Printed in the United States of America

As new scientific information becomes available through basic and clinical research, recommended treatments and drug therapies undergo changes. The author(s) and publisher have done everything possible to make this book accurate, up to date, and in accord with accepted standards at the time of publication. The author(s), editors, and publisher are not responsible for errors or omissions or for consequences from application of the book, and make no warranty, expressed or implied, in regard to the contents of the book. Any practice described in this book should be applied by the reader in accordance with professional standards of care used in regard to the unique circumstances that may apply in each situation. The reader is advised always to check product information (package inserts) for changes and new information regarding dose and contraindications before administering any drug. Caution is especially urged when using new or infrequently ordered drugs.

I would like to dedicate this book to my family.
My husband, John, and my three sons, Michael,
Patrick, and Nicholas, have been wonderfully
supportive as I have completed this project.
TMW

To my students who continually impress me with their
idealism and inspire me to always strive for excellence.
MVR

The increasing volume of pharmacology-related information presents a challenge to acquire and maintain current knowledge in the area of pharmacotherapeutics. The number of new drugs coming on the market each year, the changes in "the best" drugs to use for any given disease state based on the latest research, the influence on patient and practitioner alike of advertising and promotion, and restricted formularies create competing pressures on the prescriber. This book is designed to provide nurse practitioner students and the nurse practitioner in the primary care setting with a thorough, current, and usable pharmacology text and reference to address these challenges.

The design of this book assumes knowledge of basic pharmacology from one's undergraduate education in nursing. Although a brief review of basic pharmacology is presented in **Chapter 2**, the focus of the book is on advanced pharmacology and the role of the advanced practice nurse in pharmacotherapeutics. The authors of the text are practicing nurse practitioners, pharmacists, or selected specialists in a field. The book is by advanced practice registered nurses, for advanced practice registered nurses.

ORGANIZATION

This book is organized around four distinct content areas: The Foundation, Pharmacotherapeutics with Single Drugs, Pharmacotherapeutics with Multiple Drugs, and Special Drug Treatment Considerations.

The Foundation

The 13 chapters in Unit I provide the foundation of advanced pharmacology and the link between this knowledge and professional practice. Chapter 1 discusses the role of the advanced practice registered nurse (APRN) in both the United States and Canada as prescriber and the knowledge needed to actualize this role. Current issues about the evolving role and education of these providers are also presented in this edition, including discussion of the Doctorate of Nursing Practice.

Discussion of the roles of other advanced practice nurses in prescribing is included. Factors involved in clinical judgment related to prescribing are a central focus, and collaboration with other health-care providers is also presented.

The pharmacology knowledge required for rational drug selection requires more depth than that given in undergraduate pharmacology, where the focus is on safe administration of drugs prescribed by someone else. Advanced pharmacology information on receptor reserve and regulation, bioavailability and bioequivalence, metabolism of drugs, including a focus on the cytochrome P450 microsomal enzyme system, half-life, and steady state are provided in **Chapters 2** and **8**. Information central to the prescribing role includes an in-depth discussion of volume of distribution and therapeutic drug monitoring. Volume of distribution is important in prescribing drugs with very large or very small volumes of distribution and for selecting drugs for patients with cardiac or renal failure, during pregnancy, or when a patient is underweight or obese. Knowing what tests to order and when to order them to assess plasma drug levels by bioassay and to monitor for adverse drug reactions are necessary in making choices about when or if dosage alterations are required or drugs need to be stopped. These topics are also covered in **Unit I**.

Legal and professional aspects of the prescriber role are presented in **Chapter 4**. Issues surrounding the legal authority of the APRN to prescribe a drug, the conditions under which the prescription may be written, and how to write the prescription are presented. Risk management issues are also discussed, including informed consent, dealing with multiple providers, and substance abuse and drug-seeking behaviors.

