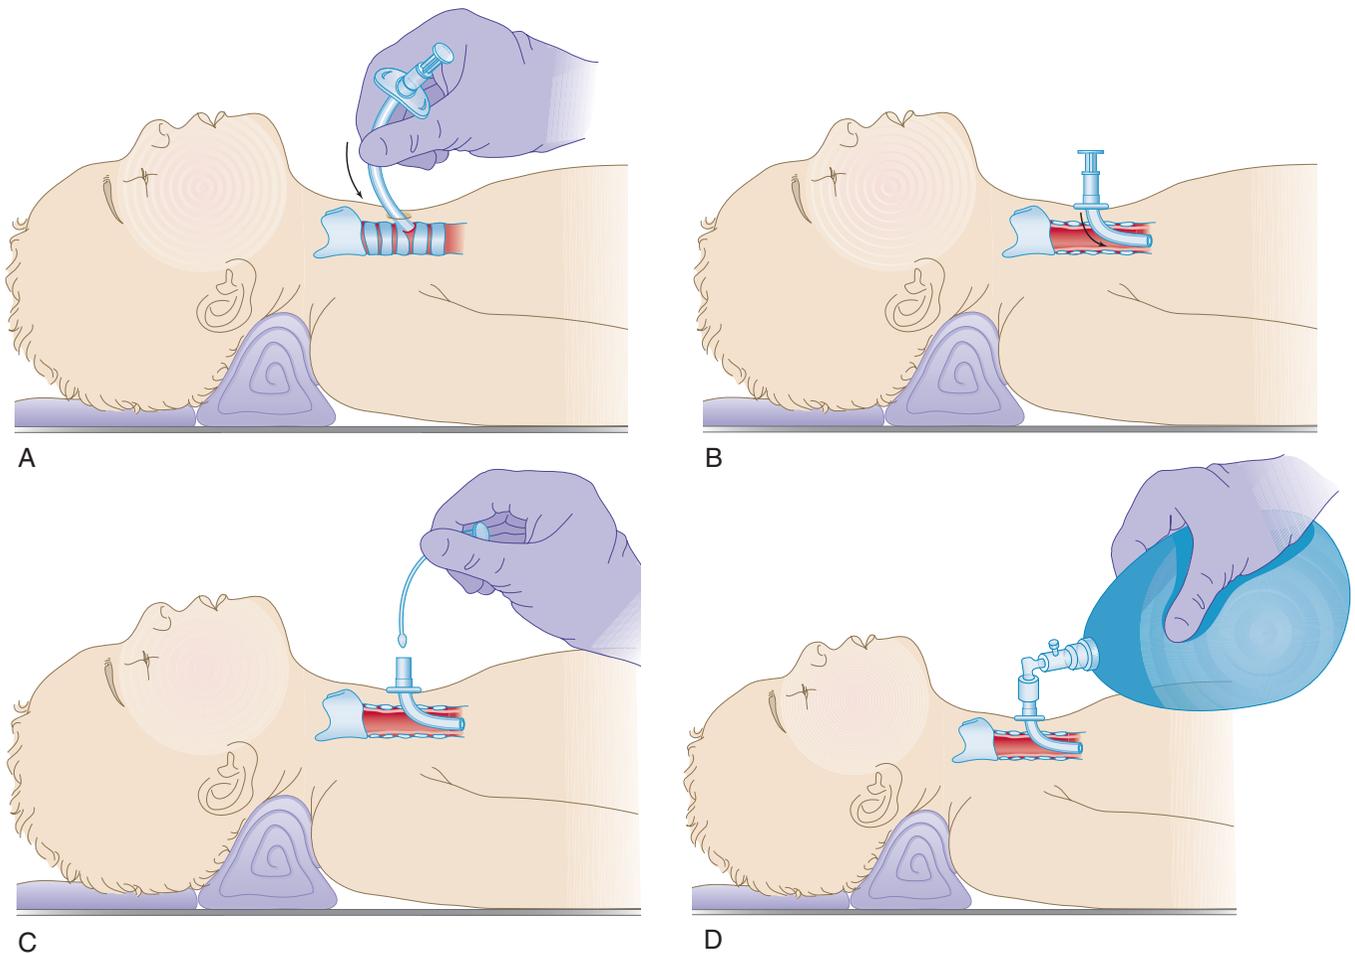

FIGURE 164-2. Placement of a tracheostomy tube. Using an arclike motion and with the obturator inserted, the tracheostomy tube is gently guided into the tracheal stoma (A) until the flanges are flush against the skin of the neck (B). The obturator is removed (C) and the resuscitor bag attached to the tracheostomy tube (D), thereby facilitating manual ventilation.

chest walls, symmetric chest rise) and ETCO_2 monitoring are used to confirm placement into the trachea. The tube is then secured using tracheostomy tube ties and padded sufficiently to avoid neck irritation.

Alternatives

Constriction tends to occur when the tracheal stoma is left unstented, a condition that may make it difficult to pass a replacement tube of the patient's usual size. In these instances, the airway should be secured with the largest size tube that the stoma will accommodate. Generally, a tracheostomy tube one-half size smaller is sufficient. Alternatively, a smaller sized endotracheal tube is placed and then the stoma is dilated to its original size through serial insertions of progressively larger endotracheal tubes.

If false passage into the paratracheal soft tissues occurs, it may be helpful to use an oxygen catheter, or an endotracheal intubating stylet with an internal oxygen source (e.g., Frova), or gum elastic bougie as a guide for the tracheostomy tube insertion using the Seldinger technique. The catheter is placed into the tracheal stoma and the patient is oxygenated. The oxygen source is separated from the catheter or stylet. The connector tip is cut off if an oxygen catheter is

used, or the intubating stylet is disconnected from its oxygen source. Next, the tracheostomy tube is slid over the catheter/stylet into the trachea. Then, the catheter or stylet is removed.

Finally, if attempts to secure the airway via the stoma fail, traditional bag-valve-mask techniques (the stoma should be covered with a gloved finger) may be applied, or the airway may be secured using oral-tracheal methods. The indication for the patient's tracheostomy should be considered before electing to administer neuromuscular blocking agents. In cases of airway anomalies (e.g., a tracheal shelf), the anatomic landmarks commonly used in direct laryngoscopy may be obscured or absent, thereby impeding a successful intubation. In such cases, it may be prudent for the clinician to provide support of the patient's own respiratory effort and call for anesthesia or otorhinolaryngology assistance.

Complications

The most common complications encountered during the replacement of a tracheostomy tube are the inability to replace the tube and the false passage of the tube into a paratracheal soft tissue tract. In addition, pneumothorax can occur with manual or mechanical ventilation.

Postprocedure Care and Disposition

Following placement of a tracheostomy tube, physical examination and noninvasive monitoring are used to confirm proper positioning. In complicated cases or for patients with continued respiratory distress, a chest radiograph and arterial blood gas analysis may provide additional information.

The tracheostomy tube is secured in place by tracheostomy ties. The ties are wrapped around the posterior aspect of the neck and are sufficiently tight when one finger can be placed between the ties and the patient's neck.⁶ Padding inserted beneath the ties helps to keep the neck dry and free from skin breakdown.

Ventilator Considerations

John A. Tilelli, MD

Key Points

Manipulations of ventilator settings have the goal of altering mean airway pressure or minute alveolar ventilation.

Assessment of the ventilator performance is performed by observing the patient for chest rise, air entry, airway pressure, saturation, and end-tidal CO₂ content.

Failure of air movement should presume a problem with the ventilator or circuit and should prompt its removal from the patient, to be replaced by bag-valve-mask ventilation.

Common complications of mechanical ventilation include underventilation (too little volume or pressure); overpressure injury, such as pneumothorax (too much volume or pressure); gas trapping; malposition or dislodgment of the endotracheal tube; circuit leak; and underventilation from inadequate sedation.

Indications

Mechanical ventilation of children with respiratory insufficiency, once a procedure solely found in the intensive care unit, is now increasingly performed in the outpatient setting. As such, patients now come to the emergency department for the management of complications of home ventilation. Furthermore, the application of mechanical ventilation in the emergency department in support of the child in need of airway control or ventilatory assistance is increasing. Emergency physicians must be familiar with the techniques of home mechanical ventilation and of the practical considerations of initiating mechanical ventilation in the patient who presents with an acute illness.

Mechanical ventilation is used most frequently to augment minute ventilation of the patient in whom airflow is impaired by weakness, fatigue, altered lung mechanics, or loss of respiratory drive, and for the application of positive pressure to the airway to improve lung volume and thereby favorably affect oxygenation. Related indications are found in the man-

agement of extrapulmonary diseases in which control of ventilation or decreasing the work of breathing might be important, such as the control of carbon dioxide tension in head injury, or the management of congestive heart failure (Table 165–1).

Occasionally, mechanical ventilation may be instituted for the delivery of medications to the airway, such as nitric oxide, helium-oxygen mixtures, bronchodilators, or antibiotics. Mechanical ventilation may be instituted as an aid to pulmonary toilet in the patient with impaired secretion clearance.

Strictly speaking, there are no contraindications to mechanical ventilation for the patient in whom the airway is controlled. Many of the issues that physicians confront in the decision to secure the airway embrace the question of whether or not mechanical ventilation should be undertaken. For infants and children with terminal disease, family members and primary care physicians can assist with decisions regarding the appropriateness of instituting mechanical ventilation (see Chapter 148, End-of-Life Issues).

Preparation and Consent

If time permits, consent for mechanical ventilation is obtained in conjunction with that for airway control. However, in the emergency department, most children requiring intubation and mechanical ventilation are critically ill, and consent is implied based on the existence of an emergency. Mechanical ventilation involves many of the same risks as that of intubation, and is often seen as an extension of the latter procedure. Special risks attributable to mechanical ventilation include the need for deeper and more prolonged sedation, the acquisition of ventilator-associated pneumonia, muscular weakness resulting from disuse, and barotrauma-induced lung disease, possibly necessitating prolonged mechanical assistance.

Preparation for mechanical ventilation involves the choice of a mechanical ventilator, and assembly of the circuit.¹ The ventilator used depends to some extent on the mode of ventilation provided. While most modern ventilators offer a choice of volume- or pressure-regulated, assisted and controlled modes, some neonatal ventilators may not be able to deliver a volume-controlled breath. Ventilators designed for adults may not be sufficiently sensitive to detect inspiration in an infant, or able to deliver a reliably small-volume breath, and thus function poorly as a child ventilator. Monitoring devices should be at the bedside and calibrated.

Table 165–1 Indications for Mechanical Ventilation**Impaired Minute Ventilation**

- *Increased work of breathing:* pneumonia, pulmonary fibrosis, small airways disease, impaired chest wall compliance such as in burns
- *Decreased ability to sustain the work of breathing:* neuromuscular disease, electrolyte disturbances characterized by weakness (e.g., hypokalemia, hypocalcemia)
- *Altered control of breathing:* trauma, sedative drugs, postictal state, congenital or acquired diseases of respiratory control such as apnea of prematurity

Alteration of Lung Mechanics

- *Positive pressure ventilation:* atelectasis, acute respiratory distress syndrome, tracheomalacia with airway closure, ascites or chest wall injury, extraventilatory air or pleural effusions

Adjunctive Management of Extrapulmonary Disease

- *Hyperventilation:* head trauma, ↑ intracranial pressure (primarily a temporizing measure)
- *Decrease work of breathing:* congestive heart failure
- *Improvement of cardiopulmonary interactions:* shock, sepsis, hypovolemia, pulmonary hypertension

Patients who come with their own mechanical ventilator offer an opportunity for the physician to assess the mode of ventilation that best suits the patient. Assessment of these patients requires the determination of the goal of home ventilation, the equipment that was being used, and the settings that were applied prior to arrival at the emergency room. The physician should understand whether the patient was being ventilated for the delivery of oxygen, augmentation of minute ventilation, or improvement of lung mechanics. An understanding of the underlying disease of the child is mandatory.² The review of the medical record of a child who has previously been ventilated may provide valuable insight into optimum ventilator settings. If the patient is to be ventilated using a device brought from home, it should be inspected by an individual familiar with its assembly and operation to assure that it is functioning properly.

The airway will have been secured prior to the institution of ventilation (see Chapter 3, Rapid Sequence Intubation; and Chapter 4, Intubation, Rescue Devices, and Airway Adjuncts). Endotracheal intubation is the most common method, but occasionally mechanical ventilation may be applied to the patient via a laryngeal mask airway or an occlusive mask device.³ After intubation, placement of a nasogastric tube may be required to relieve abdominal distention, a maneuver that may improve respiratory mechanics. Bagging the patient will give information on the compliance of the lungs and chest wall. A patient with decreased compliance may be difficult to bag, predicting the need for high mean airway pressures and difficulty with pressure-regulated ventilation. Auscultation of the patient during bagging is of further assistance in determining the initial ventilator settings. Expiratory wheezes as the result of small airways disease might suggest that a ventilatory technique of prolonging expiration would be helpful in reducing gas trapping. Symmetric breath sounds provide some assurance that the airway is secured in a manner in which both lungs can be ventilated equally, but may be deceptive. Review of a chest radiograph with the patient on the mechanical ventilator will confirm satisfactory

FIGURE 165–1. Servo-i ventilator. All controls are accessible from the simple panel surrounding the display screen. (Photo courtesy of Maquet.)

tube placement, equal lung ventilation, the absence of gas trapping, and satisfactory tidal volume.

Sedation is almost always required for mechanical ventilation, except in the patient who arrives in stable condition having been chronically mechanically ventilated. Frequently, the same agents that were administered during intubation may be continued during mechanical ventilation. The need for neuromuscular relaxation should be judged by the possible benefits to respiratory mechanics of paralysis, versus the loss of a neurologic examination.⁴ Whether or not paralysis is initiated, analgesics, anxiolytics, and sedatives should be administered based on the clinical condition of the patient. Benzodiazepines and narcotics are appropriate. With or without neuromuscular relaxation, satisfactory sedation can be maintained in the great majority of patients with these agents alone.⁵ Etomidate and propofol, while unsatisfactory for prolonged sedation, may be useful in the emergency setting.^{6,7}

Equipment

A wide array of mechanical ventilators is available for clinical use. Some generalities can be made. The Servo-i is prototypic of a modern mechanical ventilator (Fig. 165–1). Air movement is provided by compressed gas, and a microprocessor controls delivery. Medical oxygen and air connections are required. The ventilator is connected to the patient via a low-compliance circuit (i.e., one that does not distend appreciably

during a respiratory cycle). Delivered air is humidified with a heated reservoir in line with the circuit. At the patient end of the circuit, a port may be present to facilitate suctioning. Uninterrupted power is recommended, unless the ventilator is equipped with a battery backup. Scavenger gas collection is necessary if the administration of anesthetic gases is anticipated.

Monitoring

All patients who are mechanically ventilated require continuous monitoring. Measurement of heart rate, respirations, and blood pressure should be routinely performed. Oxygen saturation via pulse oximetry is also routine. End-tidal carbon dioxide determination provides important insurance that the ventilator is attached to the patient and is functioning properly, and may decrease the need for repeated blood gas determinations⁸ (see Chapter 5, Monitoring in Critically Ill Children). Ventilators are manufactured with alarms to detect changes in airway pressure and changes in delivered volume; these should always be turned on and have appropriate tolerances for the ventilator settings. Additionally, many modern mechanical ventilators continuously display information relevant to the delivery of gas. Airway pressure, gas flow, delivered volume, and inspired oxygen concentration are typical of the parameters that are displayed. Likewise, the temperature of humidified air is monitored. The size of a modern emergency room may not be conducive to prompt detection of an alarm. As a result, central monitoring is desirable.

Notwithstanding the degree of assurance provided by automated alarm systems, all patients should be located in an area where they may be continuously observed and intervention promptly undertaken if the need arises. Supervising personnel should have a working knowledge of the ventilator alarms, and the appropriate interventions if the patient deteriorates or if there is a malfunction.

Technique

Modern mechanical ventilation offers a variety of modes, each useful under a given set of circumstances.⁹ The emergency physician should have a working knowledge of the basic modes, realizing that the desired result is delivery of satisfactory minute ventilation and the improvement of lung mechanics.

Conceptual Framework

The conceptual framework of mechanical ventilation is as follows.

Tidal Volume

The volume of a single breath, either spontaneously or provided by the ventilator, is termed the *tidal volume*. It represents the total of the effective ventilation (i.e., alveolar, and wasted ventilation or dead space). Volume lost in the ventilator circuit due to its compliance characteristics is generally not included in the determination of tidal volume.

Minute Volume

The volume of gas moved in 1 minute, totaling that spontaneously inspired by the patient plus the sum of the assisted breaths, is the *minute volume*. Its relative magnitude is an

estimate of the degree to which ventilation is supported by the mechanical ventilator itself.

Mandatory Ventilation

The ventilator may initiate a breath at a predetermined volume or pressure, at an appointed rate. It may be coordinated with a patient breath, initiated to correspond to an inspiratory effort (synchronized) either intermittently or continuously. The ventilator senses patient effort as a negative pressure on the airway, typically -1 to -3 cm H₂O. The sensitivity of the ventilator is determined by adjusting the negative pressure required to initiate a ventilator breath. If the sensitivity is set too low, the patient may not exert enough force to trigger a breath. If the ventilator is too sensitive, ventilator breaths may be initiated one on top of another, leaving insufficient time for exhalation. Synchronized intermittent mandatory ventilation is the most common mode employed in the acute setting.

Assisted Ventilation

The ventilator may assist a patient breath by providing airflow and pressure during an inspiratory effort. This assisted breath is initiated by patient effort, as a negative inspiratory pressure, similar to that provided by a synchronized mandatory breath. In contrast, assisted breaths are limited to the augmentation of respiration by adding supplemental pressure to the airway as the patient needs it. Patients are more comfortable and have improved distribution of ventilation in assisted as opposed to mandatory modes.¹⁰ Pressure support gives assistance to the patient to overcome the airway resistance of an endotracheal tube, and is customarily administered at 10 cm water pressure.¹¹

Mode of Ventilation

The ventilator may provide air during an inspiratory cycle by delivering gas either at a fixed volume of air irrespective of the pressure required to give that breath, or at a fixed pressure over time, without control of the total volume delivered. Each mode carries risks and benefits. Volume-controlled modes provide a predictable volume, while pressure-regulated ventilation may reduce the risk of pneumothorax and barotrauma.¹²

PRESSURE-CONTROLLED/TIME-CYCLED VENTILATION

In pressure-controlled ventilation, gas is delivered at a fixed pressure applied to the airway for a determined period of time, thereby allowing the lung to fill. The tidal volume is measured by calculating the volume of expired gas. A change in the compliance of the lung will result in a change in the delivered tidal volume. Extraventilatory air, patient agitation, or occlusive secretions may dramatically decrease the delivered gas volume.

VOLUME-CONTROLLED VENTILATION

Gas may be provided to the airway regardless of the pressure and the lung allowed to fill to a calculated volume. In this mode of ventilation, tidal volume is preserved regardless of changes in patient lung compliance. Delivered volume is more predictable, but the risk of pneumothorax and barotrauma may be higher.¹³ The first manifestation of a pneumothorax in this mode may be a rise in the pressure observed during the inspiration of a tidal volume.

PRESSURE-REGULATED/VOLUME-CONTROLLED VENTILATION

It is possible to combine pressure- and volume-regulated modes. Gas is delivered to the airway until a maximum pressure is achieved, and inspiration is prolonged until a predetermined tidal volume is delivered. If the tidal volume cannot be delivered by the end of an inspiratory period, it is wasted. Barotrauma is limited in this mode, and the risk of the development of extraventilatory air is modulated.¹⁴

End-Expiratory Pressure

At the end of inspiration, positive distending pressure may be applied continuously during exhalation. Positive end-expiratory pressure (PEEP) is useful in maintaining alveolar volume and airway patency throughout the respiratory cycle. PEEP is also useful in overcoming airway resistance in patients who are on pressure-controlled ventilation without pressure support.

Compliance

The volume of air moved with the application of a given pressure to the airway is termed *compliance*. It may be determined during active inspiration (termed *dynamic compliance*) or with no air movement (*static compliance*). Poorly compliant lungs are “stiff” and require high pressures to ventilate. This may be the case in acute respiratory distress syndrome or pulmonary fibrosis, or may be due to alterations in chest wall rigidity, as occur with ascites or scoliosis.

Airway Resistance

Resistance is defined by the airflow produced by the application of pressure to the airway. High pressure generating low airflow is characteristic of increased resistance. The product of resistance and compliance is termed the *time constant*, which determines the ideal rate of filling of the lung. Airway resistance is not constant throughout the respiratory cycle. During inspiration, positive pressure dilates the airway. Airway diameter decreases during exhalation, increasing the resistance to airflow. As a result, the presence of small airway narrowing (e.g., status asthmaticus) may necessitate the prolongation of the expiratory phase to allow for complete exhalation of a ventilator breath.

Ventilation/Perfusion Mismatch

Inspired gas must be delivered to an alveolus with an adjacent perfused capillary for gas exchange to occur. The delivery of gas to unperfused alveoli results in increased dead space and ineffective ventilation. On the other hand, failure to ventilate a perfused alveolus results in unoxygenated blood returned to the heart with accompanying obligatory

cyanosis. Ventilation/perfusion (V/Q) mismatching results from the maldistribution of ventilation, perfusion, or both, with resulting hypoxemia and hypercarbia. It may be a consequence of hypovolemia, overdistention, atelectasis, or airway occlusion.¹⁵ Its solution is in the restoration of circulation and optimization of lung volume and airflow.

Inspiratory Time and Gas Flow

Inspiration must be long enough for air to enter the lung and distribute to the alveoli evenly. In volume-controlled modes, gas is given at a specific flow rate over a given time. Pressure-controlled modes deliver gas at a fixed pressure over a preset time. Short inspiratory times (usually < 0.7 seconds) may cause turbulent airflow, which interferes with gas delivery and distribution. Prolongation of inspiration increases mean airway pressure, and may improve gas exchange in the low-compliance lung. The inspiration:expiration (I : E) ratio expresses the duration of inspiration with respect to exhalation. In the ventilation of a lung with near-normal compliance and diffusion characteristics, the I : E ratio is typically near 0.5. In the poorly compliant lung with impaired diffusion, inspiration may be prolonged to an I : E ratio of 2 to 3. In this circumstance, the I : E ratio is termed *inverted*. Prolongation of inspiration is not without consequences. At a given rate, as inspiration is prolonged, exhalation is shortened. The resulting increase in mean airway pressure may decrease cardiac output. Shortened exhalation, especially in small airways disease, may lead to overdistention and gas trapping.¹⁶

Goal of Mechanical Ventilation

The goal of mechanical ventilation is to provide satisfactory alveolar ventilation to the patient at a predictable pressure, limiting the mismatch of ventilation and perfusion. Commonly, ventilation is initiated by estimating the respiratory rate, end-expiratory pressure, amount of pressure support given to spontaneous breaths, and inspired oxygen concentration. The mode of ventilation is determined by the therapeutic goal. In the presence of low-compliance lung disease, such as acute respiratory distress syndrome, mean airway pressure is more easily manipulated with pressure-controlled ventilation. As small tidal volumes may be difficult to reliably deliver, neonates and infants may be more satisfactorily ventilated with this technique. Volume-controlled modes more predictably manipulate minute volume and thereby may be appropriate in the patient with hypercarbic respiratory failure. If pressure-controlled ventilation is performed, the peak pressure and flow are ordered. If volume-controlled ventilation is used, a tidal volume is ordered. Typical settings differ based on patient age, underlying disease, and the specific ventilator used (Table 165–2).

Table 165–2 Initial Ventilator Settings

	Infant	Toddler	Child	Adolescent
Tidal volume	8–10 ml/kg	10 ml/kg	8 ml/kg	6–8 ml/kg
Rate	20 bpm	16 bpm	12 bpm	10 bpm
Peak pressure	25–30 cm H ₂ O			
Peak end-expiratory pressure	5 cm H ₂ O			
Pressure support	10 cm H ₂ O			
Inspiratory time	0.8 sec	0.9 sec	1.0 sec	1.0 sec

Optimum flow characteristics are dependent on the circuit and the size of the patient's airway. Significant volume may be lost in the tubing and humidifier.¹⁷ Adequacy of ventilation is determined by observing chest rise, and verifying air entry by auscultating breath sounds. A chest radiograph is useful in demonstrating that overdistention or collapse is not present. It must be emphasized that the final determination of adequacy of ventilation is made by blood gas analysis (see Chapter 5, Monitoring in Critically Ill Children). Hypercarbia generally requires an increase in alveolar ventilation, by increasing tidal volume or rate, or controlling overdistention. Hypoxemia is responsive to increased inspired oxygen concentration or techniques aimed at reducing V/Q mismatching, such as increased PEEP.

In the face of severe lung disease, it may not be possible to achieve normal arterial blood gas tension in the ventilated patient. This is especially true in the patient with respiratory failure due to small airways disease such as status asthmaticus. Overaggressive ventilation with an excessively large tidal volume or short expiratory time in the face of severe pulmonary parenchymal disease may worsen gas trapping and increase the risk of pneumothorax. In this circumstance, limiting ventilatory support and tolerating increased carbon dioxide tension with the intention to maintain an arterial pH over 7.2 and partial pressure of carbon dioxide of 60 to 70 mm Hg may modulate these risks without jeopardy to the patient. This technique, termed *permissive hypercapnea*, has been demonstrated effective in the management of congenital diaphragmatic hernia.¹⁸ It is likewise useful in other forms of restrictive and obstructive airways disease and in modulating barotrauma.¹⁹

Alternatives

In the absence of a mechanical ventilator, bag-valve-mask ventilation may be undertaken for as long as the patient is in the emergency room. Mechanical ventilation is primarily performed in conjunction with airway management in the form of endotracheal intubation or tracheostomy. The patient with respiratory insufficiency due to neuromuscular weakness or obstructive apnea who has not been intubated, however, may benefit from nasally applied bilevel positive airway pressure (BiPAP), a noninvasive form of intermittent, pressure-controlled ventilation.²⁰ This technique has also been reported useful in the management of chronic lung disease, tracheomalacia, sleep apnea, pulmonary edema, and acute respiratory distress syndrome.²¹ It may provide transitional support in the process of weaning a child from mechanical ventilation.²² BiPAP is being used with increasing frequency in the outpatient setting.²³ Initiation of BiPAP is similar to that of pressure-controlled ventilation. The peak pressure is typically between 8 and 15 cm H₂O, and the end-expiratory pressure is near 3 to 5 cm H₂O. Tidal volume is not measured. Continuous gas flow between 1 and 5 L of oxygen per minute is applied as a bias at the end of the airway. Breaths may be triggered by patient effort, or provided at a constant backup rate. BiPAP carries risks to the intubated patient beyond those of mechanical ventilation. Abdominal distention may complicate BiPAP, as some air may be forced down the esophagus. The airway is not protected, and emesis carries an increased risk of aspiration. Children may not tolerate the tightly fitting

nasal mask. Patient agitation may interfere with minute ventilation.

Several techniques not customarily included in the discussion of conventional mechanical ventilation deserve mention. High-frequency ventilation administers breaths at a very high rate, 400 breaths per minute or more. A pulse of pressure is applied to the airway with active or passive expiration. The usual pressure change during a cycle is approximately 30 to 40 cm H₂O. The mean airway pressure is held constant, usually greater than 20 cm H₂O. The physiology of high-frequency ventilation is not well understood, but the technique has been demonstrated to be useful in oxygenating and ventilating children with pulmonary parenchymal disease too noncompliant for conventional ventilation, and in the setting of extraventilatory air.^{24,25}

Helium-oxygen mixtures may improve ventilation in patients with critically large or small airway resistance (e.g., croup or asthma).²⁶ It may be delivered via ambient air, or via the mechanical ventilator. As the density of the helium-oxygen mixture is lower than that of air, the ventilator must be calibrated for its use.

Nitric oxide, a pulmonary vasodilator, may assist in the management of pulmonary hypertension and acute respiratory distress syndrome with V/Q mismatch.²⁷ It is applied through the ventilator circuit at a concentration of 1 to 20 ppm, and requires exhaled air to be processed through a scavenger gas system. Its use requires the pretreatment determination of pulmonary artery pressure by echocardiography. Methemoglobinemia may accompany prolonged use at high concentrations.

Negative pressure ventilation is another noninvasive technique used in patients with high-compliance lungs, in which the driving force is generated by a cuirasse or jacket that generates negative pressure on the chest wall. It is useful in children with chronic neuromuscular diseases or cardiac conditions in which positive pressure ventilation might be poorly tolerated.²⁸

Complications

The complications of mechanical ventilation are manifold (Table 165–3). The true incidence of acute complications arising from the institution of mechanical ventilation is unknown. Overdistention contributes to hypoxemic dead space, and the incidence of pneumothorax.²⁹ Excessive intrathoracic pressure, caused by high mean airway pressures or PEEP, interferes with cardiac output.³⁰ Careful attention to sterile technique during intubation and suctioning clearly reduces the incidence of ventilator-associated pneumonia.³¹

Table 165–3 Complications of Mechanical Ventilation

Acute

Extraventilatory air (pneumothorax, pneumomediastinum)
Overdistention
Interference with cardiac output
Infection (ventilator-induced pneumonia)

Chronic

Tracheomalacia and other forms of airway injury
Fibrosis (barotrauma)
Infection

Of these complications, pneumothorax is the most life threatening. A high index of suspicion must be maintained, and pneumothorax must be entertained in all patients with a sudden decline in tidal volume with increased airway pressure, especially in the context of recent bagging, suctioning, or small airways disease. It is signaled by a deterioration of pulmonary compliance, hypoxemia, and tachycardia leading to eventual bradycardia. Unattended, or aggravated by continued ventilation or bagging, air will accumulate by ball-valve effect. Ultimately, cardiac arrest will occur. Resuscitative efforts will be unsuccessful without the evacuation of accumulated air.

Given the complexity of mechanical ventilation, it is surprising that the overall complication rate is low. In a study of 23 chronically ventilator-dependent children, only 1 child died in a 2-year study period.³² Other studies have reported a 5-year survival rate of 65%.³³ Patients will frequently present with complications of ventilation, the most important of which is ventilator-associated pneumonia. Commonly occurring organisms are gram-negative organisms such as *Pseudomonas* and *Klebsiella pneumoniae*, and gram-positive organism such as *Staphylococcus aureus* and *Enterococcus faecalis*.

Postprocedure Care and Disposition

Early identification of complications of mechanical ventilation and maintenance of a secure airway require continuous patient monitoring until patients are transferred to inpatient units. Repeated examination, assessment of vital signs, chest radiography, and arterial blood gas analysis will guide ongoing care.

Occasionally, a patient who is intubated and mechanically ventilated acutely in the emergency department may improve sufficiently before admission to consider the discontinuation of ventilatory support. This may be the case, for example, in the patient intubated for respiratory failure in the postictal state who quickly recovers respiratory drive. Parameters for weaning from mechanical ventilation include the demonstration of stable blood gases, normal respiratory rate for age, satisfactory air entry on auscultatory examination, and the absence of manifestations of respiratory distress such as tachycardia or retractions. Support is generally withdrawn by decreasing one of the ventilator parameters at a time, and then observing the patient to be stable for a period of hours before making further changes. The discontinuation of mechanical ventilation may be contemplated when the mandatory ventilation rate is near 5 breaths/min, the end-expiratory pressure is 5 cm H₂O, the mean airway pressure is under 18 cm H₂O, and the fraction of inspired oxygen is less than 35%. The ability to wean the patient to continuous positive airway pressure with pressure support only—that is, with no mandatory rate—has been advocated as predictive of successful extubation in adults,³⁴ but has been found unnecessary in children.³⁵

Chapter 166

Incision and Drainage

Sean F. Isaak, MD and John F. O'Brien, MD

Key Points

Surgical incision and drainage is the treatment of choice for cutaneous abscess.

Emergency physicians can effectively treat most pediatric cutaneous abscesses seen in the emergency care setting.

Most healthy patients with a cutaneous abscess do not require antibiotic treatment unless they have an associated cellulitis.

Inadequate drainage is a prominent cause of complications from cutaneous abscess.

Indications and Contraindications

Localized skin infections may develop in any area of the body, and are a frequent result of local breakdown of epidermal defense mechanisms, with invasion by normal resident bacterial flora. Such infections often follow abrasions, lacerations, various dermatitides, insect bites, or skin maceration (e.g., from diapers).¹ Infections of the soft tissue often begin as cellulitis, with some bacteria causing tissue necrosis, liquefaction, and accumulation of leukocytes as well as debris within a walled-off area of purulent fluid. The natural course of an untreated abscess is gradual cavity enlargement with spreading through tissue planes until final release of contents into an external or internal surface.²

The distinction between a cutaneous abscess and cellulitis is often difficult to make clinically. A cutaneous abscess must be drained because it may extend to compress or injure nearby structures, may contribute to bacteremia with possible sepsis, and will not resolve with antibiotic therapy alone. Decompression of an abscess may alleviate pain. Conversely, incision and drainage (I&D) of cellulitis will not improve and may even worsen outcome. Both cellulitis and abscesses may cause localized erythema, pain, and induration, although a superficial abscess is distinguished by local fluctuance. If the distinction is not clear (e.g., deeper abscesses), sterile aspiration with an 18-gauge needle may return purulent fluid, indicating a need for I&D.

Recently, ultrasound has been used to confirm the presence of a cutaneous abscess in difficult cases,³ and to exclude mimics such as mycotic aneurysms. Typical sonographic findings of an abscess include a mass that is totally or partially anechoic and a deformable fluid collection upon compression, which may have sharp margins and distorted subcutaneous tissue⁴ (see Fig. 166–1). Sonographically directed aspiration and drainage may also simplify the procedure. Plain radiography can be used to exclude radiopaque foreign bodies.

There are circumstances in which drainage of an abscess in the emergency care setting is not appropriate. An abscess may require drainage in the operating room under general anesthesia if sufficient sedation and analgesia cannot be achieved, if patient cooperation cannot be accomplished, if the abscess appears complex due to size or relation to vital structures, or if there is the possibility that an alternate, more serious diagnosis is present. In particular, the possibility of a mycotic aneurysm or pseudoaneurysm may mandate careful operating room management. Consultation with a surgeon is warranted in any circumstance in which more than a simple I&D procedure is anticipated.

Preparation and Consent

I&D has been described as one of the most painful procedures performed in the emergency department,⁵ in part due to the difficulty in obtaining adequate local anesthesia. A large tender area and unfavorable local conditions for anesthesia make this process challenging. Several options exist to achieve optimal anesthesia (see Chapter 172, Local and Regional Anesthesia).

1. Topical anesthesia with various agents may suffice for small abscesses. Topical lidocaine, epinephrine, and tetracaine (LET) gel, lidocaine/prilocaine (EMLA) cream, and lidocaine by iontophoresis⁶ have been used to locally anesthetize small abscesses. Use of topical ethyl chloride or fluoromethane spray in this setting should be discouraged, as the resulting short duration of anesthesia is usually insufficient.
2. Local anesthetics may be injected intradermally along the path of the proposed incision site. However, this technique will only help alleviate the pain of incision, not the discomfort associated with disruption of loculations, manipulation of inflamed tissue, or wound packing. Infiltration of high-concentration, buffered

and warmed lidocaine or similar local anesthetic using a small-gauge (27- to 30-gauge) needle with slow injection rate minimizes pain related to anesthesia.⁷

3. Ring or field block anesthesia, in which infiltration of anesthetic is advanced 1 cm beyond the periphery of the erythematous tissue, may be effective in conjunction with injection of the incision site. This method may require a large amount of anesthesia, and close adherence to maximal dosing must be observed.
4. Regional block is the anesthetic of choice if the abscess is in an anatomically suitable location.
5. Procedural sedation and analgesia is an effective alternative method of anesthesia for I&D (see Chapter 159, Procedural Sedation and Analgesia).

Special situations, including multiple abscesses as well as large abscess size, should prompt calculation of maximal anesthetic dose and increased consideration for general anesthesia (see Chapter 160, Wound Management). Preprocedural antibiotics should be used in patients at risk for bacterial endocarditis or distant infection of prosthetic material by possible transient bacteremia from abscess I&D, and should follow American Heart Association (AHA) recommendations⁸ (see Chapter 64, Pericarditis, Myocarditis, and Endocarditis). Antibiotic choice should be dictated by the likely organism in the anatomic region of the abscess.

Equipment

Various scalpel blades may be utilized depending on characteristics of the abscess, with the no. 11 blade usually most suitable. Large abscesses (>5 cm diameter) may be managed with a no. 10 blade. Other equipment required for abscess drainage includes hemostats, forceps, scissors, and packing materials. Several different packing materials are available, with the 1/4- to 1-inch iodoform gauze most commonly used. Various balloon catheters (e.g., Word catheter) and other pliable drainage catheters (e.g., Pezzer catheters) may obviate the need for packing material changes during abscess follow-up.

Techniques

The involved area is cleaned with an antiseptic solution (e.g., povidone-iodine) and draped with sterile towels. For healthy patients, I&D is the definitive treatment and cultures are not warranted. There are certain conditions in which wound culturing is important. Examples include gas-containing abscesses, infections that involve fascia or muscle, abscesses that penetrate the abdominal cavity, or anatomic locations that may involve deep structures (e.g., central triangle of the face, which drains into the cavernous sinus).⁹ Some patients with cutaneous abscess may benefit from Gram stain and culture to direct antibiotic therapy. These include the immunocompromised, parenteral drug users, and those with systemic involvement or extensive areas of cellulitis. Some experts also recommend routine cultures to determine the prevalence of organisms (e.g., methicillin-resistant *Staphylococcus aureus* [MRSA]) and the development of antibiotic resistance patterns in communities.¹⁰ If indicated, obtain cultures by needle aspiration through sterile prepared skin or aspirate without delay after the incision is made to improve anaerobic yield.¹¹

To optimize cosmetic results, the incision should be made parallel to Langer's lines. A no. 11 blade is usually suitable to make a stab incision at the edge of greatest fluctuance (Fig. 166–1a), which is extended the entire length of the area of purulence to maximize drainage. Inadequate incisions lead to insufficient drainage and limited access to the wound cavity. Use of elliptical incisions may aid drainage, but should not be used in cosmetically important areas due to their tendency to leave unattractive scars. An elliptical incision should be considered when the skin overlying the abscess is necrotic or includes draining sinuses.¹¹ Cruciate incisions rarely improve drainage success, and may cause more wound edge necrosis and lead to poor cosmetic results.

Loculations may exist within the abscess cavity with isolated areas of purulent material. To disrupt loculations, the area is probed gently with either a hemostat or gloved finger (Fig. 166–1b and 166–1c). Caution should be used when probing with a gloved finger as fractured bone or sharp foreign bodies may be present in the abscess. The deep wall of the abscess should not be aggressively manipulated since this may lead to bleeding or damage to nearby structures.¹² Saline irrigation of the abscess cavity facilitates removal of remaining purulent material and necrotic debris (Fig. 166–1d). Curettage is reserved for clearing the abscess of debris not removed by irrigation. However, no study has demonstrated that irrigation or curettage is necessary or improves outcome in the management of abscesses. The wound is loosely filled with a single continuous piece of iodoform gauze, petrolatum gauze, or other packing material, leaving one end exiting the wound to assist later removal (Fig. 166–1e). Other drainage devices may be substituted for gauze at the discretion of the operator. Finally, the wound is covered with dry, sterile dressings sufficiently absorbent to contain significant drainage.

Alternatives

Alternative treatments for cutaneous abscess include needle aspiration, marsupialization, and abscess resection, as well as incision with curettage and primary suturing under antibiotic coverage. Needle aspiration alone is seldom appropriate for abscess management as it rarely provides adequate drainage. However, breast abscesses have been managed by sonographically guided aspiration (often repeated one or more times) with irrigation and local instillation of antibiotics without placing indwelling drains.¹³ Marsupialization refers to suturing the abscess walls open, with granulation and secondary closure of the abscess cavity, and is occasionally used for Bartholin's gland abscesses. Complete abscess resection may be curative for epidermoid cysts when the entire wall of the abscess cavity may be visualized and safely removed. Incision with curettage of abscesses followed by primary suturing and appropriate antibiotic coverage has been utilized with limited success.¹⁴ Use of antibiotics without drainage of cutaneous abscess will fail unless adequate spontaneous drainage occurs. However, spontaneous drainage of abscesses is often inadequate, and frequently requires further I&D to facilitate cure.

Complications

The main complications of abscess management arise from inadequate incision size and incomplete drainage. Incisions

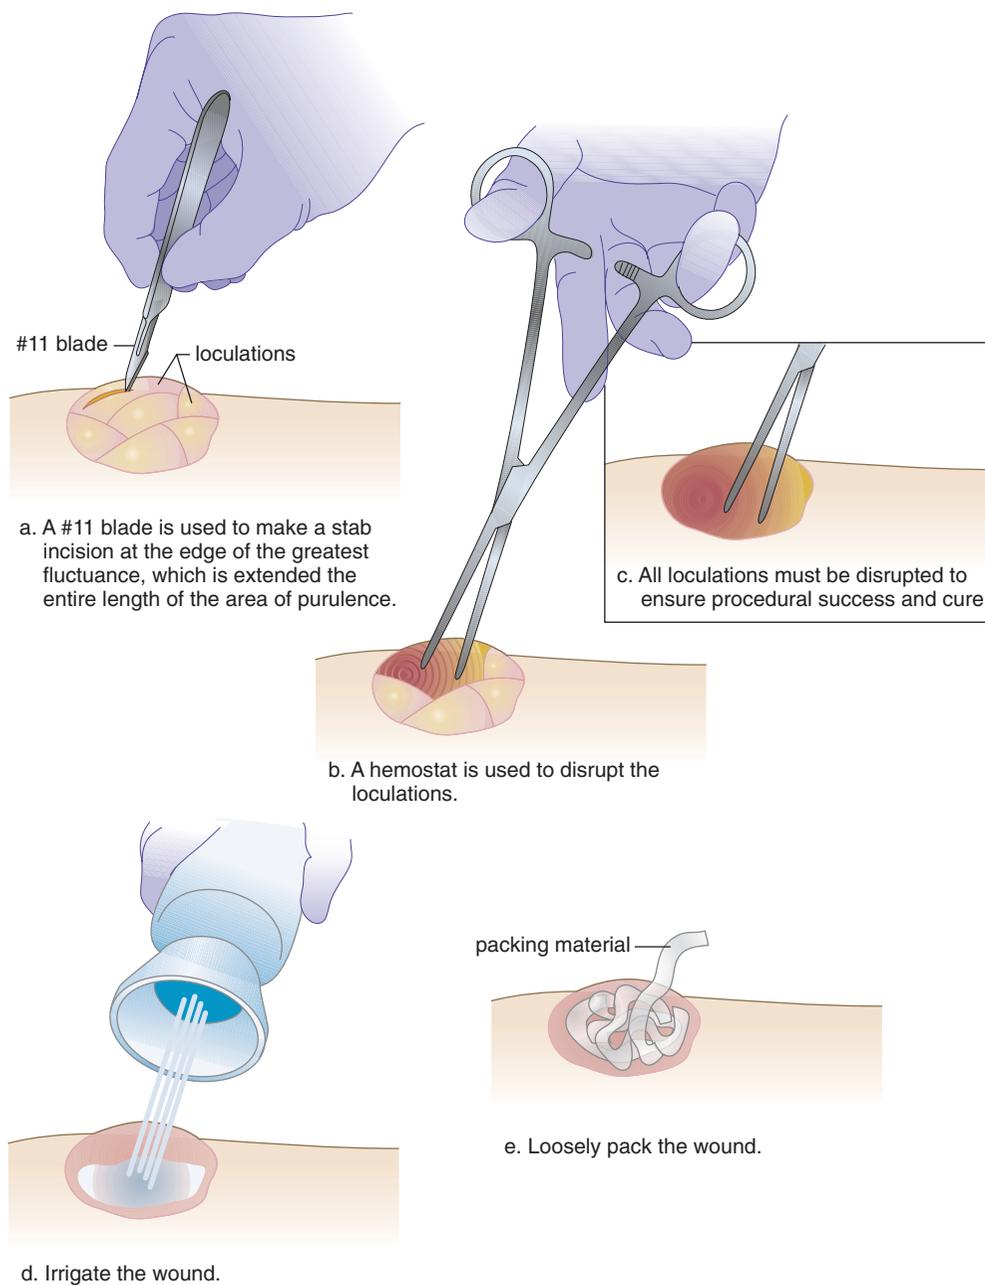

FIGURE 166-1. Technique for incision and drainage.

that are too small limit the amount of drainage and access to the interior of the abscess. Failure to attain sufficient incision length may be secondary to an underestimate of the size of the abscess or inability to provide adequate analgesia to accomplish the procedural goal. Incomplete abscess drainage may lead to osteomyelitis, tenosynovitis, septic thrombophlebitis, necrotizing fasciitis, and fistula formation.² In addition, infection may become systemic with resultant bacteremia or endocarditis. Incisions that are too deep or excessively large may result in injury to adjacent structures or poor cosmetic results.

Bleeding is a frequent complication from the incision of inflamed tissue at an abscess site, and is in general easily resolved with a few minutes of local tissue compression. This should be distinguished from rare but more serious

complications related to laceration of a major vessel or neurovascular bundle, which should prompt immediate surgical consultation.

Postprocedure Care and Disposition

Most patients with normal host defenses do not need antibiotics unless there is an associated cellulitis. Postprocedure antibiotics have not been shown to affect the outcome of cutaneous abscesses. MRSA has been identified as a major pathogen in skin and soft tissue infections in the emergency department.¹⁵ Even the rising prevalence of community-acquired MRSA among healthy children does not change the fact that I&D without any antibiotics cure most abscesses.^{16,17}

A single dose of appropriate antibiotic is indicated as preprocedure prophylaxis in patients who are at high or moderate risk of infective endocarditis as defined by AHA guidelines.⁸ Patients who may require more extensive antibiotic therapy include children with cellulitis, signs of systemic involvement (fever, toxicity, or significant tachycardia), and immunocompromised states (see Chapter 120, Skin and Soft Tissue Infections).

Organisms causing abscesses can be predicted based on anatomic location.^{9,18-20} This knowledge may guide initial antibiotic therapy when indicated. Selective use of Gram stains may also assist in appropriate antibiotic choices. Overall, *S. aureus* is the most common organism isolated from cutaneous abscesses. Children tend to have a large number of anaerobes in cutaneous abscesses that are perirectal, adjacent to mucous membranes, and on the head or fingers, particularly at nail bed areas.¹⁹ The antibiotic chosen should be based on the most likely causative organism.²¹ For

cutaneous abscesses, consider an antistaphylococcal penicillin or first-generation cephalosporin. In the penicillin-allergic patient, clindamycin may be useful and extends anaerobic coverage. Trimethoprim-sulfamethoxazole, rifampin, clindamycin, doxycycline (if the patient is >8 years old), or linezolid may be required in areas with a known high prevalence of MRSA.¹⁰ Vancomycin or clindamycin should be used in patients suspected to have community-associated MRSA bacteremia, and gram-negative or extended anaerobic coverage may be necessary based on anatomic considerations.¹⁰

The American Academy of Pediatrics has published an algorithm for managing abscesses and furuncles in areas of high MRSA prevalence¹⁰ (Fig. 166–2). Hospital admission is required for cutaneous abscess in children who need general anesthesia for drainage, or those with systemic toxicity, immunocompromised states (e.g., diabetes), and abscesses in vulnerable locations (hand, face, perineal region) or involving deep structures (tendon sheaths, fascia, or muscles).

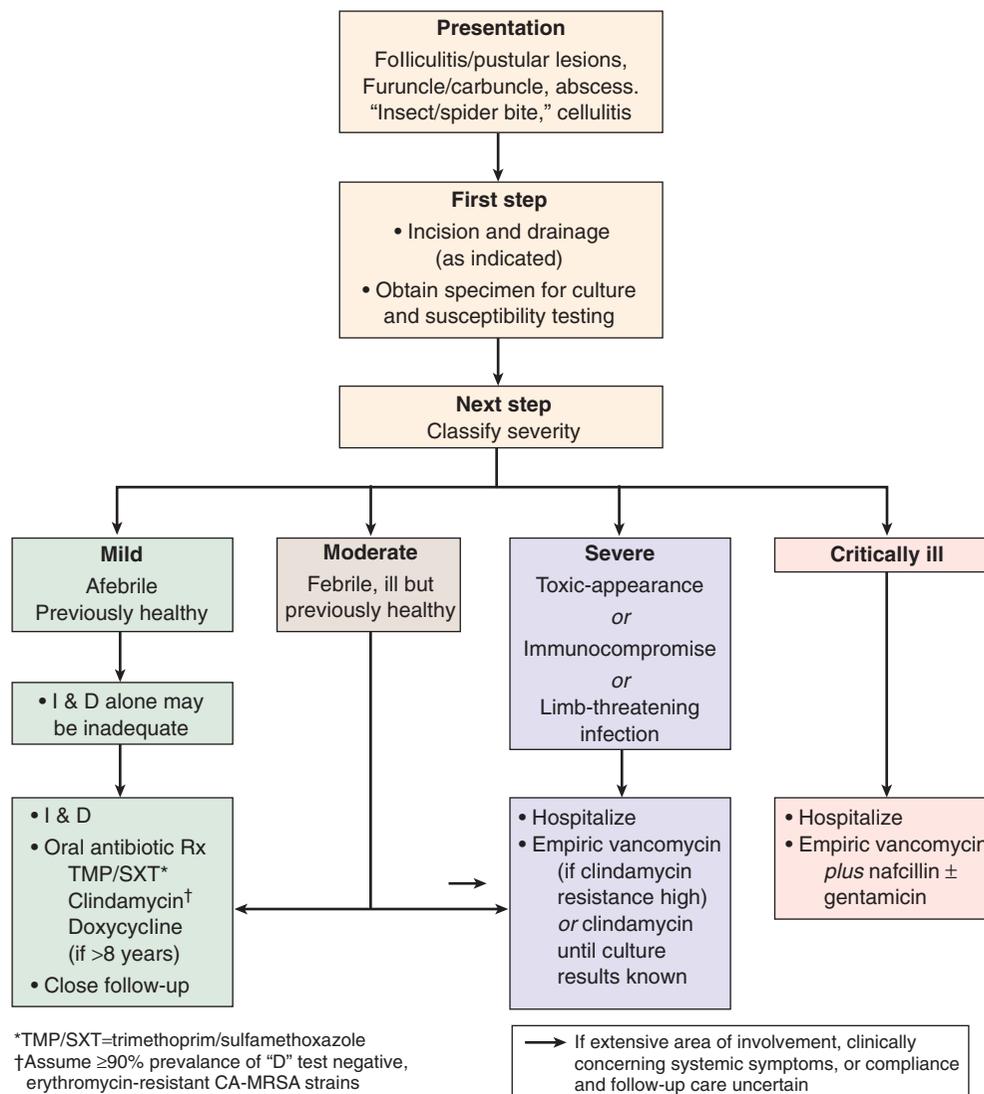

FIGURE 166–2. Algorithm for managing children with suspected community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) skin and soft tissue infections suggested by the American Academy of Pediatrics. Initial outpatient management of suspected infections is schematically illustrated and assumes CA-MRSA strains are prevalent in the community. Data from Baker CJ, Frenck RW Jr: Change in management of skin/soft tissue infections needed. AAP News 25:10, 2004. (From Kaplan SL. Implications of *Staphylococcus aureus* as a community acquired pathogen in pediatric patients. Infect Dis North Am 19: 747–757, 2005.)

Following I&D, the child should return for a recheck visit in 24 hours for facial abscesses or up to 48 hours for other cutaneous abscesses. At this time, packing material is removed and the wound reassessed for signs of healing and evidence of ongoing drainage. Packing should not be left in place longer than 48 hours. If the wound continues to drain, it should be repacked and reexamined in 24 to 48 hours. If the wound has minimal or no drainage, and has decreased surrounding cellulitis, then the patient should begin warm soaks approximately four times a day until the wound closes. Repeated examination is not necessary once the wound exhibits signs of healing. Most cutaneous abscess incisions will heal within 7 to 10 days.

Antibiotic therapy, if indicated, is usually necessary for only 5 to 7 days. Postoperative pain management should always be provided when necessary, with recognition that I&D alone generally reduces pain significantly. On rare occasion, immobilization of the incised area may reduce pain and protect the wound.

Ventriculoperitoneal and Other Intracranial Shunts

Russell Migita, MD and Tony Woodward, MD, MBA

Key Points

Infants and children with shunt malfunction can present with nonspecific symptoms.

Parents should be asked if current symptoms are similar to those that occurred with previous shunt malfunctions.

Shunt infection is uncommon. If it occurs, it is most likely to happen during the first weeks to months after shunt placement or revision.

Shunt malfunction can rarely be definitively ruled out with a single test or finding.

Shunt tap or burr hole puncture can be life saving in a patient with impending herniation.

Indications and Contraindications

Cerebrospinal fluid (CSF) shunts are placed in patients to drain fluid from ventricles, cysts, and subdural collections to areas that are able to absorb that fluid, such as the peritoneum or atrium. CSF shunt placement is the most common neurosurgical procedure performed in the United States.¹ Shunts are most commonly placed in pediatric patients for actual or potential hydrocephalus/fluid space collections due to spina bifida or intraventricular hemorrhage and have improved mortality from these conditions. Unfortunately, CSF shunts may fail, with potentially life-threatening consequences.^{2,3} Up to 39% of patients have shunt failure during the first year after placement, and 80% of patients require revision within 12 years of shunt placement or revision.⁴⁻⁸ All infants and children with the possibility of shunt failure or infection require evaluation of the shunt.

A child with a shunt malfunction may initially present with nonspecific symptoms such as irritability, vomiting, personality change, or headache.⁹ Other features include

swelling around the external shunt hardware (valves, reservoir, and tubing), bulging fontanelle, gait disturbance, and vision changes.¹⁰ Late signs include altered mental status, seizures, posturing, coma, and hemiparesis. During the first 5 months after placement, the strongest indicators of shunt failure include nausea and vomiting (positive predictive value [PPV], 79%; likelihood ratio [LR], 10.4), irritability (PPV 78%, LR 9.8), decreased level of consciousness (PPV 100%), erythema (PPV 100%), and bulging fontanelle (PPV 92%, LR 33.1).¹¹ In addition, parents should be asked if the current symptoms resemble those of prior obstructive episodes.¹² Shunts may fail due to hardware failure, kinks in the tubing, disconnection,¹³ blockage of the shunt by blood or proteinaceous or infectious material, or migration of the shunt at either the proximal or distal end. They may also fail due to CSF overdrainage, which can cause ventricular collapse and parenchymal blockage.¹⁴

Shunt infection is usually secondary to contamination encountered at the time of surgery, and 90% of infections will present within the first 6 months after placement, most commonly during the first 2 to 3 months.¹⁵ A recent population-based study found an overall infection rate of 2.7% per procedure.¹⁶ Infants have the highest risk, with infection rates of 15.7%.¹⁷ Patients with infected shunts usually present with low-grade fever and may also show signs of shunt obstruction.^{18,19}

Shunts consist of four main components: (1) a proximal catheter that is placed in the obstructed or fluid-filled (cyst) central nervous system site; (2) a reservoir, which may consist of one (single) or two (double) chambers; (3) a valve that controls the rate of CSF drainage (differential pressure, flow control, gravitational, programmable, or siphon type); and (4) a distal catheter that drains into a site that allows absorption of the fluid. Newer shunts may have an electronically (externally) programmable component that prevents overdrainage of CSF.²⁰

An evaluation of shunt function should be performed for any suspected obstruction or infection. The shunt reservoir or tubing may be entered with a needle to attempt to relieve pressure and withdraw CSF. This shunt puncture procedure may be indicated when infection is suspected or when it is necessary to measure an opening pressure.²¹ Burr hole puncture involves inserting a needle directly through the skull

burr hole into the CSF space to relieve pressure. Some reservoirs are located within the burr hole, and puncture of these shunts will generally damage the shunt mechanism. This procedure carries a risk of morbidity but may be life saving in instances of cerebral herniation after medical interventions have been maximized.

Preparation and Consent

In addition to the physical examination of the patient and underlying shunt apparatus, evaluation of shunt function is generally augmented by radiographic examination with both plain radiographs and computed tomography (CT). Plain radiographs assess shunt continuity and roughly establish the locations of the proximal and distal ends of the shunt. CT scans assess ventricular size and brain parenchyma. Prior CT scans are valuable to compare ventricular/fluid cyst size, though up to one third of CT scans are not able to rule out shunt malfunction.²² Unless circumstances warrant immediate life-saving intervention, informed consent should be obtained prior to invasive shunt evaluation or management.

Equipment

No special equipment is required for the external evaluation of the shunt. Shunt puncture and burr hole puncture require universal precautions and preparation (sterile gloves, goggles, mask, gown), topical antiseptic (isopropyl alcohol, Betadine, povidone) to clean the skin, a medical razor to shave hair immediately around the puncture site, and sterile towels to ensure a sterile surgical site. Ventricular shunt puncture is performed under sterile conditions with a 23- or 25-gauge butterfly needle, while burr hole puncture uses a 3.5-inch, 22-gauge spinal needle with stylet.

Monitoring

All patients at risk for increased intracranial pressure (ICP) require continuous visual and electronic monitoring. Vital sign changes that may indicate increased ICP include apnea and Cushing's triad (bradycardia, hypertension, and decreased/variable respiratory effort and rate). Patients require cardiorespiratory monitoring with apnea alarms and pulse oximetry. Vital signs should be measured regularly.

Techniques

Clinical Examination

Many different types of shunt systems exist. The most common types include the single-reservoir and double-reservoir ("double-bubble") shunts. The clinician should be familiar with the different types of shunts that are in use at his or her hospital, and should be aware of other types of shunts that may be encountered in transferred or out-of-area patients. First, the skin is inspected over the shunt for erythema or swelling, and palpated for discontinuity. Swelling suggests a shunt disconnection, while overlying erythema and warmth along the shunt track suggest infection.

Pumping the Shunt

The utility and consideration of "pumping the shunt" is controversial. Shunts are constructed with reservoirs that serve

as a site of entry for fluid retrieval and evaluation. These reservoirs have also historically been used as a means to manipulate flow as well as quickly and noninvasively evaluate the shunt at the bedside. Longitudinal studies show that pumping the shunt has a sensitivity of 11% to 20% and a specificity of 63% to 99% for detecting obstruction.^{11,23,24} One author found a PPV of only 17% to 21%; however, others have described a PPV of 80% to 86% for pumping the shunt. The negative predictive value in these studies ranged from 65% to 81%. Pumping the shunt should be considered as a potential adjunct to the comprehensive history, physical evaluation, and radiographic evaluation of the suspected malfunctioning shunt. Some shunt valves cannot be evaluated by pumping. The technique cannot be used to definitively rule in or rule out malfunction (Fig. 167-1).

Shunt Puncture

To perform a shunt puncture, the child is positioned in a reclining position. The reservoir is identified, and the surrounding area is cleaned with isopropyl alcohol, and shaved if necessary. The area is prepped with povidone or Betadine. Sterile gloves must be used and a sterile field established. Most reservoirs are dome shaped and should be entered tangentially to a depth of a few millimeters. The reservoir is entered with a 23-gauge butterfly needle until a pop is felt (Fig. 167-2). Care is needed to avoid advancing the needle too far so that it does not become embedded in the back wall of the reservoir. The needle may need to be adjusted until flow is achieved. Button-type Rickham-style reservoirs are situated in the burr hole and are punctured perpendicular to the scalp. The opening pressure is measured by holding the butterfly tubing upright and measuring the distance from the external auditory meatus to the top of the fluid column.²⁵ Opening pressure has a poor specificity for shunt obstruction.²⁶ Ideally, fluid is collected by gravitational or pressure-backed free flow, or if necessary, by gently aspirating with a syringe. CSF is sent for routine CSF studies. For diagnostic taps, a volume of 5 to 10 ml is generally sufficient. If the shunt is being tapped due to cerebral herniation, fluid is removed until the patient's condition improves. This quantity is generally 50 to 100 ml for children with signs of cerebral herniation.

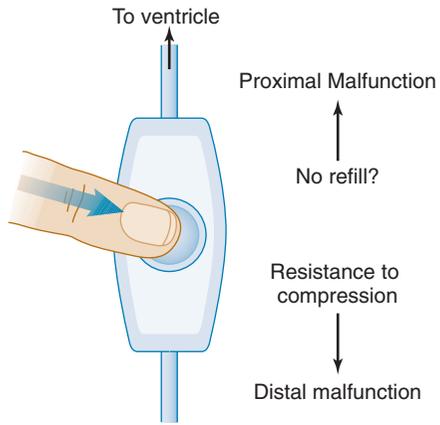

Burr Hole

Emergency department burr hole puncture is reserved for children with signs of herniation in situations in which medical management and interventions have been maximized and operative options are not readily available. The hair and scalp are prepped, the burr hole is palpated, and a 3.5-inch, 22-gauge needle is introduced through the burr hole perpendicular to the scalp. The needle is advanced slowly, removing the stylet periodically until CSF flow is achieved. The ventricle is generally reached by a depth of 5 cm. The stylet is removed and fluid is allowed to drain until the pressure has been released. Burr hole puncture will often damage the shunt, and patients will require definitive operative revision (Fig. 167-3).

Complications

The risk of iatrogenic infection is approximately 1% after a shunt tap.²¹ The most common pathogen encountered is

Single Reservoir

Double Reservoir

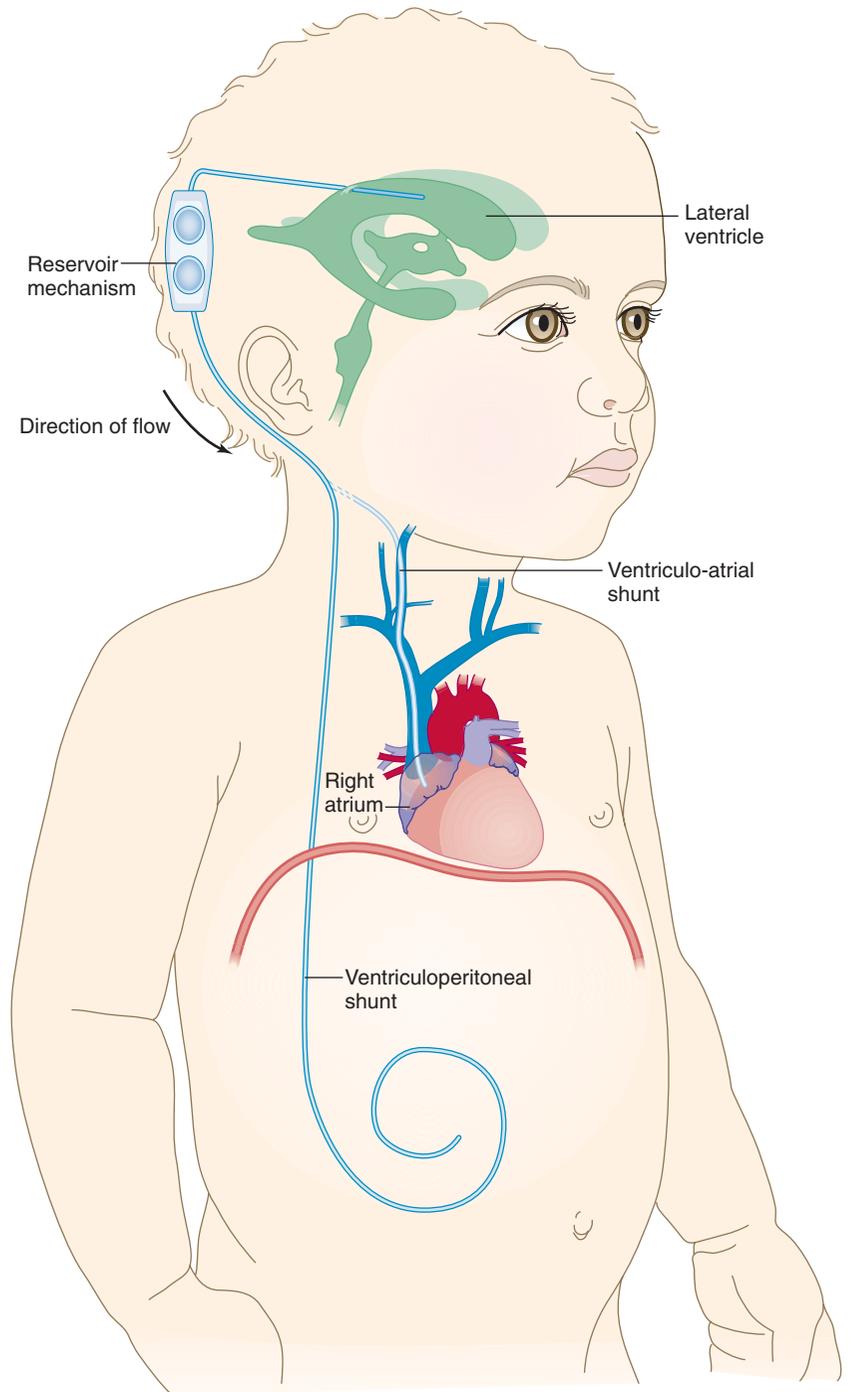

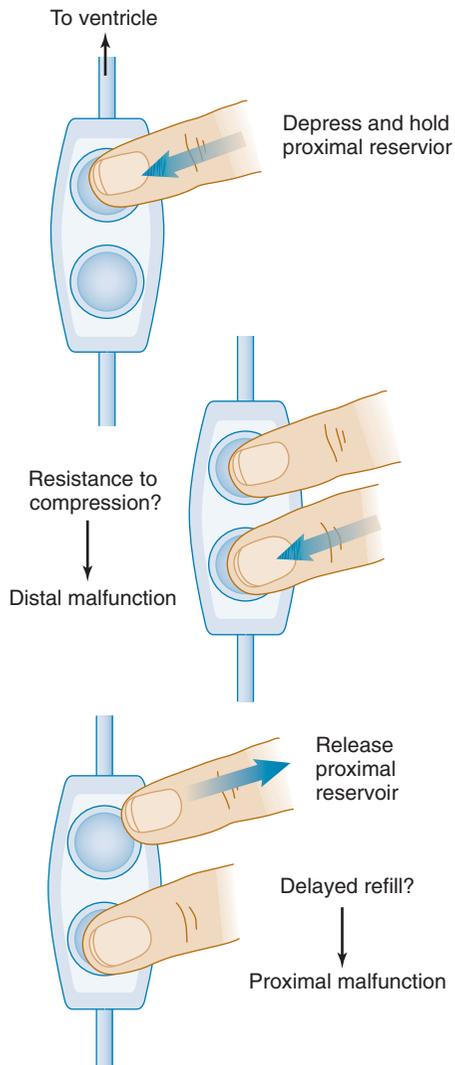

FIGURE 167-1. Pumping double- and single-bubble shunts.

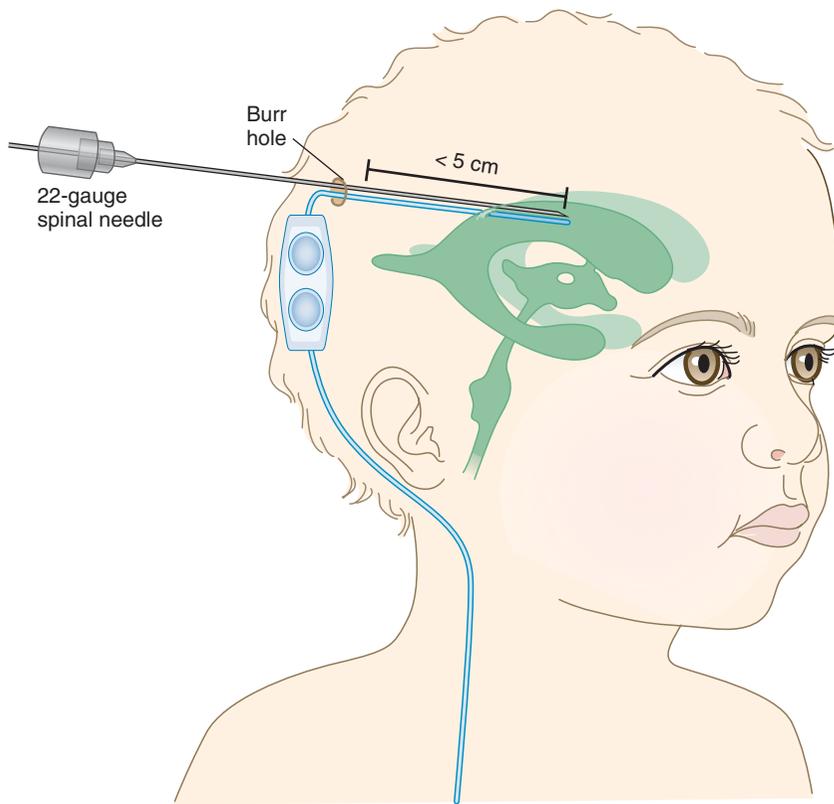

FIGURE 167-2. Shunt puncture.

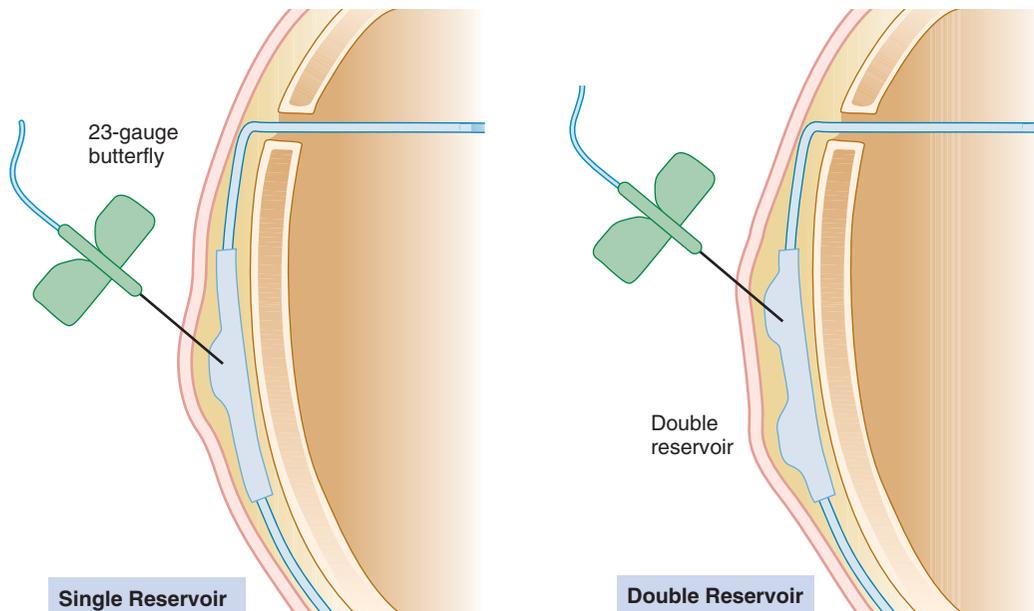

FIGURE 167-3. Burr hole puncture.

Staphylococcus epidermidis. Shunt taps also can cause damage to the shunt mechanism if not performed properly. Burr hole puncture carries the added risk of infection or direct parenchymal or vascular injury, such as intracranial abscess formation. A burr hole puncture also can cause sudden changes of ICP that can lead to fluid shifts, subdural hematoma, intracerebral hemorrhage, and edema. Ventricular punctures

through the burr hole almost always damage the shunt mechanism.

Postprocedure Care and Disposition

Neurosurgical evaluation, and continuous cardiopulmonary observation with frequent assessment of neurologic status

will be required in symptomatic patients after shunt evaluation. A negative (easy compression and reinflation of reservoir; no erythema, edema, or palpable separation along the shunt tract) noninvasive evaluation of the shunt does not completely rule out the possibility of malfunction. Further evaluation may include shunt tap, plain radiographs, CT scan, magnetic resonance imaging, and shunt flow studies. After a shunt tap, the results of laboratory evaluation of the CSF must be followed, including results of the CSF culture. Patients who require burr hole puncture almost always require operative shunt revision. Prophylactic antibiotics are generally not required.

Chapter 168

Thoracostomy

Nicole P. Carbonell, MD and Thomas E. Terndrup, MD

Key Points

Needle decompression must be performed immediately for suspected tension pneumothorax.

Local and systemic anesthesia should be used during insertion of tube thoracostomies.

Complications from tube thoracostomy can be minimized by following appropriate technique, including sterility, attention to anatomic landmarks, and confirmation by radiography following placement.

Indications and Contraindications

Abnormal Pleural Collections

Tube thoracostomy is a bedside procedure that allows drainage of a variety of abnormal collections from the thoracic cavity. A pneumothorax is a collection of air in the pleural space. In a simple pneumothorax, air in the pleural space separates the lung and pleura, while a tension pneumothorax results in intrapleural air trapping, potentially causing decreased venous return and shock if sufficiently severe. An open pneumothorax occurs when injury produces a full-thickness chest wall defect that connects the pleural cavity to the body surface. If the chest wall defect has less resistance to airflow than the airways, air preferentially passes in and out of the chest wall defect when the patient takes a breath, interfering with inspiratory airflow. An open pneumothorax with ingress of air is called a “sucking” chest wound.

A tension pneumothorax develops when the volume of air trapped in the pleural spaces increases positive intrapleural pressure. Increased intrapleural pressure may shift the mediastinum, compress the vena cava, and lead to decreased cardiac preload, hypotension, shock, and death.^{1,2} While the most common etiology of tension pneumothorax is secondary to complications from positive pressure ventilation, other causes include bronchial or major parenchymal injury, the inadvertent sealing of a sucking chest wound, or as a complication of a spontaneous pneumothorax.

A hemothorax, or blood in the pleural cavity, results from intrathoracic hemorrhage from lacerated lung parenchyma, the heart, great vessels or their branches, the diaphragm, or intercostal or chest wall vessels. Up to 40% of a patient’s total blood volume may be lost into the pleural cavity.¹ A combination of air and blood in the pleural space is a hemopneumothorax.

Other abnormal pleural collections requiring tube thoracostomy include chylothorax, pulmonary effusion, and empyema. A chylothorax results from a disruption of the thoracic duct. An effusion is fluid in the pleural cavity, and an empyema is a purulent collection. Pulmonary effusions can often be treated with thoracentesis alone, but the presence of an empyema necessitates tube thoracostomy.

Indications

The significance of these abnormal pleural collections is their interference with respiratory and cardiovascular mechanics. Management depends on several factors, including the etiology and size of the lesion, condition of the patient, need for patient transport, and need for positive pressure ventilation. All tension pneumothoraces are life threatening and should be treated with immediate needle decompression followed by tube thoracostomy.

Tube thoracostomy is indicated for any collection that requires continuous drainage over time. Large or symptomatic simple pneumothoraces, open pneumothoraces, recurrent pleural effusions, empyema, and chylothorax should all be managed with tube thoracostomy. Tube thoracostomy may also be indicated in patients with pulmonary contusion or subcutaneous emphysema who undergo prolonged transports, general anesthesia, or positive pressure ventilation, because such patients are at high risk for developing a tension pneumothorax. Less commonly, tube thoracostomy may be used therapeutically for rapid rewarming of pleural structures during intensive management of severe hypothermia, for thoracoscopy to evaluate pleural lesions, or for instillation of agents used to promote scarring or healing of recurrent pneumothoraces.

For the hemothorax, tube thoracostomy drains blood that may interfere with respiratory mechanics and may serve as a nidus of infection. It also allows precision measurement of blood loss, monitors the rate of hemorrhage, and helps to prevent organization of the hematoma into a fibrothorax.² Aggressive fluid resuscitation and administration of blood products are important for patients with massive hemo-

thorax before significant evacuation is begun. An existing hemothorax may tamponade a briskly bleeding vessel, and clinically significant hypotension may result if the tube thoracostomy is performed before volume resuscitation.^{3,4} An initial amount of blood drainage of 15 ml/kg or subsequent drainage of 3 to 4 ml/kg/hr for 4 hours is an indication for open thoracotomy.⁵ Commercial devices exist to collect, filter, anticoagulate, and autotransfuse blood drained by tube thoracostomy.

An open pneumothorax is managed first with occlusion of the chest wall defect with a three-sided dressing, followed rapidly by tube thoracostomy at an alternate site. The dressing creates a flutter-type valve that prevents air entry during inspiration, but allows trapped air to escape during expiration. Tube thoracostomy followed by repair of the chest wall defect is the treatment of an open pneumothorax.

Contraindications

There are no absolute contraindications to tube thoracostomy. Relative contraindications include a local dermatologic disorder or a coagulopathy. The site of chest tube insertion can be modified to avoid a problematic skin lesion. Coagulopathies should be corrected, but life-saving procedures should not be withheld. Other relative contraindications include multiple adhesions or blebs, recurrent pneumothoraces mandating surgical treatment, massive hemothorax without adequate volume replacement, or the need for an immediate open thoracotomy. It is widely recommended that a chest tube not be inserted at the site of a penetrating chest wound.

Preparation and Consent

Anatomy and Physiology

The anatomy and physiology of an infant's or child's thorax affects the pathophysiology and management of abnormal pleural collections. A child's chest wall is less ossified and much more elastic than that of an adult, thus rib fractures are uncommon and severe chest injury may be masked by the absence of external clinical findings. Other intrathoracic injuries, such as pulmonary contusions, occur frequently. A child's mediastinum is also more mobile, thus mediastinal shift with resultant tracheal and caval angulation is more common in a child.^{1,2,6,7} The shorter, smaller diameter, and more compressible trachea worsens the potential pathophysiologic consequences of small airway and chest wall injuries.² Finally, the distal airways are relatively narrow, which creates increased peripheral airway resistance. Greater positive airway pressures required for mechanical ventilation in children also increase the risk of iatrogenic barotrauma.

Neonates seem to have the greatest incidence of spontaneous pneumothorax, probably due to the dramatic changes in pulmonary physiology that occur during and immediately after birth.⁸ Mechanical obstruction of alveoli can occur in the setting of meconium aspiration. Compression of the chest wall in the birth canal puts the respiratory muscles at a mechanical disadvantage. With the first extrauterine breath, the transpulmonary pressure rises from 40 cm H₂O to as much as 100 cm H₂O. Transmission of this increased pressure to alveoli can lead to overdistention, rupture of alveoli, and development of a pneumothorax.⁸⁻¹⁰

History and Physical

The history of a child with an abnormal pleural collection should include the details of the incident, the child's past medical and surgical history, medications, and allergies. Detailed information regarding the mechanism of the trauma and the use of personal protective gear or restraints helps the physician predict the pattern of injury. Nonaccidental trauma, falls, motor vehicle collisions, and other transport-related mechanisms such as roller blades and skateboards account for most of the blunt trauma resulting in thoracic injury.

Physical examination findings in patients with pleural collections include increased work of breathing and abnormal or diminished breath sounds. The physical examination in a child is not as predictive of thoracic injury as that of an adult. External signs of chest wall trauma may be absent due to the increased compliance of the thoracic cage. In the setting of a tension pneumothorax, one would expect cyanosis, diminished breath sounds, and hyperresonance on the affected side. Contralateral deviation of the trachea and jugular venous distention are late and uncommon findings in children. The shorter neck and wide transmission of breath sounds across the thorax of the child render abnormal auscultatory findings less obvious. Therefore, the sole presentation of a tension pneumothorax in a child may be respiratory distress followed by overt signs of shock.

Diagnostic Evaluation

The chest radiograph is the primary screening study in the evaluation of all abnormal pleural collections. In the setting of suspected tension pneumothorax in a severely compromised infant or child, it is inappropriate to delay decompression for chest radiography. It is helpful to divide the collections into traumatic and nontraumatic to direct the diagnostic evaluation. For the noninjured patient without a tension pneumothorax, posteroanterior and lateral radiographs of the chest should be obtained to determine whether the collection contains air or fluid. For infants, anteroposterior (AP) and decubitus radiographs are normally required, and when uncertainty exists about an occult pneumothorax, expiratory chest films or chest computed tomography (CT) may be required. Radiographic signs of a pneumothorax include an asymmetric lucency extending beyond lung markings, sharply outlined mediastinal structures, and a shifted mediastinum.² If the AP radiograph shows fluid, lateral decubitus radiographs should be obtained. All effusions may require thoracentesis to further delineate whether they are transudative, exudative, or purulent, as well as to provide symptomatic relief when substantial. A chest CT is often helpful when the chest radiograph is completely "whited out" to distinguish whole lung consolidation from a free-flowing or a loculated effusion.¹¹ Disadvantages of a CT scan include increased radiation exposure, cost, the associated risks of sedation, and the possibility that the CT scan may miss a multiloculated collection. Thoracic ultrasound is useful to identify air or fluid in the pleural cavity and to delineate the extent of loculation and organization of the effusion or empyema.¹¹ Such information is very useful in determining whether the collection can be treated at the bedside with tube thoracostomy or whether surgical intervention is necessary.

In the setting of trauma, the supine AP chest radiograph is taken early during the secondary survey. In this position,

air layers anteriorly, and radiographic signs of a pneumothorax may be subtle or absent. Researchers have shown that CT better describes the characteristics and extent of injury than chest radiographs, but is not clear that this extra information changes patient management.¹²⁻¹⁷ Occult pneumothoraces are often an unexpected finding on an abdominal CT scan of pediatric trauma patients. A prospective study of 538 pediatric trauma patients undergoing both chest radiography and abdominal CT found that 55% of pneumothoraces found on the CT (11 of 20) were not identified on the initial chest radiograph. However, only 1 of the 11 occult pneumothoraces required tube thoracostomy.¹⁸ This study validates the notion that the increased information obtained with the CT may not alter patient management, and that not all occult traumatic pneumothoraces require tube thoracostomy.

Consent

Informed consent for tube thoracostomy in minors should be obtained from parents or the most appropriate legal guardian if available. Emergency consent is implied for life-saving procedures. Assent by the child is normally required in children age 7 years or older.

Pain Management and Sedation

Proactive and effective pain management in children should be a priority for all practitioners who care for infants and children. Tube thoracostomy is painful regardless of who is performing the procedure. If the patient is awake, infiltrative local anesthetic is clinically prudent. Intravenous opioids, dissociative agents, and anxiolytics should be used early in management, with small, titrated doses depending upon the individual needs of the patient.¹⁹ Using a small-gauge needle, preferentially 27 or 30 gauge, as well as buffering the lidocaine with bicarbonate, substantially decreases the pain associated with the infiltration of subcutaneous and local lidocaine anesthetic.

Equipment

The contents of a typical prepackaged tube thoracostomy tray are listed in Table 168-1. Other adjunctive supplies include adhesive tape, tincture of benzoin, antiseptic solution, proper-sized chest tubes, and a drainage apparatus with sterile water for water seal, plastic tubing, and connectors. All equipment should be assembled and inspected before beginning the procedure. The size of the chest tubes will vary with the patient's size and type of collection to be drained. Larger tubes are used to drain blood or pus; smaller tubes drain air (Table 168-2). The appropriate-sized chest tube can

Table 168-1 Contents of a Typical Tube Thoracostomy Tray

No. 0 silk sutures
Scalpel
Sterile towels

be estimated from the patient's weight. The clinician should ensure adequate lighting, monitoring equipment, and assistant personnel.

Drainage Systems

All chest tubes need a fluid drainage system, except for those with flutter valves used periodically for simple pneumothoraces. With the extrathoracic end of the tube placed underwater at a level below the chest, air under positive intrapleural pressure escapes into the bottle and cannot reenter the pleural space. A single bottle system works only for the drainage of air. If fluid is draining in a single-bottle system, it will build up in the bottle, increase pressure of the water seal system, and render it ineffective. A two-bottle system allows fluid to collect in the second bottle while still providing an escape for pressurized intrapleural air. Suction improves the rate of drainage of fluid or air, but can damage the lung parenchyma or pleura if applied directly to the system. Adding a third bottle to the two-bottle system connected to the water seal bottle and filled to a level corresponding to the desired level of suction (usually 15 to 20 cm H₂O) avoids this problem. The vent allows the entrance of air from the environment when the wall suction applied is greater than the set level. Commercially available plastic chest tube drainage units usually employ the three-bottle system (Fig. 168-1).

Table 168-2 Determination of Appropriate Chest Tube Size by Patient Age and Weight

Patient Age	Weight (kg)	Tube Size (French)
Premature	3	10-14
0-6 mo	3.5	12-18
6-12 mo	7	14-20
1-3 yr	10-12	14-24
4-7 yr	16-18	20-32
8-10 yr	24-30	28-38

Monitoring

Patients with chest tubes need continuous cardiac and pulse oximetry monitoring. Once analgesia or sedation is administered, continuous monitoring for efficacy and complications is necessary. Routine assessment of respiratory rate and effort, arterial blood pressure, and level of consciousness is performed, and oxygen is monitored continuously. Guidelines promulgated by the American College of Emergency Physicians and American Academy of Pediatrics should be incorporated into institutional guidelines for monitoring during tube thoracostomy (see Chapter 159, Procedural Sedation and Analgesia).

Technique

Needle Decompression

Needle decompression is the first step for the direct treatment of a tension pneumothorax. Endotracheal intubation and positive pressure ventilation in severely ill patients with an undiagnosed pneumothorax may worsen the patient's condition, and immediate decompression is required. The patient is positioned in supine with the head of the bed elevated 30 degrees. The insertion site is swabbed with antiseptic, and a local infiltrative anesthetic is used if time permits. A large-gauge needle or angiocatheter is inserted perpendicularly over the superior aspect of the third rib, and walked over the rib into the lower portion of the second intercostal space at the midclavicular line (Fig. 168–2). A rush of air is usually heard or felt as the pleural space is entered and pressurized air is evacuated. When using an angiocatheter, it should be

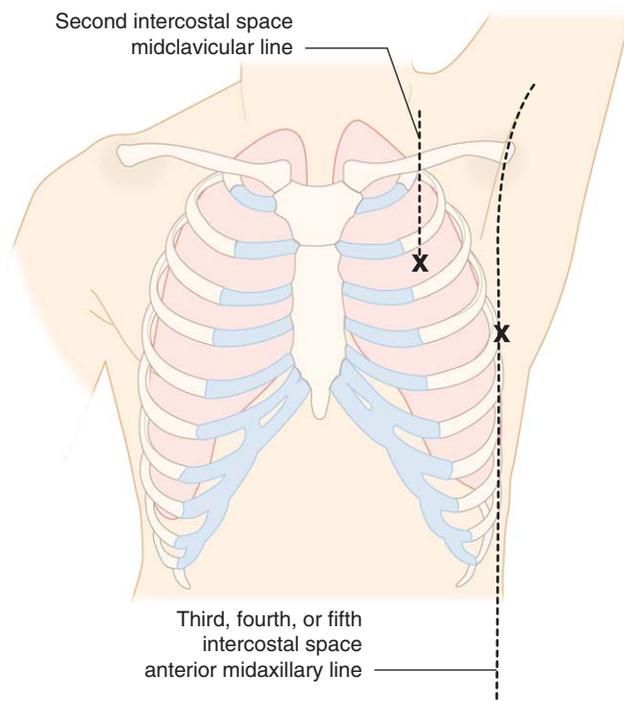

FIGURE 168–2. Sites of needle decompression and tube thoracostomy. (From Connors KM, Ternstrup TE: Tube thoracostomy and needle decompression of the chest. In Henretig FM, King C [eds]: *Textbook of Pediatric Emergency Procedures*. Baltimore: Williams & Wilkins, 1997, p 399.)

advanced into the pleural space, then the needle is removed and the catheter left in place.

Tube Thoracostomy

The patient is positioned in supine with the head of the bed elevated 30 degrees. The preferred insertion site is the fourth or fifth intercostal space at the anterior or midaxillary line^{20–22} (see Fig. 168–2). Using universal precautions, the insertion site is prepared and sterilely draped. A generous wheal of local anesthetic is made over the rib below the insertion site, anesthetizing the subcutaneous tissue overlying the upper rib, the periosteum, and the pleura. To anesthetize the pleura, the needle is advanced into the pleural space where air or fluid can easily be aspirated. Then, it is withdrawn slowly while aspirating until no air or fluid returns. At this point, injected lidocaine should anesthetize the pleura. Caution should be used not to exceed 5 mg/kg of total lidocaine to avoid systemic toxicity.

An incision is made with a scalpel through the skin and subcutaneous tissue at the site of the skin wheal. In an infant or a small child, a 0.5- to 1-cm incision will be adequate, while in a larger child or adolescent, a 2- to 4-cm incision may be necessary. Next, blunt dissection is performed through the subcutaneous tissue by opening and closing a Kelly clamp. Tunneling over the next rib provides a better seal against air leaks while the tube is in place, and may help to prevent pleural fistulas when it is removed. Dissection is continued to the upper surface of the upper rib, avoiding the neurovascular structures located on the inferior margin of the rib. Next, the tip of the clamp is slid over the superior rib margin through the intercostal muscles and parietal pleura with firm but controlled pressure. A “pop” or sudden loss of resistance and a rush of air or fluid should be felt when the pleural is punctured. The tip of the clamp is placed 1 cm into the thoracic cavity and spread widely to open the pleura. The clamp is then withdrawn and the pleural space checked with a finger to confirm placement and strip any adhesions between the lung and parietal pleura. The chest tube is guided into the pleural space with the finger or with a Kelly clamp inserted through the tip of the chest tube. If the patient is large, the probing finger is left in the pleural space and the tube is guided along the track of the finger while attached to a curved clamp (Fig. 168–3).