Nurse practitioners have a history of high levels of patient satisfaction with the care provided. This is related, in part, to their holistic approach to each patient. Several chapters are devoted to information that reflects this approach. Cost, knowledge deficits, dealing with complex treatment regimens, and negotiating a shared responsibility for drug management are discussed in **Chapter 6**. Many patients choose to use complementary therapies such as herbal remedies. **Chapter 10** discusses herbal therapy and other complementary therapies.

A relatively new area in pharmacotherapeutics is ethnopharmacology. As more research is done in this area, treatment guidelines are beginning to include which drugs are best for different racial groups. Cultural and ethnic considerations in prescribing drugs are the subject of **Chapter 7**. Pharmacogenomics involves the influence of both race/ethnicity and individual genetic make-up on drug metabolism. **Chapter 8** provides a discussion of the role of pharmacogenomics in prescribing.

Consideration of drug and food interactions has long been a part of nursing knowledge, but the interrelationship between nutrition and drug therapy beyond these interactions has been largely overlooked. **Chapter 9** provides a discussion of this interrelationship, including nutritional supplementation and nutrition as therapy.

In an age of integrated use of technology, the APRN must be able to acquire information about drugs and to deliver care to patients using technology. The use of electronic health records (EHR) to aid in prescribing decision making is found in **Chapter 11**.

Cost issues cannot be ignored when making prescribing decisions. **Chapter 12** provides a discussion of pharmacoeconomics.

Over-the-counter drugs may be prescribed by the APRN or chosen by patients on their own. These drugs are often erroneously perceived to be less powerful and have fewer adverse reactions than prescription drugs. Understanding their role in pharmacotherapeutics is the focus of **Chapter 13**.

Pharmacotherapeutics With Single Drugs

The next two units are organized around specific drugs and the diseases they are used to treat. The chapters in Unit II are organized to provide easy access to information based on specific drug classes. Many practitioners have a personal formulary of drugs they use for disease processes that they commonly see. When presented with a patient requiring drug therapy, they know the class of drug from which they will make a rational drug choice. The information they seek is about drugs within that class that would be most appropriate for their patient.

Pharmacokinetics, pharmacodynamics, and pharmacotherapeutics for each drug class are discussed in the chapters in Unit II. The chapters include tables with easy-to-access information on the pharmacokinetic properties of each drug, drug interactions, clinical use and dosing, and available dosing forms. A major focus is on rational drug selection and on monitoring parameters. Patient education specific to each drug class is provided—designed around administration of the drug, adverse drug reactions to monitor for and what to do if they occur, and lifestyle modifications that complement the drug therapy.

To provide the most up-to-date, accurate, and relevant information possible, contributors to this unit are practicing clinicians and the newest published guidelines are consistently used. The "Clinical Pearls" features, drawn from the daily practice of these contributors, are incorporated throughout the text. Drugs currently in development that may influence drug choices in the near future are also included in the "On the Horizon" features.

Pharmacotherapeutics With Multiple Drugs

The chapters in Unit III provide drug information from the viewpoint of the disease processes they are commonly used to treat. Patients often have complex health and illness issues and treatment needs requiring multiple drugs in different drug classes. Unit III facilitates acquisition of complex prescribing knowledge by providing information from a disease process format. The diseases in this unit are those commonly seen in primary care and for which multidrug therapy from more than one drug class may be recommended.

Pharmacotherapeutics is discussed in Unit III in relation to the pathophysiology of the disease and the goals of treatment. Each chapter explores how patient variables, economic considerations, concurrent diseases, and drug characteristics influence rational drug selection. Evaluating outcomes along with guidelines for consultation and referral are included. Where relevant, the newest published professional guidelines are incorporated. Each patient is unique and no set of guidelines or treatment algorithm applies to each patient. However, these tools, drawn from the clinical knowledge and experience of experts in a given specialty, are helpful in rational drug selection, especially for the student and novice practitioner. Clinically based case studies,

provided in an online supplement to this edition, provide a framework for application of pharmacotherapeutic knowledge.

Special Drug Treatment Considerations

Unit IV focuses on special populations. Age-related variables are explored in **Chapter 50**, "Pediatric Patients," and **Chapter 51**, "Geriatric Patients." Gender variables are considered in **Chapter 48**, "Women as Patients," and **Chapter 49**, "Men as Patients."