For a fluid collection, the chest tube is directed posteriorly and superiorly. For pneumothorax alone, it is directed anteriorly and superiorly. It is critical to insert the chest tube far enough that all the side holes lie within the pleural space. The tube is connected to a drainage system, and secured with a suture. A purse-string type suture placed around the chest tube where it enters the chest wall secures the tube and closes the incision when the tube is removed. After suturing, an occlusive dressing with petrolatum gauze is placed around the base of the tube as it enters the skin. This is covered with two pieces of gauze that are each cut from the middle of one side to the center and oriented 90 degrees to each other. Then the area and the tube are securely taped down.

Chest tube placement should be verified by a chest radiograph as soon as possible. Serial radiographs confirm the resolution of the collection. Any sudden change in the patient's cardiorespiratory status should be considered to be a recurrence of the collection until proven otherwise. Patients receiving mechanical ventilation are especially at risk for

Baltimore: Williams & Wilkins, 1997, p 401.)

recurrence of the original collection or the development of a new pneumothorax.

Alternatives

Conservative Management

Children with a simple, iatrogenic, or occult traumatic pneumothorax are often asymptomatic.^{23,24} A few studies suggest that conservative management may be safe in children.¹⁸ Observation alone is appropriate when the patient is other-

wise healthy, the pneumothorax is unilateral and small, and the patient is not likely to require positive pressure ventilation, general anesthesia, or a lengthy transport. Patients managed conservatively require an observation period. While normal pleural blood flow reabsorbs the air at about 1.25% per day, supplemental oxygen increases the rate of absorption by as much as sixfold.²⁵ Therefore, the patient should be placed on a pure oxygen mask or nasal oxygen immediately and continuously until the appropriate end point is reached. Serial radiography monitors the progression of the collection. Estimating the size of a pneumothorax is often

inaccurate, but most authorities agree that a small pneumothorax occupies less than 10% to 20% of the thoracic cavity.^{20,26}

Catheter Aspiration

Larger, simple spontaneous or iatrogenic pneumothoraces may be managed by catheter aspiration. Catheter aspiration has several advantages over tube thoracostomy. It is simpler to perform, less traumatic, leaves a smaller scar, and generally results in less patient discomfort.^{25,27,28} Trauma patients with a tension pneumothorax, hemothorax, persistent air leak, hemodynamic instability, or other serious injuries are not candidates for this procedure. Underlying lung pathology (e.g., restrictive or reactive lung diseases) is also a relative contraindication for catheter aspiration.

Complications

Patients undergoing tube thoracostomy infrequently have serious complications.²⁹ Complications from incorrect insertion include damage to local anatomic structures, ineffective drainage, and infection. Damage to the thoracic nerve and intercostal arteries may lead to bleeding and a winged scapula. Injury to the intercostal nerve results in continued pain or numbness at the thoracostomy site. Blunt dissection and avoiding the neurovascular bundle on the inferior margin of the rib minimizes the risk of neurovascular injury. Foley catheter tamponade of hemorrhage from a lacerated intercostal artery has been reported in a neonate.³⁰ Other complications include damage to thoracic or abdominal organs. The blunt dissection technique minimizes this risk by providing an easy passage for the tube. Using a finger to explore the tract and pleural space also minimizes the risk of diaphragm penetration or subcutaneous placement. A high-lying diaphragm occurs in the setting of forced expiration, hemidiaphragm paralysis, previous thoracotomy, intra-abdominal injuries, and the supine position. Abdominal placement of a chest tube can occur in this setting.³¹ If a high-lying diaphragm is suspected, sit the patient upright to reduce the possibility of injury.

A chest tube inserted too far presses against the pleura or thoracic structures and causes rare but serious complications. Cardiogenic shock secondary to right atrial compression can occur.³² Horner's syndrome due to pressure on the inferior cervical ganglion has been reported.^{33,34} Diaphragm paralysis due to phrenic nerve injury has also been reported.³⁵ A chest tube not inserted far enough for all drainage holes to lie within the pleural cavity increases the risk of an air leak and subcutaneous emphysema. Correcting the position of the chest tube and applying suction under a water seal is the treatment for both air leaks and subcutaneous emphysema.³⁶

Complications can result even with a properly placed tube. The tube itself may move or become disconnected. Re-expansion pulmonary edema and hypotension have been described following drainage of large, long-standing effusions in young patients.^{25,37} Treatment for re-expansion pulmonary edema is supportive. Finally, significant scarring can occur at the insertion site. Placing a chest tube in the midclavicular line or even too high in the anterior axillary line of premature neonates has resulted in severe breast deformities.³⁸ Lateral placement of the chest tube minimizes the cosmetic impact of scarring.

Finally, infectious complications may occur. Splinting due to pain at the insertion site may lead to pneumonia or atelectasis. Intercostal nerve blocks, intravenous opioids, and use of incentive spirometry help prevent these complications. Infection at the insertion site is minimized by good sterile technique. The role of prophylactic antibiotics for tube thoracostomy is unclear. The adult literature is inconclusive, but one study demonstrated a benefit of fewer infectious complications and a shorter hospital stay resulting from the administration of a first-generation cephalosporin during tube thoracostomy.³⁹ Despite this research, most authorities do not recommend prophylactic antibiotics for tube thoracostomy in children.⁴⁰

Postprocedure Care and Disposition

All patients with a chest tube need admission for observation, serial radiography, and eventual removal of the chest tube following resolution of their injury or illness. The exception to this is the rare case of simple pneumothorax drained with a catheter aspiration and a flutter valve that might be safely managed on an outpatient basis with close follow-up. In the emergency department, patients must be continually monitored for further deterioration from their illness or injury. Ongoing management of hemodynamic, neurologic, respiratory, analgesia-sedation, and other patient care needs must be maintained throughout the course of the patient's acute clinical problems.

Hernia Reduction

Mark C. Clark, MD and John A. Brennan, MD

Key Points

Indirect inguinal hernias present with a mass at the internal ring of the inguinal canal (vs. other inguinal and scrotal masses).

Hydroceles are usually smooth, nontender, and mobile; have brilliant transillumination (bowel can transilluminate); and do not extend into the internal ring of the inguinal canal.

Even with irreducible incarcerated inguinal hernias, strangulation is rare.

Most attempts at reduction of an incarcerated inguinal hernia should be successful.

Irreducible inguinal hernias in girls may be an incarcerated ovary.

Evidence of bowel obstruction is not a contraindication to manual reduction of an inguinal hernia.

Indications and Contraindications

When to Reduce an Inguinal Hernia

Unless the child is extremely ill appearing with signs of toxicity from gangrenous bowel, manual reduction should be attempted.¹ In a survey of 40 senior pediatric surgeons, 100% would attempt manual reduction in clinically stable patients without signs of peritoneal irritation.² The advantages of early reduction of an incarcerated inguinal hernia are that it prevents strangulation from occurring, decreases the risk of testicular atrophy, and stabilizes the child before surgery. Pediatric surgeons have an increased complication rate when operating on an incarcerated inguinal hernia compared to nonincarcerated hernias³ (see Chapter 84, Abdominal Hernias).

In the past, evidence of bowel obstruction has been considered a contraindication for a manual reduction of a hernia. In one study in which 12 of 14 infants less than 2 years old showed radiographic evidence of bowel obstruction, the

success of manual reduction was not affected by this finding. In a survey, 75% of pediatric surgeons replied they would still attempt manual reduction for incarcerated inguinal hernias even if the child had abdominal distention and radiographic evidence of intestinal obstruction.²

When Not to Reduce an Inguinal Hernia

Manual reduction should not be attempted by the emergency physician in a child who appears toxic or febrile or has bloody diarrhea, entrapped viscera that are black or blue, peritoneal signs, or leukocytosis greater than 15,000/mm³.^{1,2} Even though it is considered nearly impossible to reduce a necrotic bowel, cases have been reported.⁴

Preparation and Consent

Preparation

Hernia reduction requires minimal preparation unless the practitioner decides to use procedural sedation. Some physicians may elect to use parental analgesia, such as intravenous or intramuscular morphine, but often manual reduction can be accomplished relatively easily and quickly so that the need for parental sedation and analgesia would be unnecessary. If the manual reduction cannot be achieved easily, then procedural sedation and analgesia should be strongly considered.

Consent

Parents should be given a description of the procedure about to be performed and the potential for complications. Since this not a surgical procedure, signed consent for treatment given during patient registration is adequate.

Equipment

The use of ice packs to decrease swelling and possibly decrease pain may make it easier to reduce an incarcerated hernia, but this has never been studied. A bed that can place a child in Trendelenburg positioning may be helpful, but again it is only a theoretical technique. Monitoring and resuscitation equipment will be needed if procedural sedation is performed (see Chapter 159, Procedural Sedation and Analgesia).

Monitoring

Most children with an incarcerated hernia are not ill unless their examination suggests dehydration from vomiting or

Table 169–1 Procedural Summary

1. Be certain it is a hernia.
2. Be sure the hernia is not strangulated.
3. Consider sedation; many would use this on the first attempt at hernia reduction.
4. Warm your hands.
5. Apply gentle, firm bimanual pressure along the entire inguinal canal, using the hand most distal to “milk out” the contents or gas within the incarcerated bowel.
6. After reducing the contents of the incarcerated bowel, pressure should be increased distally as compared to the proximal inguinal canal.
7. If the bowel fails to reduce after 5 minutes of continuous pressure, use sedation with the patient in the Trendelenburg position, and place an ice pack on the groin.
8. Repeat the above bimanual technique, hopefully after the child has fallen asleep.
9. If successful or unsuccessful reduction occurs, call the pediatric surgeon.
10. Admit nearly all patients who presented with an incarcerated inguinal hernia.

toxicity from strangulation. In the typical patient with an incarcerated hernia, monitoring vital signs beyond what is customary for a pediatric emergency patient is not necessary. If procedural sedation or analgesia is given, then appropriate monitoring will need to be instituted (see Chapter 159, Procedural Sedation and Analgesia).

Techniques

No prospective study has examined the success rate of different techniques for manual reduction. Instead, most authors report using some combination of sedation, ice packs, elevation, and gentle manual reduction (Table 169–1). The patient’s leg should be externally rotated and abducted. When pediatric surgeons were surveyed, they used gentle manipulation 95% of the time, sedation 75%, elevation 55%, and ice packs in only 18% of cases.² The technique for manual reduction is to apply bimanual pressure along the inguinal canal and use the hand most distal to “milk out” the gas or contents of the incarcerated bowel (Fig. 169–1). After reducing the contents

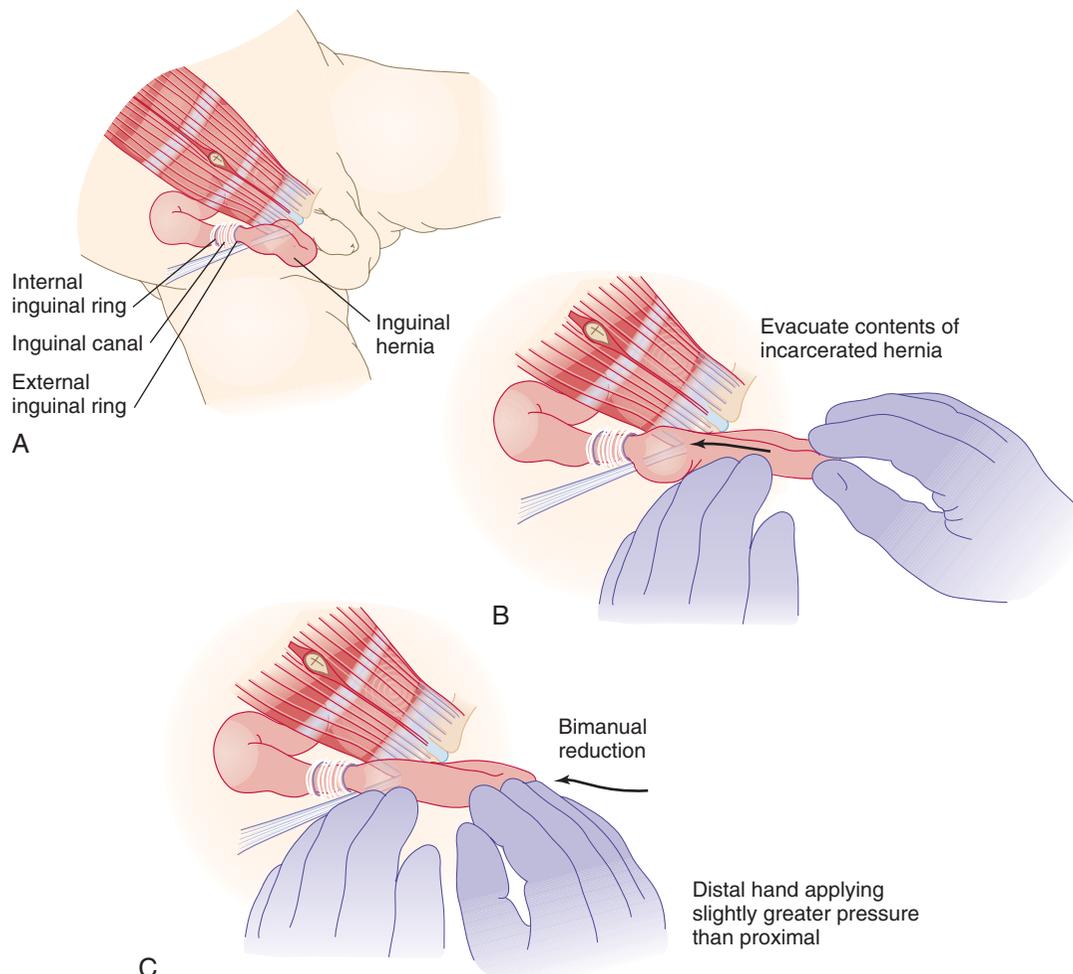

FIGURE 169–1. Bimanual reduction of an inguinal hernia.

of the incarcerated bowel, pressure should be slightly increased over the distal hernia as compared to the proximal aspect to reduce the bowel. The pressure should be held constant up to 5 minutes. If this fails, most would recommend—and many would use even on the first attempt—sedation, Trendelenburg positioning, and a covered ice pack or cold pack to the groin. When the child relaxes, or ideally falls asleep, gentle pressure as described should be attempted again^{1,2,4-7} (see Chapter 159, Procedural Sedation and Analgesia).

In recent years there has been gradual improvement in the manual reduction rate of incarcerated inguinal hernias. Most recently, two studies have had 95.5% (151 of 158) and 100% (30 of 30) success rates in reduction of incarcerated inguinal hernia in children less than 2 years old (the age group in which incarceration occurs most commonly).^{5,6} Earlier studies had reported successful reductions in the 70% to 80% range.^{3,7}

Alternatives

Placing the child in Trendelenburg position with parenteral sedation has been described. The sedated child is placed in Trendelenburg position and then observed for up to 1 hour. The success rate has been reported to be as high as 75%.

Complications

Reducing a Strangulated Hernia

The most serious complication of manual reduction of an incarcerated inguinal hernia is reduction of necrotic or strangulated bowel. It is uncommon to find gangrenous bowel even in an irreducible incarcerated inguinal hernia. The incidence of intestinal infarction is extremely low. Between 1960 and 1965, the intestinal resection rate among 351 patients with incarcerated inguinal hernias was 1.4%. A review of three series published since 1978 indicated no resection of bowel in 221 patients with incarcerated inguinal hernias. Still, there have been reported cases of a necrotic bowel being reduced.^{4,8}

Incomplete Hernia Reduction

After reducing an inguinal hernia, the physician should be sure the inguinal canal is empty, especially the internal ring. There have been reports of an incompletely reduced bowel, such as Richter's hernia (one wall of the bowel still incarcerated), resulting in a necrotic bowel.⁹ Most experts recommend that children with a reduced incarcerated inguinal hernia be admitted to the hospital to observe for such complications and to schedule for semi-elective repair of the hernia. It is known that a previously incarcerated bowel has a propensity to recur relatively soon after the last incarceration.^{2,3,5,7,9-13}

Incarcerated Ovary

In a female, if an incarcerated inguinal hernia will not reduce, an incarcerated ovary is likely.⁷ It was previously thought that an asymptomatic irreducible ovary could be managed by elective surgical reduction. It is now known that there is a relatively high incidence of future torsion with strangulation in this situation. For this reason, females with incarcerated ovaries require urgent surgical correction.^{7,14}

Testicular Infarction

The vascular supply to the testis can be compromised by the incarcerated inguinal hernia, resulting in ischemic necrosis and atrophy of the testis. Ischemic changes in the testes are relatively common with incarcerated inguinal hernias, but the rate of infarction is actually low. Children most at risk for this complication are premature infants, infants less than 6 months of age, and those who have unsuccessful manual reduction who require emergency herniotomy.^{5,7,15,16}

Irreducible Inguinal Hernia

Two factors influence the success of an attempted hernia reduction. The longer the duration of symptoms at the time of presentation and the younger the child, the higher the incidence of nonreduction.⁷ The complication rate for irreducible inguinal hernias is 22% to 33% with emergency surgery as opposed to 1.7% to 4.5% for manually reduced hernias followed by elective repair.^{3,12} Children with irreducible incarcerated inguinal hernias need emergent surgery consultation, usually intravenous broad-spectrum antibiotics, correction of fluid and electrolyte abnormalities, and nasogastric suctioning if severe vomiting, abdominal distention, or bowel obstruction is present. Emergency herniotomy will have to be performed.^{12,17} The primary reason pediatric surgeons now admit children with reduced incarcerated inguinal hernia for early semi-elective repair is to prevent the future possibility of recurrent incarceration and irreducibility with their associated complications.^{2,3,5,7,9-13}

Postprocedure Care and Disposition

Parents should be taught how to reduce an inguinal hernia and to return to the physician if the hernia becomes incarcerated. All children should have a referral to a pediatric surgeon. Some pediatric surgeons believe that, if an inguinal hernia becomes incarcerated and reduced, admission for urgent herniorrhaphy is necessary since recurrent incarceration is a substantial risk.

Access of Ports and Catheters and Management of Obstruction

Stacey Murray-Taylor, MD and Neil Schamban, MD

Key Points

The use and complexity of vascular access devices has significantly increased.

There are four broad categories of vascular access devices: chronic venous access catheters, implantable venous access devices, peripherally inserted central catheter lines, and midline catheters.

The emergency department must be able to manage infected lines, clotted devices, and device malfunctions.

Preparation and Consent

Although the majority of children who require intravenous access in the emergency department receive it via peripheral vein cannulation, an increasing number of children arrive with long-term vascular access in place. The most common access agents are catheters and ports.

Chronic Venous Access Catheters

Silastic central venous catheters are also known as Hickman and Broviac catheters (Fig. 170–1). The Hickman is a modification of the Broviac catheter.¹ The difference between the two is minor, and they function in very similar manners; they remain the most popular long-term, indwelling catheters in children. They range in size from 2.7 to 12 French.² They are implanted surgically and are tunneled underneath the skin to an exit point on the wall of the anterior chest or abdomen. The subcutaneous portion possesses a Dacron cuff that forms an anchor and creates a barrier to help prevent the spread of bacteria from the skin.¹ As the tissue heals, it also allows for the fixation of the catheter without the need for external immobilizing sutures. This may account for the lower rates of thrombus and infection in these catheters. The catheter may possess one or two lumens. Each lumen is composed of its own inner core with a cuff and its own heparin lock–style cap.

Implantable Venous Access Devices

Currently the most commonly used ports are Port-A-Cath, Infuse-A-Port, and MediPort ports. These implantable access ports were developed for long-term access. They are surgically placed in the subcutaneous tissue and tunneled a short distance to a central vein (Fig. 170–2). The reservoir is a small region, either stainless steel or firm plastic, usually implanted just over the pectoralis major muscle. The side facing the skin consists of a thick rubber membrane. The diaphragm of the port may be punctured up to 2000 times prior to replacement.² The ports also contain a self-sealing silicone septum, thereby decreasing the risk of infection.

Consent

The general consent signed by the patient or guardian is generally all that is needed to access these catheters and ports.

Equipment and Technique

Chronic Venous Access Catheters

Hickman and Broviac catheters are easily accessible via sterile technique. The dressing is removed from the catheter. Next, the exit site should be cleaned with standard aseptic technique, followed by clamping the catheter and removing the cap. A 10-ml syringe is attached to the port and the catheter may then be unclamped. Approximately 5 ml of blood is removed and discarded. Then, using a new syringe, blood samples are obtained and/or medications are infused. The catheter is reclamped when this process is complete. A heparin solution is flushed and a new injection cap is placed. It cannot be overstated that these catheters require meticulous aseptic techniques when accessing and handling the device.

Implantable Venous Access Devices

To access implantable ports, a special needle containing a side hole (Huber needle) is required. To access the port, the subcutaneous reservoir is palpated. The overlying skin is cleansed with standard aseptic technique. Then, a 10-ml syringe is attached to extension tubing, which is in turn attached to a 20- to 22-gauge Huber needle. The needle is

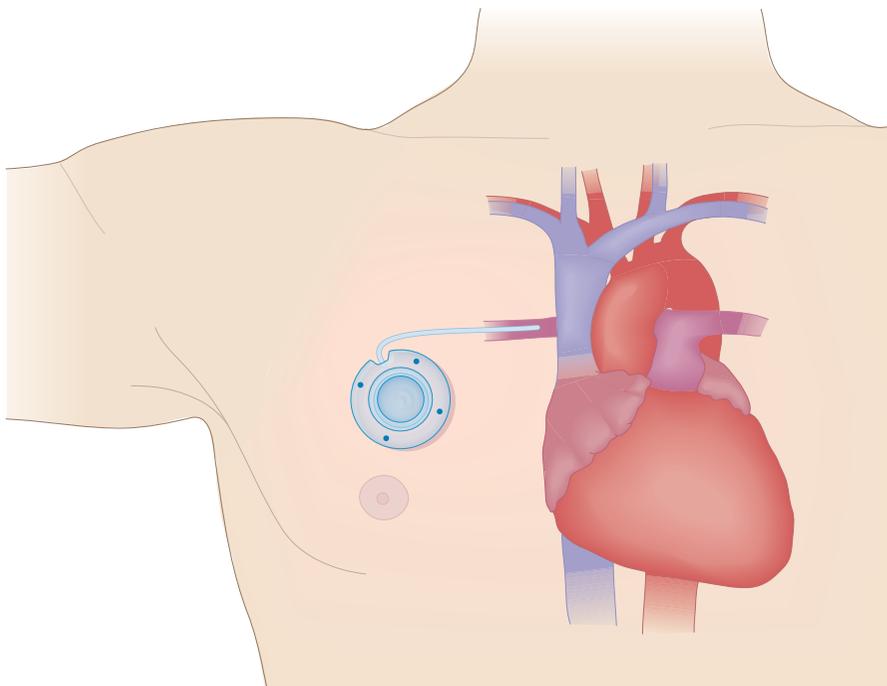

FIGURE 170-1. Implantable venous access device (ports).

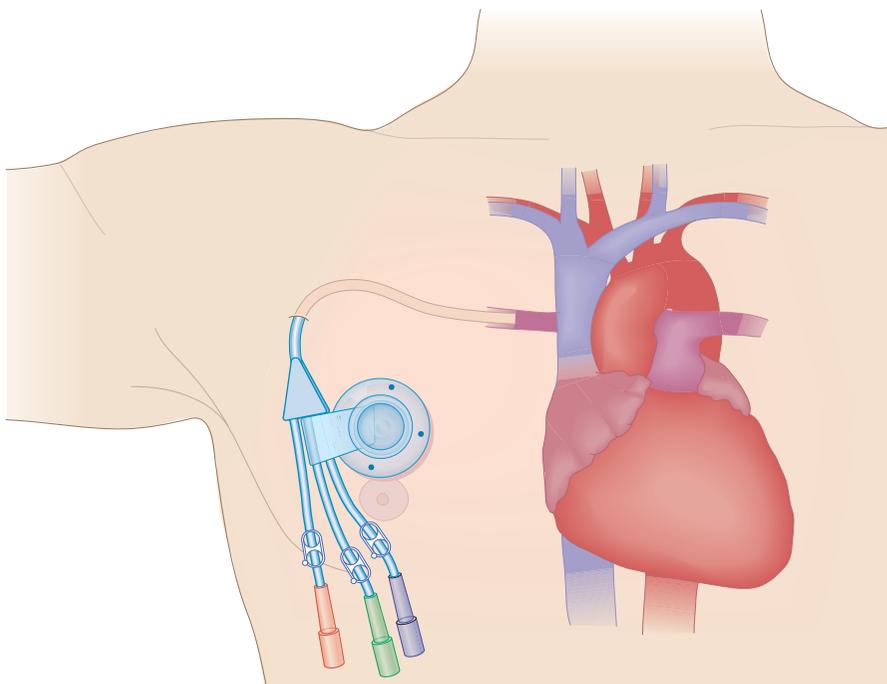

FIGURE 170-2. Chronic venous access catheters (Hickman and Broviac).

inserted through skin and aspirated until blood is returned. Fluids can then be infused. The Huber needle is stabilized with sterile gauze and transparent dressing.

Complications

Maintenance

The requirement of daily catheter maintenance for the Hickman or Broviac catheters is one of the main disadvantages. These catheters are external to the skin and require

daily cleaning and dressing changes with washing. This can be time consuming and may require additional education for health care providers and the family. Ports are subcutaneous. As a result, they require no daily maintenance. They can be washed like any other part of the body, with frequent visual inspections to observe for signs of infection.

Emotional Impact

A subtle but equally important aspect to consider is the disfigurement and psychological effects on a young child or

adolescent. As mentioned above, ports are subcutaneous. Visually, there is simply a bump under the skin while Hickman and Broviac catheters are external and more apparent.³

Common Complications

Common complications that may occur include infection, malpositioning, excessive negative pressure, and clot formation. Many children with VADs are immunocompromised increasing their risk for infections with atypical pathogens (e.g., *Pseudomonas* in patients with neutropenia). Importantly, the close approximation of these devices to the skin increases the risk for infections with skin flora (e.g., *S. aureus* and *S. epidermidis*). Thus, antibiotic coverage for children with infections and VADs must take into consideration organisms associated with their underlying disease and skin flora. Clot formation⁴ and resulting catheter obstruction are two of the most serious complications. Infection is a very serious complication as well. Stringent aseptic technique must be used when accessing catheters, and proper cleaning and maintenance are vital. Visual inspection of the catheter site is also important to ascertain early signs of a skin infection around the catheter site. Fever, chills, and malaise should always be taken seriously, and a workup to exclude catheter infection is appropriate.

For all indwelling vascular access devices, clotting can be a major complication.⁵ Clotting should be suspected if an attempt to draw blood produces a dry tap or if infusing and flushing the catheter or port is difficult. Helpful maneuvers to obtain blood include raising the patient's arm above the head, Valsalva maneuvers, reverse Trendelenburg positioning, and gentle traction on the catheter. If occlusion is suspected, increasing the pressure to the syringe should not be attempted as catheter rupture may occur. Prior to using heparin or fibrinolytic agents to declot a catheter that is not working, a chest radiograph should be obtained to verify that the catheter tip is in the correct location and has not been dislodged or migrated. If the location of the catheter tip is still in question, a dye study can be helpful to localize it.

Once the catheter is known to be obstructed, declotting measures will need to be undertaken.⁶ It is advisable to obtain an early consultation with the specialist who placed and cares for the catheter. Clotted catheters may need to be replaced, which is a major procedure for the patient. If no blood can be aspirated, 2 ml of 1:1000 heparin solution should be instilled into each lumen and allowed to dwell for 1 hour. If the line still remains obstructed, a fibrinolytic agent will need to be used. Tissue plasminogen activator is currently the agent of choice. For children less than 2 years of age, 2 mg/ml is infused into the line. For younger children, 0.03 to 0.1 mg/kg is infused.⁷ The fibrinolytic agent should be allowed to dwell for 20 minutes to 1 hour before aspiration is attempted.^{2,8} Usually the occlusion is dissolved at least partially. If this is not successful, an additional attempt may be made in 1 hour (see Chapter 130, Disorders of Coagulation).

Chapter 171

Lumbar Puncture

Kathleen Brown, MD and Deena Berkowitz MD, MPH

Key Points

Proper patient positioning is the most important determinant in obtaining a cerebrospinal fluid specimen.

Local anesthesia should be administered to all patients, including infants.

Sedation is often necessary in preschool and school-age children.

Administration of antibiotics should not be delayed to obtain a computed tomography scan or perform a lumbar puncture if meningitis is suspected.

Indications and Contraindications

Lumbar puncture (LP) is most often performed in the emergency department as a diagnostic test. Cerebrospinal fluid (CSF) obtained from an LP can be used to diagnose central nervous system infections, including bacterial, viral, fungal, protozoan, and mycobacterial infections. CSF analysis also allows for immunologic confirmation of certain diseases (e.g., Guillain-Barré syndrome, multiple sclerosis, Lyme disease) as well as verification of subarachnoid hemorrhage and CSF malignancies. For children with pseudotumor cerebri, the opening pressure during LP is a valuable diagnostic tool and the withdrawal of spinal fluid is therapeutic. An LP is indicated when any of these diagnoses is in question.

Patients with hemodynamic or pulmonary instability should not undergo LP until they are stabilized. Other contraindications to performing LP include suspicion of increased intracranial pressure (ICP), local cellulitis, and bleeding disorder.¹ Physical examination findings such as markedly decreased level of consciousness, focal neurologic findings, and papilledema have been noted in reported cases of cerebral herniation after LP.² Computed tomography (CT) scan is sometimes used to assess for the possibility of increased ICP in patients with suspected meningitis. While some patients with CT evidence of increased ICP have undergone LP without herniation, CT findings of increased ICP place

patients at a dramatically increased risk for herniation if an LP is performed. Therefore, LP should be avoided when any signs of increased ICP are seen on CT. In contrast, a normal CT does not guarantee that herniation will not occur. While cerebral edema may cause slitlike lateral and third ventricles, generalized low attenuation of the white matter, and obliteration of the basilar and suprachiasmatic cisterns, there is considerable variation in ventricular and cisternal size, diminishing the accuracy of a single CT scan in the setting of increased ICP.²⁻⁴ Most experts agree that infants and children with a normal mental status, no papilledema, a normal neurologic examination, normal pupils, and no history of intracranial mass or shunt can safely undergo LP without a CT scan.^{5,6}

None of these relative contraindications should prevent the practitioner from administering antibiotic therapy if there is a strong suspicion of bacterial meningitis. The time period in which the CSF becomes sterilized varies by etiologic agent.⁷ In cases in which LP must be deferred for a significant amount of time, antigen studies may be helpful in detecting the etiologic agent.

Preparation and Consent

Once the patient is deemed stable for LP, the procedure should be carefully explained to the patient or legal guardian. This includes the risks of infection and traumatic injuries and benefits of the procedure itself, and if necessary, the risks and benefits of sedative medication to facilitate the LP. The patient/guardian should be aware that a nurse or other hospital personnel will be assisting with the procedure. The family should be given the option of being present for the procedure.⁸⁻¹⁰ Written informed consent should be documented in the chart prior to the start of the procedure.

An LP is a painful procedure, and thus all patients regardless of age should receive some form of analgesia. Lidocaine infiltration is commonly used in older patients and can be used in all age groups. The belief that local infiltration will “obscure landmarks” and make the procedure more difficult is not supported in studies.^{11,12} Alternative or complementary methods of providing local anesthesia include topical mixtures such as a eutectic mixture of local anesthetics (EMLA).^{13,14} Sucrose is effective in reducing pain in neonates and young infants undergoing painful procedures.¹⁵

LP may provoke anxiety in children. Both pharmacologic and nonpharmacologic methods of reducing anxiety should

be considered. Allowing family members to be present may reduce anxiety in both the child and the family members.⁸⁻¹⁰ Pharmacologic sedation may be necessary, especially in preschool and younger school-age children who are not able to understand the procedure and may struggle and make positioning more difficult. There are many reports in the literature of LPs in children facilitated by various pharmacologic agents.¹⁶ Practitioners should use those agents that they are most familiar with and that are most appropriate for the individual patient (see Chapter 159, Procedural Sedation and Analgesia; and Chapter 172, Local and Regional Anesthesia).

Equipment

Gloves, mask, and gown should be used for the procedure. Prepackaged LP kits are available in infant, pediatric, or adult sizes. The kits include

- CSF manometers
- Spinal needles—22-gauge, 1.5-inch for infants; 22-gauge, 2.5-inch for toddlers through early school-age children; and 22-gauge, 3.5-inch for older children and adolescents
- Three-way stopcock
- Sterile drapes
- Chlorhexidine solution
- Sterile gauze pads
- 3 to 4 specimen tubes
- 1% lidocaine
- Syringe and injection needles

The needle used for puncturing the dura should contain a stylet. The use of a “butterfly” needle or any needle without a stylet is associated with an increased risk of the development of epidermoid tumors after lumbar puncture.^{17,18}

Monitoring

Patients with increased work of breathing, concerns for apnea, the newly born, infants, and those on mechanical ventilation should be on a cardiorespiratory monitor during the procedure. An LP should not be performed on patients with hypotension or respiratory distress. For infants and toddlers who are often held firmly in the fetal position, the assistant restraining the patient should periodically check that the patient’s airway is not being compromised. Consideration should be given to cardiorespiratory and oximeter monitoring for all patients being held in the fetal position.

Techniques

Lateral Decubitus Position

The gurney should be flat and the patient should be lying on his or her side (Fig. 171–1). The patient’s body should be perfectly perpendicular to the bed. The patient should assume the fetal position. In young patients, the assistant should maximally flex the spine without compromising the airway. This is usually accomplished by using one hand to flex the neck and the other to hold the knees flexed into the abdomen. The desired sites for lumbar puncture are the interspaces between L3–4 or L4–5. To locate these spaces, the apex of the pelvic bone (the iliac crests) is identified. On an imaginary

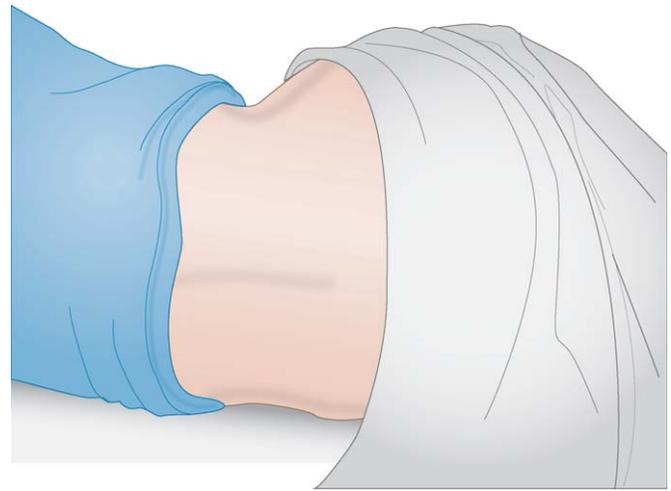

FIGURE 171–1. Lateral decubitus technique with patient lying on his or her side on the flat gurney.

line running from one iliac crest to the other, the interspace will be palpable in the center of this line.

Using sterile technique, the skin is cleaned with chlorhexidine and then the child is draped beneath the flank and around the entry site. The site is infiltrated with 1% lidocaine, being careful not to enter the spinal canal or blood vessel with the anesthetic. Once the entry area between the two spinous processes is located, the spinal needle’s stylet is checked to see that it is secure. The spinal needle is introduced with the bevel facing up toward the ceiling. The needle is inserted slowly, aiming cephalad toward the umbilicus and making sure that the needle’s trajectory is parallel to the spinous process. Needle entry into the subarachnoid space is often preceded by a pop. If this occurs and no fluid returns, the bevel should be rotated 90 degrees; if fluid still does not return, the needle should be withdrawn 2 to 3 mm. If still unsuccessful, landmarks should be examined with the needle in place to determine the optimal location for needle placement with subsequent attempts.¹⁹⁻²³

To obtain opening pressures, the manometer is attached to the needle’s hub once the CSF is flowing. The column of fluid is allowed to rise until it is stable and varies with respiration, at which point the pressure should be read. Some authors suggest that the reading should be taken in the lateral decubitus position with the legs extended and that flexion may falsely elevate the reading. However, there is little evidence to support this assertion.²⁴

At least three sample tubes are filled with CSF, collecting 1 ml of fluid in each tube. The stylet is reinserted and the needle removed, applying pressure if needed. The iodine solution is cleaned off the puncture site and a Band-Aid applied. CSF samples should be isolated, labeled, and removed from the field before discarding the LP kit.

Sitting Position

The patient should be positioned in a seated position on the edge of the gurney with maximum spinal flexion. The patient’s feet are placed on a chair so that the legs are bent, the hips are flexed, and the knees are together. This will serve to open the interspinous spaces. The assistant should flex the patient’s neck with one hand while holding the arms between

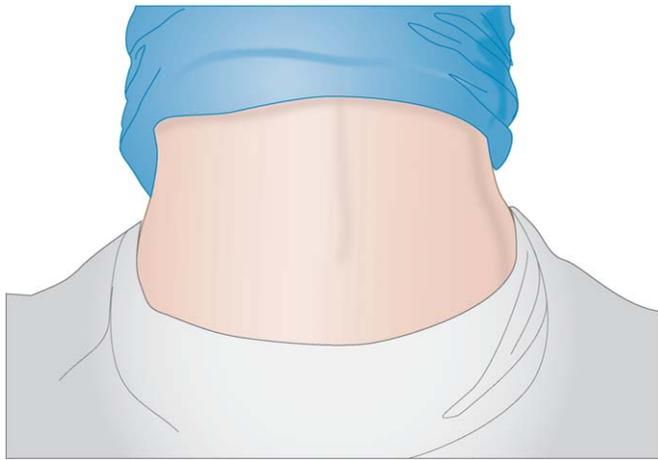

FIGURE 171-2. Sitting position.

the trunk to stabilize the patient. Older patients and those with respiratory disorders often find this position more comfortable (Fig. 171-2). The correct insertion site should be identified and the needle inserted just above either the L4 or L5 interspace. Opening pressures should not be measured from this position. Sedation may be required for a safe LP to be performed (see Chapter 159, Procedural Sedation and Analgesia).

Complications

Common complications of the procedure include a positional or “spinal headache,” nonpositional headaches, local pain, and backache. Positional headaches occur in about one third of adults who undergo an LP. A recent prospective study of children ages 2 to 16 years who underwent diagnostic LP found a 40% incidence of backache, 27% incidence of any type of headache, and 9% incidence of positional headache. Frequency of complaints was higher in older children. Among children greater than 10 years old, complaints were more frequent in girls.²⁵ Using the smallest needle gauge possible and ensuring the appropriate level orientation should help reduce the rate of postprocedure “spinal headaches.”

Less common complications include spinal cord bleeding, infection, apnea, and ecchymosis where the child was restrained too forcefully. Rare complications include cerebral herniation, transient ocular muscle palsy, subarachnoid or subdural hemorrhage, and acute neurologic deterioration.

Postprocedure Care and Disposition

First, the clinician should document the procedure and how it was tolerated by patient. The patient and caregiver should be reminded of the possibility of headache and backache. Post-LP headaches usually last 2 to 7 days. Pain is relieved by lying flat, drinking plenty of fluids, and taking acetaminophen or ibuprofen. If the symptoms are severe and are not relieved within a few days, an epidural blood patch may be necessary.²⁶

Prophylactic bed rest is often prescribed in an attempt to prevent positional headaches after an LP. However, a recent study in children and adolescents who had undergone diag-

nostic LPs found that patients who were randomized to 24 hours of bed rest had a significantly higher incidence of headaches and backaches than those allowed free mobility.²⁷ Studies in adults also have not shown a benefit from prophylactic bed rest.²⁸

Chapter 172

Local and Regional Anesthesia

Kimberly R. Roth, MD and Christopher King, MD

Key Points

Topical anesthesia is essentially painless and may decrease the need for restraint and sedation.

The major limitation to the use of topical agents in the emergency department is their slow onset.

Infiltration anesthesia is a safe, effective, and rapid method for providing local anesthesia.

Nerve blocks have a higher risk of systemic toxicity due to inadvertent intravascular injection. Aspiration should be performed every time the needle is repositioned.

Bier blocks are a safe alternative to generalized sedation and analgesia during a fracture or dislocation reduction.

of using topical agents makes it possible for nurses to administer the anesthesia for certain wounds, potentially reducing the length of stay for a patient in the emergency department.⁵

The main disadvantage to topical anesthetics is that they are slow in onset compared with infiltration anesthesia. For this reason, topical agents are contraindicated in situations in which anesthesia is needed quickly. Additionally, topical anesthetics are less effective when used for lacerations in areas of the body that have less subcutaneous vasculature, such as the extremities. However, even in these areas, prior application of topical anesthesia to a laceration has been shown to reduce the pain associated with subsequent infiltration anesthesia.⁵

Preparation and Consent

Before using topical anesthesia, it is important to know the patient's past medical history, current medications, allergies, and previous experience with anesthetic agents. In selecting a topical agent, the clinician must take these patient factors, as well as the nature of the procedure to be performed, into consideration so that complications are avoided.

Tetracaine, Adrenaline, and Cocaine

A solution of tetracaine 0.5%, adrenaline 1:2000, and cocaine 11.8% (TAC) can be used as a topical anesthetic agent for the repair of minor lacerations in children. Its utility was first demonstrated in 1980.¹ TAC was at one time the preferred topical anesthetic agent for most lacerations. However, misuse of TAC (e.g., on mucous membranes or extensively abraded skin) has caused serious complications, including prolonged seizures and death, primarily due to cocaine toxicity.^{6,7} As a result, the popularity of TAC has waned significantly in recent years and it is no longer recommended.

Lidocaine, Epinephrine, and Tetracaine

A solution of lidocaine 4%, epinephrine 1:2000, and tetracaine 0.5% (LET) is as effective as TAC.^{7,8} LET is also less expensive and safer, and avoids the controlled substance issues associated with TAC. LET is indicated for open wounds that do not involve mucous membranes, as excessive absorption of lidocaine, while not as dangerous as excessive cocaine absorption, may result in toxicity. Because it contains epinephrine, LET is contraindicated in areas with end arterial supply (penis, digits, pinna of ear). It is

TOPICAL ANESTHESIA

Indications and Contraindications

Topical anesthesia offers a noninvasive way of providing local anesthesia. This essentially painless method is particularly beneficial for pediatric patients, as the fear of “getting a needle” is eliminated.

Topical anesthetics can be used for relatively small wounds—and in certain circumstances, for intact skin—to provide anesthesia for simple procedures. In randomized clinical trials, topical anesthetics have been shown to be as efficacious as lidocaine infiltration for the repair of certain minor lacerations in children.¹⁻³ These agents also offer a few key advantages over infiltration anesthesia. First, eliminating pain with administration often improves cooperation and decreases the need for restraint and sedation in young children.⁴ Furthermore, a more positive experience by the child with laceration repair can make subsequent suture removal easier to perform.¹ Another advantage is that topical agents do not distort wound edges and thereby may enhance tissue approximation and cosmetic outcome. Finally, the simplicity

available both as a solution and in gel form. The two preparations are equally efficacious, but the gel is easier to apply and has less of a tendency to run off into mucosal surfaces or the eyes.⁹

EMLA Cream

A eutectic mixture of local anesthetics (EMLA 5% cream) was approved by the Food and Drug Administration in 1992. The active ingredients are lidocaine and prilocaine. EMLA is indicated for use on intact skin for simple procedures such as venipuncture, accessing MediPort catheters, and lumbar puncture. It provides a maximal depth of analgesia to needle insertion of 5 mm.¹⁰ The main limitation to the use of EMLA in the emergency department is its slow onset. It is effective in 65% of individuals after application for 60 minutes, but it is more effective if left in place for 90 to 120 minutes.¹⁰ While some studies suggest that EMLA may be safe and effective for open wounds, it is not currently approved for this indication.^{11,12}

L.M.X.4

L.M.X.4, or 4% liposomal lidocaine (formerly called ELA-Max) is indicated for intact skin and requires a 30-minute application. No occlusive dressing is necessary to achieve full effect; however, an occlusive dressing may help the cream stay localized and prevent accidental ingestion or mucous membrane deposition in toddlers. Randomized trials comparing a 30-minute application of L.M.X.4 to a 60-minute application of EMLA found no difference between the two agents.^{13,14} L.M.X.4 also has the advantage of producing a longer duration of analgesia, as the lipid carrier helps maintain a prolonged localization of the lidocaine.¹⁵

Equipment

Depending on the topical anesthetic to be used, the following equipment is needed:

- LET solution: cotton-tipped applicator, cotton ball, gauze, and adhesive tape
- LET gel: cotton-tipped applicator, gauze, and adhesive tape
- EMLA (5-g tube): occlusive dressing (Tegaderm or plastic wrap)
- L.M.X.4 (5-g tube): occlusive dressing if desired (Tegaderm or plastic wrap)

Techniques

Prior to the administration of the topical anesthetic, the neurovascular status of the involved area must be assessed. All necessary supplies should be readily available. Although the procedure is painless, the clinician should consider whether a child may require restraint by an assistant, papoose board, or both.

LET Solution

Whenever possible, any debris or clotted blood should be removed from the wound. The solution is first “painted” into the laceration using a cotton-tipped applicator. A ball of cotton that has been soaked with the solution is then placed over the wound and secured with gauze and adhesive tape for 20 to 30 minutes.

Table 172-1 Maximum Doses for EMLA

Age	Weight	Dose
0–2 mo	<i>or</i> <5 kg	1 g over maximum of 10 cm ²
3–11 mo	<i>and</i> >5 kg	2 g over maximum of 20 cm ²
1–5 yr	<i>and</i> >10 kg	10 g over maximum of 100 cm ²
6–11 yr	<i>and</i> >20 kg	20 g over maximum of 200 cm ²

LET Gel

As with the solution, any debris or clotted blood should be removed from the wound when possible. The gel is applied using a cotton-tipped applicator or gloved finger. Gel should cover the wound and extend for a 1-cm perimeter around the wound. The area is then covered with gauze and adhesive tape for 20 to 30 minutes.

EMLA Cream

A layer is applied to the intact skin ($\frac{1}{4}$ -inch thick, or approximately 2.5 g—half of the standard 5-g tube—for children >12 months). The EMLA is then covered with an occlusive dressing and left in place for 60 to 90 minutes. Application time should not exceed 4 hours. Recommendations for maximum dose by age are as follows: 1 g for children birth to 2 months of age, 2 g for those 3 to 11 months, 10 g for those 1 to 5 years, and 20 g for those 6 years and older¹⁶ (Table 172-1).

L.M.X.4

A $\frac{1}{4}$ -inch thick layer, or approximately 2.5 g (half of the standard 5-g tube), is applied to the intact skin. An occlusive dressing is not necessary, but the area may be covered to prevent spread of the cream if desired. L.M.X.4 should be left in place for 30 minutes to achieve full effect.

Alternatives

The primary alternative to topical anesthesia is infiltration anesthesia. Infiltration anesthesia generally has an onset of less than 5 minutes, which represents a significant advantage in the emergency department. Investigators are currently searching for new ways to provide rapid topical anesthesia. Recent research in adult volunteers suggests that cutaneous analgesia with EMLA cream can be achieved in as little as 5 minutes after a brief pretreatment of the area with a low-energy ultrasound device.¹⁷ Further study of this method is needed in pediatric patients.

Complications

Local anesthetics can produce toxicity when large amounts are systemically absorbed. Reports of systemic toxicity from topical anesthetic agents have involved mucous membrane application of large concentrations or accidental ingestion by toddlers. Thus the likelihood of causing systemic toxicity can be minimized by taking care not to apply any topical agents to mucous membranes and by not exceeding maximum recommended drug dosages.⁷

The most common complications of topical anesthetic agents are local skin reactions. The vast majority of reactions are mild and self-limited. Skin reactions to EMLA are

common and virtually always benign. Reactions include transient blanching of the skin, pallor, and edema, which occur in approximately 50% of patients. Although not a frequent reaction, clinicians should be aware that a petechial or purpuric local eruption can occur following EMLA administration and should resolve without sequelae.¹⁸

Although rare, administration of EMLA may cause methemoglobinemia due to the prilocaine component. In prospective studies using a one-time age-appropriate dose of EMLA, increases in serum methemoglobin levels were small and of no clinical significance.^{16,19,20} However, infants less than 3 months of age may be at greater risk due to decreased activity of methemoglobin reductase. For these patients, EMLA should be used with appropriate caution.¹⁸ In addition, patients younger than 12 months of age who are taking other potential methemoglobin-inducing agents (e.g., sulfonamides, phenytoin) should not receive EMLA due to possible additive effects.¹⁶ Glucose-6-phosphate dehydrogenase deficiency is a contraindication to EMLA use.

INFILTRATION ANESTHESIA

Indications and Contraindications

Infiltration anesthesia is a local injection of anesthetic directly into tissues. Indications for this procedure include incision and drainage of abscesses, repair of certain lacerations, and removal of soft tissue foreign bodies. For large wounds, especially when located in areas such as the plantar aspect of the foot, infiltration anesthesia may not be appropriate because the patient will experience excessive pain and/or the maximum dose of the anesthetic will be exceeded. Local infiltration may also distort wound edges and obscure important anatomic landmarks; therefore, it is relatively contraindicated for wounds in which tissue distortion would hinder optimal wound closure and cosmetic outcome (e.g., lacerations through the vermilion border).

Local anesthetic agents share a common basic structure consisting of an aromatic ring attached to an amine group by an intermediate chain. The intermediate chain is either an ester linkage (–COO–) or an amide linkage (–CONH–). Local anesthetics are classified into two groups based on this intermediate chain: “esters” (procaine, tetracaine) and “amides” (lidocaine, prilocaine, bupivacaine). Esters are very rapidly metabolized by pseudocholinesterase and therefore have less inherent toxicity. Amides undergo slower enzymatic degradation in the liver.

Large wounds requiring more than the recommended dose of anesthetic should be closed under general anesthesia or using a regional block with analgesia and sedation (Table

172–2). Moreover, allergy to one class of anesthetic (amide or ester) precludes use of other drugs in the same class. Lidocaine is the most commonly used local anesthetic. Reactions to this agent are usually due to the methyparaben (MPB) preservative, which is not present in dental injectors and cardiac forms of this drug. Patients with prior allergy to *para*-aminobenzoic acid (PABA) are at risk for allergy to anesthetics with MPB preservatives since they have similar chemical structures.

Preparation and Consent

Before administering infiltration anesthesia, it is important to know the patient’s past medical history, current medications, allergies, and previous experience with anesthetic agents. The choice of an appropriate anesthetic should be based on these patient factors as well as the anticipated duration of the procedure. Table 172–3 is a summary of infiltration anesthetic agents commonly used in children.

Lidocaine is the most commonly used agent for infiltration anesthesia. It has a rapid onset and a duration of action that is suitable for most minor procedures performed in the emergency department. Lidocaine has also been shown to produce less pain on injection when compared to other local anesthetics.²¹ When epinephrine is added to lidocaine, it facilitates hemostasis and limits vascular “washout” of the anesthetic from the injection site, thereby providing a longer duration of effect. Epinephrine also permits larger doses of anesthetic to be given safely, because the “release” of lidocaine into the blood occurs gradually as the vasoconstrictive effect of the epinephrine slowly wanes. It is acceptable to use lidocaine with epinephrine at all sites except those near end-arterial

Table 172–2 Maximum Dose of Local Anesthetics Without (and With) Epinephrine

Anesthetic	Maximum Dose
Bupivacaine (Marcaine, Sensorcaine)*†	2.5 mg/kg (3 mg/kg)
Lidocaine (Xylocaine)*	5 mg/kg (7 mg/kg)
Mepivacaine (Carbocaine)	4 mg/kg (7 mg/kg)
Prilocaine	5.5 mg/kg (8.5 mg/kg)

*Due to cardiac toxicity, never use for intravenous regional anesthesia or hematoma block.

†Not recommended for use in children under 12 years old.

*For intravenous regional anesthesia (Bier blocks), the maximum lidocaine dose is 3 mg/kg, with even less for mini-Bier block. Use preservative-free lidocaine without epinephrine for Bier or hematoma blocks.

Table 172–3 Local Anesthetic Agents Used for Infiltration Anesthesia

Anesthetic Agent	Class	Onset (min)	Relative Potency	Duration (min)
Procaine	Ester	5–10	1	15–30
Chloroprocaine	Ester	2–5	1	15–30
Lidocaine	Amide	2–5	2	30–90
Prilocaine	Amide	2–5	2	30–90
Mepivacaine	Amide	2–5	2	45–90
Etidocaine	Amide	2–5	6	120–180
Bupivacaine	Amide	5–10	8	120–360

Table 172–4 Example of How to Calculate Appropriate Anesthetic Dose

Anesthetic solutions are typically labeled with drug concentration as a percentage. This example uses 1% lidocaine for laceration repair in a 10-kg child.

1% solution = 1 g drug/100 ml of solution
 1 g drug/100 ml = 1000 mg/100 ml = 10 mg/ml

Remember: the maximum dose of lidocaine is 5 mg/kg. If the child weighs 10 kg, the maximum dose allowed would be 50 mg.

Remember: 1% lidocaine is 10 mg/ml. Therefore, 50 mg lidocaine = 5 ml lidocaine.

Maximum dose for this patient is 5 ml of 1% lidocaine.

distributions (i.e., digits, penis, ear pinna, tip of nose) and areas of decreased perfusion (i.e., narrow wound flaps, infected wounds). The maximum recommended dose of lidocaine without epinephrine is 5 mg/kg; the addition of epinephrine allows for a maximum dose of 7 mg/kg. Anesthetic solutions are manufactured with drug concentration expressed as percentages. Physicians and other health care providers should become familiar with how to use these percentages to calculate the appropriate weight-based anesthetic dose for a child (Table 172–4).

Bupivacaine is another commonly used agent in the emergency department. It has a longer duration of action and is useful when prolonged anesthesia is desired. This agent can significantly reduce the amount of pain experienced after wound repair for at least 6 hours.²² The maximum recommended dose is 2.5 mg/kg. Bupivacaine is an inherent vasoconstrictor, and the addition of epinephrine confers no advantage.²³ The toxicity profile is among the worst of the amide anesthetics, and bupivacaine-induced toxicity can be highly resistant to standard resuscitative measures.

If a patient reports an allergy to local anesthetics, the circumstances of this should be carefully assessed. True allergic reactions to local anesthetics are rare. Most reported reactions reflect unintentional intravenous injection or the absorption of epinephrine, which may produce dizziness, headache, or agitation.²⁴ In fact, less than 1% of adverse reactions caused by local anesthetics are attributed to true allergies.²⁵ True hypersensitivity may manifest as urticaria, bronchospasm, anaphylaxis, and in extreme cases, cardiovascular collapse. Individuals are more likely to develop an allergy to agents in the ester group that form *para*-aminobenzoic acid (PABA) derivatives. Amide anesthetics, such as lidocaine, have a much lower risk of allergic reaction, although this complication has been reported.²⁵

While testing for an anesthetic allergy is useful, it is not feasible to perform in the emergency department. Therefore, when the history of allergy is convincing, local anesthetics should be avoided. An alternative to lidocaine for local infiltration is diphenhydramine. Antihistamines are structurally similar to lidocaine; however, allergic cross-reactivity has not been reported.²⁶ A randomized trial comparing 1% lidocaine with 1% diphenhydramine for local injection prior to laceration repair showed no difference in anesthetic efficacy.²⁷ Diphenhydramine may also be used for large lacerations after the maximal lidocaine dose has been reached. However, diphenhydramine causes pain on injection, requires dilution, and can cause traumatic discoloration of the skin.

Equipment

Alcohol swab or antimicrobial solution
 1% lidocaine (with or without epinephrine depending on the location)
 5- or 10-ml syringe
 27- or 30-gauge, 1.5-inch needle
 Gauze
 Sodium bicarbonate

Technique

There are two methods of infiltration anesthesia: direct infiltration and field block. Preparation is the same for both methods. A careful neurovascular examination of the area should be performed prior to administration of the anesthetic. An effort should be made to keep the needle and syringe from the child's view if possible. Young children may require manual restraint by an assistant, restraint using a papoose board, or both. Once the child is properly positioned, the skin around the wound should be cleansed with an antimicrobial solution or an alcohol swab.

Direct infiltration involves inserting the needle through the open wound to administer anesthetic along the length of the wound edges. This method is indicated for most minimally contaminated wounds. Injection into the wound is less painful than injecting through intact skin. The needle is inserted just beneath the dermis at the junction of the superficial fascia (subcutaneous tissue). In this tissue plane, there is less resistance and the anesthetic is quickly distributed to the sensory nerves. As the needle is advanced, a small amount of anesthetic should be injected, forming a wheal in the skin. Alternatively, the needle can be fully advanced on insertion and anesthetic slowly injected as the needle is withdrawn. The needle is then removed and the procedure is repeated at an adjacent site, entering the skin just at the margin of anesthesia provided by the previous injection. This is continued until all edges and corners of the wound are anesthetized. Aspiration is generally unnecessary with this technique since only a small amount of local anesthetic is injected at any given point while the needle is either advancing or withdrawing. Aspiration is recommended when injecting in areas of major blood vessels or when injecting deeper than the subcutaneous space. With this technique, full anesthetic effect of lidocaine is usually achieved within 2 to 5 minutes. The needle tip can be used to lightly touch the wound edges as a test for adequate anesthesia.

Field block (or parallel margin infiltration) requires creating an area of anesthesia that encircles the entire wound. This method is preferred in areas of gross contamination (e.g., incision and drainage of an infected wound or abscess) to prevent tracking of debris into the surrounding tissues. Preparation is the same as for direct infiltration up to the point of needle insertion. For this method, the needle is inserted through intact skin approximately 1 to 2 cm from the wound or abscess. For lacerations, the needle is directed parallel to the wound edge and fully advanced into the subcutaneous tissue plane. For all lesions, anesthetic is slowly injected as the needle is withdrawn, forming a small wheal in the skin. The needle is then reinserted at the end of the first wheal where the skin is anesthetized. This is repeated until the circumference around the lesion has been completely infiltrated.

Full anesthetic effect of lidocaine is usually achieved in 2 to 5 minutes.

Although intended to reduce the pain of simple procedures, the injection of a local anesthetic can be painful itself. Several techniques can help minimize the pain of injection. First, a slow rate of injection produces less tissue distention, which is the main reason for pain and burning on injection. The rate of injection can be effectively controlled by using a long, small-gauge needle (27- or 30-gauge, 1.5-inch needle). Buffering lidocaine with sodium bicarbonate also reduces the pain of injection with no increase in wound infection rates.^{28,29} Anesthetics are not manufactured with buffering agents because it reduces their shelf life. Sodium bicarbonate can be added to lidocaine prior to infiltration using 1 ml of 1 mEq/ml sodium bicarbonate to 9 ml of lidocaine. Of note, sodium bicarbonate may precipitate bupivacaine and, therefore, is not generally used with this agent. Warming lidocaine has also been shown to significantly reduce pain with infiltration.²⁸ In the emergency department, this can be accomplished by placing the lidocaine in a fluid warmer. Finally, distraction techniques can be very effective in children undergoing minor procedures.³⁰ Distraction can be provided by the person performing the procedure, an assistant, or the parent. Many pediatric emergency departments have child life specialists on staff. These specialists are a very valuable resource in helping children overcome the anxiety of an emergency department procedure.

Alternatives

In general, infiltration anesthesia is safe, effective, and easy to perform. However, there are several adjuncts and alternatives to this method that may prove useful. Application of topical anesthetics should be considered for non-mucous membrane sites, if time permits. As mentioned previously, this has been shown to make a subsequent lidocaine injection less painful. Procedural sedation may also be a helpful adjunct in infants and young children undergoing lengthy procedures or repair of wounds that necessitate significant patient cooperation. Finally, nerve block anesthesia is an alternative when adequate local infiltration would require an excessive dose of lidocaine, inflict excessive pain, compromise blood flow (e.g., fingertip), or distort important anatomic landmarks.

Iontophoresis is a needle-free system in which a small electrical current draws ionized lidocaine through the skin and into the underlying soft tissues. Although further research is needed, small trials in children have shown that lidocaine iontophoresis can achieve dermal anesthesia in less than 15 minutes and reduce the discomfort associated with venipuncture and minor procedures.³¹⁻³³

Complications

Minor complications of infiltration anesthesia include bleeding and infection. Bleeding is usually minor and easily controlled by direct pressure. The addition of epinephrine to lidocaine enhances local hemostasis. Lidocaine does have some antibacterial activity *in vitro*; the injection of anesthetic prior to obtaining wound cultures should be avoided if possible, as it may lead to false-negative culture results. Although local anesthetics may hinder growth of cultures, there is no evidence that they prevent wound infections. Con-

versely, clinical trials have shown that local anesthetics, epinephrine, and buffering agents do not increase the risk of wound infection.²⁹

Systemic toxicity is the most serious potential complication of local anesthetics, occurring in approximately 0.1% to 0.4% of administrations. Systemic toxicity is determined by total dose and the rate of absorption into the blood. It is imperative that physicians and other health care providers be familiar with the weight-based dosage limits for infants and children. Furthermore, recommended dosages are based on appropriate deposition of the anesthetic within the subcutaneous tissue. Unintentional intravascular injection may produce toxic effects even at a dose below the maximum “safe dose.”

Infants are at increased risk of systemic toxicity from local anesthetics compared with adults. Infants less than 6 months of age have decreased activity of the enzymes responsible for metabolism and degradation of local anesthetics.^{24,34} Infants also have decreased concentrations of the serum proteins that bind local anesthetics, primarily α 1-acid glycoprotein and albumin. With decreased protein binding, the free fraction may be elevated and contribute to systemic toxicity even when the total plasma concentration is within an acceptable range.³⁵ However, for local administration of infiltration anesthesia that does not result in inadvertent intravascular injection, this likely bears no clinical significance.

Although there is variation among individuals, signs of toxicity generally develop in an orderly progression from central nervous system (CNS) effects to cardiovascular involvement.³⁶ Early signs are numbness of the tongue and mouth, metallic taste, light-headedness, tinnitus, visual disturbance (e.g., nystagmus), and slurring of speech. This may progress to muscle twitching, confusion, unconsciousness, and seizures. Seizures are a warning sign of impending cardiac toxicity. Cardiac effects include ectopy, atrioventricular conduction disturbances, hypotension, dysrhythmias, and cardiac arrest.²⁴

If a patient does not inform the physician of the early symptoms, seizure may be the first sign of toxicity. This is especially relevant to pediatric patients, as infants and young children are often developmentally unable to communicate symptoms of early toxicity. A child’s agitation from early toxicity may be mistakenly interpreted as pain or anxiety during the procedure. Furthermore, if children are receiving adjunctive procedural sedation, the early signs of toxicity may be suppressed and therefore difficult or impossible to identify.

If early symptoms of toxicity develop, use of the local anesthetic agent should be discontinued and the patient should be monitored closely. Treatment of CNS toxicity is necessary only if the patient develops seizure activity. In the case of toxicity due to inadvertent intravenous administration, seizures are usually brief as the drug is redistributed from the CNS. In the case of toxicity due to an excessive dose, seizures may be prolonged or recurrent until the anesthetic is metabolized. Intravenous lorazepam is usually highly effective for terminating seizures caused by lidocaine toxicity. Prolonged seizures may actually exacerbate toxicity because of the resulting metabolic acidosis that often occurs. Acidosis causes local anesthetics to dissociate from serum binding proteins, resulting in additional unbound or free anesthetic being delivered to the brain and heart.^{23,34,37}

Bupivacaine-induced cardiac toxicity can be highly resistant to standard resuscitative measures and carries a mortal-

ity rate as high as 50%.³⁷ Recent animal studies show that diazepam may prolong the half-life of bupivacaine and preferentially raise cardiac levels of the anesthetic. Consequently, some authors now recommend phenytoin for treatment of bupivacaine-induced seizures.^{34,37} Phenytoin and fosphenytoin may also have a role in treating bupivacaine-induced dysrhythmias. The use of phenytoin (a class I_B anti-dysrhythmic agent) to successfully terminate ventricular dysrhythmias in bupivacaine-toxic infants has been reported.^{38,39}

In summary, significant morbidity and mortality from local anesthetics is quite rare. The vast majority of reports result from excessive dose of the anesthetic agent. Physicians and other health care providers should obtain an accurate weight on the patient, be familiar with dosage guidelines, and monitor patients closely for toxicity when nearing the maximum recommended dose of a local anesthetic.

NERVE BLOCK (REGIONAL) ANESTHESIA

Indications and Contraindications

Nerve blocks produce regional anesthesia by injection of a local anesthetic near a nerve or nerve group supplying a specific area. Among the indications for nerve block anesthesia are: (1) extensive wounds for which local infiltration would require multiple injections or would exceed the maximum recommended dose of anesthetic; (2) wounds for which local infiltration would distort wound edges; (3) areas in which local infiltration would be excessively painful (e.g., plantar surface of the foot⁴⁰); and (4) areas in which local infiltration may compromise blood flow (e.g., fingertip). Nerve blocks are relatively contraindicated in patients with a known coagulation disorder due to the possible risk of arterial puncture and significant bleeding during the procedure. They also are relatively contraindicated in areas of the body with preexisting neurologic deficits because of the potential for causing further nerve damage during the procedure.⁴¹

Preparation and Consent

The clinician should review the area of distribution of a nerve to ensure that the block will provide adequate anesthesia at the site where the procedure will be performed (Table 172–5). Of note, successful anesthesia may require blocking two or more nerves depending on the area involved. Accurate needle placement obviously depends on a clear understanding of the location of surface landmarks in relation to the underlying neural anatomy.

Adequate sensory anesthesia will generally be provided by administration of 1% lidocaine for most procedures performed in the emergency department. Lidocaine with epinephrine is typically not used for nerve blocks due to the close proximity to arteries. In addition to systemic effects, intra-arterial injection of epinephrine may cause severe local vasospasm that could further compromise injured tissue. Epinephrine is contraindicated in areas with end-arteriolar supply, such as the digits. If significant postprocedure pain is anticipated, 0.25% bupivacaine may be used to provide a longer duration of anesthesia. The recommended maximum weight-based dose of anesthetic should not be exceeded.

Table 172–5 Nerve Blocks Commonly Performed in the Emergency Department

Type of Nerve Block	Indicated for Procedures in the Following Locations
Supraorbital and supratrochlear nerves	Forehead, anterior scalp
Infraorbital nerve	Upper lip, lateral-inferior portion of nose
Mental nerve	Lower lip
Digital nerves	Fingers or toes
Median nerve	Palmar aspect of lateral three and one-half fingers, radial half of palm
Ulnar nerve	Ulnar aspect of medial one and one-half fingers, ulnar half of palm and dorsum of hand
Radial nerve	Radial aspect of dorsum of hand, variable area of dorsum of lateral three fingers
Sural nerve	Posterolateral ankle and heel, plantar surface lateral foot and fifth toe
Posterior tibial nerve	Plantar surface medial foot, sole, and toes one through four

Modified from Roberts J, Hedges J: *Clinical Procedures in Emergency Medicine*, 4th ed. Philadelphia: Elsevier Saunders, 2004.

Equipment

- Alcohol swab or antimicrobial solution
- 1% lidocaine (typically without epinephrine) or 0.25% bupivacaine
- 10-ml syringe
- 27- or 30-gauge needle for initial skin wheal
- 22- or 25-gauge needle for injecting deeper structures
- Standard resuscitation equipment (in the emergency department)

Techniques

The details of each nerve block depend on the specific block to be performed (see Table 172–5). In general, pertinent bony landmarks and neural anatomy should be reviewed. Once the patient is properly positioned, the skin at the injection site should be cleansed with alcohol or an antimicrobial solution. Aseptic technique should be used throughout the procedure. While palpating the surface landmarks, the clinician should determine the likely course of the underlying nerve. A 27- or 30-gauge needle is inserted into the subcutaneous tissue and anesthetic is injected to form a superficial skin wheal. The needle is withdrawn and changed to a 22- or 25-gauge needle. This needle is then reinserted through the skin wheal in close proximity to the nerve. The plane of the needle bevel should be parallel to the long axis of the nerve when possible to minimize potential trauma to the nerve.⁴² After the needle has been inserted to the appropriate depth, aspiration is performed by applying suction with the syringe. If no blood is aspirated, the anesthetic can be slowly injected. Any blanching of an extremity at this point suggests intra-arterial injection. If this occurs, no further anesthetic should be injected, the needle should be withdrawn slightly, and then anesthetic should be slowly injected again.

Paresthesias elicited with either insertion of the needle or injection of the anesthetic may indicate penetration of the needle tip into the nerve bundle. If this occurs, the needle should be repositioned (usually by withdrawing slightly)

until paresthesias are no longer experienced by the patient. Whenever a nerve block is performed, the anesthetic should be administered slowly both to minimize the pain of injection and to allow the clinician to detect signs of systemic toxicity (i.e., due to inadvertent intravascular injection) before a large dose of anesthetic has been injected.

Unlike infiltration anesthesia, which is effective almost immediately, the onset of nerve block anesthesia is influenced by the proximity of the deposited anesthetic solution to the nerve for which the block is intended. In other words, diffusion of the anesthetic through the tissues plays an important role. Onset may be within a few minutes if the anesthetic is injected adjacent to the nerve. However, the full effect of a nerve block may take 15 to 30 minutes if the anesthetic is deposited more than a few millimeters from the nerve. Thus a nerve block that seems to have “failed” after several minutes may in fact prove to be highly effective once more time passes.

Alternatives

Alternatives include local infiltration anesthesia, intravenous regional anesthesia (Bier block), deep sedation (usually with ketamine) in the emergency department, and operative intervention under general anesthesia.

Complications

Specific complications will vary with the particular nerve block being performed. In general, complications are rare and usually result from poor technique. While there are no data regarding the complication rate for nerve blocks performed in the emergency department, studies from the anesthesiology literature report a complication rate less than 1% for distal nerve blocks.

Nerve blocks can fail when needle placement is inaccurate. This complication probably occurs most frequently with nerve blocks of the ankle because the landmarks used are relatively imprecise. Needle breakage may occur if a patient moves suddenly during injection. For this reason, a 22- or 25-gauge needle is recommended when injecting anesthetic. A hematoma may form if a vessel is unintentionally punctured. Local infection is another possible complication; therefore, the needle should be inserted through noninfected skin and aseptic technique should always be used.

Intraneuronal injection can damage the nerve, resulting in pain and/or various degrees of nerve dysfunction. The exact origin of the injury is not well understood. Three factors may contribute: direct trauma from the needle, microvascular injury resulting in nerve ischemia, or direct toxicity of the anesthetic agent.⁴³ The risk of nerve injury can be minimized by properly positioning the needle, avoiding excessive needle movement, and repositioning the needle if paresthesias occur. Concentrated anesthetics can produce a chemical irritation of the nerve. For this reason, 1% lidocaine or 0.25% bupivacaine are recommended for nerve blocks.

Systemic toxicity from the anesthetic agent can occur as a result of an excessive dosage or inadvertent intravascular injection. Nerve structures are often in close proximity to blood vessels, and thus particular care must be taken to avoid intravascular injection when performing nerve blocks. Aspiration of the syringe should be performed prior to injecting anesthetic every time the needle is repositioned.

Postprocedure Care

The anesthetized area is at risk of injury until sensation has returned to normal. Caution must be taken when applying heat, ice, or circumferential dressings because patients may not be able to sense impending problems while still anesthetized. For distal extremity blocks, patients should be informed that they may not have full control of the extremity until the anesthetic wears off. For this reason, patients who have had an ankle block performed should be advised not to drive until sensation is fully recovered.⁴²

INTRAVENOUS REGIONAL ANESTHESIA

Intravenous regional anesthesia (Bier block) can be used in the emergency department to provide anesthesia of the distal arm for repair of wounds, reduction of fractures and dislocations, and débridement of burns. While a detailed description of this method is beyond the scope of this text, the basic concept involves exsanguination of the distal extremity using elevation and the application of a tourniquet, followed by administration of intravenous lidocaine distal to the tourniquet (Table 172–6). With proper technique, Bier block provides rapid, safe, and satisfactory anesthesia.

Table 172–6 Technique for Mini-Bier Block—Regional Anesthesia

Indication: fracture reduction below the elbow

Medication: 0.5% lidocaine without epinephrine, without preservatives

Technique:

- Apply cardiac monitor.
- Insert intravenous (IV) line in dorsum of ipsilateral hand ± contralateral arm for resuscitation.
- Place a double pneumatic or two single pneumatic tourniquets above elbow.
- Exsanguinate limb by elevation for few minutes or by elevation + wrapping arm with Esmarch rubber or Ace elastic bandage in distal-to-proximal fashion.
- With extremity elevated, inflate proximal cuff 50 mm Hg above systolic blood pressure (BP).
- Remove bandage and lower extremity back to horizontal.
- Tourniquet pressure must be maintained 50 mm Hg > systolic BP throughout.
- Infuse 1.5 mg/kg of lidocaine diluted to total of 10 ml into hand IV over 60–90 sec.
- Successful block may manifest as blanching skin with erythematous patches.
- As paresthesia/warmth spreads proximally, the lower/distal cuff is inflated to 50 mm Hg above systolic BP, followed by deflation of the proximal cuff. The tourniquet pressure is now exerted over an already anesthetized area. Anesthesia is usually complete by 10 min, with muscle relaxation. Tactile and proprioceptive sensation, with some motor function, may be retained.
- Infuse additional 0.5 mg/kg of 0.5% lidocaine if anesthesia is poor at 15 min.
- Do not exceed maximum dose of 100 mg IV.
- Once adequate anesthesia reached, remove IV and bandage site.
- Leave tourniquet in place at least 15–20 min and no more than 60–90 min after infusion. When procedure is finished, completely deflate the cuff in cycles for 5 sec, then reinflate for 2 min. Repeat inflation/deflation (5 sec/2 min) several times until capillary refill is normal. Observe patient for at least 1 hr before discharge.

Chapter 173

Digital Injuries and Infections

PART 1 ■ INJURIES

Gloria Cecelia C. Jacome, MD, Jennifer L. Waxler, DO, and
Patricia Sweeney-McMahon, RN, MS

Key Points

Subungual hematomas result from crush injuries or blunt trauma to the distal phalanx and are manifested by throbbing pain and dark red to black discoloration. Greater than 30% blood collection between the nail and the vascular nail bed warrants evacuation as persistent pain is usually only relieved by this maneuver.

Subungual hematomas greater than one-half the size of the nail are associated with fractures of the distal phalanx and have nail bed lacerations that may or may not require repair.

Nail avulsion not appropriately treated can lead to morbidity.

Onychocryptosis is commonly referred to as an ingrown nail. An ingrown toenail occurs when the nail plate impinges upon, and then pierces, the lateral nail fold epithelium. It can be caused by improperly performed nail trimming, repetitive trauma, and tight-fitting shoes.

The fingernail rests on the nail bed, also termed the *matrix*. The distal nail covers the sterile matrix; the proximal nail arises from and covers the germinal matrix. The tissue adherent to the proximal dorsal nail is the eponychium (also termed the *cuticle*), and the potential space between the nail and the eponychium is the nail fold (Figs. 173–1 and 173–2).

SUBUNGUAL HEMATOMA

Indications and Contraindications

Nail regeneration following injury varies with age, climate, and the involved digit. Relatively rapid growth occurs in the adolescent and young adult, in warm weather, and in the middle and index fingers.¹ To gain optimal nail regeneration, early and precise repair of the disrupted bed and fold is

required.¹ Crush injuries to the fingertip result in compression of the nail bed between the nail and underlying bone, often creating a straight, stellate, or tearing laceration.² The blood usually remains fluid for 24 to 36 hours and is easily expressed with slight pressure (Fig. 173–3).

Nearly 10–25% of these injuries are associated with a tuft fracture. Simple lacerations in the middle or distal third of the nail bed are the highest in frequency; distal tuft fractures that accompany subungual hematomas are usually comminuted, but reduction is seldom necessary.^{2,3}

Equipment

The most commonly used equipment includes

- Chlorhexadine
- Normal saline
- Anesthesia for digital block
- Oversized heated paper clip
- No. 11 scalpel blade
- Handheld electrocautery device
- Splint
- Sterile dressing

Techniques

Decompression of the hematoma is the goal of therapy; it can be achieved with the following techniques. Care should be taken, no matter which methodology, is used to make multiple holes or a single hole that is large enough to allow continued drainage.

Handheld Electrocautery Device

The cautery is a sterile, disposable, lightweight device generating temperatures up to 2200° F.^{4,5} This permits rapid and painless penetration of the nail plate without significant pressure.⁴ Variations of the cautery involve different tips (fine, loop, elongated) and different temperature ranges (700° F to 2250° F) for specialized needs. The unit comes prepackaged in a sterile envelope for single use, and the power source is contained in the unit (Fig. 173–4).

One can modify the electrocautery device to burn a larger hole by “fattening” the end of the wire loop and rotating the device slowly as the nail is penetrated, or by using it to remove

FIGURE 173-1. Anatomy of the fingernail.

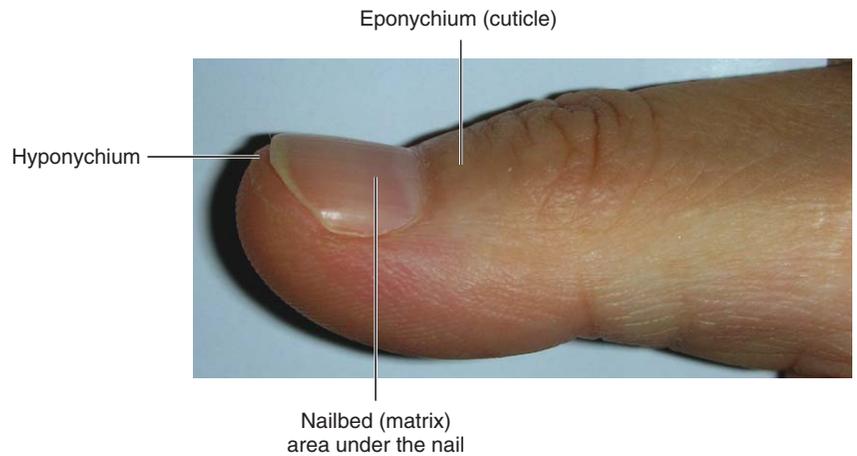

FIGURE 173-2. Anatomy of the nail bed.

FIGURE 173-3. Subungual hematoma.

a small rectangle of nail. In addition to convenience, this device is desirable because the wire stays hotter longer, thus enhancing nail penetration.

Trephination of the Nail

Trephining the nail by drainage requires making an incision beneath the distal end of the nail. This can be accomplished

FIGURE 173-4. Surgical cautery.

with a no. 11 scalpel blade, a 19-gauge needle, or a fine-point hand drill. Because of the pain involved and the pressure required to produce the hole in the nail, a digital anesthetic block is often needed with this methodology.^{4,6-8}

Heated Paper Clip Method

Heat penetration of the nail can occur with a heated, unfolded paper clip. Care must be taken not to sear the underlying tissue, which would plug the hole, thereby defeating the purpose of the treatment.^{4,7}

Procedure

The same general procedure is used with each of the previously described techniques. Patients must wash their hands thoroughly with an antimicrobial agent from the affected area to the elbow prior to the procedure. The nail is prepped with chlorhexadine and allowed to dry completely. A site is selected for maximum evacuation of blood and wiped with an alcohol swab just prior to incision. No matter

FIGURE 173–5. Nail avulsion.

which device is utilized, the hot tip should be applied perpendicular to the nail plate without pressure being applied.⁵

Once the nail plate is penetrated, the tip of the device should be withdrawn quickly to prevent coagulation of the hematoma or burning of the nail plate or nail bed.⁵ The trapped blood will evacuate rapidly through the small hole, and light pressure to the nail should permit total evacuation of the hematoma. The wound should be dressed with absorbent gauze, and a splint should be applied only if there is an underlying fracture.

Alternatives

With disruption of the nail fold, or with displaced fracture fragments, many studies recommend nail removal and primary repair of the laceration for an excellent prognosis.¹ However, nail removal and nail bed exploration are not warranted or justified with subungual hematoma and an intact nail and nail margin.^{2,4,9}

Complications

Subungual hematoma is associated with fractures of the distal phalanx in 10% to 25% of patients. Nail loss is possible but less likely when the evacuation of hematoma is undertaken within 24 hours of injury. If the nail is lost, there will be nail regeneration, possibly with an abnormal shape. While infection is uncommon, osteomyelitis of the tuft fracture is a theoretical complication. The value of routine antibiotic prophylaxis in such cases is unproven.⁴

If immediate drainage does not occur, pain may last for days and discoloration will last until the involved nail grows out in 3 to 6 months or is shed. There may be some residual horizontal white markings, called *leukonychia*, that have no structural or functional consequences.

Postprocedure Care and Disposition

Because of the potential for a secondary infection, the finger should be soaked three times a day using an antimicrobial soap, until the underlying space has closed. An Alumafilm splint or a bulky dressing can be applied to protect the fingertip for up to 3 days until the tenderness subsides. For those injuries associated with a fracture, 2 to 3 weeks of immobilization is recommended to allow the distal tuft to heal.

In cases of delayed presentation of a subungual hematoma, there may be damage to the nail bed and matrix. Parents should be warned of the possibility of onycholysis, nail deformity, and infection.

A distal phalangeal tuft fracture in combination with a subungual hematoma requires a nonurgent orthopedic consultation, but should not preclude evacuation, if necessary.

NAIL AVULSION

Indications and Contraindications

A traumatic injury to the distal portion of the nail may necessitate partial or complete removal of the nail. Avulsion of the nail at its base is usually caused by a forceful blow to the distal end of the nail. Because the proximal border lies free and is covered by an eponychial rim, the nail is torn away from the germinal matrix (Fig. 173–5). There may also be a tearing away from the underlying nongerminal matrix and/or a fracture of the distal phalanx.

Preparation and Consent

Before performing any procedure or treatment, a radiograph should be obtained to look for a fracture. A digital anesthetic block may be necessary for pain control and to facilitate the procedure.

Equipment

- Anesthetic for digital block
- Chlorhexadine
- Clamp
- Normal saline for irrigation
- Absorbable suture material
- Xeroform gauze dressing

Techniques

A digital block is performed (see Chapter 122, Local and Regional Anesthesia), and the injured and adjacent digits are cleaned with chlorhexadine solution and draped appropriately. A straight, closed clamp is inserted under the distal nail margin. When it reaches the area where the nail is free because of the avulsion, the jaws are spread. The nail can then be eased away without distraction of the wound or any fracture, and the hematoma irrigated. The nail bed can then be sutured (Fig. 173–6). Usually the sutures adequately stabilize any fracture. If the nail is removed after the injury, consideration should be given to placing a “splint” such as sterile petroleum gauze under the eponychium to prevent premature closing of this space, which would interfere with new nail growth.

Alternatives

As an alternative, the nail may be fixed with a fine Kirschner wire or 5-0 colored, monofilament nylon on a fine P-3 or PRE-2 needle.^{1,7} The suture should be snug but not tight, and may be tied over Xeroform gauze to prevent adherence to the nail bed.⁷ A small piece of Xeroform gauze may also be placed

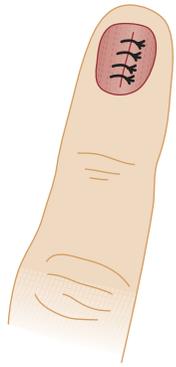

FIGURE 173-6. Nail bed repair.

between the nail bed and the eponychial fold to prevent adherence.

Complications

There is some evidence that leaving the nail in place may act as a splint, but this technique may delay healing and lead to a severe deformity and is therefore not recommended. The hematoma should be removed by gentle irrigation so that it does not act as a nidus for infection. A free-floating proximal nail may be a chronic irritant and may cause mechanical disruption of new nail growth.

Postprocedure Care and Disposition

Sutures are removed at about 1 week. Ten days after injury, the nail bed becomes hard and nontender, and no dressing is required. The new nail grows in over a 3- to 4-month period.

ONYCHOCRYPTOSIS

Indications and Contraindications

Treatment of onychocryptosis is primarily based upon the subjective discomfort of the patient and the history of acute versus chronic infection. The clinical presentation of onychocryptosis can be divided into three stages¹⁰ (Fig. 173-7):

Stage I: tenderness and swelling of the lateral nail fold that occurs when the nail impinges upon the structure

Stage II: accumulation of granulation tissue, accompanied by sharp pain, erythema, and more swelling, as the nail pierces the lateral nail fold

Stage III: ingrown toenail, in which epithelial tissue develops over the granulation tissue, making it difficult to lift the nail out above the lateral nail groove

The type of treatment chosen is based on clinical stage at presentation.

Equipment

- Chlorhexadine
- Peroxide
- Normal saline and sterile water
- Anesthetic for digital block
- Cotton-tipped applicators

FIGURE 173-7. Onychocryptosis.

- Nail splitter
- Scalpel blade (no. 11 or 15)
- Small hemostat or clamp
- Phenol solution 88% or silver nitrate Q-tip cautery
- Antibiotic ointment
- Nonadherent dressing material, or dry dressing
- Postoperative shoe

Techniques

Conservative Treatment

A cotton wedge is used to lift the nail plate up out of the nail groove. This should be repeated daily by the patient. Frequent warm soaks in antibiotic solutions are helpful, with expected resolution within 1 to 2 weeks.

When the accumulation of granulation tissue prevents the nail plate from being lifted, cauterization with silver nitrate should be considered. Steroid treatment, either intralesionally or with topical rich-potency steroids over a period of 1 to 2 days, is an effective adjunct treatment.

Surgical Treatment

Surgical treatment involves removal of the nail spicule and débridement of hyperkeratosis. This procedure is primarily reserved for ingrown toenails with minimal inflammation and a small amount of incurvation.

Partial nail removal (88% phenol solution application) is indicated for ingrown toenails associated with chronic inflammation, severe pain, and infection (with the exception of paronychia). The patient should be referred to a foot care specialist (e.g., podiatrist or orthopedic surgeon) for this procedure.

Complications

Complications include regrowth of the ingrown toenail, infection, and a postsurgical reaction to the remaining cuticle or nail. An inclusion cyst may also form around the nail

remnants; curettage of the nail groove and posterior nail fold may be necessary. Total nail removal is indicated when there is extensive infection.

If infection has been present for more than 1 month, osteomyelitis should be considered and radiographs obtained.

Postprocedure Care and Disposition

A nonadherent dressing should be applied and the patient instructed to avoid tight, poorly fitting shoes. In addition, the patient should be instructed to trim the nails in a horizontal fashion. Systemic antibiotics are indicated only if significant cellulitis is present or if the patient is at high risk for infection.

PART 2 ■ INFECTIONS

Gloria Cecelia C. Jacome, MD, Jennifer L. Waxler, DO, and
Patricia Sweeney-McMahon, RN, MS

Key Points

Paronychia, one of the most common infections of the hand, is a collection of pus in the potential space between the cuticle and proximal fingernail. Although usually limited to this area, it may occasionally spread to include tissue under the nail as well, forming a subungual abscess.

Paronychial infection develops when a disruption occurs between the seal of the proximal nail fold and the nail plate that allows a portal of entry for invading organisms.

A felon is an abscess of the distal pulp or pad of the fingertip, most often following a penetrating injury, that rapidly progresses from mild cellulitis to extensive necrosis and nerve degeneration. The most common pathogen is *Staphylococcus aureus*, although gram-negative organisms have also been described.

Pain caused by a felon is usually more intense than that caused by paronychia.

A felon will not extend proximal to the distal interphalangeal joint.

Herpetic whitlow is an infection of the distal phalanx caused by an invasion of the herpes simplex virus through broken skin, causing severe pain. When vesicular fluid is cloudy, herpetic whitlow may mimic a pyogenic bacterial infection. Surgical intervention is contraindicated as this may potentiate a secondary bacterial infection and delay healing.

Herpetic whitlow is commonly reported in adult women with genital herpes and children with coexistent herpetic gingivostomatitis. Health care workers exposed to oral secretions (e.g., dental hygienists, respiratory therapists) are at increased risk for developing herpetic whitlow.

Predisposing factors for onychomycosis include increasing age, immunosuppression, poor peripheral circulation, smoking, and tinea pedis. Spontaneous resolution is rare and is less likely as the nail plate become more extensively involved and thickened.

PARONYCHIA

Indications and Contraindications

Clinically, paronychia presents as either an acute or a chronic condition. Acute paronychia (AP) most commonly results from minor trauma with or without a foreign body present. Nail biting, thumb sucking, aggressive manicuring, and hangnails may allow entry of bacteria into the soft tissue of the nail fold.¹ Patients typically present with a red, swollen, painful area around the nail.

Chronic paronychia (CP) resembles AP clinically, but the cause is multifactorial with a different pathogenesis.² CP often is caused by *Candida albicans*, and may respond to treatment with a topical antifungal/steroid agent.^{1–4} Chronic insults such as frequent exposure to wet conditions, or situations in which the person is not properly protected against predisposing factors such as chemicals or cleaners, destroy the normal epidermal barrier.

Antibiotics are not indicated if drainage is complete or if the surrounding area of cellulitis is minimal. If the infection has produced purulence beneath the dorsal roof of the nail, a portion of the nail must be removed to ensure complete drainage.