The final chapter in the book deals with one of the most common yet often perplexing issues with which prescribers deal: pain. **Chapter 52** focuses on management of both acute and chronic pain across the age continuum. The fourth edition includes the most current information on newer drugs used to treat chronic pain and new pain assessment tools for patients with dementia. The chapter includes a discussion of the legal aspects of prescribing related to drug-dependent patients and includes coverage of Material Risk Assessment and Pain Management Contract documents.

FEATURES

Throughout the text, care has been taken to provide the reader with a consistent and logical presentation of material. Visual appeal is provided through the generous use of tables, illustrations, and flowcharts. Other features are unique to the specific units:

Unit I chapters

In-depth pharmacology base for advanced pharmacotherapeutics
Herbal and complementary therapies
Ethnopharmacology and pharmacogenomics
Nutrition and nutraceuticals as therapy
Pharmacoeconomics
Information technology including EHR and how it is used in a busy practice

Unit II chapters

Tables for ease of access to information
    Pharmacokinetics tables
    Drug Interactions tables
    Dosage Schedule tables
    Available Drug Dosage Forms
Rational drug selection and monitoring parameters
Patient Education
Clinical Pearls
On the Horizon feature

Unit III chapters

Integration of pathophysiology and pharmacotherapeutics
Integration of professional treatment guidelines
Drugs Commonly Used tables
Patient Education displays

Unit IV chapters

Variables related to special populations
Pediatrics
Geriatrics
Women
Men
Pain management

SUMMARY

Every effort has been made to make this text as comprehensive, accurate, and user-friendly as possible. The generous use of tables for ease of access to information, the focus on rational drug selection, the inclusion of often hard-to-find monitoring parameters, and the integration of patient education throughout the text are examples of this user-friendly approach. The authors hope that you will find this a valuable resource both as a student and in your practice.

ACKNOWLEDGMENTS

TERI MOSER WOO, RN, PHD, CPNP-PC, FAANP

Teri has been a pediatric health-care provider for 30 years. She received her BSN from Oregon Health Sciences University (OHSU) in 1984. Teri earned an MSN in Childrearing Family Nursing in 1989 and a post-Masters Pediatric Nurse Practitioner Certificate in 1993 from OHSU. In 2008, she earned a PhD in Nursing from the University of Colorado College of Nursing, Denver. Teri was president of the Oregon Pediatric Nurse Practitioner Association from 1998 to 2000 and from 2011 to 2013 and is a Fellow in the American Academy of Nurse Practitioners. She is an Associate Professor and Associate Dean for Graduate Nursing Programs at Pacific Lutheran University School of Nursing in Tacoma, Washington. Teri continues to practice as a Pediatric Nurse Practitioner for Kaiser Permanente in pediatric ambulatory care.

MARYLOU V. ROBINSON, PHD, FNP-C

Marylou V. Robinson received her BSN from the Walter Reed Army Institute of Nursing, University of Maryland; her Master's as a CNS from The Catholic University of America, her post-Master's as an FNP from Pacific Lutheran University, and her PhD from Oregon Health & Science University. After a 22-year U.S. Army career spanning from Vietnam to Desert Storm, she joined academia. Currently, she is an Associate Professor at the University of Colorado College of Nursing at the Anschutz Medical Campus. She has been a National Ski Patroller for over 26 years.

CONTENTS

THE FOUNDATION

THE ROLE OF THE ADVANCED PRACTICE NURSE AS PRESCRIBER

Teri Moser Woo • Marylou Robinson

Nurses have been administering medications prescribed by another provider for many years. The knowledge base to safely perform this activity has been an integral part of basic nursing education. With the advent of the advanced practice nurse, the role of the nurse in relation to medications has evolved to include prescribing the medications as well as administering them. The prescriber role requires additional knowledge beyond that taught in undergraduate nursing programs. More than that, it requires the willingness and ability to assume a different level of responsibility for this activity. Advanced practice nurses other than nurse practitioners (NPs) may gain prescriptive authority or prescribe under protocol; therefore, the term *advanced practice registered nurse* (APRN) will be used in this chapter to include NPs, certified nurse midwives (CNMs), certified registered nurse anesthetists (CRNAs), and clinical nurse specialists (CNSs) with prescribing authority, as determined by the individual state nurse practice act. The focus of the discussion will remain primary care prescribing.