Equipment

The most commonly used equipment includes

- Chlorhexadine
- Normal saline
- Anesthesia for digital block
- No. 11 scalpel
- Splint and sterile dressing

Techniques

The patient should wash the hand thoroughly with an antimicrobial agent from the affected area to the elbow prior to the procedure. The affected area is prepped with chlorhexadine and allowed to dry completely.

Drainage may be accomplished without anesthesia in selected patients but frequently requires a digital nerve block. Softening the eponychium by soaking is sometimes advised to facilitate separation from the nail. The nail is separated by placing the flat portion of a no. 11 scalpel on top of the nail with the point of the blade directed toward the center of the abscess. The blade is gently guided between the nail and the eponychial (cuticle) fold so that the tip of the blade reaches the center of the most raised portion of the abscess. Without further advancement, the scalpel should be rotated 90 degrees, with the sharp side toward the nail, gently lifting the eponychium from its attachment to the nail (Figs. 173–8 and 173–9). Pus should extrude from the abscess cavity. Because the skin is not cut, no bleeding should occur.^{5,6}

After the pus is expressed, the abscess is irrigated and packed with a small piece of plain gauze. The finger is placed in a splint for protection. A wick of gauze can be placed beneath the eponychium for 48 hours to ensure continued drainage.

FIGURE 173–8. Paronychia.

Optimal management of CP includes protective measures to avoid exposure to environmental causes and topical steroids to reduce the inflammatory reaction. Topical steroids are the best treatment of CP, producing improvement or cure in up to 88% of patients.²

Alternatives

Milder cases of AP may be treated with warm soaks for 15 minutes two to four times daily, with or without systemic antibiotics.⁷ If infection persists, warm soaks in addition to an oral antistaphylococcal antibiotic and splint protection of the affected part are indicated.⁵

Complications

Direct incision and drainage of the cuticle is not recommended.³ Complications include osteomyelitis of the distal phalanx and a chronic, indolent infection of the paronychium. Occasionally surgery may be indicated. Difficulty in avoiding or limiting exposure to predisposing environmental factors explains why clinical improvement is more frequent than clinical cure.² A primary squamous cell carcinoma of the nail fold may masquerade as a paronychia and should be considered in unusual, refractory cases. These cases need to be referred to a specialist.¹

Postprocedure Care and Disposition

Most paronychiae will resolve in 5 to 10 days. One or two postprocedure visits should be scheduled to evaluate healing and reinforce home care. In 24 hours, the patient may be started on frequent soaks in warm tap water. The patient may easily remove the packing after the first soak, and cover the

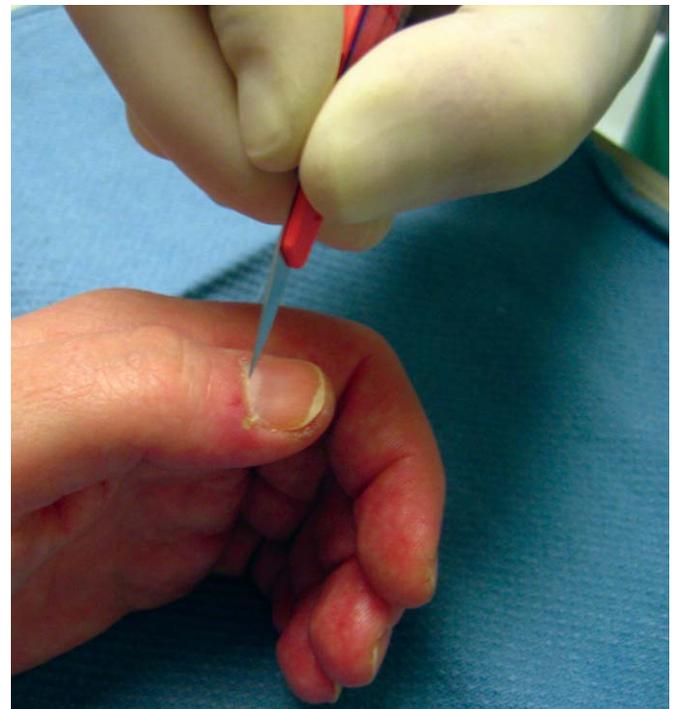

FIGURE 173–9. Paronychia drainage.

area with a dry, absorbent dressing. An antibiotic ointment or antifungal agent may be used on the site for a few days.

Counseling the patient to avoid predisposing factors is paramount in the aftercare instructions for chronic paronychia. For chronic infections, after aerobic and anaerobic cultures are obtained, an antistaphylococcal penicillin or a first-generation cephalosporin should be given. Clindamycin or amoxicillin–clavulanate potassium may be considered if anaerobes and/or *Escherichia coli* are suspected organisms.

A tetanus booster should be administered when appropriate.

FELON

Indications and Contraindications

A felon occurs in stages. The initial stage consists of mild pain; fibrous septa limit swelling in the closed pulp space. The intermediate stage includes swelling and redness, which become clinically obvious. The entire pulp is very tender (Figs. 173–10 and 173–11). The late stage occurs with cessation of pain due to extensive necrosis and nerve degeneration.

The most commonly affected digits are the thumb and index finger. Common predisposing causes include wooden splinters, glass, abrasions, and other minor puncture wounds. A felon also may arise when an untreated paronychia spreads into the pad of the fingertip. Felons have been reported following multiple finger stick blood tests.

Fibrous septa extend from the volar skin of the fat pad to the periosteum of the phalanx. These subdivide and com-

partmentalize the pulp area, making a felon a closed-space infection. Occasionally, the high pressure in the fingertip pad will cause a felon to spontaneously drain, resulting in a visible sinus.

Preparation and Consent

Mechanism of injury should be determined. The patient should understand the complications of the specific surgical modality used for treatment. Appropriate anesthesia must be provided (see Chapter 172, Local and Regional Anesthesia).

Equipment

Equipment commonly used includes

- Bupivacaine
- 1.25-cm Penrose drain
- No. 11 scalpel
- Finger tourniquet
- Hemostat
- Gauze pack
- Finger splint
- Tape
- Chlorhexadine
- Normal saline

Techniques

If diagnosed in the early stages of cellulitis, a felon may be amenable to treatment with elevation, oral antibiotics, and warm water or saline soaks.^{3,8,9} Radiographs should be obtained to evaluate for osteomyelitis or a foreign body. Tetanus prophylaxis should be administered when necessary.

If fluctuance is present, incision and drainage are appropriate. The incision is performed under digital anesthesia with a long-acting agent (i.e., bupivacaine). Simple longitudinal incision in the midline accomplishes this most effectively and has the fewest complications.^{3,8,9} A tourniquet may be applied to enhance visualization of the surgical field.

Of two commonly used techniques, the volar longitudinal incision and the high lateral incision, the former is preferred. An incision is made 3 to 5 mm from the distal interphalan-

FIGURE 173–10. Felon (palmar view).

FIGURE 173–11. Felon (lateral view).

geal (DIP) joint flexor crease and extend to the end of the distal phalanx. The depth of the incision is to the dermis. The subcutaneous tissues are gently dissected and explored with a small hemostat. Necrotic skin edges are excised, and the abscess is decompressed and irrigated.

A high lateral incision is made on the nonoppositional side of the appropriate digit (ulnar side of the index, middle, and ring fingers, and radial aspect of the thumb and fifth digit) starting 5 mm distal to the flexor DIP crease and continuing parallel to the lateral border of the nail plate, maintaining approximately 5 mm between the incision and the nail plate border. This distance should allow for avoiding the more volar neurovascular structures. The incision is extended to just distal to the unattached portion of the nail plate. The subcutaneous tissue is sharply dissected just volar to the cortex of the distal phalanx. The wound is explored by dissecting bluntly and decompressing and irrigating any abscess. This procedure allows complete visualization and débridement of necrotic tissue. However, it will require a long time to heal and can produce a sizable scar and an unstable finger pulp.

With both techniques, the wound is packed with sterile gauze. The gauze should be removed in approximately 24 to 48 hours, and the wound allowed to close by secondary intention. Gram staining should guide initial antibiotic therapy. The most commonly isolated organism is *Staphylococcus aureus*. An empirical antibiotic (first-generation cephalosporin or antistaphylococcal penicillin) should be prescribed for an uncomplicated felon for 5 to 14 days, depending on the clinical response and severity of infection.⁸ Methicillin-resistant *S. aureus* has been reported in felons, and therefore the clinical response, as well as bacterial cultures, should be followed closely.⁹ A snug dressing and splint should be applied. Discharge instructions and medications should include elevation, opioid analgesics, and a follow-up appointment in 2 to 3 days.

Alternatives

Incision techniques not recommended include the “fish-mouth” incision, the “hockey stick” (or “J”) incision, and the transverse palmar incision.^{3,8} Fish-mouth incisions may destroy the blood supply to the fingertip.⁹ Longitudinal midline incisions on the volar surface may leave scars over an important area for sensation but do not have the other disadvantages of lateral incisions. Any incision that is made too deeply and proximally can injure the flexor tendon sheath and initiate a tenosynovitis.

Complications

Potential complications of a felon and felon drainage include an anesthetic fingertip, a neuroma, and an unstable finger pad. Because the septa attach to the periosteum of the distal phalanx, spread of infection to the underlying bone can result in osteomyelitis.⁸

If untreated, the expanding abscess can extend toward the phalanx, producing an osteitis or osteomyelitis, or toward the skin, causing necrosis and a sinus tract on the palmar surface of the digital pulp. Other complications include soft tissue and bony-tuft necrosis, septic arthritis of the DIP joint, and flexor tenosynovitis.

FIGURE 173–12. Herpetic whitlow.

Postprocedure Care and Disposition

Postprocedure care includes antibiotics, loose packing, splinting, and elevation of the hand for approximately 24 hours. Dry dressing changes with twice-daily saline soaks, range-of-motion activities, and, eventually, scar massage may accelerate return to normal activity.⁸

HERPETIC WHITLOW

Indications and Contraindications

This condition is characterized by the presence of erythema, swelling, pain, and the presence of vesicular or pustular lesions (Fig. 173–12). Patients may also experience fever, lymphadenitis, and epitrochlear or axillary lymphadenopathy. Usually there is a slow response to treatment and a tendency for recurrence. Herpetic whitlow is a self-limited condition that resolves in 2 to 3 weeks.¹⁰

Preparation

A thorough history, including a history of localized trauma to the nail cuticle as well as occupational history, may be helpful in distinguishing herpetic whitlow from paronychia.

Equipment

Equipment commonly used to treating herpetic whitlow includes culture swab and dry dressing material.

Techniques

A Tzanck smear that demonstrates multinucleated giant cells in a scraping taken from the base of an unroofed vesicle, or a positive herpes culture, will confirm the diagnosis. Because viral shedding continues until the epidermal lesion is healed, contact with the lesion should be avoided by keeping the affected digit covered with a dry dressing.³

Treatment within the first 48 hours of symptom onset with acyclovir, famciclovir, or valacyclovir may lessen the severity of infection, but randomized controlled trials have not been performed.³ Treatment with antivirals may be beneficial for recurrent herpetic whitlow if initiated during the prodromal stage.³

Alternatives

Oral acyclovir has a role in the treatment of immunocompromised patients and patients with recurrent infections, but its role in healthy patients is less clear. Topical acyclovir has not been shown to be effective in either the treatment or prophylaxis of this disorder. Serologic tests are not helpful.

Complications

Surgical intervention such as incision and drainage of the herpetic lesion is contraindicated as this may potentiate a secondary bacterial infection and delay healing.

Postprocedure Care and Disposition

Strict infection-control precautions should be followed. Health care workers should refrain from patient contact until all lesions have crusted over and viral shedding has stopped. Patients should be advised that the infection recurs in 30% to 50% of cases, but the initial infection is typically the most severe.

ONYCHOMYCOSIS

Indications and Contraindications

Onychomycosis is most frequently caused by members of the *Trichophyton* species: *Trichophyton rubrum* and *Trichophyton mentagrophytes*.¹¹ Four types of onychomycosis, characterized according to clinical presentation and the route of invasion, are recognized (Fig. 173–13).^{12,13}

FIGURE 173–13. Onychomycosis.

- Distal subungual onychomycosis (DSO): the most common form; characterized by the invasion of the nail bed and underside of the nail plate beginning at the eponychium
- Proximal subungual onychomycosis (PSO): uncommon subtype; organisms invade the nail unit via the proximal nail fold through the cuticle area, penetrate the newly formed nail plate, and migrate distally
- White subungual onychomycosis (WSO): less common than DSO; occurs when certain fungi invade the superficial layers of the nail plate directly
- *Candida* onychomycosis: occurs in patients with chronic mucocutaneous candidiasis; caused invasion of the entire nail plate by *C. albicans*

Onychomycosis can also be caused by trauma, which is more frequently seen in the hallux and fifth toenails, where the greatest shoe friction occurs. However, in younger children (less than 7 years of age), there may be a higher prevalence in the fingernails.¹⁴

Preparation and Consent

The clinical appearance of the nail (subungual hyperkeratosis, yellowish brown discoloration, onycholysis) and the patient's history (older age, hyperhidrosis, onychogryposis, poor peripheral circulation, immunosuppression, nail trauma) will help differentiate fungal from nonfungal etiologies of nail dystrophies.

Mycologic confirmation of the diagnosis should be performed before starting treatment to avoid unnecessary exposure to systemic antifungals.

Equipment

Common equipment used to treat onychomycosis includes KOH preparation, culture swab, nail clipper, and dry dressing material.

Techniques

Direct microscopy of the sampled material serves as a screening test for the presence or absence of fungi and can provide clues about the identity of the microorganism. However, careful matching of the microscopic and culture results is necessary for accurate diagnosis and appropriate therapy. Histologic examination of nail clippings stained with periodic acid–Schiff provides a permanent record of the specimen.

For fungal infections limited to the distal nail, simple surface nail plate filling with topical anti-tinea therapy is often effective (e.g., ciclopirox, terbinafine, bifonazole, and amorolfine creams). With more extensive involvement, oral antifungal medications are indicated (e.g., fluconazole, itraconazole, and terbinafine). When the nail matrix is involved, the hypertrophy becomes fixed and the condition is usually irreversible.

Alternatives

Although nail surgery is useful in some cases, it is painful and disfiguring, and should be limited to one or only a few

nails if used at all.¹³ Surgical approaches to treatment of chronic onychomycosis include nail plate avulsion with nail bed débridement and periodic limited débridement of the involved nail using a Dremel tool.

Complications

Recurrent inflammation and secondary bacterial infection are the most common complications. There is a 20% treatment failure rate caused by inaccurate diagnosis, misidentification of the pathogens, or the presence of a second disorder such as psoriasis, as well as characteristics of the nail (slow growth and excessive thickness), presence of a high fungal inoculum, drug-resistant microorganisms, and the presence of diabetes, poor circulation, or immunodeficiency disorder.¹⁵

Postprocedure Care and Disposition

In addition to specific drug therapies, patients may benefit from several hygiene measures that may prevent relapses. Patient should wear thong sandals in public showers and slippers in hotel rooms and should rest their shoes periodically to limit exposure to infectious fungi. Antifungal powders should be used once a week to help keep shoes free from pathogens. Certain individuals seem to have a genetic predisposition to fungal infections, and may experience relapses despite careful care and effective therapy.

Chapter 174

Epistaxis Control

Kenneth B. Briskin, MD

Key Points

The overall assessment of the patient is the first priority in patients with epistaxis.

Adequate lighting and universal precautions are essential for effective treatment.

Posterior packing is associated with significant morbidity and discomfort. These patients should be admitted.

Beware of blood streaming down the posterior pharynx following anterior packing, indicating inadequate packing or a posterior source of epistaxis.

Indications and Contraindications

Epistaxis occurs at all ages, but in children it is most common between the ages of 2 and 10 years. It can cause significant anxiety in both patients and parents. Typically most parents have tried first aid measures prior to presenting to the emergency department. The specific procedure to control epistaxis will depend on the history. The approach to nosebleeds should be in an orderly, stepwise fashion. There are no specific contraindications to the procedures for epistaxis control, but most cases can be treated with simple measures, avoiding unnecessary discomfort for the patient¹ (see Chapter 49, Epistaxis).

Preparation and Consent

The patient who presents with epistaxis needs to be approached in a logical and consistent fashion (Fig. 174–1). The initial evaluation should include the history of bleeding, especially the duration and laterality. Factors in identifying the etiology of epistaxis include frequency of epistaxis, other abnormal bleeding, bruising, recent infection, history of trauma, surgery, and exposure to chemicals.^{2,3} Patients may have a history of hypertension or antiplatelet medications (e.g., aspirin or nonsteroidal anti-inflammatory drugs). The patient's overall condition and vital signs should be evaluated and treated initially.

The pertinent anatomy needs to be understood in order to appropriately treat epistaxis. The most common site of epistaxis is from Kiesselbach's plexus on the anterior nasal septum. The septum is fed from both the internal and external carotid systems. The sphenopalatine artery, facial artery, and anterior and posterior ethmoid arteries all contribute to the nasal blood supply and can be the source of epistaxis.⁴

The frequency of bleeding, which nostril is involved, history of trauma, past medical history, current medications, and family history are important initial points to plan treatment.^{5,6} An examination of the nose with good lighting should be performed, if possible. Blood should be drawn and sent for hemoglobin, platelets, coagulations studies, and possible type and cross, if severe bleeding is present or if a bleeding disorder is suspected² (see Chapter 49, Epistaxis; Chapter 129, Acute Childhood Immune Thrombocytopenic Purpura and Related Platelet Disorders; and Chapter 130, Disorders of Coagulation). Premedication with a topical vasoconstrictor, such as oxymetazoline (Afrin) or neosynephrine mixed with 4% topical lidocaine, will help with anesthesia and initial bleeding control.

Consent should be obtained, outlining the plan for treatment. The patient and parents need to understand the rationale involved with each stage of treatment. It should be made clear that further surgical procedures may be necessary if initial maneuvers to control the bleeding fail. The risks of the procedure, as outlined later, need to be clearly conveyed.

Equipment

The equipment for control of nosebleeds should be kept together in an epistaxis tray at all times (Table 174–1). Keeping this tray complete obviates the need to spend time looking for separate pieces of equipment in the emergency department and other parts of the hospital. This can expedite the control of the bleed and ease the anxiety of the patient, family, nurse, and physician. A good, working headlight is invaluable to help in identification of the bleeding site. A strong suction with a Frazier tip is necessary to keep the field clear. Universal precautions must be observed by all personnel using protective face shields, gowns, and gloves. Rarely, if bleeding is uncontrollable, intubation may be necessary. All of this equipment should be in place prior to attempting to treat the nose. Dislodging the nasal clot without the proper equipment available can accelerate bleeding and turn a difficult situation into a crisis.⁷

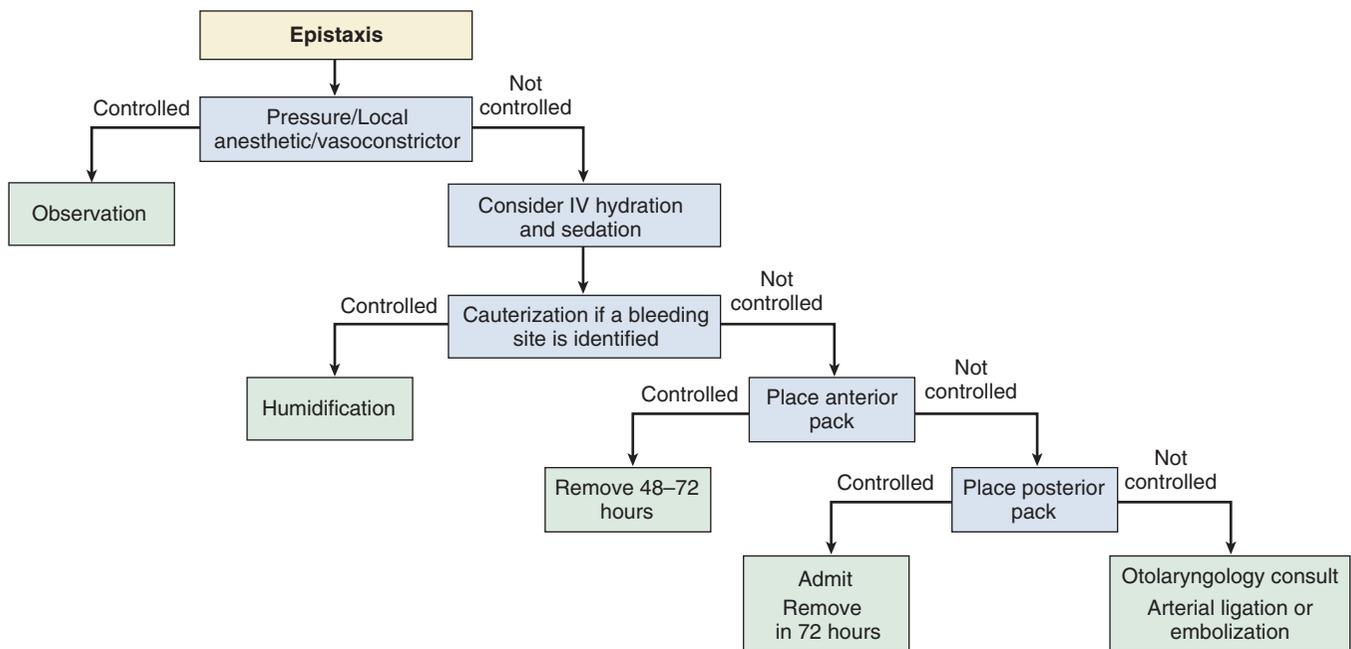

FIGURE 174-1. Emergency department management of epistaxis.

Table 174-1 Epistaxis Tray

4% topical lidocaine
Oxymetazoline nasal spray (Afrin)
Cotton balls
Medicine cup
Nasal speculum
Bayonet forceps
Frazier suction tips (8F and 10F)
Yankauer suction tip
Scissors
Tongue blades (wood and metal)
4 × 4 gauze sponges
10-ml syringes
1-inch tape
Bactroban
Gelfoam
Surgicel
Silver nitrate sticks
Petrolatum gauze, {1/2} inch × 72 inches
Self-expanding packs (small, medium, large)
Epistat double balloon catheter
Additional equipment if posterior pack (Epistat) not available:
Foley catheter (30 ml)
C-clamp
Endotracheal tube size 6, cut into 2.5-cm sections

Monitoring

The degree and method of monitoring patients with epistaxis depends on the history of bleeding, patient cooperation, and past medical history. An initial assessment is made, and those patients who have a history of excessive bleeding require cardiac monitoring. Uncooperative patients and those who require posterior packing will need sedation. These patients need cardiac and blood pressure monitoring, and pulse oximetry.^{8,9} Patients who are stable and cooperative do not require monitoring during epistaxis control.

Techniques

The procedures for controlling epistaxis should be approached in a stepwise fashion (see Fig. 174-1). First aid measures are initially employed. Patients should use digital compression, applying pressure with the thumb and index finger to the nares directly inferior to the nasal bones. Ice can be applied to the nasal dorsum, but there is little evidence to support this practice. The patient should be encouraged to bend forward to avoid swallowing large amounts of blood.¹⁰

If first aid measures are not successful, cautery is the next step in treatment. Sedation may be necessary for the anxious child. A headlight and suction are necessary to identify the bleeding point. Cotton pledgets soaked in oxymetazoline and 2% lidocaine, placed in each nostril, provide for topical anesthetic and vasoconstriction. The nasal speculum is placed into the nose and the blades opened. The clot should be suctioned, and the interior of the nose examined. Most bleeding comes from Kiesselbach's plexus on the anterior septum, and this area should be examined first. When the bleeding site is identified, a silver nitrate stick is placed over the site and held for about 10 seconds.^{1,11} Once the bleeding is controlled, a small piece of absorbable gelatin sponge (Gelfoam) can be placed over the site. Cauterizing both sides of the septum at the same time can deprive the septal cartilage of blood supply. This can lead to a perforation and should be avoided. Patients should use nasal saline spray twice a day for the week following this procedure.

If the patient continues to bleed after cauterization, or the bleeding is too profuse to identify the site, nasal packing is necessary. Cotton pledgets with vasoconstrictor and anesthetic are placed. Many self-expanding packs are now available that put pressure on the bleeding site (Fig. 174-2). These nasal packs are quickly and easily inserted even by those with little experience. These packs should be coated with an antibiotic ointment prior to insertion. This lubricates the packs

FIGURE 174-2. Examples of anterior nasal packing materials.

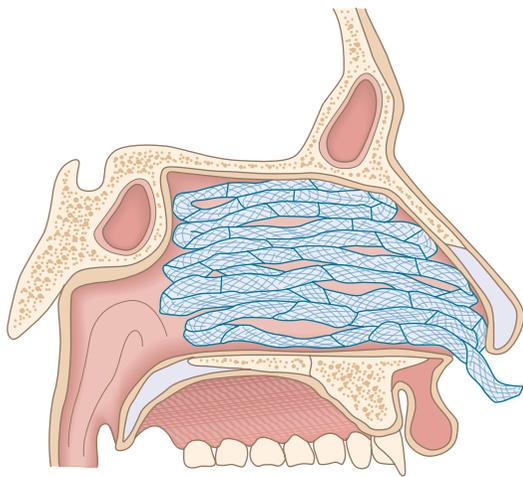

FIGURE 174-3. Anterior nasal packing. Note the layering of packing in the nasal cavity from the floor to the roof.

and may help to avoid complications of rhinosinusitis and toxic shock syndrome.^{12,13}

Petrolatum-impregnated strip gauze is the more traditional pack used for persistent epistaxis. This provides for more pressure at the bleeding site, but requires more experience to place properly. This packing can be very uncomfortable for the patient during placement and may require more sedation. To place the gauze, it is grasped approximately 7 cm from the end with a bayonet forceps. The gauze is inserted all the way back in the nasal cavity along the floor of the nose. The end of the gauze should slightly drape out of the nostril. The gauze is then regrasped about 7 cm from where it exits the nose and is placed on top of the first layer to the back of the nasal cavity. This process is repeated until the entire nasal cavity is filled on that side (Fig. 174-3). Both free ends of the gauze should protrude from the nose. This helps to prevent the pack from falling into the nasopharynx.²

Oral antibiotics such as amoxicillin-clavulanate or clindamycin are generally recommended while the packing is in place. The packs block the exit of sinus secretions and sinusitis can develop. There have been reports of toxic shock syn-

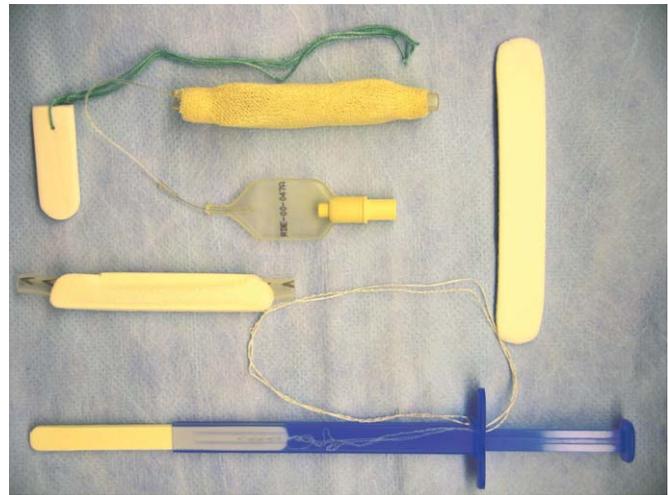

FIGURE 174-4. Posterior packing can be achieved with a dual-balloon pack more easily than traditional methods with a Foley catheter.

drome from nasal packing.¹³ The packs should be left in place for approximately 72 hours.¹⁴

If properly placed anterior packs are not successful in stopping the epistaxis, posterior packs may need to be placed. Fortunately, the need for this type of packing is rare in the pediatric population. The patient will likely need sedation and analgesia because placement of posterior packs is uncomfortable. In the past, either gauze or a Foley catheter was placed in the posterior nasopharynx as a buttress to pack against. These can be very difficult to place.² More recently, balloon catheter packs have become available that are much easier to insert (Fig. 174-4). These packs have two balloons, one anterior and one posterior. The nose is anesthetized as previously described. The catheter is lubricated with antibiotic ointment and inserted into the nostril back to the nasopharynx. The balloons, one in the nasopharynx and one in the nasal cavity, are filled with saline. This puts pressure on the bleeding site. Posterior nasal packs can be associated with hypoxia and hypercapnia. These patients should therefore be admitted and closely observed. Packing is generally removed in 48 to 72 hours.^{1,7}

Alternative Techniques

If the patient continues to bleed despite these maneuvers or rebleeds after packing removal, other interventions are necessary. An otolaryngologist should be consulted for consideration of arterial ligation. In the past, transantral internal maxillary artery ligation had been advocated. More recently, the endoscopic ligation of the sphenopalatine artery has been effective.^{15,16} Angiography with arterial embolization is another technique used to control these difficult cases. This has been used with great success and minimal morbidity.¹⁷

Chapter 175

Removal of Ocular Foreign Bodies

Gregory Garra, DO

Key Points

A high index of suspicion for corneal or globe perforation should be maintained in all patients with traumatic ocular injury and in any patient with exposure to a projectile.

Ocular foreign body removal using a sterile needle or burr requires a cooperative patient.

Embedded foreign bodies over the central visual axis should be referred to an ophthalmologist for treatment in an attempt to prevent corneal scarring.

Examination

Extraocular foreign bodies often present with symptoms of irritation or pain. The standard evaluation of a patient presenting with a complaint of a foreign body in the eye consists of a thorough external examination, while maintaining a high index of suspicion for globe or corneal perforation. Signs and symptoms of globe or corneal perforation may be subtle. Up to 20% of patients with globe perforation will report no discomfort, and vision may not be impaired. External inspection with a slit lamp may reveal focal conjunctival swelling or hemorrhage, scleral hemorrhage, hyphema, pupil irregularity, iris prolapse, a positive Seidel's test (streaming of fluorescein stain from the site of penetration), loss of contour of the cornea, or a shallow anterior chamber. It is not only important to appreciate the presence of such an injury but also to prevent further damage by avoiding unnecessary examination techniques. In cases in which the patient's behavioral disposition prohibits such careful examination, it may be necessary to administer procedural sedation or involve an ophthalmologist for examination under general anesthesia.

Examination of the eye should begin with measurement of monocular and binocular visual acuity. In children younger than 3 years or in nonverbal children, vision assessment is accomplished by evaluating the child's ability to fix and follow interesting objects. Picture tests, such as Allen figures or LEA symbols, may be used to determine visual acuity in

children 2 to 4 years old. Snellen letters or numbers may be utilized for children older than 4 years.¹ Testing at 10 feet is recommended for all visual acuity tests. In children of appropriate age in whom visual acuity cannot be obtained, finger counting, presence of shadows, or light perception should be ascertained.

The external ocular examination should consist of a general inspection of the lids and periorbital soft tissue. It is important to note the position of the globe relative to its surrounding bony structure. Injuries to the lids should be inspected for full-thickness injury, margin involvement, or injury to the lacrimal drainage system.

The pupil must be examined for size, shape, and response to light. An irregularly shaped pupil in the setting of trauma may represent corneal or scleral rupture. Likewise, the presence of an afferent pupillary defect in the injured eye is a poor prognostic sign in the setting of ocular trauma.²

Foreign bodies are frequently trapped between the inner surface of the lids and the globe. Therefore, it is important that all patients presenting with foreign body sensation have their lids everted and inspected. Lower lid eversion is easily accomplished by instructing the patient to gaze upward while the examiner applies gentle downward and inward traction of the lower lid. Examination of the upper lid and superior fornix is facilitated by instructing the patient to gaze downward. The examiner, grasping the lid margin and eyelashes, exerts a downward and outward traction on the upper lid while using a cotton-tipped applicator as a fulcrum for everting the tarsal plate.

Examination of the sclera, conjunctiva, cornea, and anterior chamber is best accomplished with the illuminated magnification of a slit lamp. It is important to proceed in a stepwise manner, progressing through the anterior segment structures: lid margins, palpebral conjunctiva, bulbar conjunctiva, scleral surface, cornea, anterior chamber, and iris. The examiner should resist the temptation to examine the site of pathology first as concomitant injuries may be overlooked. Evaluation of the lid margins and conjunctiva is accomplished by moving the slit lamp in a sweeping motion across the surface. The sclera and overlying conjunctiva should be examined for the presence of swelling, focal hemorrhages, or discoloration. The cornea is examined in a similar fashion, scanning across the surface assessing for the presence of inflammation, infiltrates, or defects. If a foreign body is identified, the examiner should make attempts at assessing the depth of penetration. Depth perception is facilitated by

adjusting the light source so that it strikes the area of interest at a 45-degree angle. Objects violating the full thickness of the cornea should be referred to ophthalmology for treatment. Fluorescein staining of the cornea will facilitate diagnosis of corneal epithelial defects. Focusing the slit lamp further into the anterior chamber, the aqueous humor is inspected for layering of red blood cells (hyphema), white blood cells (hypopyon), or the presence of cell flare. The iris is assessed for regularity or defects.

In situations in which a perforated cornea or ruptured globe is suspected, further diagnostic maneuvers that may inflict additional damage on the eye should not be attempted. The affected eye should be covered with a protective shield and secured in a fashion that prevents pressure to the globe. The patient should be maintained with the head elevated at a 45-degree angle. Analgesics, antiemetics, and antibiotics should be administered while awaiting emergent ophthalmology evaluation.

Indications and Contraindications

Suspected globe rupture or corneal perforation is an absolute contraindication for emergency department foreign body removal. The examiner should be vigilant in protecting the eye from further injury. Deeply embedded or multiple foreign bodies should be referred to ophthalmology to minimize corneal damage. Removal of a foreign body should not be attempted if the patient is unable to cooperate with positioning.

Preparation and Consent

Topical anesthesia should be administered to facilitate examination, diagnosis, and treatment. Tetracaine 0.5% or proparacaine 0.5% may be instilled into the lower lid fornix. Anesthesia generally lasts up to 30 minutes. Proparacaine reportedly causes less discomfort on instillation³ and may be the superior alternative in the pediatric population. In patients who are allergic to ester anesthetics such as tetracaine or proparacaine, a suitable alternative for ocular anesthesia would be lidocaine 2% to 4% topical solution or gel.

Equipment

- Slit lamp
- Sterile cotton-tipped applicators
- Antibiotic ointment
- Foreign body spuds or 25- to 27-gauge needle attached to a syringe

Monitoring

No specific monitoring is required for routine slit-lamp examination.

Techniques

The technique used for removal largely depends upon whether the foreign body is embedded into the cornea. Loosely adherent foreign bodies may be removed by using gentle irrigation. The patient should be placed in Fowler's position with the

head turned to the side of the affected eye. Using a sterile, isotonic, buffered solution, the eye should be gently irrigated in an attempt to displace the foreign body.

Conjunctival or scleral foreign bodies may be amenable to removal by swabbing the surface with a cotton-tip applicator moistened with saline or a thin layer of ophthalmic ointment.

Patients with adherent superficial or more deeply embedded corneal foreign bodies benefit from localization with slit-lamp magnification and removal using a foreign body spud (Fig. 175–1) or needle. Patient cooperation is essential for successful foreign body removal using a slit lamp and foreign body spud. An explanation of the purpose of the slit lamp may serve to alleviate fear. The patient should be comfortable seated in front of the slit-lamp apparatus. Smaller children are best placed in a caregiver's lap to provide reassurance and aid with positioning in the slit lamp.

After the cornea is anesthetized, the patient is seated with his or her chin nestled firmly in the chin rest and propped forward such that the forehead is stabilized against the forehead band (Fig. 175–2). The eyes should be at the same level as the black stripe (eye-level guide) on the chin rest support pole. The head and body can be further stabilized by having

FIGURE 175–1. Foreign body spud (commercial [bottom] and self-fabricated [top]).

FIGURE 175–2. Patient positioning in slit lamp apparatus.

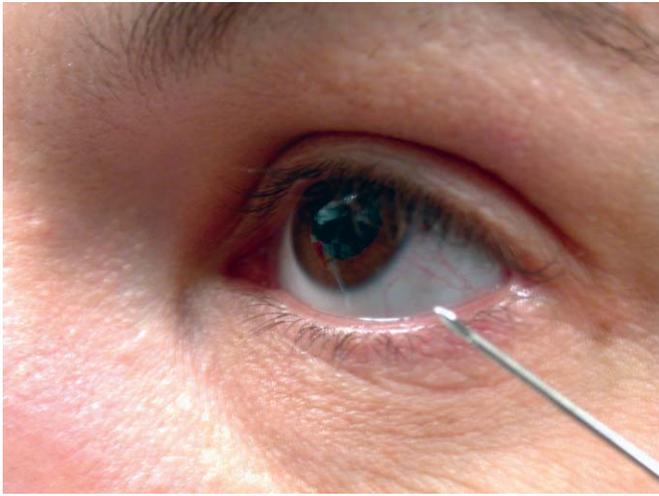

FIGURE 175-3. Approach to foreign body removal utilizing a sterile needle.

the child grasp the handholds on the slit lamp and having the caregiver apply a gentle, reassuring pressure to the back of the head. Ocular play can be eliminated by having the patient fixate on a stabilized object such as the examiner's ear. Once the foreign body is visualized, the main column of the slit lamp can be stabilized by tightening the screw on the base. This will allow the examiner to work with both hands, one to keep the patient's eye open and the other to remove the foreign body. Stabilization of the operating hand (and foreign body spud or needle) is accomplished by resting the dorsal surface of the fourth and fifth digits against the patient's cheekbone. This technique will reduce the chance of inadvertent globe perforation should the patient move unexpectedly. Using a foreign body spud or a medium-bore needle (22- to 25-gauge) attached to a tuberculin syringe, the foreign body is approached tangentially from the lateral aspect of the orbit under direct visualization (Fig. 175-3). As the needle edge approaches the foreign body, further manipulation of the needle should be attempted under visualization through the binoculars of the slit lamp. The beveled edge of the needle is used to gently tease away or lift the foreign body off the cornea.

Reexamination with a slit lamp should follow foreign body removal to ascertain the presence of another foreign body, residual damage, or rust ring deposition.

Alternatives

Examination under general anesthesia is a reasonable alternative for examination and treatment of an uncooperative patient. Emergent ophthalmology consultation is warranted in all cases of globe rupture for definitive diagnosis and treatment.

Complications

Patients with corneal foreign bodies generally have a concomitant abrasion resulting from the foreign body itself. Attempts at removal can cause further abrasions or injury. Most corneal abrasions will heal within 24 to 72 hours.⁴

Interruption of the corneal epithelium may predispose the patient to infection, ulceration, scarring, or posttraumatic corneal erosions. The most serious complication of foreign body removal is a corneal perforation. This is minimized by using the described technique in which the examiner's hand is stabilized on the patient's cheek. Immediate ophthalmology consultation should be obtained for suspected corneal perforation or laceration.

Metallic objects that become embedded into the cornea will often leave a rust deposit. Rust rings can result in further corneal inflammation, staining, or scarring. Removal of the rust ring is accomplished by scraping away the stained epithelium with the edge of a small-gauge needle or using a handheld ophthalmic drill.⁵ In general, residual rust rings can be assessed and treated during follow-up with an ophthalmologist.

Postprocedure Care and Disposition

A slit-lamp examination must be repeated after foreign body removal to evaluate for residual foreign bodies or rust ring and to ensure no additional trauma occurred during the procedure. Corneal abrasions resulting from ocular foreign bodies should be treated with antibiotic ointment and pain medication. Eye patching does not appear to speed the healing of corneal abrasions or provide greater benefit in pain reduction.⁶ Mydriatics are no longer recommended for the treatment of pain in patients with corneal abrasions.⁷ Topical antibiotic ointments serve two purposes, antimicrobial activity and lubricant. Bacitracin, erythromycin, or gentamycin is a reasonable first-line treatment option. Ointment is more lubricating than drops. Contact lens wearers should be prescribed an antipseudomonal antibiotic and instructed to avoid contact lens use until resolution of the corneal abrasion.⁸ Pain management should be considered paramount and treated with either nonsteroidal anti-inflammatory drugs or narcotic analgesics.

Following removal of the foreign body, peripheral or small abrasions should be referred to ophthalmology for re-evaluation in 3 to 5 days, unless symptoms worsen. Large or central abrasions should be re-evaluated in 24 hours to assess corneal re-epithelialization. Residual rust rings should be referred to ophthalmology for re-evaluation in 24 hours. Incomplete removal of the foreign body will result in continued corneal inflammation and delay healing of the epithelium. The epithelium may slough off and heal or grow over the foreign body, leaving a scar or corneal opacity.

Pacemakers and Internal Defibrillators

Alfred Sacchetti, MD and Steve Levi, MD

Key Points

Placing an external magnet over the pulse generator of a pacemaker turns off all programmed functions and forces the pacemaker to pace at a fixed rate (asynchronous mode).

If placing an external magnet does not lead to a paced rhythm, undersensing, a dead battery, fractured pacer leads, or pacing device component malfunction may be the cause.

Symptomatic patients with pacer dysfunction can be managed by placing a transcutaneous pacer.

Oversensing can lead to significant bradycardia or asystole when the pacemaker inappropriately senses electrical activity that is not an atrial or ventricular depolarization and does not pace. Treatment consists of placing a magnet over the pacer and converting the pacer to asynchronous mode.

Selected Technical Issues

Pacemakers

- Evaluation of pacemaker function
- Battery failure
- Failure to capture
- Failure to pace (output failure)
- Oversensing
- Undersensing
- Pacemaker syndrome
- Pacemaker-mediated tachycardia
- Runaway pacemaker
- Infection
- Defibrillation and cardioversion in patient with pacemaker

Internal defibrillators

- Evaluation of internal defibrillators
- Failure to convert arrhythmia
- Discharge of defibrillator (appropriate and inappropriate)

Discussion of Individual Technical Issues

Pacemakers

Cardiac pacemakers are becoming an increasingly common component in the care of children with cardiac diseases. As with adult patients, the most common indication for pacemaker insertion in children is symptomatic bradycardia. In patients with complete or partial heart block, the site of the block, type of escape rhythm, and permanence of the block are also factors. Patients with a block below the atrioventricular (AV) node or who are symptomatic regardless of the site of block should receive a permanent pacemaker. Heart block may originate from congenital problems in any portion of the conduction system, from channelopathies, or from surgical damage stemming from repair of structural anomalies. Children with dilated cardiomyopathies or bundle branch blocks may utilize multiple-chamber pacing patterns to synchronize atrial and/or ventricular activities. In children with anatomic repairs and univentricular heart syndromes, multilead ventricular pacing has been used to coordinate mechanical heart activity and thus maximize cardiac output. Rate control devices are also placed for overdrive pacing of intra-atrial reentrant tachycardias, a common arrhythmia in children following atrial surgeries.¹⁻⁵

In general, pacemakers are described by four or five letters (Table 176–1). The first letter describes the chamber or chambers being paced. The second letter describes the chambers being sensed. The third letter describes the action taken on a sensed event. For example, the most common mode is DDD. In this mode, both chambers are paced and sensed and, for each sensed atrial or ventricular event, the pacemaker both inhibits the chamber sensed and paces the other chamber. The fourth letter describes rate modulation. A rate-responsive pacemaker has a motion or temperature sensor that raises or lowers the rate of the pacemaker to match heart rate and metabolic demands by increasing cardiac output.⁶ The fifth letter describes the anti-tachydysrhythmia functions.

Pacer leads may be placed transvenously into the endocardial surface of the heart chamber or coronary sinus. They may also be screwed into the epicardium of the heart. Epicardial leads are more common in children because of the

Table 176–1 North American Society of Pacing and Electrophysiology Generic Pacemaker Code

I Chamber Paced	II Chamber Sensed	III Response to Sensing	IV Programmability, Rate Modulation	V Anti-tachydysrhythmia Functions
O—none A—atrium (A) V—ventricle (V) D—dual (A and V)	O—none A—atrium V—ventricle D—dual (A and V)	O—none T—triggered I—inhibited D—dual (A triggered and A + V inhibited)	O—none P—simple programmable M—multiprogrammable C—communicating	O—none P—pacing S—antidysrhythmia shock D—dual pacing and shock

difficulties in maneuvering transvenous leads within the heart of patients with complex anatomic repairs. Whenever possible, the pulse generator for the pacemaker is placed in an infraclavicular pocket on the child's anterior chest wall. An abdominal wall insertion may be used in very small children or those requiring epicardial leads. Recently, femoral vein approaches to transvenous pacemakers have been developed that also utilize an abdominal wall site for the pulse generator. Pacemakers placed in a small child generally contain redundant lead length to accommodate the growth of the child.⁷⁻¹⁴

All characteristics of a permanent pacemaker may be set via a dedicated programmer device. Unfortunately, each company has a unique programmer that only functions with their devices. However, all pacemakers respond to placement of an external magnet. Placement of a magnet over the pulse generator of a pacemaker turns off all programmed functions and forces the pacemaker to pace at a fixed rate regardless of the heart's activity.