ROLES OF REGISTERED NURSES IN MEDICATION MANAGEMENT

Registered Nurses

Experienced registered nurses (RNs) often find themselves in the position of discussing what might be the "best" drug a patient should receive with a physician or other prescribing provider. The RN is an advocate for the patient and his or her input should be sought and highly valued in the prescribing process. Collaboration between the nurse and prescriber improves patient safety and the quality of care the patient receives; however, the responsibility for the final decision regarding which medication to prescribe remains with the prescriber.

Advanced Practice Registered Nurses

APRNs have a higher level of responsibility related to pharmacotherapeutics than RNs. The nature of this responsibility depends on whether the APRN can prescribe medications. States vary in their laws related to prescriptive authority for APRNs. Twenty-one states have fully independent prescribing by nurse practitioners (AANP, 2013b; National Council of State Boards of Nursing, 2015). Some states have full or limited prescribing allowed by CNSs, including Alaska, Colorado, Connecticut, Hawaii, Iowa, Idaho, Minnesota, Montana, Nevada, New Mexico, North Dakota, Oregon, Utah, Vermont, Washington, DC, and Wyoming (National Council of State Boards of Nursing, 2015).

Because nonprescribing APRNs have in-depth knowledge of the drugs used in their specialty areas, their collaboration with the health-care providers who are prescribing is valuable. They may assist in determining the pharmacotherapeutic protocols for their patients and may be credentialed by their organization to select drugs within those protocols to be administered to their patients. These roles related to pharmacotherapeutics represent an intermediate level of responsibility between the staff RN, who administers drugs chosen by another provider, and the NP, who prescribes a drug without the need for a protocol. APRNs also collaborate with other providers in designing and implementing research protocols to test the efficacy of a new drug. They also have a central role in educating nurses and other providers in the appropriate use of these new drugs.

ROLES AND RESPONSIBILITIES OF APRN PRESCRIBERS

APRNs exist in a range of practices and include certified RN anesthetists, certified nurse midwives, and others whose title includes the words *nurse practitioner* or *advanced practice registered nurse*. The responsibility for the final decision on which drug to use and how to use it is in the hands of the APRN prescriber. The degree of autonomy in this role and the breadth of drugs that can be prescribed vary from state to state based on the nurse practice act of that state. Every year, the January issue of the *Nurse Practitioner* journal and an issue of the *American Journal for Nurse Practitioners* present a legislative update providing a summary of each state's practice acts as they relate to titling, roles, and prescriptive authority. As of January 2015 (Philips, 2015), the following were true of NP regulation of practice and prescribing authority:

- All states have title protection for NPs.
- Only Oregon has mandated third-party reimbursement parity for NP services.
- In all but five states, the control of practice and licensure is within the sole authority of the state's board of nursing. These five states have joint control in the board of nursing and the board of medicine.
- Scope of practice is determined by the individual NP's license under the nurse practice act of the licensing jurisdiction. Some have a graduated scope based on experience level. New prescribers need to understand that their employment sites may restrict this legal scope of practice but cannot extend it.
- In 17 states and the District of Columbia, NPs have independent scope of practice and prescriptive authority without a requirement or attestation for physician collaboration, consultation, delegation, or supervision.
- Six states have full autonomous practice and prescriptive authority following a period of postlicensure/postcertification supervision or collaboration.

The 2010 Institute of Medicine's (IOM) publication *Future of Nursing: Leading Change, Advancing Health* called for removing scope of practice barriers and allowing NPs to practice to the full extent of their education and training (IOM, 2010). Many states are responding to this call, with the expectation that the above list will be significantly modified in years to come.

ADVANCED KNOWLEDGE

General knowledge about the pharmacokinetics and pharmacodynamics of drugs, how to administer them safely, and what to teach the patient is learned in undergraduate nursing courses and subsequently refined in practice. Additional knowledge, critical thinking, and assumption of a higher level of legal responsibility are required to assume the prescriber role. Knowledge of medicine, pharmacology, and nursing intertwine in the NP role. As a prescriber, it becomes the role and responsibility of the NP to determine the diagnosis for which the drug will be ordered, prescribe the appropriate drug, monitor the expected outcome of the drug, and incorporate a holistic assessment of the impact of disease and therapy on patient lives.

The APRN role requires advanced knowledge about pathophysiology, medical diagnoses, and pharmacology to choose an appropriate drug. Determining the medical diagnosis is not within the scope of this book, but rational drug selection requires knowledge of the disease processes (medical diagnoses) for which a drug may be prescribed and the mechanism of action of a specific drug and how it affects this disease process. Rational drug selection is discussed throughout the book.

The prescriber role requires advanced pharmacology knowledge beyond that taught in basic nursing education. Knowledge required for rational drug selection includes, for example, bioequivalence and cost when deciding whether to use a generic form of a given drug; the enzyme systems used to metabolize a drug for deciding about potential drug interactions; and the pharmacokinetics of a drug for determining the loading, maintenance, and tapering doses. The terms may sound familiar, but the underlying depth of information and the role of this information in determining the best drug to prescribe are beyond basic nursing pharmacology knowledge. Volume of distribution, for example, receives little discussion in undergraduate nursing pharmacology texts, but it is often critical in determining dosage for drugs with very large or

small volumes of distribution and in selecting drugs for patients with cardiac or renal failure, pregnant patients, or patients who are underweight or obese. Assessment of plasma drug levels by bioassay may be a familiar concept, but the use of this knowledge to determine whether a drug should be prescribed or the prescription altered will be new. The RN may know a given drug's effect on renal functioning, but the prescribing APRN needs to know what tests to order and when to order them to appropriately monitor that functioning, as well as when or if to alter the dosage or stop the drug. Diagnostic tests and their role in drug monitoring may be briefly covered in a basic nursing pharmacology course, but appropriate modification of drug therapy based on results is added knowledge that an APRN needs to be a safe prescriber.

A nurse who is studying to be an APRN will need additional knowledge about prescriptive authority. Does the chosen drug fit within the legal authority of an APRN to prescribe in his or her state? What are the conditions under which the prescription may be written, and how does one correctly write it? What constraints may be in place because of the patient's health insurer or lack of health insurance?

Additionally, the APRN needs to be aware of new drugs that come on the market, medication alerts, and label changes due to postmarketing analysis. In 2014 there were a record 41 novel new drug entities approved by the U.S. Food and Drug Administration (FDA), with an average of 25 new drugs approved annually (U.S. Food and Drug Administration Center for Drug Evaluation and Research, 2015). The FDA sends out alerts to health-care providers via the MedWatch Safety Alert system as new information becomes available from post-marketing surveillance and modifies drug labels as appropriate. Ever-changing drug information requires the APRN to remain up-to-date on drug information at all times.

BENEFITS OF AN APRN AS PRESCRIBER

Although the focus of this book is on pharmacotherapeutic intervention, alternative treatment options are also part of the armamentarium that can be used to treat a given disorder and may interact with the pharmacotherapeutic intervention. Discussion of common therapies that may be chosen as treatment options or that are integral to drug therapy is integrated throughout the drug-specific and disease-specific chapters.

Some therapies have traditionally been part of what all nurses teach, and they remain central to the role of the APRN, for example, lifestyle management issues for a cardiac patient, relaxation techniques for a patient experiencing stress, and appropriate exercise for a patient with low back pain or arthritis. Herbal therapies have been part of the health practices of people throughout history, but it is only recently that health-care providers have acknowledged them and considered them in planning treatment. If the APRN chooses to use herbal therapy or the patient is using this therapy as suggested by another provider, there must be reliable resources

about the therapy and its impact on prescribing. This book includes a separate chapter on herbal therapy and the uses of complementary therapies and also integrates the use of herbal interventions throughout.