Evaluation of Pacemaker Function

Evaluation of pacemaker activity and function is through surface monitoring of cardiac electrical activity. Because a pacemaker's impulse is transmitted through the myocardium and not along any specialized conduction pathways, the wave front spreads slowly, leading to wide, bizarre-appearing QRS complexes on electrocardiograms (ECGs) and cardiac monitors. The pacemaker impulse appears as a very thin spike on the monitoring device, generally followed by depolarization of one or more chambers. Newer cardiac monitors have the ability to isolate the pacemaker spikes and highlight them specifically on the monitor screen.

Pacemakers have two general functions: sensing and pacing. The sensing function of a pacemaker describes its ability to detect electrical activity within a given chamber of the heart. The interval between intrinsic electrical events is used to calculate the child's heart rate and determine the need for pacing activity. Pacemakers placed to treat bradyarrhythmias will initiate pacing when the native heart rate falls below the desired rate, while those implanted to treat tachyarrhythmias begin activity when too rapid a heart rate is detected. The sensing function of a pacemaker can be estimated through observation of a continuous cardiac monitor. Initiation of pacemaker activity when the native rate falls below or exceeds threshold settings indicates proper pacer sensing. Initiation of pacing activity while the heart rate is still within an acceptable range indicates failure of the pacemaker to properly sense or analyze electrical activity in the heart.

Assessment of capture requires pacer activity to determine if the impulses generated by the pacemaker produce mechan-

ical activity in the heart. Proper capture is confirmed by demonstration of appropriate heart activity following each pacer spike. In a child whose native heart rate is within his or her defined range, no pacer activity should be evident and no evaluation of the pacemaker's capture will be possible. In these patients, the pacemakers may be placed into the asynchronous mode by placement of the magnet over the pulse generator to suppress the sensing function and begin pacing at a fixed interval. Pacer spikes should be evident on the cardiac monitor with associated QRS complexes. No QRS complexes in the presence of pacemaker activity indicate failure to capture. The complete absence of pacer spikes indicates a malfunction in either the lead or the pulse generator.

An accurate history and physical examination associated with a 12-lead ECG are the first steps in the evaluation of a child with a pacemaker. Chest radiography is obtained to ensure that all components and leads are connected. Relevant questions include the indications for the pacemaker, the number of leads, the age of the pacemaker, and the name of the company that produces the device. The name of the company is necessary should a pacer representative need to be called to interrogate the pacemaker. All of this information is contained on wallet cards provided when the pacemaker is inserted. Family members may need to be asked specifically about this card.

Battery Failure

A pacemaker's battery life varies from 3 years in a dual-chamber pacemaker for a small child to 15 years for a large single-chamber pacemaker that works infrequently. When the battery starts to fail, there is a gradual slowing of the paced rate if the pacemaker is pacing continuously. When the battery nears complete failure, there may be failure to capture or failure to pace.

Failure to Capture

Failure to capture indicates that a pacing spike is present on the ECG without associated cardiac depolarization. Causes of failure to capture include high thresholds with an inadequately programmed output, pacemaker component failure, disconnection or dislodgment, impending battery depletion, air in the pulse generator pocket with a unipolar pacemaker, and elevated thresholds due to drugs or metabolic abnormality. A patient's cardiac rhythms will revert to the specific arrhythmia for which the pacemaker was inserted. For children with underlying bradyarrhythmias, this may lead to complaints of syncope, light-headedness, and fatigue. In children with pacemakers inserted for overdrive pacing, complaints of palpitations, syncope, or nervousness may be noted. The diagnosis of capture failure is confirmed by placing the

pacemaker into its fixed mode and demonstrating a pulse generation without associated myocardial activity. Emergency department (ED) treatment of capture failure depends on the clinical scenario.

If use of a magnet does not generate a pacing rhythm with myocardial activity and palpable pulses, a number of possibilities must be considered. If pacemaker spikes appear on the monitor without capture, then scar tissue may have formed at the lead insertion site, requiring a stronger impulse to initiate capture. Treatment is through the reprogramming of the pulse generator to increase lead output. If no pacemaker spike is noted on the monitor, the device may not have any battery function remaining. Treatment of these patients requires replacement of the pulse generator. An absent pacemaker spike may also indicate a fracture of the pacemaker lead or insulation. Chest radiographs should be obtained on these patients to search for lead fractures. Regardless of the cause, any symptomatic patient with a pacemaker dysfunction requires transcutaneous pacing or placement of a temporary transvenous pacemaker. Consultation with an electrophysiologist for pacemaker evaluation and definitive treatment is prudent.

Failure to Pace (Output Failure)

Failure to pace, or failure to output, is often due to oversensing and inhibition of output. It could also be due to true failure to output from the pacemaker or circuit interruption that prevents the electrical signal from reaching the heart. The reasons for failure to output are circuit failure, pacemaker component failure, fracture or dislodgement, total battery depletion, oversensing of noncardiac activity, cross talk (atrial pacing output is sensed by the ventricular sensing circuit, with subsequent inhibition), air in the pocket of a unipolar device, and unipolar pacemaker not in the pocket.

Oversensing

Oversensing occurs when the pacemaker inappropriately senses electrical activity that is not an atrial or ventricular depolarization. This oversensing may result from lead fracture, insulation breakdown, or lead placement in proximity to skeletal muscle. Because oversensing creates the impression of cardiac activity when none is present, it can lead to suppression of pacemaker activity and clinical asystole. Oversensing is easily treated with conversion of the pacemaker to an asynchronous mode through placement of a magnet.

Undersensing

Undersensing occurs when the pacemaker fails to detect or sense normal cardiac activity. Children may be asymptomatic or may complain of palpitations. The ECG may be normal or may not show a normal response to electrical signals (e.g., a DDD system showing P waves without corresponding QRS signals). Functional undersensing occurs when a normal cardiac depolarization is not sensed because it falls within a programmed refractory period. Sensing abnormalities can be seen secondary to insulation defects, component failure, or normally functioning pacing systems that fail to detect atrial or ventricular extrasystoles. Other causes include a new bundle branch block, ventricular and atrial arrhythmias, lead problems, battery failures, and programming errors (too high of a sensing threshold).

Fusion beats and pseudofusion occur as a result of superimposition of an ineffective pacemaker stimulus on a spon-

aneously occurring P wave or QRS complex. Fusion beats occur when a paced beat is superimposed upon a normal cardiac depolarization. Pseudofusion occurs when the normal cardiac beat morphology is altered by the superimposed pacing artifact. This usually occurs when the pacing rate and the intrinsic rate are similar. Pseudofusion also can be due to delayed activation due to intraventricular conduction abnormalities.

Reprogramming the pacemaker's sensing threshold to allow the extrasystoles to be sensed can resolve undersensing. Alternately, leads may need to be repositioned. In the ED, placing a magnet over the pacemaker may convert resulting abnormal rhythms to a relatively stable fixed rate.

Pacemaker Syndrome

Pacemaker syndrome occurs with suboptimal pacing modes or programming that leads to abnormal AV synchrony (especially with VVI or VVO pacers) or AV dyssynchrony (with increased atrial pressure, cannon waves, etc.). When this occurs, there is no atrial contribution to cardiac output. Patients may have diminished cardiac output, hypotension, syncope, and shortness of breath. Management consists of reprogramming, repair, or replacement of the pacemaker.

Pacemaker-Mediated Tachycardia

Reentry tachycardia can occur with dual-chamber pacers with atrial sensing and the pacemaker acting as part of the reentry circuit. The rate is variable but cannot rise above the programmed upper limit of the pacemaker. Application of a magnet usually stops this reentry circuit. Adenosine, carotid massage, and external pacing (pulse width of 40 msec) are alternative ways to end this tachycardia if the rhythm is refractory to magnet application.

Runaway Pacemaker

A runaway pacemaker occurs when inappropriate rapid discharges occur, potentially leading to ventricular tachycardia or fibrillation. It is most commonly due to pacemaker component failure. Applying a magnet may slow the rate, and emergency pacemaker interrogation and reprogramming will be required. If magnet application is unsuccessful, surgery may be needed to disconnect the leads.

Infection

As with all implanted foreign objects, any portion of a pacemaker may become infected. Intravascular components, such as pacemaker leads, behave essentially the same as bacterial endocarditis when infected. Infections of the pulse generator appear as inflammation over the insertion site with erythema, swelling, and tenderness. Regardless of how benign such infections appear, any inflammation in this area should be treated aggressively with blood cultures, intravenous antibiotics, and immediate consultation with an electrophysiologist and surgeon.¹⁵

Defibrillation and Cardioversion in Patients with Pacemakers

If electrical cardioversion or defibrillation is required in a patient with a pacemaker or defibrillator, the paddles should be placed as far from the pulse generator as possible. Also, paddles should be placed perpendicular to the axis of the pacemaker generator and electrodes (usually anteroposterior

placement). An external pacemaker must be ready after any cardioversion/defibrillation since the electrical shock may disrupt the internal pacemaker and external pacing may be required.

Internal Defibrillators

Tachyarrhythmias are a common problem in pediatric patients either as congenital reentry tracts, ion channel abnormalities, or disruptions of normal conduction pathways secondary to corrective anatomic surgery. Some atrial arrhythmias may be treatable with overdrive pacing but, for many tachyarrhythmias, cardioversion remains the only effective means of termination.^{1,2}

Automated implantable defibrillator (AID) is a generic term used to describe all devices that convert cardiac rhythms through myocardial depolarization. Unlike surface paddles, which depolarize the entire heart, AIDs utilize specifically placed electrodes to depolarize only a strategic portion of the heart to effect rhythm conversion. Modern defibrillation leads employ large-surface-area coils located in the chambers they are trying to defibrillate, which is almost always the ventricles. This configuration, in combination with a biphasic waveform, has drastically reduced the defibrillation thresholds of energy needed to terminate arrhythmias.¹⁶

Evaluation of Internal Defibrillators

As with pacemakers, it is best to have an electrophysiologist and a technician perform a formal interrogation of the AID when evaluating its performance. Unless an arrhythmia occurs during the ED visit while the patient is monitored, it will be difficult for ED personnel to assess the AID's sensing or rhythm conversion functions. Similarly, inappropriate discharge can be recognized only if the device discharges while the child is monitored and in a stable rhythm. Unlike with a pacemaker, placement of a magnet on an AID simply inactivates all functions in the device rather than placing it in a fixed mode.

The clinical presentation of a child with a malfunctioning AID depends on the indication for the device and the nature of the problem. Internal defibrillator dysfunction generally presents as either a failure to convert a dysrhythmia or inappropriate discharge when a tachyarrhythmia is not present.

Failure to Convert Arrhythmia

Failure to convert an arrhythmia will generally result in an ED complaint of palpitations, syncope, or, if a lethal arrhythmia occurs, cardiac arrest. Conversion failure may stem from an inability of the AID to recognize the presence of the tachyarrhythmia. If the rate of the rhythm is below the threshold for which the AID is programmed, the arrhythmia will not be recognized and cardioversion will not be attempted. Alternately, not every discharge of the AID will result in a rhythm conversion, and even a properly functioning defibrillator may not successfully convert an arrhythmia. Finally, as with pacemakers, lead fracture can also be a source of conversion failure.

Discharge of Defibrillator (Appropriate and Inappropriate)

Inappropriate discharge of an AID is impossible to determine without a formal interrogation of the device. The child may complain of feeling the device discharge without any of the

sensations typically associated with his or her arrhythmia. However, it is still possible that the AID converted the arrhythmia before the patient became symptomatic. If the device is observed to discharge inappropriately in the ED, a magnet should be secured in place over the device to prevent any further discharges until formal interrogation and reprogramming can be performed.

A child who has had an appropriate discharge of the AID requires evaluation for underlying malignant arrhythmias. This may involve an evaluation for electrolyte abnormalities, anemia, and hypoxia, and a new and old medications review. Most children will require admission for continued cardiac monitoring and correction of the underlying disease.

Summary

As with every child, the ED disposition of children with pacemakers or internal defibrillators will be a function of the underlying condition, the presenting complaint, and the degree to which the problem was resolved during the ED visit. If the treating clinicians can assure that the child's device is functioning correctly at the end of the ED visit, then a discharge to home is appropriate. In some patients, evaluation of the device may prove entirely normal in the ED and the cause of the child's complaints will not be evident. In these children, discharge to home may still be considered if the underlying problem is relatively minor, such as a supraventricular tachycardia with no associated symptoms. Arrangements for an outpatient Holter monitor and close outpatient follow-up are prudent. In children with more severe underlying rhythm disturbances, such as syncope associated with heart block or ventricular fibrillation, hospital admission or formal consultation with an electrophysiologist will be required.

Paraphimosis Reduction

Fred Schwartz, MD

Key Points

Paraphimosis is the inability to return the retracted foreskin of an uncircumcised male back to its original position. This condition is a urologic emergency and requires urgent reduction.

In most cases, manual reduction can be safely performed by the emergency department (ED) physician. Alternative methods have been utilized for paraphimosis reduction as well, though none has been well studied in the pediatric population.

If ED reduction is unsuccessful, prompt surgical consultation should be obtained.

Indications and Contraindications

In children, paraphimosis most commonly occurs after a parent has fully retracted the foreskin of the son (Fig. 177-1). The condition may also follow urethral catheterization if the practitioner fails to return the retracted foreskin back to its normal position.

Preparation and Consent

Examination will typically reveal swelling of the retracted foreskin that constricts the neck of the penis. This interferes with venous drainage from the glans, resulting in glans enlargement to the point that the prepuce cannot be retracted over it. Pain may or may not be present. If left untreated, necrosis may develop, the signs of which include blackened areas on the glans or prepuce.

No diagnostic testing is required prior to paraphimosis reduction.

Analgesic medications are required prior to reduction. Local anesthesia consists of lidocaine 2.5%, and prilocaine 2.5% cream applied to the glans and distal penis. Often, procedural sedation is also required. Although dorsal penile blocks are sometimes used in adults, it is more appropriate to utilize sedation in the pediatric population.

Equipment

- Glove
- Bucket of ice
- Lidocaine 2% gel, or lidocaine/prilocaine (2.5/2.5%) cream, or lidocaine 1% without epinephrine
- 27-gauge needle with syringe for local anesthetic
- 18- or 20-gauge needle with syringe
- Babcock tissue clamps
- Tuberculin syringe
- Hyaluronidase, 150 units/ml (1 ml)
- 4 × 4 gauze
- No. 11 blade scalpel (if dorsal slit is considered)

Monitoring

Monitoring of the patient is necessary only if the patient undergoes sedation (see Chapter 159, Procedural Sedation and Analgesia).

Technique

Decreasing Edema

Local anesthesia is administered alone or in combination with parenteral sedation with analgesia. Prior to manual or surgical attempts at reducing a paraphimosis, an attempt at decreasing penile edema is indicated. A latex or rubber glove is partially filled with ice and water. The partially filled glove is then placed around the glans and distal swollen penis so that it conforms to the shape of these structures. At least 15 to 20 minutes are allowed to pass before manual reduction attempts. Another method for reducing edema is the injection of hyaluronidase (~1 ml) directly into the connective tissue. This agent causes fluid to cross tissue planes and quickly decreases edema.¹

Manual Procedures

Manual reduction is attempted after anesthesia, analgesia with sedation, and local measures to reduce edema. Prior to attempting foreskin manual reduction, the foreskin should be compressed manually with 4 × 4 gauze or the distal penis wrapped with an elastic or Kerlix bandage for 10 to 15 minutes. To reposition the foreskin, direct pressure is applied on the glans with the thumbs of both hands while pulling the prepuce forward with the index and middle fingers. Gentle, steady pressure is maintained until the foreskin

FIGURE 177-1. Paraphimosis. The foreskin has been retracted proximal to the glans penis and has become markedly swollen secondary to venous congestion. (From Urologic disorders in infants and children. *In* Nelson's Textbook of Pediatrics, 17th ed. p 18114.)

returns to its normal position, completely covering the glans (Fig. 177-2).

If this maneuver is unsuccessful, the retracted foreskin is grasped with the Babcock clamps. Traction is gently applied to reduce the foreskin over the glans (Fig. 177-3).

Alternatives

Puncture Technique

To perform this technique, an 18- or 21-gauge hypodermic needle is inserted into the edematous foreskin at several sites to release the trapped fluid. External drainage can improve edema, with subsequent manual reduction of the foreskin.^{2,3}

Dorsal Slit

If a severely constricting band of tissue cannot be reduced by conservative or minimally invasive therapy, an emergency bedside dorsal slit procedure can be performed, followed by a delayed circumcision. Ideally, this procedure is performed in the operating room. However, if timely consultation is unavailable and there is concern about impending necrosis, emergency department (ED) performance of this procedure is appropriate. To perform this procedure, a dorsal nerve block or local anesthesia is administered at the site of intended incision and sedation with analgesia is administered. An incision is made vertically through the foreskin while avoiding the glans and dartos fascia, which lies just under the skin. Finally, the distal and proximal end of the incision are approximated with absorbable sutures (Fig. 177-4).

Complications

If the paraphimosis is not successfully reduced, gangrene or permanent damage to the penis may develop. A urologist should be emergently consulted.⁴

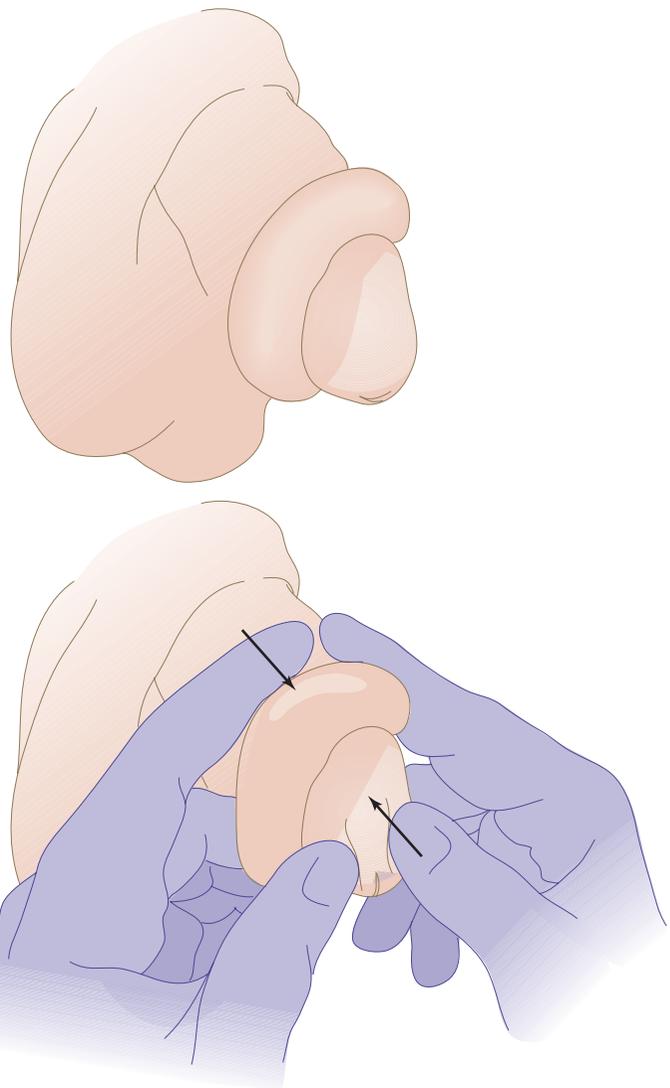

FIGURE 177-2. Manual reduction technique.

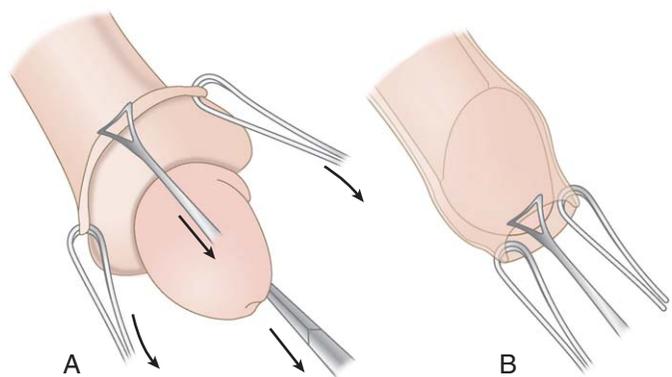

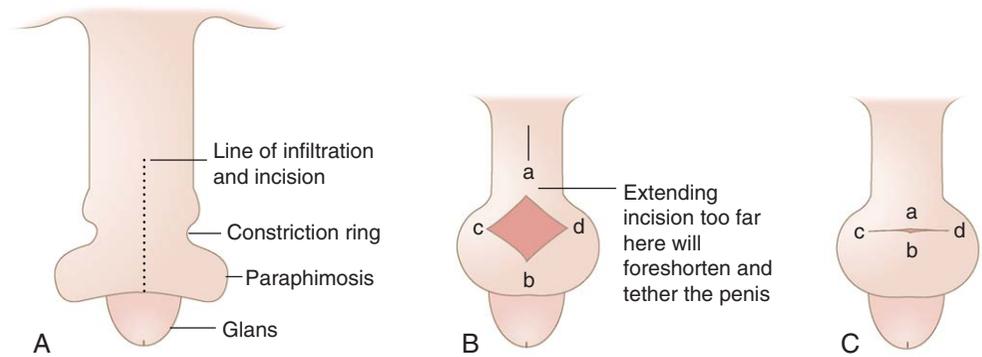

FIGURE 177-3. **A**, Application of Babcock clamps to reduce paraphimosis. **B**, Foreskin reduced. (From Skoglund RW, Chapman WH: Reduction of paraphimosis. *J Urol* 104:137, 1970. Reproduced by permission. © Williams & Wilkins, 1970.)

FIGURE 177-4. Anesthetizing the penis for surgical treatment of paraphimosis. **A**, Line of infiltration of local anesthesia used before performing dorsal slit. **B**, Incision for paraphimosis. A diamond-shaped defect results from incision of the foreskin. **C**, The two apices of the dorsal slit (*a* and *b*) are approximated after the foreskin is reduced. (From Roberts J, Hedges J: *Clinical Procedures in Emergency Medicine*, 4th ed. Philadelphia: Elsevier Saunders, 2004, pp 739–744.)

Postprocedure Care and Disposition

Once the paraphimosis is reduced, the patient may be safely discharged home. The outcome is usually excellent, with rapid return to normal function. The length of the ED stay is generally determined by the duration of the sedation only. A urology follow-up should be arranged for possible elective circumcision to prevent recurrences.

Chapter 178

Fracture Reduction and Splinting Techniques

Gregory Garra, DO

Key Points

Open fractures, grossly unstable or unacceptably displaced fractures, irreducible dislocations, and injuries associated with circulatory compromise or compartment syndrome require emergent orthopedic consultations.

Neurovascular assessment should be documented both before and after any orthopedic manipulation or splinting.

Fractures resulting from high-energy injuries or long-bone fractures should be assessed for signs of compartment syndrome: pain, paresthesia, paralysis, pallor, and pulselessness.

Correct splinting of a fracture should immobilize the joint above (proximal to) and below (distal to) the injury in a position of function.

Indications and Contraindications

Indications for orthopedic consultations vary between institutions. An accurate clinical and radiographic interpretation is essential for formulating an appropriate treatment plan. Description of the injury should include the status of the overlying skin (open vs. closed, with or without tenting of the skin), orientation of the fracture line, anatomic location of the fracture, amount of displacement, degree of angulation, presence of shortening or malrotation, involvement of joint or growth plate, and neurovascular status. Generally accepted indications for emergent orthopedic consultation include open fractures, grossly unstable or unacceptably displaced fractures, irreducible dislocations, and injuries with associated vascular compromise or compartment syndromes. In emergency departments (EDs) with teleradiology, information provided by electronically transmitted radiographs to orthopedic specialists may help to further improve treatment plans.¹ Splinting is used to temporarily stabilize an

unstable fracture in the ED or to immobilize an injury that requires orthopedic follow-up.

Immediate reduction is indicated for all dislocations that are associated with absent or diminished pulses. Open dislocations often need reduction in the operating room with thorough irrigation of the involved joint and débridement of devitalized tissue. In addition, hip dislocations must be performed within 1 hour—for every minute they are out, the avascular necrosis rate rises 1% in adults; more time is allowed for children. Most other simple, closed dislocated joints can be reduced in the ED.

Preparation and Consent

As with any procedure, proper preparation is paramount. The extremity should be completely exposed. The extremity should be free of potential tourniquets such as jewelry, pant legs, or shirt sleeves. All materials must be measured and cut to size prior to formation of the splint. The length can be estimated by laying the dry splint next to the area to be splinted. The width of the splint should be slightly greater than the diameter of the limb to be immobilized. Elastic bandages should be open and readily available to secure the splint in place. Tape should be available to secure the elastic bandages. Splints involving the fingers or toes should have padding placed between digits to prevent maceration of interdigital surfaces.

Safe and effective management of fracture-related pain in the ED reduces patient distress during initial evaluation and often facilitates definitive management of the fracture.² Analgesics should be given in almost all cases of musculoskeletal injury. Administration of medicine should occur as early as possible to prevent unnecessary suffering. Procedural sedation should be considered for fractures and dislocations that require manipulation. In anticipation of procedural sedation, patients should be instructed by nursing personnel to refrain from oral intake until further notification.

Equipment

Plaster Slabs

Nearly any splint can be fabricated from cotton bandages (Webril), plaster, and elastic bandages. Most splints can be

formed by “sandwiching” plaster between two layers of padding. The first layer of padding will rest atop the patient’s skin and should be six to eight sheets thick. This is especially important over bony prominences where pressure sores can result. The padding should be slightly longer and wider than the plaster to avoid contact with the skin and prevent irritation. The middle layer is composed of plaster, which will maintain position and immobility. Thickness of the plaster layer depends upon the extremity being immobilized. As a general rule, splints applied to the lower extremity should be constructed of 12 to 15 layers of plaster sheeting to be of adequate strength. Splints to the upper extremity can be constructed of 8 to 10 layers of plaster sheeting. The third or top layer consists of a thin layer of padding (two to three sheets) to prevent the elastic bandage from adhering to the plaster and losing compressibility.

Prefabricated Molds

Although limited in scope and application, prefabricated molds may have some application in the management of pediatric fractures.³ The most commonly available prefabricated molds are finger splints, volar wrist splints, knee immobilizers, inflatable ankle molds, and posterior ankle molds.

Prefabricated Splinting Material

Products that combine fiberglass and polypropylene padding into a single preparation are commercially available. They generally cost more than plaster rolls and cotton bandages but reduce the amount of preparation time and are quite versatile.

Fluoroscopy

Although not routinely available to most emergency physicians, portable fluoroscopy equipment may facilitate reduction of fractures and dislocation by providing real-time visualization of the bony structures.

Radiology: Pre- and Postreduction Needs

Evidence on simple anterior shoulder dislocation suggests that one set of radiographs may be sufficient.⁴⁻⁶ Few data exist on the need for pre- and postreduction radiographs of simple dislocations involving the patella or interphalangeal joints. Dislocations of other joints and fracture/dislocations should have both pre- and postmanipulation radiographs.

Monitoring

Vascular function should be assessed both before and after reduction maneuvers. Signs of vascular compromise such as delayed capillary refill or weak/absent pulses require emergent intervention. Significant swelling within a closed space can result in increased pressure and further compromise of blood flow. Systolic pressure measurement using Doppler ultrasound is a sensitive predictor for arterial injury. When compared to the unaffected extremity, the arterial pressure should be more than 0.9 times the contralateral value. A value less than 0.9 has a sensitivity of 95% and a specificity of 97% for major arterial injury.⁷ Angiography is useful in confirming a suspected arterial injury.

Nerve injuries may result from fractures, dislocations, or manipulation of an orthopedic injury. Proper neurologic evaluation should focus on motor and sensory function of

the individual peripheral nerves supplying the injured extremity. Although nerve injuries are not immediately reversible, documentation and follow-up are important.

Techniques

Reductions

Shoulder

Numerous methods for shoulder reduction are described. Each method has its advantages.

EXTERNAL ROTATION

The external rotation technique is a gentle technique that may obviate the need for procedural sedation.⁸ With the elbow flexed at 90 degrees, gentle, slow external rotation is applied to the humeral head. Most reductions will occur between 70 and 110 degrees of external rotation. If unsuccessful, applying longitudinal traction on the humerus while abducting the humeral head may facilitate reduction.

SCAPULAR MANIPULATION

This technique involves rotating the inferior border of the scapula medially while applying longitudinal traction to a 90-degree flexed shoulder. The patient may be positioned prone on the gurney or sitting upright.⁹

STIMSON TECHNIQUE

This technique is performed with the patient positioned prone with the affected arm hanging off the stretcher. A 10- to 15-pound weight is strapped to the distal forearm or wrist and allowed to hang for 20 to 30 minutes. Gentle external rotation of the humeral head may facilitate reduction. This technique may be combined with scapular manipulation in failed cases.¹⁰

Nursemaid’s Elbow (*Radial Head Subluxation*)

Nursemaid’s elbow is a common injury of young children and usually results from sudden traction of the distal forearm/wrist applied to an extended elbow. Two methods of reduction are available. In both methods, the child should be placed in the parent’s lap so that both the parent and child are facing the physician. The parent is instructed to hold the uninjured arm. The physician embraces the child’s hand as in a handshake, placing the other hand on the radial head. Reduction is accomplished by recreating the forces that resulted in the injury. Gentle longitudinal traction is applied at the elbow, the wrist is supinated, and pressure is applied to the volar aspect of the radial head. Flexion at the elbow is the final maneuver that serves to reduce the radial head. If this maneuver is unsuccessful, the physician may attempt an alternative technique that involves wrist hyperpronation with elbow flexion. Both methods are reported to have equal success. However, the hyperpronation method may be less painful.¹¹

Fingers and Toes

Dorsal dislocations of the interphalangeal joints of the hand are commonly encountered in the ED. Reduction of the second to fifth digits is easily accomplished by applying longitudinal traction and slight hyperextension of the affected digit, followed by flexion of the affected joint. In simple

dislocations that do not involve an avulsion fracture or entrapment of the volar plate of the interphalangeal joint, the physician will feel the dislocation slide smoothly over the rounded surface of the head of the phalanx.

Reduction should always be followed by an appropriate examination of ligamentous integrity as well as neurovascular function. Injury to the central slip of the extensor tendon may result in the formation of a boutonnière deformity. Signs suggestive of central slip injury are swelling and ecchymosis at the base of the middle phalanx. Tendon injury should be suspected if the patient loses more than 15 to 20 degrees of active extension of the affected finger with the wrist and metacarpophalangeal joints in full flexion.¹² All patients with suspected central slip injury should be treated with a dorsal finger splint across the proximal interphalangeal (PIP) joint in extension, leaving the distal interphalangeal (DIP) joint free. Follow-up evaluation with a hand surgeon is warranted.

Hip

Hip reductions should be done in consultation with an orthopedic surgeon as they are frequently associated with other injuries to the lower extremity or pelvis. Hip dislocations should be corrected within 6 hours of the injury to minimize the incidence of avascular necrosis of the femoral head¹³ and sciatic neuropathy.¹⁴ Two types of dislocations can result: anterior and posterior. Both injuries require procedural sedation. Anterior hip dislocations are treated by applying in-line traction with flexion and internal rotation of the hip. Multiple methods for reducing posterior hip dislocations are described.¹⁵ One of the more commonly employed methods (the Allis maneuver) places the patient in a supine position. An assistant stabilizes the pelvis by applying a downward force over the bilateral iliac crests. Longitudinal traction is applied to the femur in the direct line of the deformity, followed by gentle flexion of the hip to 90 degrees, followed by gentle internal and external rotation of the hip until reduced.

Knee

Many knee dislocations may reduce spontaneously. Therefore, physicians must maintain a high index of suspicion in patients who report such an event or present with injury to three or more of the major knee ligaments.¹⁶ These injuries are often associated with injuries to the popliteal artery and peroneal nerve. Most authorities recommend angiography to assess vascular integrity in all suspected knee dislocations. However, a thorough physical examination, checking foot pulses and the ankle-brachial index, may obviate the need for such studies.¹⁷ Prompt reduction is important to prevent further neurovascular injury. Knee reductions should be performed in consultation with an orthopedic surgeon. Both anterior and posterior knee dislocations uniformly involve disruption of ligamentous structures, resulting in a highly unstable joint. Reduction is accomplished by applying in-line traction to the lower extremity, with manipulation of the proximal tibia according to the direction of the dislocation.¹⁶ For anterior dislocations, the femur is lifted, while for posterior dislocations, the proximal tibia is lifted while an assistant applies countertraction. The injured extremity should be immobilized and elevated. The patient should be admitted for serial neurovascular examinations.

Patella

Dislocations of the patella usually result in its lateral displacement. Most dislocations reduce spontaneously with terminal knee extension. For those patients presenting with patellar dislocation, reduction is accomplished in the supine position by flexing the hip to 90 degrees, extending the knee to 180 degrees, and applying gentle pressure on the patella directed toward the midline. Following reduction, evaluation of the major knee ligaments is necessary to rule out a concurrent injury. The joint should be immobilized in full extension. Orthopedic follow-up is important to assess for osteochondral fractures and factors that predispose to recurrent dislocations.¹⁸

Ankle and Elbow

Dislocations of the ankle generally result from high-energy trauma and therefore are frequently associated with fractures and significant soft tissue injury. As with other dislocations, injuries associated with neurovascular compromise must be treated immediately. Radiographs are necessary to determine the direction of the dislocation and associated injuries and will facilitate reduction techniques. Although no specific method is described, reduction is typically accomplished by applying longitudinal traction to the foot with gentle manipulation. For dorsal dislocations, the foot is plantar flexed. For anterior dislocations, the foot is dorsiflexed. Immobilization with a posterior mold is necessary until definitive fixation can be arranged.

The elbow is the most commonly dislocated joint in the pediatric population, and dislocations frequently result from a fall on an outstretched hand. As a result of the mechanism, most elbow dislocations are posterior. Soft tissue injuries and associated fractures are common. Prereduction radiographs are necessary to determine the direction of the dislocation, identify associated injuries, and direct management. Elbow dislocations with associated bony fractures generally require treatment with open reduction and internal fixation. Several methods for reduction are described. One such method is reported to be simple and safe, requiring no anesthesia or assistant. The patient is placed supine and the affected limb is draped across the chest. The physician palpates the olecranon and gently pushes it into position while applying traction on the forearm and flexion to the elbow.¹⁹ As with other injuries, neurovascular assessment is important. The most commonly injured neurovascular structure is the ulnar nerve. Vascular injuries are rare.²⁰

Splinting

The choice of splinting techniques used to protect and immobilize fractures and reduced dislocations is extensive. Often, more than one technique can be used for the same injury. Clinicians must keep in mind that the purpose of the splint is to immobilize injuries so that deforming rotational and flexion/extension forces have minimal effect on the fracture site. For this reason, specific angles of flexion/extension and degrees of supination/pronation are often recommended for particular fractures (Table 178–1).

Upper Extremity

SLING AND SWATHE

This device is available as a commercially prepared product or can be fashioned by placing the patient's arm in a shoulder

Table 178–1 Splinting Positions for Various Fracture Types

Fracture Type	Preferred Splinting Position*
Clavicle fracture	Sling; a figure-of-eight bandage is rarely used
Proximal and middle humerus fracture	Long arm hanging cast, coaptation splint, or sling and swathe
Elbow trauma	For undiagnosed injury at elbow, splint elbow at 20–30 degrees of flexion until radiography
Elbow dislocation—postreduction	Long arm posterior splint with elbow flexed 90 degrees
Supracondylar fracture	Type I (nondisplaced or humeral line intersects capitellum)—elbow at 90 degrees of flexion and forearm/wrist neutral or pronated
Lateral condyle fracture	If less than 2–4 mm displacement, long arm splint with elbow flexed 90 degrees, and neutral or supinated forearm
Medial epicondyle fracture	If less than 5 mm displacement, posterior splint or long arm cast with elbow flexed 90 degrees
Olecranon fracture	If ≤ 2 mm displaced, posterior splint with elbow flexed to less than 75 to 80 degrees
Radius fracture	<ul style="list-style-type: none"> • Proximal radius—long arm cast or sugar-tong splint with forearm supinated • Middle radius—long arm cast or sugar-tong splint with forearm neutral • Distal radius—sugar-tong splint with forearm pronated For each of these fractures, make sure that the distal fragment is immobilized in a degree of rotation such that it is aligned with the bicipital tuberosity.
Radioulnar fracture (fracture of both bones of forearm)	<ul style="list-style-type: none"> • Fractures with the apex of the fracture in volar position and distal fragment angulated dorsally—reduce by pronating and splint in pronation • Fractures with the apex of the fracture in dorsal position and distal fragment angulated volarly—reduce by supinating and splint in supination Splint both fractures with flexed elbow and wrist in supination or pronation as described. For unstable fractures, splint elbow in extension.
Metacarpal neck fracture	Splint with metacarpophalangeal joint in maximum flexion, and interphalangeal joints extended
Metacarpal shaft fracture	“Beer (or soda) can” position with metacarpophalangeal joint flexed 70 degrees
First metacarpal, scaphoid, and first proximal phalanx fractures	Thumb spica splint
Knee dislocation—postreduction	Long leg splint with knee flexed 15 degrees
Patella dislocation	Long leg splint with knee in full extension
Tibia spine fracture	Long leg splint with knee flexed 10–20 degrees
Proximal tibia fracture	Long leg splint with knee in full extension
Distal tibia spiral fracture (toddler’s fracture)	Long leg splint with knee flexed 30–40 degrees
Distal tibia fracture	
Ankle tibiotalar dislocation—postreduction	Long leg splint with ankle flexed 90 degrees

*Splint positions assume fractures are nondisplaced or minimally displaced. The exact amount of displacement, degree of angulation, and rotation differ for each fracture type and differ among different experts. Fractures that are more displaced often require pinning or surgery.

sling and securing it against the chest by wrapping the torso with an elastic bandage. The sling serves to support the upper extremity while the swathe limits range of motion at the shoulder and elbow.

SHOULDER IMMOBILIZER

These commercially available devices maintain immobilization of the shoulder, humerus, and elbow by fastening the distal humerus and forearm to a strap that encircles the chest.

SUGAR-TONG SPLINT

This splint is used to immobilize fractures of the wrist and distal forearm, minimizing flexion/extension of the elbow and supination/pronation of the wrist. The splint is applied to the volar and dorsal surfaces of the forearm and hand, extending from the palmar aspect of the midhand around the elbow to the dorsal aspect of the midhand. Proper positioning should maintain 90 degrees of flexion at the elbow and slight extension at the wrist (Fig. 178–1). The splint should not impede flexion of the fingers at the metacarpophalangeal joint and should allow full range of motion of the thumb.

VOLAR SPLINT

This splint has limited applicability and has been largely replaced with prefabricated molds. The splint serves only to limit flexion and extension at the wrist. As a result of the

limited immobilization, volar splints should only be used for stable fractures, such as torus fractures or sprains.

THUMB SPICA SPLINT

This splint is used to immobilize injuries to the first proximal phalanx, first metacarpal, or scaphoid bone. There are multiple variations of a thumb spica splint; however, any variation should accomplish immobilization of the first metacarpophalangeal joint, metacarpal-carpal joint, and wrist. The splint is applied to the dorsum of the forearm and hand and encapsulates the thumb. Proper positioning should maintain slight dorsiflexion at the wrist, thumb abduction, and slight flexion at the interphalangeal joint, extending from the interphalangeal joint of the thumb to the proximal third of the forearm (Fig. 178–2).

LONG ARM SPLINT

The posterior long arm splint is used for the management of injuries to the elbow or proximal forearm. The splint is applied to the ulnar aspect of the forearm, extending from the distal third of the humerus to the midhand. Appropriate positioning maintains the elbow at 90° of flexion with slight extension or neutral positioning of the wrist (Fig. 178–3). The forearm may be maintained in either supination or pronation.

ULNAR GUTTER SPLINT

This splint is used to immobilize fractures of the fourth and fifth metacarpals. A variation of the splint, the radial gutter

FIGURE 178-1. Sugar-tong splint.

FIGURE 178-2. Thumb spica splint.

splint, can be used for management of second and third metacarpal fractures. The splint is applied to the ulnar aspect of the forearm, extending from the tip of the fingers to the proximal forearm (Fig. 178-4). Proper positioning maintains slight flexion at the interphalangeal joints, 90-degree flexion at the metacarpophalangeal joint, and slight extension at the wrist.

FINGER SPLINT

Finger splints are available as commercially prepared products that are generally fashioned from aluminum and foam.

FIGURE 178-3. Long arm splint.

FIGURE 178-4. Ulnar gutter splint.

FIGURE 178-5. Finger splint.

The splint is applied to the dorsal aspect of the finger, extending from the fingertip to the dorsum of the wrist. The proper positioning should maintain slight flexion at the interphalangeal joints (Fig. 178-5). Flexion contracture of the PIP joint is a frequent complication following ligamentous injury, especially after immobilization in more than 20 degrees of finger flexion.²¹ Treatment of a mallet finger injury (avulsion fracture of the dorsal surface of the base of the distal phalanx) is slightly different, requiring hyperextension of the DIP joint only. Commercially prepared products are available or can be fashioned from aluminum and foam.

Lower Extremity

JONES DRESSING

Although not technically a splint, this bulky dressing does create substantial immobilization of the ankle joint. The dressing is fabricated from cotton and elastic bandages. The lower extremity is wrapped with cotton bandage in a bulky

FIGURE 178–6. Posterior ankle mold.

fashion from the proximal aspect of the lower extremity to the forefoot. The cotton bandage is covered with a compressive, elastic bandage. Proper positioning will maintain 90 degrees of angulation at the ankle joint.

POSTERIOR ANKLE MOLD

This splint is used to immobilize injuries of the ankle, hindfoot, or midfoot. The splint is applied to the dorsal surface of the leg extending from the proximal third of the leg around the heel to the plantar surface of the forefoot. Proper positioning maintains the foot at a 90-degree angle to the tibia (Fig. 178–6).

Alternatives

The major alternative to splinting with either plaster slabs, prefabricated molds, or commercially prepared prefabricated splinting material is to place the injured extremity in a cast. Pinning and open reduction with internal fixation may be required if splinting/immobilization does not keep a fracture aligned appropriately.

Complications

Complications arising from application of a splint are uncommon. However, clinicians must be aware of the potential for problems such as pressure sores, allergic reactions, joint stiffness, infections, thermal burns, thrombophlebitis, compartment syndrome, and neurovascular compromise from a tightly fitted splint.

Compartment syndrome is a clinical condition characterized by elevated pressure within a confined fascial space causing circulatory compromise, swelling, and tissue necrosis.²² Increased pressure within closed tissue spaces results from intrinsic or extrinsic factors. Intrinsic factors such as bleeding, soft tissue injury or swelling, tissue toxins, or venous stasis result in increased compartment size and pressure. Extrinsic factors such as constrictive dressings or casts, excessive traction on a fracture limb, or thermal injuries and frostbite exert compressive forces on the closed tissues and reduce compartment size (see Chapter 22, Compartment Syndrome).

Maceration of the skin caused by sweating may result in a breakdown of skin integrity, predisposing to bacterial or fungal skin infections. Pressure sores and skin necrosis typi-

cally result from extrinsic circumferential compression over inadequately or improperly padded bony prominences. Patients with complaints of persistent pain or burning under a splint should be promptly inspected for complications.

Postprocedure Care and Disposition

Discharge instructions should include recommendations for rest, icing, and elevation. In the first 24 to 48 hours, elevation and icing of the injured extremity will limit swelling and prevent untoward events. Patients with upper extremity splints should be instructed to use a sling for comfort and to maintain elevation of the fingers relative to the elbow. Patients with lower extremity splints should limit activity for the first 48 hours and utilize crutches for ambulation. Patients should be educated on the signs and symptoms of neurovascular compromise, and instructed to loosen the splint and return immediately to the emergency department for increased pain or tingling of the extremity. Patients should be encouraged to leave the splint in place until follow-up evaluation with a specialist.

As with any ED visit, appropriate follow-up should be arranged. Although no clear guidelines exist, patients with injuries that are likely to require operative intervention or further manipulation should be seen by an orthopedist within 48 hours. Stable, nondisplaced, nonangulated fractures and simple dislocations of the shoulder, patella, and interphalangeal joints may be re-evaluated within 1 week.

Ultrasonography

Barry G. Gilmore, MD and Jay Pershad, MD

Key Points

Bedside ultrasonography (US) in the emergency department is considered an extension of the physical examination.

The utility of ultrasonography in assessing blunt abdominal trauma in pediatric patients is currently limited by trends in nonoperative management for injuries that result in hemoperitoneum.