Nutrition is also a common issue in nursing, but often the nurse's knowledge of nutrition related to pharmacology is limited to food–drug interactions or the low-sodium diet for a patient with hypertension. Knowledge regarding how foods and nutrition affect drug prescribing is integrated throughout the book; how foods are used as therapy is included in Chapter 9, "Nutraceuticals."

Choosing among pharmacological and other treatment options also involves advanced knowledge. The right choice depends on accurate information about the patient and his or her situation and the effects of any alternative treatment options on health outcomes. Choices also depend on the patient's culture, preferences for different health outcomes, attitudes toward taking risks, and willingness to endure often uncomfortable adverse drug effects during treatment for some possible future benefit.

Characteristic of APRNs and their practice are consideration of the whole patient, the joint setting of therapeutic goals with other members of the health-care team, and the inclusion of the patient in each decision about care. This holistic approach remains a central element in APRN practice and is often cited by patients and other providers as a hallmark and distinguishing feature of APRN practice when compared with other primary care providers. Adherence to a drug treatment regimen has traditionally been less than optimal. Statistics cited often place patient adherence (taking the drugs as prescribed) at less than 50 percent. Research shows that adherence is better for prescriptions given by NPs than by physician assistants (Manhattan Research, 2013). The reasons for the difference include consideration of the whole patient and inclusion of the patient in decision making. Another factor in improved adherence is patient education; APRNs spend more time than other providers in teaching their patients about the disease process and the relationship of the treatment regimen to it (Gielen, Dekker, Frecke, Mistiaen, & Krozen, 2013; Manhattan Research, 2013). Each of these important aspects of drug choice and utilization is covered in this book.

CLINICAL JUDGMENT IN PRESCRIBING

Prescribing a drug results from clinical judgment based on a thorough assessment of the patient and the patient's environment, the determination of medical and nursing diagnoses, a review of potential alternative therapies, and specific knowledge about the drug chosen and the disease process it is designed to treat. In general, the best therapy is the least invasive, least expensive, and least likely to cause adverse reactions. Frequently, the best choice is to have lifestyle, nonpharmacological, and pharmacological therapies working together. When the choice of treatment options is a drug, several questions arise.

Is There a Clear Indication for Drug Therapy?

In the age of health-care reform and increased awareness of the limitations of drugs, whether a medication is the best option for treatment has become an important question. For example, in treating acute otitis media, guidelines regarding the use of antibiotics has been evolving. A high percentage of otitis media infections resolve without intervention, so how does one know that the antibiotic was the cause of the cure? Of concern is organisms' resistance to antibiotics, with antibiotic overtreatment considered a contributing factor to resistance. Before drug therapy is chosen, the indication for and necessity of using a drug should be carefully considered.

What Drugs Are Effective in Treating This Disorder?

Several drugs may be effective in treating a condition, so which one is best for a particular patient? Even if only the most effective class of drug is considered, few classes of drugs include only one drug. How does one determine "best"; what are the criteria? Are there nationally recognized guidelines that can be used? The Agency for Health Care Quality (AHCQ), the National Institutes of Health (NIH), and many specialty organizations publish disease-specific treatment guidelines that include both pharmacological and nonpharmacological therapies.

What Is the Goal of Therapy With This Drug?

What is the best drug to achieve treatment goals? Various goals are possible in the choosing of therapy. The goal may be cure of the disease and short term in nature. If cure is the goal, troublesome adverse effects may be better tolerated and cost may be less of an issue. If the goal is long-term treatment for a chronic condition, adverse effects and costs take on a different level of importance, and how well the drug fits into the lifestyle of the patient can be a critical issue.

Under What Conditions Is It Determined That a Drug Is Not Meeting the Goal and a Different Therapy or Drug Should Be Tried?

At the onset of therapy, the provider and patient should have a clear understanding of what outcome or goal is expected of the medication prescribed. Follow-up and monitoring times are established to see how well treatment with the drug is meeting the goal. Often, monitoring parameters are published for a drug but may need to be adjusted based on the age or concurrent disease processes of the patient. Part of the decision-making process may include questions about when to consult with or refer the patient to a specialist.

Are There Unnecessary Duplications With Other Drugs That the Patient Is Already Taking?

The patient's medication history should be reviewed at each encounter to detect duplications or medications that may be discontinued. Sometimes drugs from different classes are given together to achieve a desired effect, and this is a therapeutic choice. It may also be that the provider is not aware of the overlap, especially if the patient is seeing several different providers. For example, a patient who is on a diuretic to treat hypertension may be receiving potassium supplementation. Another provider may decide to use an angiotensin-converting enzyme (ACE) inhibitor to treat heart failure. An ACE inhibitor can also be used to treat hypertension. Rather than a treatment regimen with three drugs, it may be possible to use a combination of an ACE inhibitor with a diuretic in one tablet, and because ACE inhibitors cause potassium retention, no supplemental potassium would be needed. Use of an integrated electronic health record can assist the provider in discovering duplication of therapy and collaborating with other providers to develop a simplified regimen.

Would an Over-the-Counter Drug Be Just as Useful as a Prescription Drug?

Increasing numbers of drugs are being moved from prescription to over-the-counter (OTC) status. This may lead to a reduction in cost for the patient, or it may increase patient costs due to insurance no longer paying for the medication. Patients may not consider OTC medications as "drugs" because they are not prescribed; therefore, a careful history of all medications would specifically ask about OTC medications.

What About Cost?

Who will pay for this drug? Can the patient afford it? Will the cost of the medication affect adherence to the treatment regimen? Cost is an issue for several reasons. Many insurance policies do not cover the cost of drugs or only provide partial coverage, so the patient must pay "out of pocket." The newer the drug, the more likely the cost is to be high based on the drug manufacturer's need to reclaim research and development costs while the corporation still holds the patent on that drug. Newest is not always best, and consideration of cost is a major factor in choosing between newer drugs and ones that have been around long enough to be available in generic form. Many insurance plans have larger co-pays for name-brand drugs than for generic medications. Multiple national retail pharmacies have developed $4.00 prescription formularies. Awareness of what is on the local discount formulary may save the patient hundreds of dollars in prescription costs and may increase compliance. Factors likely to lead to poor adherence include a drug that is expensive in relation to a patient's finances, a drug that must be taken daily as part of a complex regimen, and a drug that is not covered by insurance.

Where Is the Information to Answer These Questions?

Nurses evaluate sources of drug information and learn which ones to trust. For an APRN, the sources of drug information expand to include the wide array of professional literature that ranges from the well-reputed journals to literature from specialty and professional organizations, the multitude of computerized drug databases (e.g., Micromedix, Lexicomp,

Epocrates), information from the U.S. Food and Drug Administration, and formula programs that can be accessed via a handheld device or computer.

The APRN prescriber needs to evaluate how reliable the drug information is. How can reliability be determined? Is the information source written by someone who may benefit from presenting biased information? Is the information source current? Today's "wonder drug" may be removed from the market tomorrow. Is the information relevant to the specific patient for whom the drug will be prescribed? If the information is a research report, what type of research design was used? Are there questions about the validity and reliability of the data? Are national or international guidelines used to inform prescribing or does the reference suggest prescribing outside established guidelines? To prescribe drugs appropriately, APRNs must be able to answer these questions; to answer them, they must master sources of information and use them on a regular basis.

COLLABORATION WITH OTHER PROVIDERS

No one member of the health-care team can provide high-quality care without collaborating with other team members. They most often collaborate with physicians, pharmacists, podiatrists, mental health specialists, therapists, and other providers, including APRNs who are not NPs, physician assistants (PAs), and other nurses.