Ultrasonography can be used in the setting of cardiac arrest to detect the presence or absence of cardiac motion or cardiac tamponade.

Vascular access can be facilitated by US.

Ultrasonography can facilitate suprapubic aspiration when catheterization is unsuccessful.

Indications and Contraindications

Over the past decade, focused bedside ultrasonography (US) has gained wide acceptance as a tool for advanced trauma care by emergency physicians, and its use is now part of the guidelines for Advanced Trauma Life Support.¹ Currently, there are six main uses of US by pediatric emergency physicians: assessment of patients who have experienced blunt abdominal trauma, assessment of patients who are experiencing cardiopulmonary arrest, visualization of a target vein during vessel cannulation, identifying intrauterine pregnancy/exclusion of ectopic pregnancy (see Chapter 90, Ectopic Pregnancy), visualization of the bladder during suprapubic bladder aspiration or prior to urethral catheterization, and localization and removal of foreign bodies in subcutaneous tissue.

Bedside US is noninvasive and inherently safe for patients of any age. There are no contraindications to the performance of US except those related to interference with a life-saving procedure (intubation, needle thoracostomy, etc.).

Preparation and Consent

Bedside US is a painless procedure that requires little patient preparation other than age-appropriate explanations, the

heating of transducer gel, and, occasionally, patient positioning. Because bedside US is an extension of the physical examination and because virtually no risks are associated with this imaging method, no specific consent separate from the general consent for emergency care is required.

Equipment

Sonographic machines come in all sizes and shapes, from the large complex instruments commonly seen in radiology departments to small, shoebox-sized, handheld machines. Most machines have numerous options and abilities unnecessary for the evaluation of most cases in the emergency department. The primary requirements for a bedside instrument are portability to the bedside, a screen of sufficient size (5 to 7 inches) and resolution (64 to 256 shades of gray), transducers (also known as probes) of different frequencies (3.5 to 7.5 MHz), sufficient image storage, and a printer.

If the personnel operating the device have adequate training and experience, the main consideration in using the device is the selection of the appropriate transducer for the task at hand. The main shapes of transducers and their operating frequencies are listed in Table 179–1.

As the transducer frequency increases (3.5 to 7.5 MHz), the resolution or clarity of the screen image will improve. However, the depth of the sound waves' penetration into the tissue will decrease, and the deeper structures will not be visualized. The choice of the best transducer is based on the balance between clarity and depth.

Once US has been completed, the key images must be documented on continuous videotape or as static pictures or digital images. The ability to review images is essential in establishing and maintaining a program of continuous quality improvement and in providing feedback to trainees.

Monitoring

There is no specific additional monitoring required during US.

Techniques

Focused Assessment Sonography for Trauma

The purpose of focused assessment sonography for trauma (FAST) is to rapidly detect intraperitoneal fluid in patients who have experienced blunt trauma to the torso (see Chapter

Table 179–1 Types of Transducers and Their Features

Transducer Frequency	Shape of Transducer	Situations of Recommended Use
3.5 MHz	Curvilinear (convex)	Adolescent/young adult blunt abdominal trauma Adolescent/young adult cardiac arrest
5 MHz	Curvilinear (convex or microconvex)	Infant/child blunt abdominal trauma Infant/child cardiac arrest
7.5 MHz	Linear	Vascular access Suprapubic aspiration Foreign body localization and management
5–7.5 MHz	Endovaginal (microconvex)	Intrauterine pregnancies Vaginal bleeding or cramping during the first trimester of pregnancy Pelvic pain

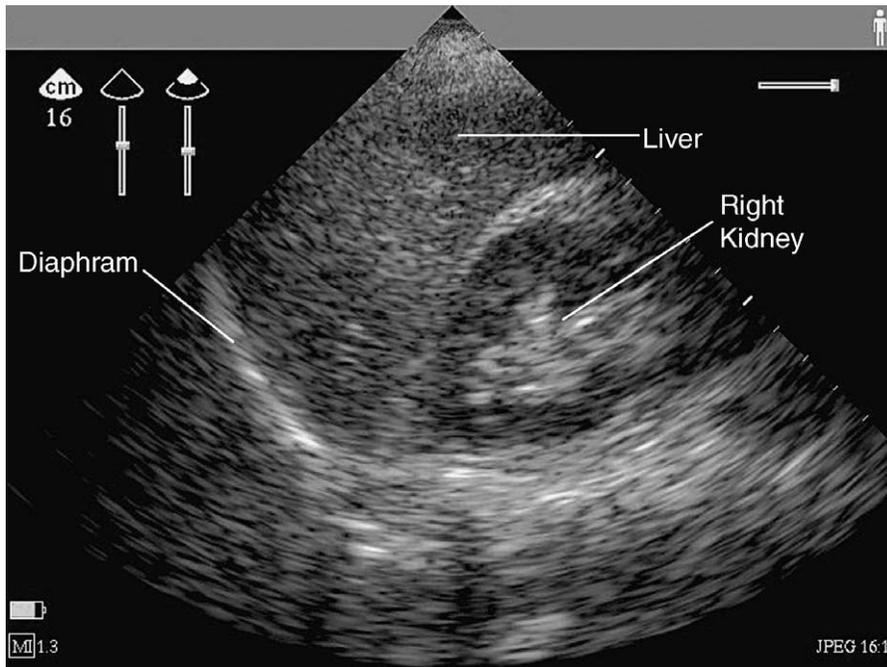

FIGURE 179–1. A positive FAST showing free fluid that appears as a black (anechoic) stripe between the liver and kidney (Morison's pouch). (From Rose JS: Ultrasound in abdominal trauma. *Emerg Med Clin North Am* 22:581–599, 2004.)

25, Abdominal Trauma). When conducted by trained emergency physicians, FAST has a sensitivity between 80% and 90% and a specificity between 95% and 100%.^{2–5} Ultrasonography can consistently detect 200 to 650 ml of free fluid, whereas computed tomography (CT) can detect 100 to 250 ml.^{5,6} FAST has greater sensitivity in the evaluation of hemodynamically unstable patients than in the evaluation of stable ones. In one study, US had 100% sensitivity and specificity in detecting hemoperitoneum related to intra-abdominal injury.⁷

FAST is usually performed immediately after the primary trauma survey and should not take longer than 3 to 5 minutes to complete. FAST is particularly useful for patients who are hemodynamically unstable, have an associated head injury or distracting injury that makes the physical examination unreliable, have progressive hypotension of unknown causes, or are unable to undergo CT.⁸ Because of the current trend toward nonoperative management of parenchymal injury (with or without hemoperitoneum) in pediatric trauma patients, the exact role of FAST has been the subject of controversy.⁹ However, US is easier to conduct in children than in adults, because children have smaller body habitus and less

mesenteric fat. Because of the dynamic behavior of abdominal injuries, serial US examinations can also be performed easily. For these reasons, FAST may assist in triage and prioritization of imaging studies for stable patients. At some institutions, protocols for blunt abdominal trauma recommend a careful physical examination, observation, and serial FAST for stable patients.^{7,10} In standard FAST, four views are used: a subxiphoid view can reveal pericardial fluid, a right intercostal view can show fluid in Morison's pouch and the right paracolic gutter, a left intercostal view permits examination of the perisplenic space and the left paracolic gutter, and a suprapubic view permits examination of the bladder, pouch of Douglas, and uterus (Fig. 179–1).

Limitations and Technical Challenges

Several limitations and technical challenges are associated with FAST. First, the results of FAST are operator dependent. Second, FAST does not generally indicate the source of the intraperitoneal fluid or permit adequate evaluation of injuries in the retroperitoneum, bowel wall or viscus, pancreas, or renal pedicle. Third, FAST is often ineffective in visualizing the splenic recess, which is between the spleen and kidney,

but visualization can be improved by placing the transducer at the level of the eighth or ninth intercostal space along the posterior axillary line. Fourth, US may fail to detect free intraperitoneal fluid in some patients, because its collection depends on patient positioning. Placement of the patient in a slight Trendelenburg position may enhance the chance of detecting abnormal fluid collections, as will serial FAST.

Focused Cardiac Ultrasonography in the Setting of Cardiac Arrest

Focused cardiac US (C-US) is an important noninvasive bedside adjunct to the physical examination in assessing cardiac contractility and determining whether pericardial effusion is present. Emergency physician–directed echocardiography during cardiac arrest is used to diagnose pericardial tamponade and confirm (or refute) a diagnosis of pulseless electrical activity (PEA)^{11–14} (see Chapter 1, Approach to Resuscitation and Advanced Life Support for Infants and Children).

A single subcostal cardiac view is included in the FAST protocol of the ATLS course.¹ Doppler echocardiography,

which is a recommended component of the Pediatric Advanced Life Support (PALS) guidelines created by the American Heart Association, has been shown to distinguish true PEA from “pseudo” PEA.¹⁵ The detection of cardiac activity by US may promote a concerted search for reversible causes. As a corollary, the absence of organized wall motion portends a futile resuscitation. Data from adult subjects in pulseless arrest suggest that bedside C-US discriminates apparent electrical asystole from underlying ventricular fibrillation, which is amenable to electrical countershock.¹⁶

The optimal technique for C-US involves the use of a cardiac transducer with an appropriate frequency (see Table 179–1). The subcostal or parasternal long axis view permits adequate assessment of pericardial effusion and wall motion (Fig. 179–2). The standard subcostal view requires placement of the transducer in the subxiphoid region, aimed extremely superiorly, with the beam directed toward the left side (i.e., with the imaging marker [notch] toward the left side). If the beam is directed to the right, the inferior vena cava entering the right atrium is visualized. The subcostal view is relatively easy to obtain in young children with a thin abdominal wall.

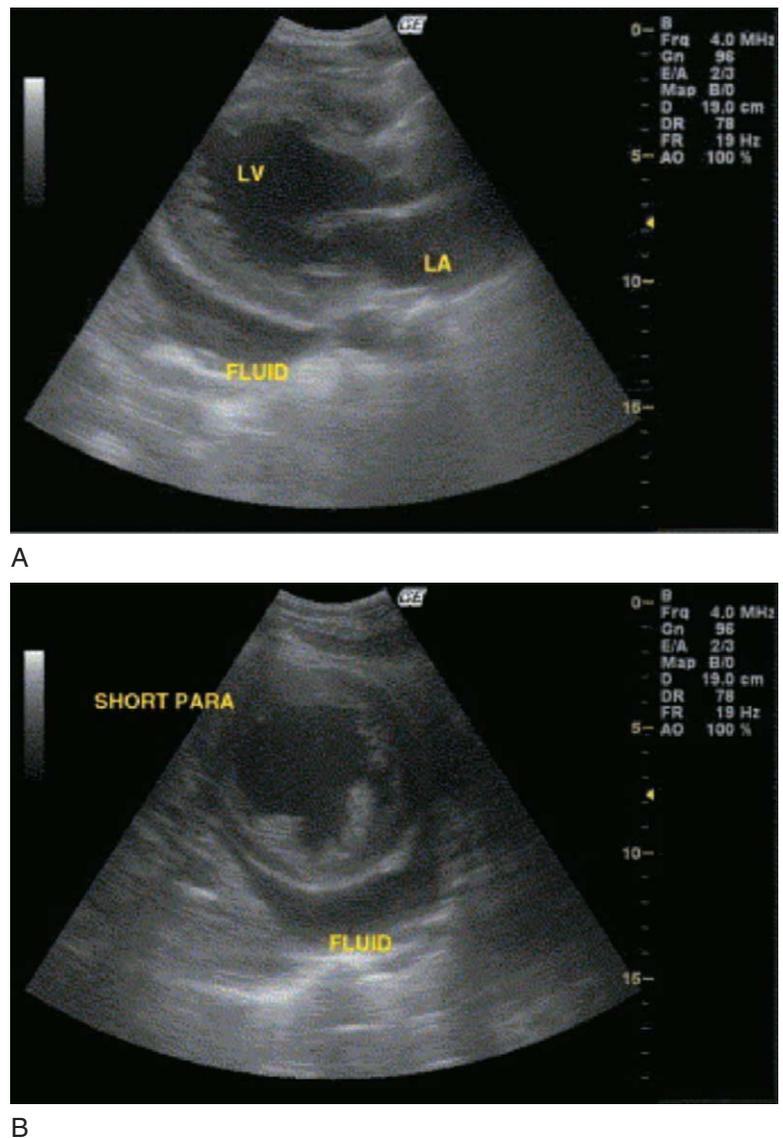

FIGURE 179–2. Focused C-US using the (A) parasternal long axis and (B) short axis views detected a large pericardial effusion (PE). Abbreviations: LA, left atrium; LV, left ventricle. (From Tang A: Emergency department ultrasound and echocardiography. *Emerg Med Clin North Am* 23:1179–1194, 2005.)

Ultrasonography in Attaining Vascular Access

Establishing central or peripheral vascular access in infants and children is a challenge, even in the best of circumstances. Compared with the traditional landmark-based practice, bedside US has the potential to significantly improve the speed and accuracy of vessel cannulation.¹⁷ In 2001, the Agency for Healthcare Research and Quality cited ultrasonogram-guided central line placement as one of its 11 evidence-based practices that should be widely implemented.¹⁸ To date there have been only a few studies of ultrasonogram-assisted venous access in children. Although limited by small sample size, these studies, which did not include emergency department patients, showed 85% and 73% reductions in the relative risk of failure and complications, respectively.¹⁹⁻²¹

Ultrasonography is most commonly used in the cannulation of the internal and external jugular veins, the subclavian vein, the femoral vein, and the brachial and cephalic veins, although theoretically any visualized vein could be cannulated^{22,23} (see Chapter 161, Vascular Access). The two main methods of ultrasonogram-guided venous access (the indirect and direct methods) are described here.

Indirect Method

The indirect method is more commonly used than the direct method and provides less true “guidance.” Once US has located the vessel of interest, a mark that corresponds to the vessel’s location beneath the surface is made on the skin. The optimal situation is usually one in which the mark is between the center of the transducer and the center of the vessel of interest. Before cannulation begins, a “compression” test (one in which the operator applies light pressure to the transducer) should always be conducted to confirm that the vessel is a vein (which easily compresses) rather than an artery (which resists compression). The indirect method requires only one person to perform it and does not involve any special preparations or equipment such as a sterile transducer sleeve or sterile gel.

A variation of the indirect method is one in which two marks (one proximal and one distal, about 1 cm apart) are made on the skin above a vein that was located by US and whose identity was confirmed by the aforementioned compression test. This approach allows the person attempting cannulation to “connect the dots.” When this variation of the indirect method is performed, the patient should be placed in the appropriate position for cannulation before the vessel is marked. Any movement after marking will change the location of the vessel.

Direct Method

In the direct method, US is used to directly visualize the placement of the needle in “real time.” This method can be done with one or two operators, and requires different preparation and equipment than does the indirect method. A sterile sheath or cover whose tip is filled with transducer gel is rolled up over the probe and secured. Great care needs to be taken to ensure that the gel contains no air bubbles, which can distort the image. The transducer is placed over the selected area and the vessel located. If the image of the vessel is centered on the monitor’s screen, the transducer can function as the directional guide. Once the skin is punctured, the

needle can be visualized by its “ring-down” effect. Just before the needle enters the vessel, it will appear to “tent” or become temporarily deformed.²⁴

The US transducer used to guide cannulation of a central or peripheral vessel should be a high-frequency (7.5-MHz) linear one. If unavailable, then the available probe with the highest frequency and smallest footprint should be selected. If a convex or curvilinear transducer is used, the image will be pie-shaped and its edges distorted. The orientation of the transducer (longitudinal or transverse) is a matter of preference and procedure. The longitudinal orientation gives information about depth and slope and helps with needle orientation, whereas the transverse orientation provides information about structures surrounding the vessel of interest.

Ultrasonography in Suprapubic Bladder Aspiration or Prior to Catheterization

Compared to urethral catheterization, suprapubic bladder aspiration (SPA) has an important advantage. The risk of contamination during SPA is minimal; therefore, urine obtained in this way yields fewer false-positive cultures. Moreover, when urethral catheterization is technically difficult, as in uncircumcised male neonates or female neonates with labial adhesions, SPA is useful. However, one limitation of SPA performed in the absence of real-time imaging has been the low success rate of the procedure.

Bedside US can serve as a useful adjunct to SPA. Bladder distention as well as position can be easily confirmed by this imaging method. In several studies, US increased the success rates of SPA: the lowest reported success rate in the absence of US was 36%, whereas the highest success rate of US-guided SPA was 100%.²⁵⁻²⁸ Ultrasonography reduces the number of unsuccessful attempts of SPA; hence, the discomfort of patients is reduced.

In US-guided SPA, the transducer is placed in the transverse plane of the suprapubic area: the operator approaches from the midline of the pelvis and angles the transducer toward the patient’s feet. The bladder will appear as an anechoic (black) structure. If the bladder appears distended, SPA can be performed relatively easily with very little risk to the patient (Fig. 179–3). A transverse diameter of the bladder greater than 3 cm has been associated with high success rates.²⁹

Ultrasonography can be used to determine whether or not a bladder is full and if urethral catheterization will be successful in infants. A bladder index (anterior-posterior diameter × transverse diameter) greater than 2.4 cm² identifies infants with at least 2 ml of urine that can be obtained by urethral catheterization with near 100% accuracy.³⁰ When the bladder index is less than 2.4 cm², obtaining at least 2 ml of urine during catheterization is unlikely.

Ultrasonography in Foreign Body Localization and Management

The most common approach to locating foreign bodies in extremity wounds has been plain radiography (see Chapter 162, Foreign Body Removal). The limitation of plain radiography is that only radiopaque foreign objects (e.g., metal, stone, and glass fragments larger than 2 or 3 mm) are detectable.³¹ However, US can overcome this limitation.

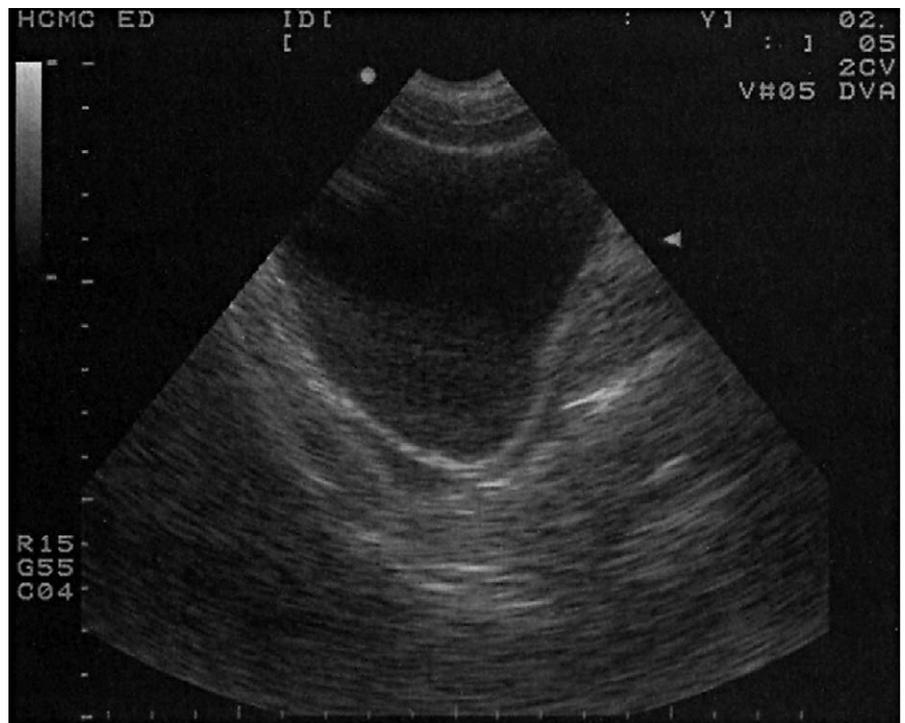

FIGURE 179-3. Suprapubic view of a distended bladder. (From Tibbles CD: Procedural applications of ultrasound. *Emerg Med Clin North Am* 22:797–815, 2004.)

Several clinical studies have demonstrated the utility of US in locating foreign bodies in extremity wounds.^{32,33} What has also been shown is that the skill and experience of the clinician and the size of the object play significant roles in successful detection.³⁴ In general, a high-frequency (7.5-MHz or higher) linear transducer is preferred because most foreign bodies are usually less than 2 cm from the surface. If a lower frequency transducer, which focuses on deeper structures, is used, a stand-off pad can improve the device's ability to detect an embedded foreign object. Stand-off pads are “invisible” to the transducer and serve to raise it to a level where it can focus more closely on the tissue surface. These pads are available commercially or can be created by filling the finger of a glove with transducer gel.

Most foreign bodies are hyperechoic: metal appears to have a “comet tail,” glass appears as a scattered “muddy” image, and rocks appear as “gallstone-like” images. Wood and plastic give fainter and less distinct images that are more challenging to detect.

Alternatives

Despite the convenience and immediate feedback that bedside US gives, it is unable to provide the necessary level of information regarding solid organ, hollow viscus, and retroperitoneal injuries. Hence, abdominal CT remains the imaging study of choice for stable patients with abdominal trauma.

Complications

Although patients may sustain complications from procedures conducted during US or from their overall clinical circumstances, complications directly attributable to US are essentially nonexistent.

Postprocedure Care and Disposition

Patients may require postprocedure care because of the nature of the procedure performed in conjunction with US, but there is no special care is required after US alone.

Pericardiocentesis

Robert Steele, MD and Andrea Thorp, MD

Key Points

Percutaneous pericardiocentesis is the treatment of choice for emergent management of decompensating patients secondary to pericardial effusions.

Ultrasound-guided pericardiocentesis is associated with decreased morbidity and mortality compared to blind needle pericardiocentesis or surgical pericardiectomy.

Following pericardiocentesis, patients should be reassessed for recurrent accumulation of pericardial fluid.

Consider surgical techniques for pericardial effusion evacuation if initial attempts at percutaneous pericardiocentesis fail.

Indications and Contraindications

In an unstable patient, needle percutaneous pericardiocentesis is the treatment of choice for emergent drainage of a pericardial effusion causing hemodynamic decompensation.¹⁻³ In a stable patient, bedside ultrasound-guided pericardiocentesis is the preferred technique because of decreased rates of morbidity and mortality relative to blind needle pericardiocentesis.^{2,4-7} Surgical techniques such as pericardiectomy, pericardial window, or thoracotomy for drainage of pericardial effusions are indicated when percutaneous pericardiocentesis has failed or the patient is hemodynamically stable enough to wait for surgical preparation and management.^{1,2,8} The placement of a percutaneous drainage catheter (pigtail catheter) after pericardiocentesis is associated with higher morbidity and mortality but is indicated if the effusion is at high risk for reaccumulation.^{2,9}

There are no absolute contraindications for blind needle pericardiocentesis in a patient with hemodynamic decompensation secondary to pericardial effusion.^{10,11} Relative contraindications to pericardiocentesis include myocardial rupture, aortic dissection, and blood dyscrasias.^{10,11} Blind needle percutaneous pericardiocentesis is relatively contrain-

dicated when the patient is stable enough to tolerate the time needed to set up an ultrasound-guided pericardiocentesis.^{2,9} Immediate thoracotomy is an important alternative in patients with penetrating injuries to the chest. An asymptomatic pericardial effusion can be medically managed with observation and fluids. Fluids should be the initial intervention as they help to increase preload and increase right atrial pressures, and may buy time while setting up for the pericardiocentesis. Dialysis may also be an appropriate alternate therapy in patients with renal failure.¹²

Patients with cardiac tamponade may present with shock, chest pain, abdominal pain, or dyspnea. Signs of cardiac tamponade include tachycardia, hypotension, tachypnea, narrow pulse pressure, and pulsus paradoxus.¹³ The combination of Beck's triad (muffled heart tones, jugular venous distention, and hypotension) is uncommon in clinical practice (see Chapter 64, Pericarditis, Myocarditis, and Endocarditis).

Preparation and Consent

Prior to performing a pericardiocentesis, clinicians should assess anatomic landmarks and underlying factors that might affect the procedure. Prior chest or abdominal surgery or underlying lung disease might displace or alter landmarks. Patients with bleeding diatheses (e.g., coagulopathy, thrombocytopenia) may require fresh frozen plasma, platelets, or other factors prior to or concurrent with performance of the procedure. Placement of a nasogastric tube should be considered if there is abdominal distention, to reduce the possibility of abdominal trauma during the procedure.

All patients undergoing emergent pericardiocentesis require continuous cardiac monitoring, airway support, and supplemental oxygen. Rescue airway equipment and a defibrillator should be at the immediate bedside in case the patient deteriorates. While preparing the patient for pericardiocentesis, one or more fluid boluses with saline should be administered at 20 ml/kg. If the patient can tolerate the position, he or she should sit upright at 45 degrees to bring the heart closer to the inner aspect of the anterior chest wall and to make the fluid gravitate to a more dependent position. If patients are unable to tolerate sitting upright, they should be placed supine with the bed in a slight reverse Trendelenburg (head up) position. Emergency physicians with available bedside ultrasonography should prepare the machine with a sterile cover over the ultrasound probe. The anterior chest

and xiphoid areas should be cleansed with an antiseptic solution (e.g., povidone-iodine or alcohol). The site of insertion should be as sterile as possible, with sterile towels draped around the insertion site. In the hemodynamically unstable pericardial effusion, blind needle pericardiocentesis should be performed immediately. Consent may be obtained if time permits, but medical intervention should take priority.

If time permits, bedside ultrasonography should be performed to confirm the presence and the size of the effusion. In this situation, verbal consent should be obtained from the parents and the pericardiocentesis should be performed under sterile technique with ultrasound guidance.

Equipment

Commercially available kits include sterile drapes, an 18-gauge angiocatheter needle, syringes in 10- and 20-ml sizes, a three-way stopcock, and an electrocardiogram (ECG) alligator clip. The essential equipment, if a kit is unavailable, includes an 18-gauge central line needle or Angiocath with a 20-ml syringe. Use of a 22-gauge spinal needle has been suggested for infants.¹⁴ Protective gear such as sterile gloves, gown, and a face mask will be needed. A local anesthetic agent such as 1% lidocaine should be used, but additional systemic sedation for a young child may be needed. If a drain will be left in the pericardial space after the pericardiocentesis is performed, the additional equipment includes a floppy-tipped guidewire with a pigtail catheter. A bedside ultrasound machine should be used if rapidly available. If ultrasound or fluoroscopic techniques will be used to confirm placement of needle and catheter, agitated saline or contrast medium may be helpful.

Monitoring

The patient should be attached to continuous cardiorespiratory monitoring, with a member of the medical staff dedicated to monitor vital signs closely during the procedure. An ECG monitor should be readily available.

Techniques

Subxiphoid Approach

For the blind needle pericardiocentesis technique using the subxiphoid approach, the xiphoid process is located and local lidocaine is injected to the inferior and left of the xiphoid. The pericardiocentesis needle is inserted at a 30- to 45-degree angle to the chest wall and aimed toward either the substernal notch or the left shoulder (Fig. 180–1). The syringe is aspirated until fluid is obtained in the needle. Once fluid is obtained, the syringe is removed, the sheath advanced, and the needle removed.¹⁰

Parasternal Approach

With this technique, the pericardiocentesis needle is introduced in the fifth intercostal space, just lateral to the left border of the sternum, and directed 90 degrees from the skin. Autopsy studies of transthoracic pacemakers in adults show that this approach is less likely to injure important vascular structures (e.g., internal mammary artery) than an approach puncturing the fifth intercostal space 4 to 6 cm from the sternal margin.¹⁵ However, this approach has not been studied

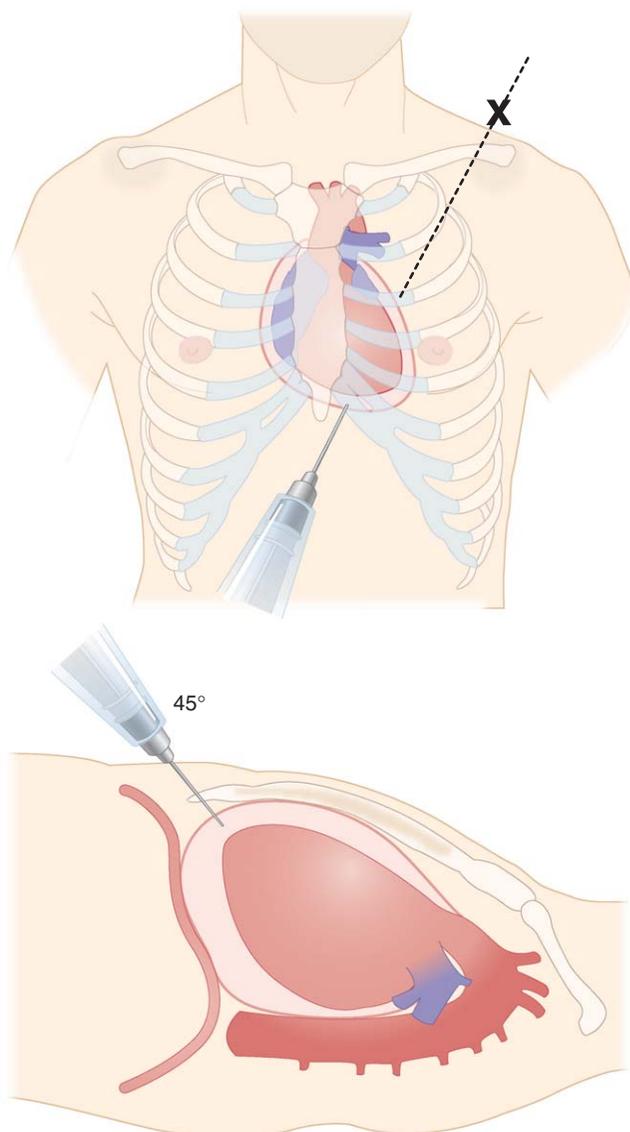

FIGURE 180–1. Subxiphoid approach of pericardiocentesis needle into the pericardial space.

in children and cannot be recommended unless anatomic or patient factors (e.g., scar tissue, trauma in the subxiphoid region) preclude use of the subxiphoid approach.

Alternatives

Many alternatives exist for this procedure. The clinical status of the patient, personal experience, and availability of equipment often dictate which technique is used.

Using the Commercially Available Kit

The three-way stopcock is attached to the needle, the 20-ml syringe to the side of the stopcock, and the transducer to the end of the stopcock. The V₁ ECG lead is attached with an alligator clip to the metal aspect of the needle. The needle is advanced as previously described until fluid is aspirated out the syringe. Ventricular wall contact causes ST-segment elevation, PR-segment depression, or premature ventricular

beats. Atrial wall puncture causes PR-segment depression, atrial arrhythmias, and atrioventricular dissociation.¹⁰ If any of these abnormalities is noted on the ECG monitor, the needle should be withdrawn and repositioned, and needle advancement repeated.

Ultrasound-Guided Procedure

Bedside ultrasonography can be used to confirm the location of the effusion and provide real-time visualization of needle advancement. The ultrasound probe is placed in the subxiphoid window or the anterior transthoracic window to view needle insertion. When the equipment is available to the emergency physician, this is the preferred method.^{2,4-7} In a small child in whom the transthoracic echocardiographic probe would obstruct most of the field, transesophageal echocardiography has been described in the literature.¹⁶ Echocardiographic evidence of cardiac tamponade includes right atrial compression, right ventricular collapse, or a swinging heart.⁶

Echocardiographic, Fluoroscopic, or Computed Tomographic Confirmation

If blood is aspirated during advancement of the needle or the placement of the needle is in question, 2 ml of agitated saline or contrast material (Echovist) can be injected under radiographic/ultrasonographic visualization.^{17,18} If the contrast or agitated saline quickly dissipates, the needle is in the ventricle. If the contrast enhances the cardiac silhouette, the needle is in the pericardial sac. Once placement is confirmed, continued radiographic visualization is no longer necessary. Agitated saline can be obtained by attaching two 10-ml syringes filled with 9 ml of sterile saline and 1 ml of air to a three-way stopcock. Saline and air are rapidly injected from one syringe into the other via the three-way stopcock. This creates bubbles, or agitated saline, that can be injected into the pericardial space to confirm placement of the needle.^{17,18}

Placement of Drainage Catheter after Pericardiocentesis

A soft-tipped guidewire can be advanced through the needle or Angiocath sheath and advanced until wrapping around the heart. A 5- to 7-French dilator is advanced over the wire. A 5- to 7-French pigtail catheter is then advanced and the guidewire is removed.

Surgical Techniques

The techniques available if pericardiocentesis fails or the patient is hemodynamically decompensating include thoracotomy, pericardial window, and single- or double-balloon pericardiotomy.

Complications

The complications depend on the technique being used. Blind needle pericardiocentesis has a high morbidity rate of 15% to 20%.^{19,20} Ultrasound guidance in elective pericardiocentesis decreases the incidence of complication to 0.5% to 3.7%.^{21,22} One of the most common complications in blind needle pericardiocentesis is puncture of a cardiac chamber. Inadvertent puncture of the left ventricle seldom, if ever, causes clinically significant bleeding. A puncture of the right ventricle carries an increased risk of bleeding due to the

thinner wall but rarely is clinically significant.^{9,23} If there is a laceration of either ventricle or the patient becomes hemodynamically unstable, thoracotomy is indicated for surgical repair.¹³ Inadvertent puncture of the coronary artery or vein is a rare complication of pericardiocentesis, and treatment of coronary perforation involves urgent surgical intervention.¹³ Pneumothorax is also a rare complication that can be treated with placement of a chest tube. Acute left ventricular failure with pulmonary edema is seen when large effusions have been drained. This is due to the rapid increase in venous return to the left heart after the cardiac compression is released. Treatment involves draining the fluid slowly and monitoring the patient's fluid balance after the procedure. Ventricular or atrial ectopic beats are common, but serious arrhythmias such as PEA can occur and should be treated according to Advanced Cardiac Life Support protocols. Other complications include air embolism, pneumoperitoneum, suppurative pericarditis, and cardiac tamponade due to trauma. Using the presence or absence of "nonclotting blood" to determine if aspirated blood is from the pericardium or ventricle is inaccurate and has been disproved as a useful discriminatory technique.

Postprocedure Care and Disposition

After completion of the pericardiocentesis, the patient should continue on cardiorespiratory monitoring for arrhythmias and evidence of heart failure. Monitoring for symptoms of recurrent effusion accumulation is needed. If reaccumulation occurs, the emergency physician should either repeat pericardiocentesis or attempt a surgical technique.^{1,2}

Chest Pain

A Quick Look at Chest Pain

Chest pain that worsens when the child is supine and is relieved when the child sits up and leans forward, fever and ST elevations on electrocardiogram	Suggests	Pericarditis (See Chapter 64, Pericarditis, myocarditis, and endocarditis)
History of sickle cell disease, fever, cough, chest pain, and an infiltrate on chest radiograph	Suggests	Acute chest syndrome (See Chapter 127, Sickle cell disease)
A child with recurrent episodes of exertional chest pain, syncope, and dyspnea	Suggests	Idiopathic subaortic stenosis (See Chapter 61, Syncope and Chapter 62, Chest pain)
Adolescent with a stressful or emotional precipitating event, chest tightness, near syncope, hyperventilation, and carpal-pedal spasm	Suggests	Panic attack (See Chapter 116, Psychobehavioral disorders)
Traumatized young child with chest pain, grunting respirations, and a stable chest wall	Suggests	Pulmonary contusion (See Chapter 24, Thoracic trauma)
Toddler or young child with the abrupt onset of upper chest pain, stridor and drooling	Suggests	Esophageal coin (See Chapter 78, Gastrointestinal foreign bodies)
Unilateral chest pain, fever, asymmetric breath sounds, cough	Suggests	Pneumonia (See Chapter 58, Pneumonia/pneumonitis)

For information on common and serious causes of chest pain, please also see:

Chapter 24 Thoracic trauma

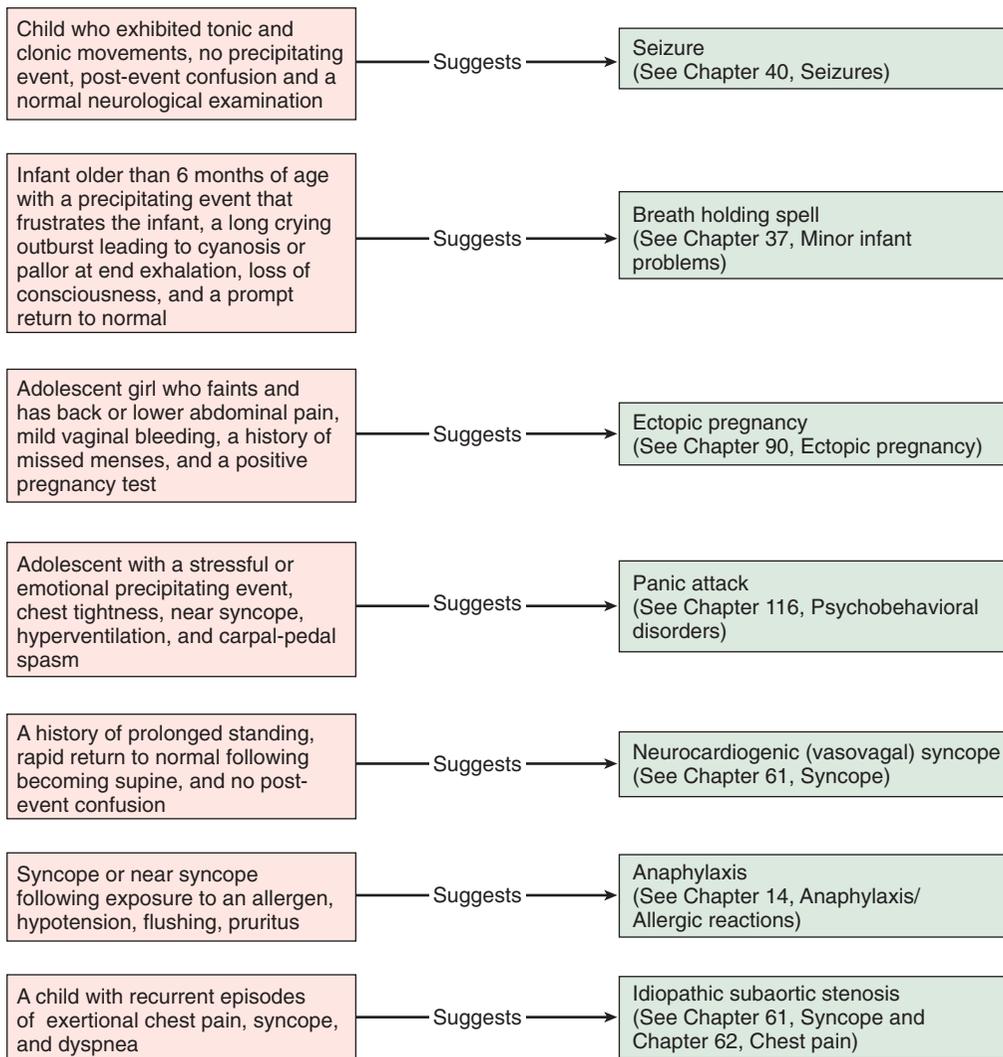

Chapter 56 Acute asthma

Chapter 62 Chest pain

Chapter 186

Near Syncope/Syncope

A Quick Look at Near Syncope and Syncope

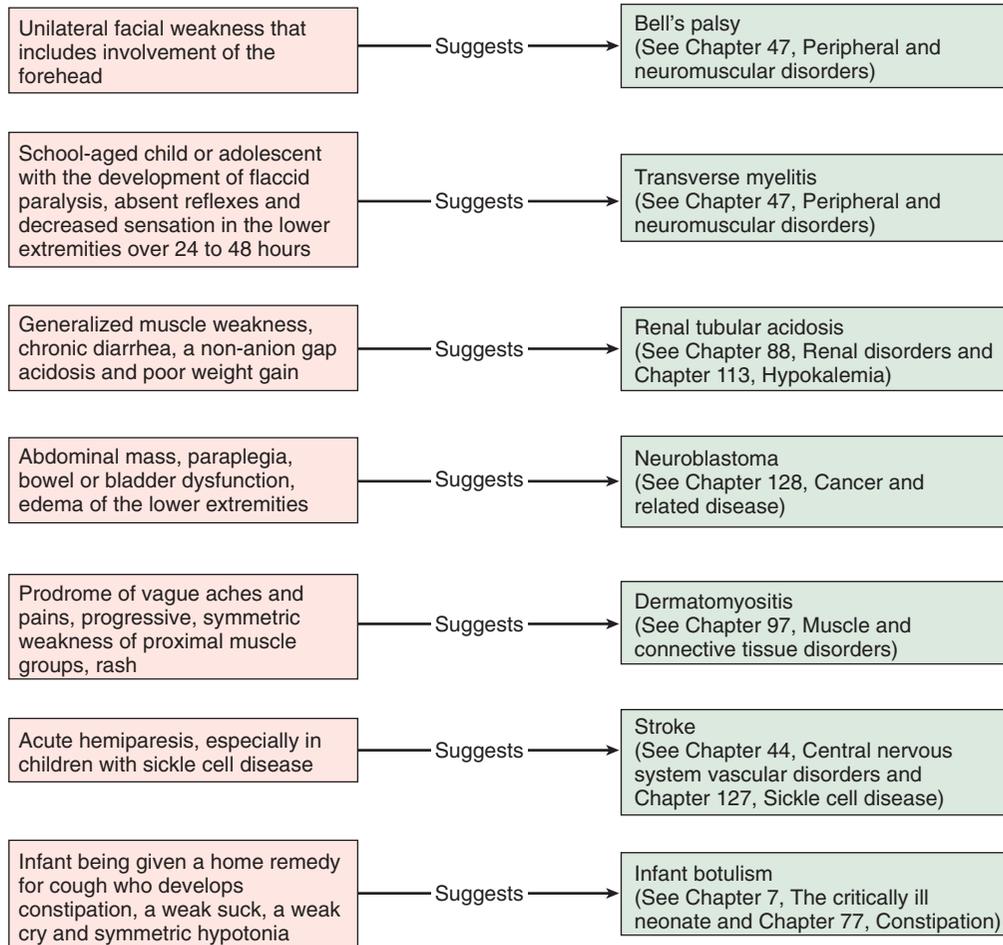

For information on common and serious causes of syncope, please also see:

Chapter 10 General approach to poisoning
Chapter 11 Altered mental status
Chapter 17 Head trauma
Chapter 28 Apparent life-threatening events
Chapter 44 Central nervous system vascular disorders
Chapter 61 Syncope
Chapter 63 Dysrhythmias
Chapter 67 Valvular heart disease
Chapter 106 Hypoglycemia
Chapter 110 Dehydration and disorders of sodium balance
Chapter 134 Toxic alcohols
Chapter 137 Cardiovascular agents
Chapter 139 Hyperthermia

Chapter 187

Muscular Weakness/Paralysis

A Quick Look at Muscular Weakness and Paralysis

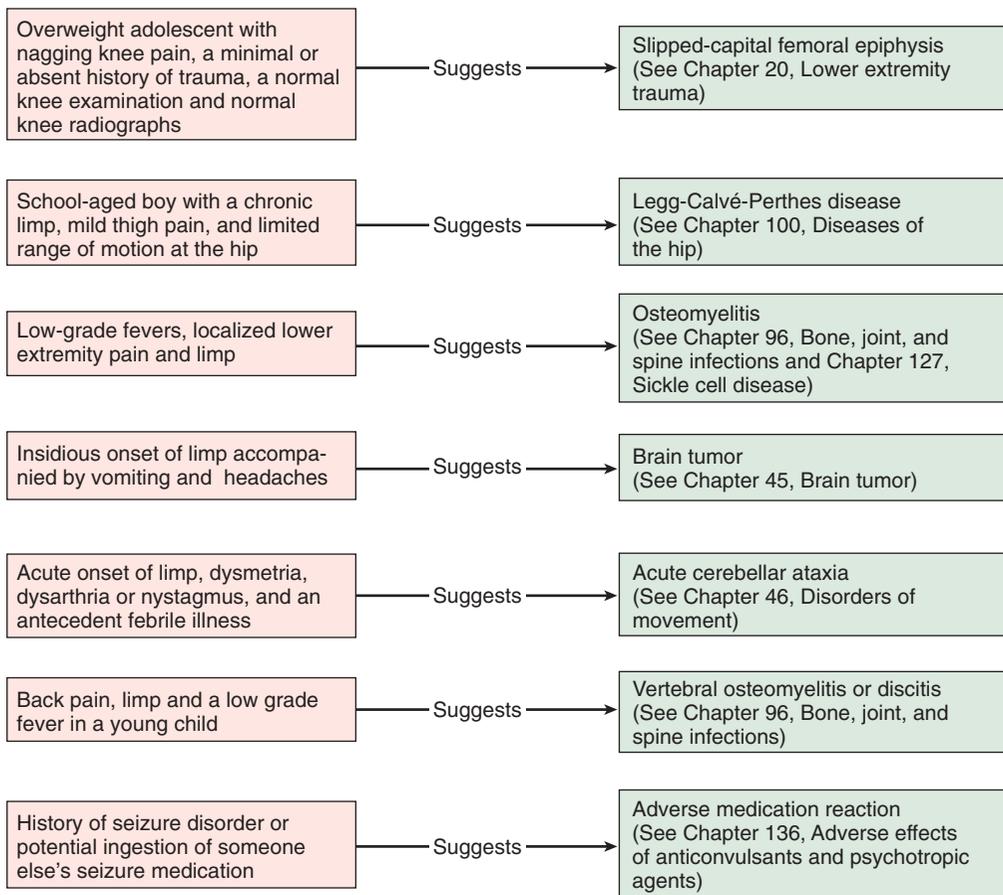

For information on common and serious causes of muscular weakness and paralysis, please also see:

Chapter 19 Upper extremity trauma
Chapter 20 Lower extremity trauma
Chapter 22 Compartment syndrome
Chapter 23 Spinal trauma
Chapter 27 Neurovascular injuries
Chapter 40 Seizures
Chapter 44 Central nervous system vascular disorders
Chapter 46 Disorders of movement
Chapter 47 Peripheral and neuromuscular disorders
Chapter 99 Rhabdomyolysis
Chapter 107 The steroid dependent child
Chapter 116 Psychobehavioral disorders

Chapter 188

Limp

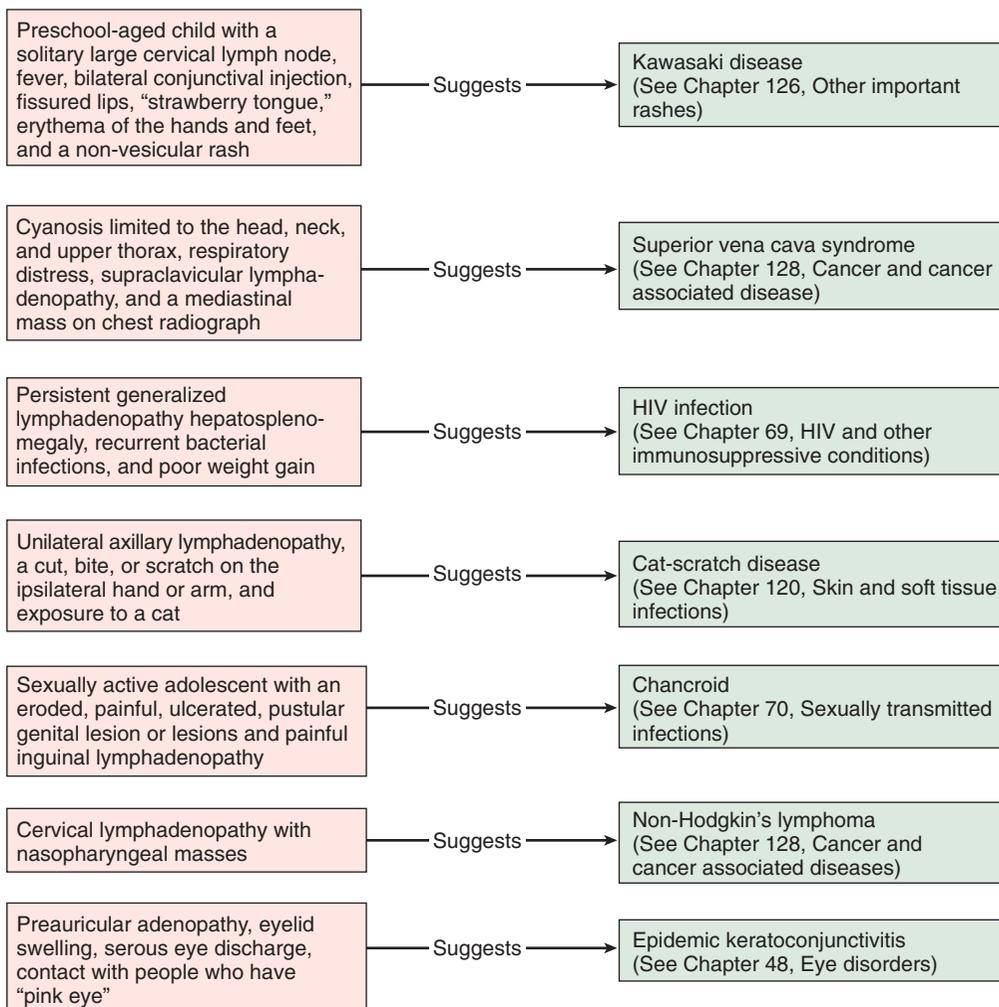

A Quick Look at Limp

For information on common and serious causes of limp, please also see:
Chapter 20 Lower extremity trauma
Chapter 27 Neurovascular injury
Chapter 97 Muscle and connective tissue disorders
Chapter 98 Overuse syndromes and inflammatory conditions

Lymphadenopathy

A Quick Look at Lymphadenopathy

For information on common and serious causes of lymphadenopathy, please also see:

Chapter 54 Neck infections

Chapter 55 Neck masses

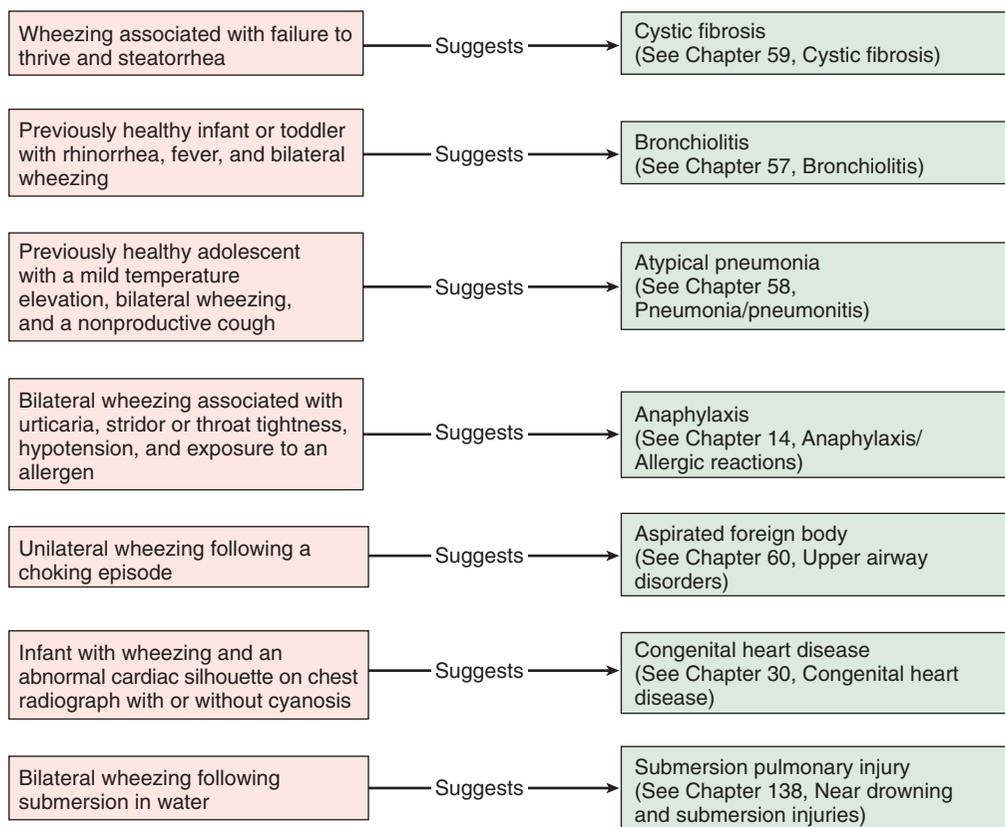

Chapter 71 Selected infectious diseases

Chapter 128 Cancer and cancer associated disease

Chapter 190

Wheezing

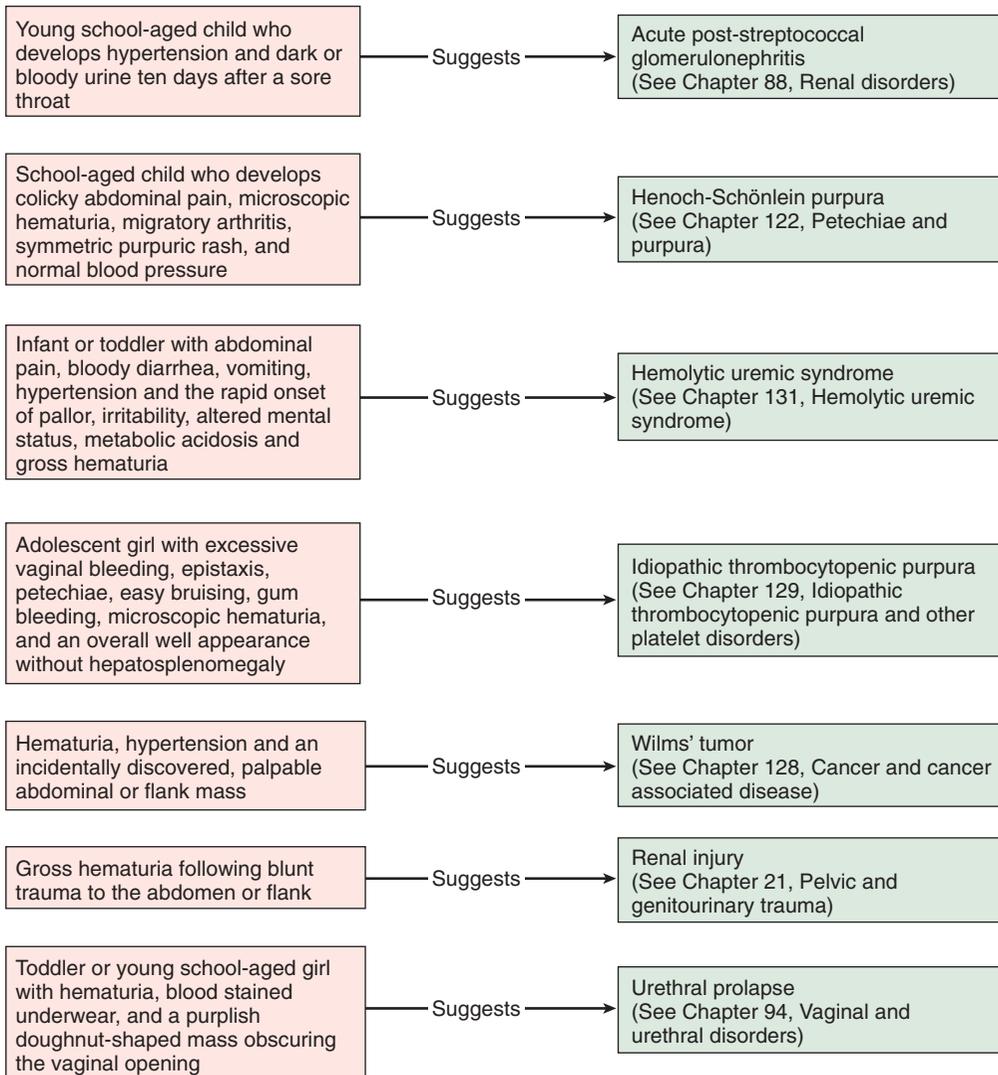

A Quick Look at Wheezing

For information on common and serious causes of wheezing, please also see:
Chapter 2 Airway emergencies: Respiratory distress and failure
Chapter 56 Acute asthma
Chapter 57 Bronchiolitis

Hematuria

A Quick Look at Hematuria

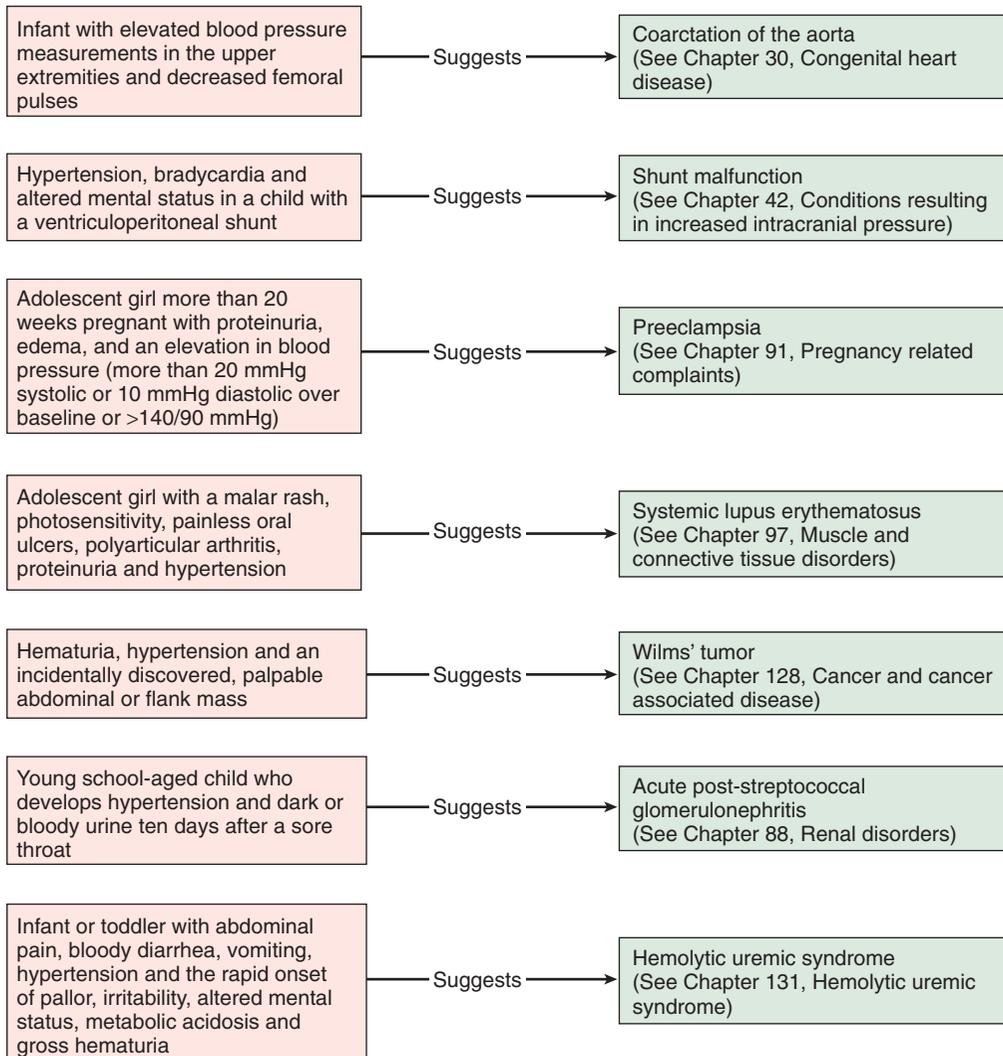

For information on common and serious causes of hematuria, please also see:
Chapter 21 Pelvic and genitourinary trauma
Chapter 25 Abdominal trauma
Chapter 26 Burns
Chapter 33 Urinary tract infection in infants
Chapter 86 Urinary tract infections in children and adolescents
Chapter 99 Rhabdomyolysis
Chapter 130 Coagulation disorders

Chapter 192

Hypertension

A Quick Look at Hypertension

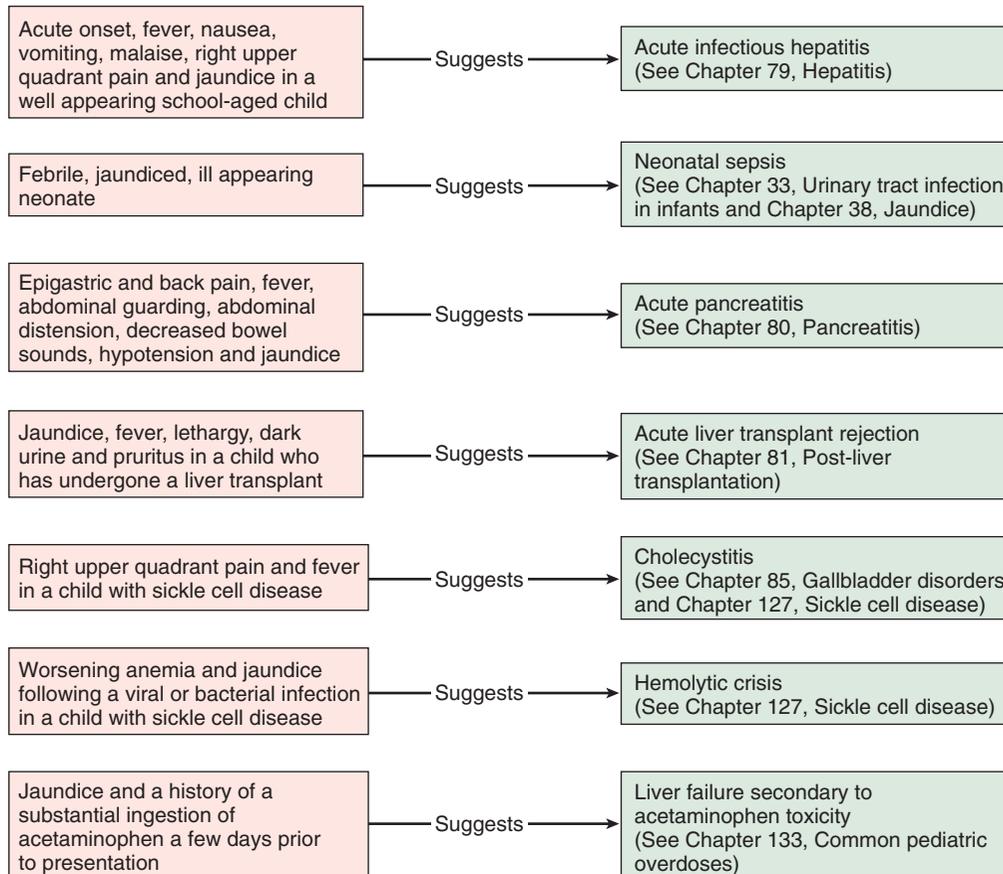

For information on common and serious causes of hypertension, please also see:

Chapter 11 Altered mental status
Chapter 17 Head trauma
Chapter 41 Headache
Chapter 44 Central nervous system vascular disorders
Chapter 65 Hypertensive emergencies

Jaundice

A Quick Look at Jaundice

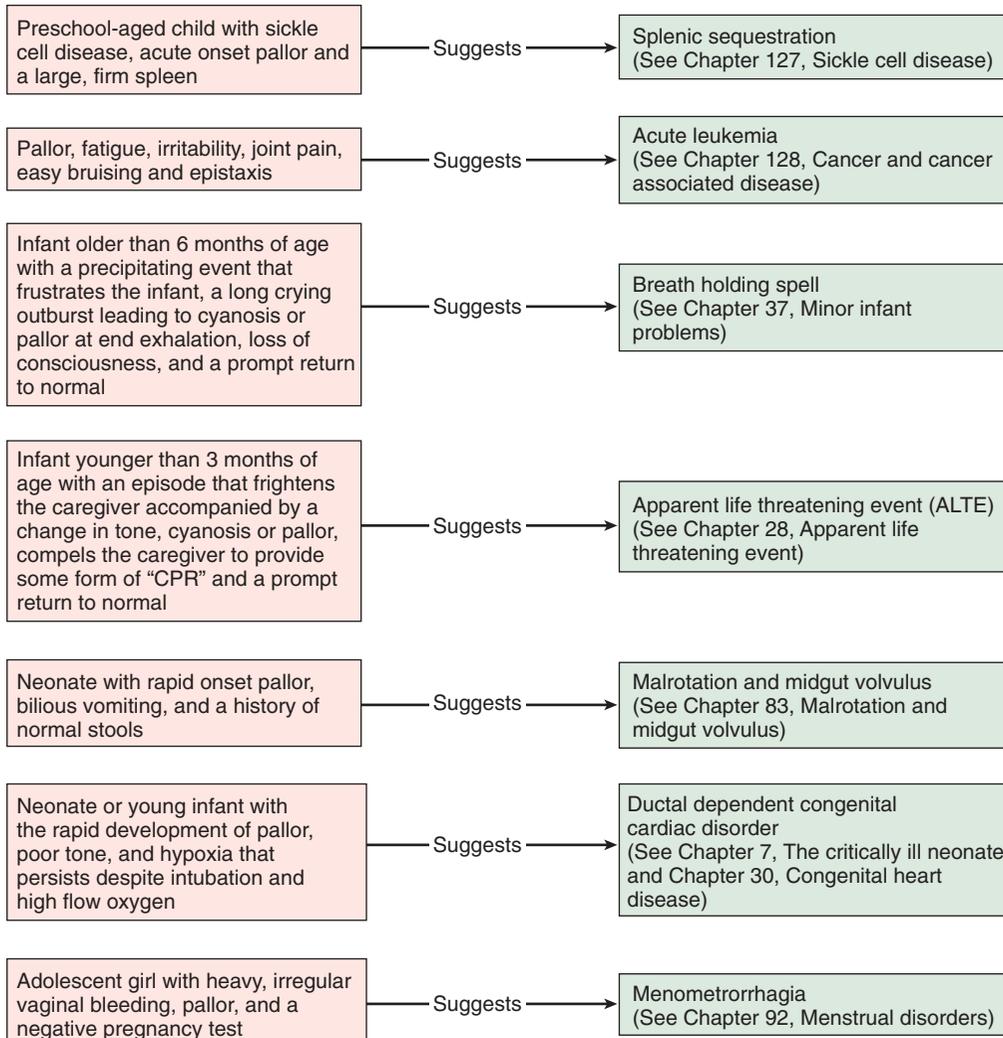

For information on common and serious causes of jaundice, please also see:
Chapter 7 The critically ill neonate
Chapter 38 Jaundice
Chapter 71 Selected infectious diseases
Chapter 85 Gallbladder disorders
Chapter 132 Utilizing blood bank resources/transfusion reactions and complications

Chapter 194

Pallor

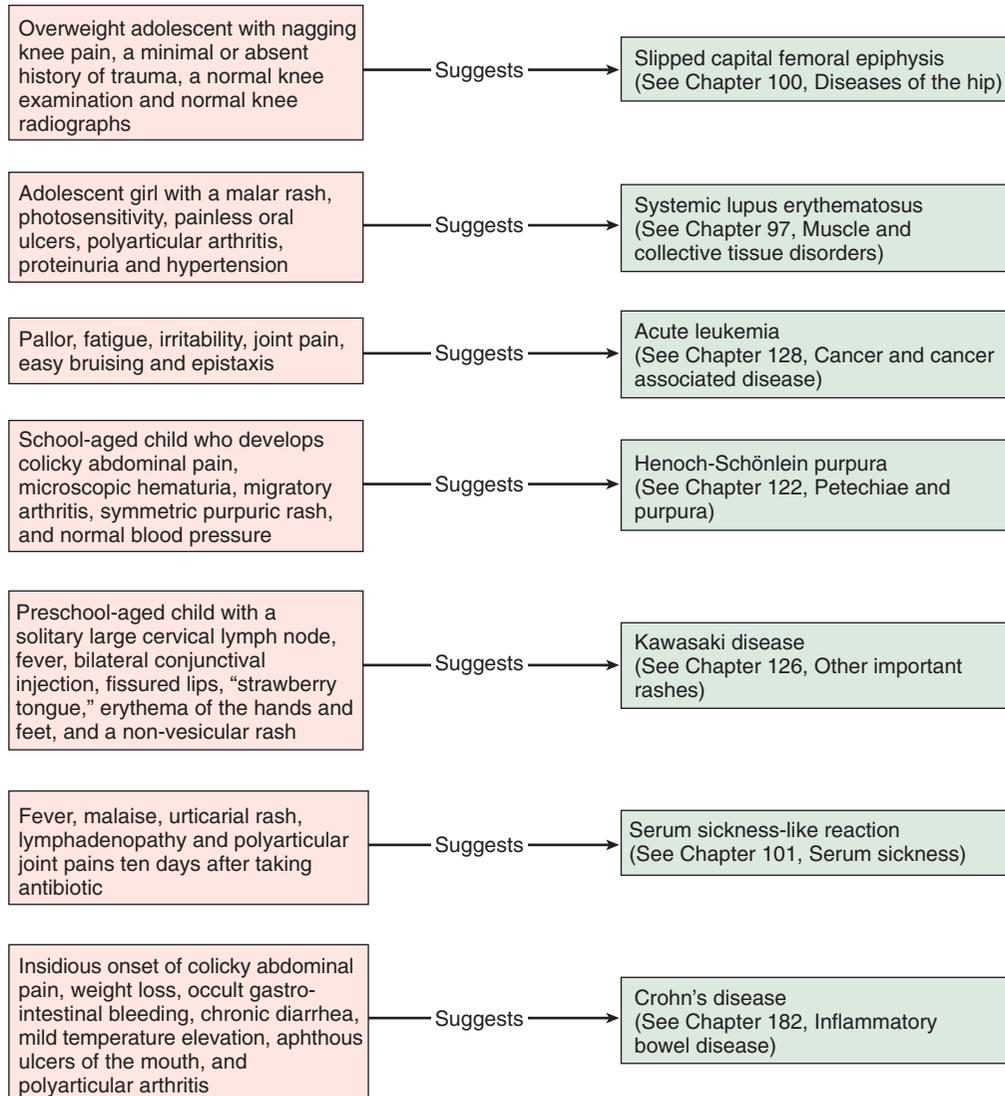

A Quick Look at Pallor

For information on common and serious causes of pallor, please also see:
Chapter 8 Circulatory emergencies: Shock
Chapter 75 Gastrointestinal bleeding
Chapter 90 Ectopic pregnancy
Chapter 91 Pregnancy-related complications
Chapter 130 Coagulation disorders
Chapter 139 Hyperthermia
Chapter 140 Hypothermia

Arthralgias/Arthritis

A Quick Look at Arthralgias and Arthritis

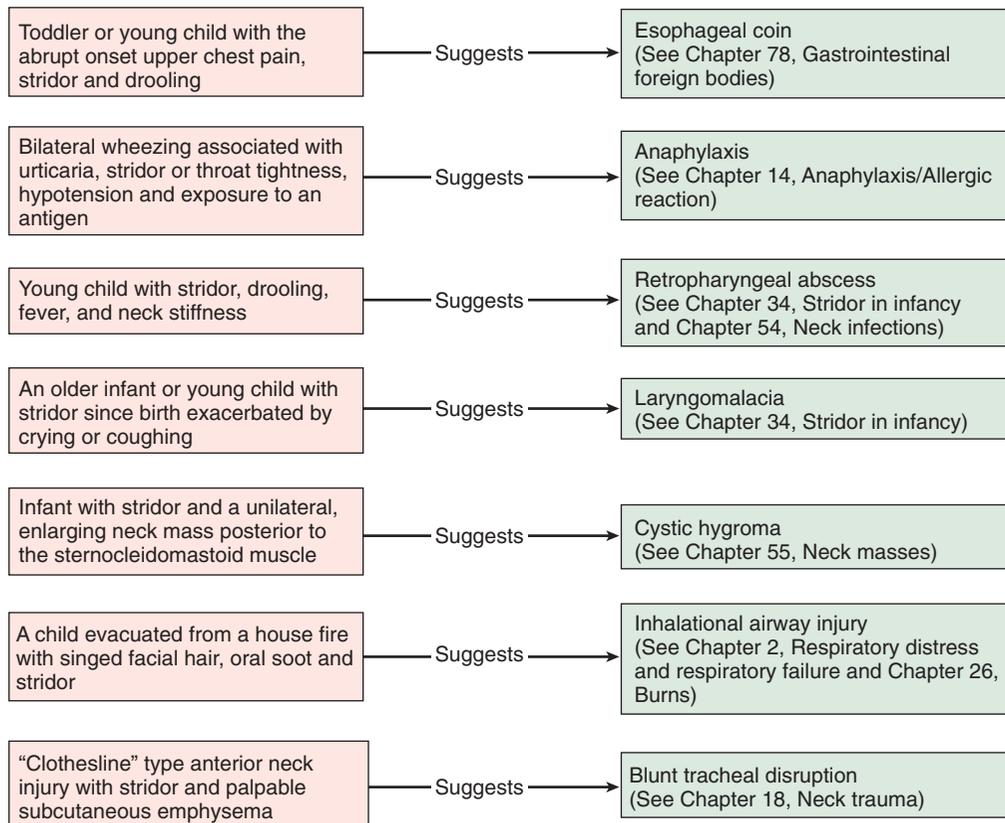

For information on common and serious causes of arthralgias and arthritis, please also see:
 Chapter 95 Musculoskeletal disorders in systemic diseases
 Chapter 96 Bone, joint, and spine infections
 Chapter 97 Muscle and connective tissue disorders
 Chapter 98 Overuse syndromes and inflammatory conditions
 Chapter 99 Rhabdomyolysis
 Chapter 102 Vaccination-related complaints and side effects
 Chapter 107 The steroid dependent child

Chapter 196

Stridor

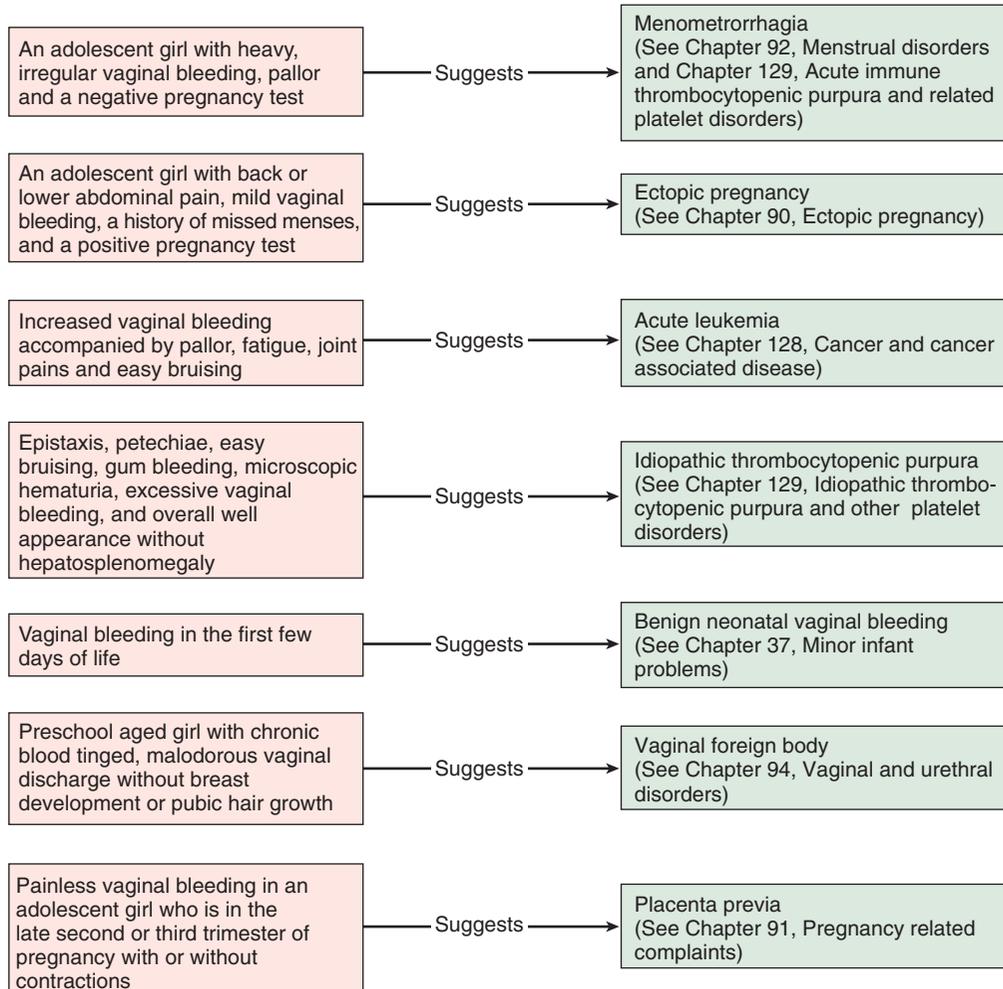

A Quick Look at Stridor

For information on common and serious causes of stridor, please also see:
Chapter 34 Stridor in infancy
Chapter 60 Upper airway disorders

Vaginal Bleeding

A Quick Look at Vaginal Bleeding

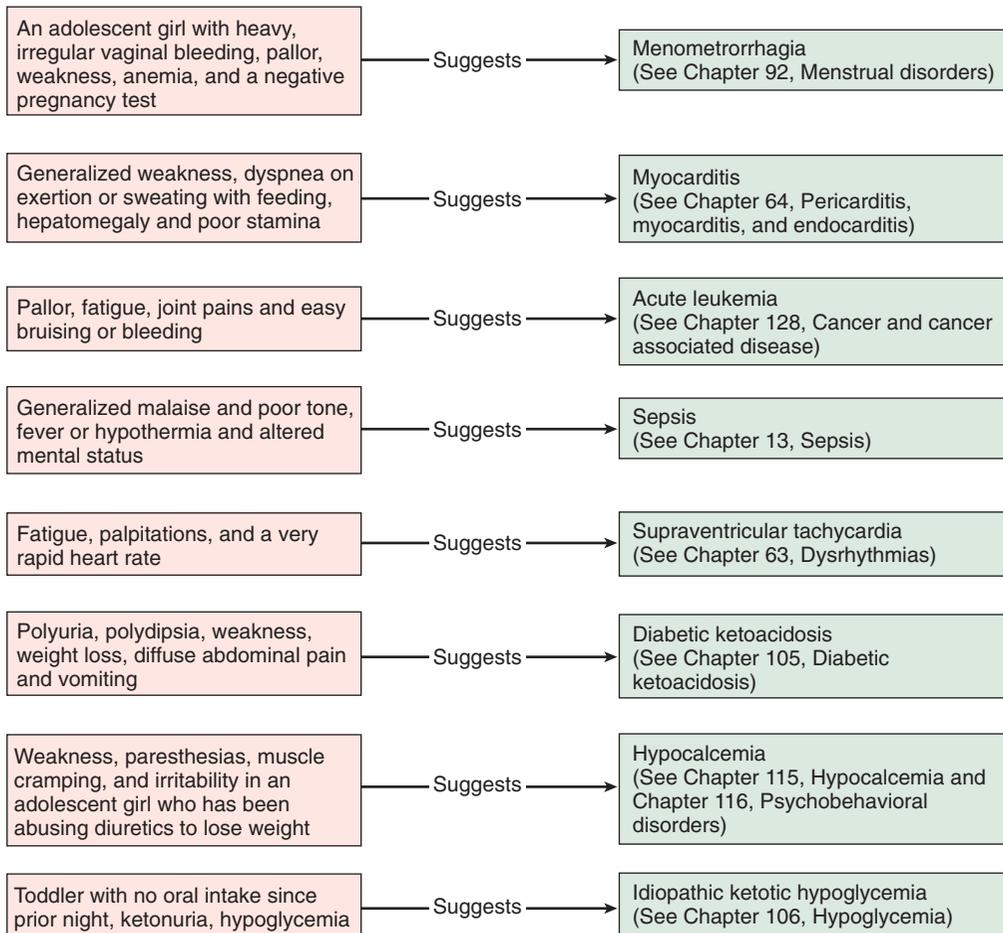

For information on common and serious causes of vaginal bleeding, please also see:
 Chapter 21 Pelvic and genitourinary trauma
 Chapter 37 Minor infant problems
 Chapter 70 Sexually transmitted infections
 Chapter 92 Menstrual disorders
 Chapter 118 Sexual abuse

Chapter 198

Weakness

A Quick Look at Weakness

For information on common and serious causes of weakness, please also see:

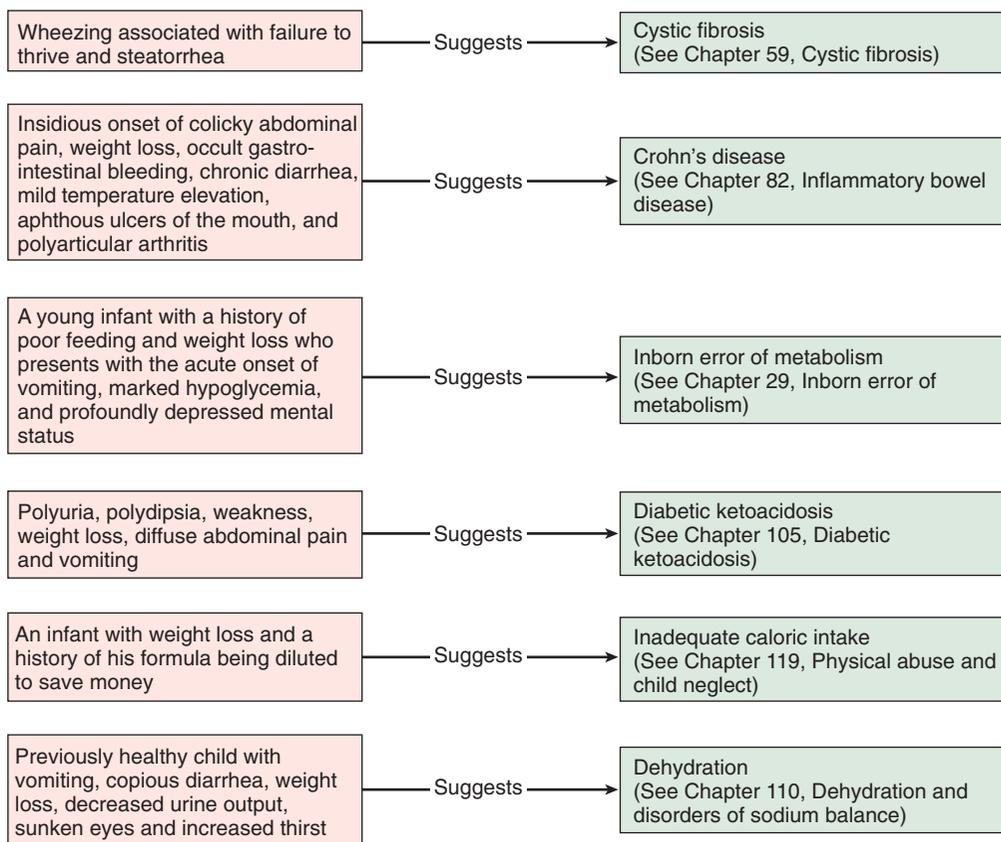

Chapter 36 Failure to thrive

Chapter 44 Central nervous system vascular disorders

Chapter 97 Muscle and connective tissue disorders

Weight Loss

A Quick Look at Weight Loss

For information on common and serious causes of weight loss, please also see:

Chapter 35 Vomiting, spitting up and feeding difficulties

Chapter 36 Failure to thrive

Chapter 69 Human immunodeficiency virus infection and other immunosuppressive conditions

Chapter 72 Vomiting and diarrhea

Chapter 109 Thyrotoxicosis

Chapter 116 Psychobehavioral disorders

Chapter 117 Major depression and suicidality

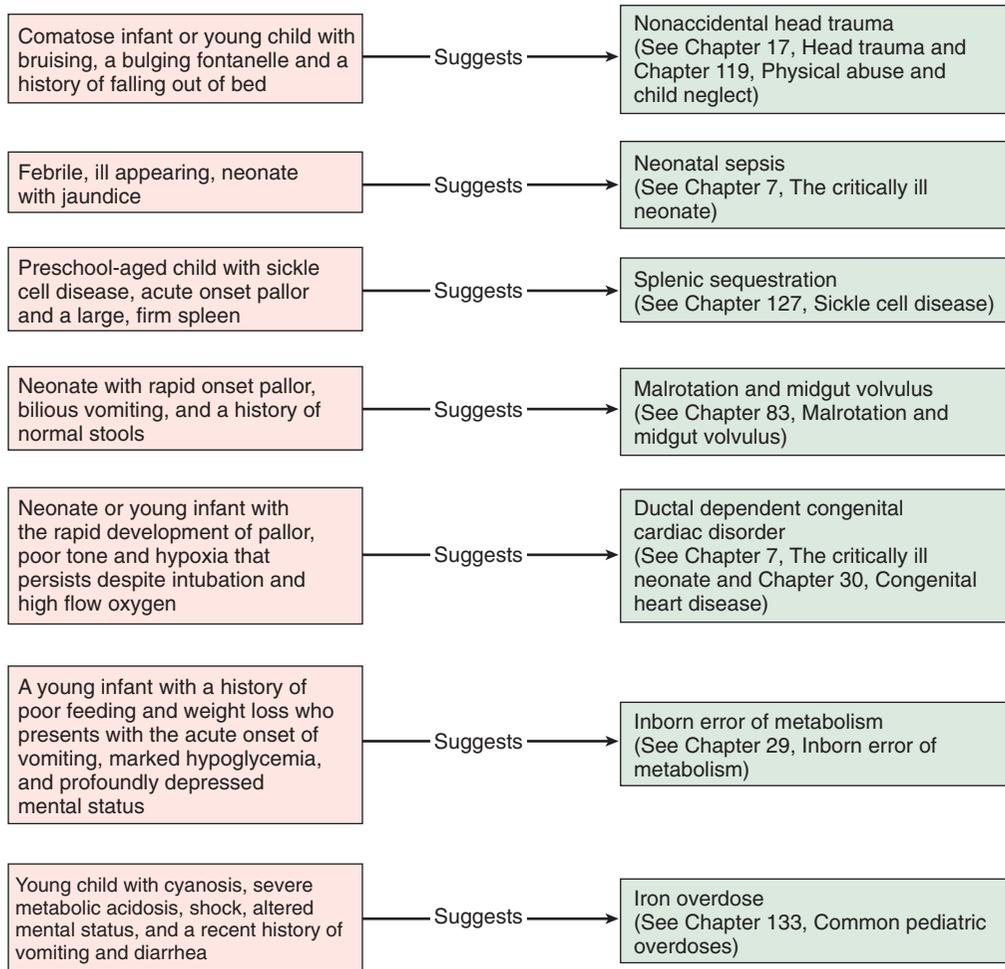

Chapter 128 Cancer and cancer associated disease

Chapter 135 Drugs of abuse

Chapter 200

The Septic-Appearing Child

A Quick Look at the Septic Appearing Child

For information on common and serious causes of the septic appearing child, please also see:

Chapter 7 The critically ill neonate
Chapter 8 Circulatory emergencies: Shock
Chapter 13 Sepsis
Chapter 74 Intussusception

Index

Note: Page numbers followed by “f” indicate figures; those followed by “t” indicate tables.

A

- Abdominal examination, chest pain and, 483
- Abdominal hernias
- anatomical location of, 636f
 - clinical presentation of, 635–636
 - differential diagnosis of, 636t
 - epigastric hernias, 635
 - femoral hernias, 635
 - important clinical features of, 636–637
 - incarceration and, 635
 - inguinal hernia, 634
 - lumbar hernias, 635
 - management of, 637
 - obturator hernias, 635
 - recognition of, 634–635
 - reducible hernias, 635
 - Richter’s hernias, 635
 - sliding hernias, 635
 - Spigelian hernias, 635
 - strangulation and, 635
 - umbilical hernias, 634–635
- Abdominal migraines, 362
- Abdominal pain. *See also* Pain management
- altered mental status and, 118t
 - management of, 1112t
 - pancreatitis and, 613–614
 - quick look at, 1266
 - sickle cell disease and, 899–900, 902
 - vomiting and, 572
- Abdominal radiographs
- bowel obstruction and, 627
 - fulminant colitis and, 626
 - inflammatory bowel disease and, 628
 - intussusception and, 583
 - liver transplantation and, 623
 - midgut volvulus and, 632
 - pyloric stenosis and, 594–595
- Abdominal trauma
- abdominal compartment syndrome and, 243
 - advanced trauma life support, 234t
 - approaches to, 226–233
 - bony pelvis and, 237, 242
 - clinical evaluation of, 233–237
 - diagnostic modalities and, 237–240
 - diagnostic peritoneal lavage and, 238, 238t
 - hollow organs and, 226, 237, 242–243
 - imaging studies and, 238–239
 - incidence of, 225–226
 - laboratory studies and, 239–240
 - major abdominal injuries, 240–243
 - management of, 240–243
 - minor abdominal injuries, 243
 - operative management and, 241t
 - penetrating injuries, 243
 - peritoneal irritation and, 238
 - physical diagnosis of life-threatening injuries, 235t
 - physical examination of, 237–238
 - primary surveys and, 233–234
 - propensity for delayed presentation and, 226
- Abdominal trauma (*Continued*)
- recognition of, 226–233
 - secondary surveys and, 234
 - solid organs and, 226, 235, 241–242
 - thoracoabdominal injuries, 243
 - trauma laparoscopy and, 243
 - trauma laparotomy and, 243
 - triage guidelines and, 244t