Physicians

Collaboration with physicians has been something of a roller-coaster ride for NPs. Early in the development of the NP role, physicians were the teachers in the NP programs and accepted NPs as physician-extenders. As the role of the NP evolved to clearly indicate that it was advanced nursing practice, and as legislation made autonomy of practice possible, the relationship became more adversarial, with the American Medical Association (AMA) issuing statements regarding the NP and PA scope of practice (AMA, 2009), often for economic reasons. An AMA document, *AMA Scope of Practice Series: Nurse Practitioner,* stated, "It is the AMA's intention that these Scope of Practice Data Series modules provide the background information necessary to challenge the state and national advocacy campaigns of limited licensure health care providers who seek unwarranted scope-of-practice expansions that may endanger the health and safety of patients" (AMA, 2009, p 4). The AMA responded to the IOM *Future of Nursing* report by reiterating that NPs are not qualified to provide patient care because of lack of hours in clinical education (Patchin, 2010).

Although this struggle still continues at the national level (Patchin, 2010; American Academy of Nurse Practitioners [AANP], 2013; AMA, 2013), NPs and physicians do work together very effectively on an individual basis and in collegial care teams. In an era of health-care reform, our joint concerns about patient care decisions require us to be allies.

Physicians may offer insight or advice on pharmacological management from their experience. A physician's expertise related to pharmacology is based on understanding biochemistry and prescribing for a given pathophysiology. The emphasis is on the disease and the drug, with less emphasis on the impact on the patient. Patient education by physicians may be limited or left to a nurse or pharmacist.

APRNs traditionally approach prescribing drugs in a slightly different manner from that of physicians. As APRNs prescribe a drug for a given pathophysiology, their nursing background leads them to place equal emphasis on understanding the impact the drug will have on the patient. Patient education is a central focus of nursing and APRN practice. Knowledge and clinical experience shared from the mingling of medical and nursing perspectives are mutually beneficial to the providers and the patient. The APRN can benefit from the in-depth knowledge about the drugs in the physician's specialty area. The physician can benefit from APRNs' focus on the impact of the drug on the patient and from their patient education skills. In the age of health-care reform, increasing emphasis is being placed on these latter issues.

Pharmacists

Collaboration with pharmacists requires an understanding of the educational preparation for and evolution of the role of the pharmacist. The profession of pharmacy requires graduate-level preparation for all pharmacists with the granting of a practice doctorate, the Doctor of Pharmacy (PharmD). PharmDs have extensive knowledge about pathophysiology and take an active role in determining the best drug to prescribe. A PharmD can assist by offering expertise on the clinical management of patients, including available dosage forms, potential adverse reactions, and drug interactions. Both physicians and APRNs increasingly consult PharmDs for their knowledge of pharmacokinetics and pharmcotherapeutics when prescribing for complex patients. In some jurisdictions, PharmDs have some independent prescriptive authority.

Other APRNs

Collaboration with other NPs and APRNs who have prescriptive privileges has two major advantages. On a one-to-one basis dealing with individual patient issues, NPs and APRNs can share "clinical pearls" from their knowledge base and collaborate to improve the care of the patient. Collaboration on issues related to scope of practice and prescriptive privilege at the state and national level is critical to obtaining and maintaining the autonomy of practice needed to provide optimal patient care.

Physician Assistants

The focus of the PA's practice is similar to that of the physician, so both the APRN and the PA can benefit from interaction with each other in much the same way as from their interaction with physicians. Many PAs desire more

autonomy in their practice, and the experience of APRNs in developing autonomy may be helpful. At this time, such autonomy does not exist, so it is important to know the laws that govern the practice of the PA as well as the APRN in the state to determine how collaboration can best occur.

Nurses Not in Advanced Practice Roles

APRNs regularly collaborate with other nurse colleagues who are not in advanced practice roles. Some have specialized knowledge, such as Certified Diabetes Educators (CDEs) and Wound and Ostomy Care Specialists (WOCS). These nurses and their assistants carry out the prescriptive orders of the APRN. For each of these care providers, it is important to remember their preparation and knowledge level and their legal responsibility in carrying out the APRN's orders.

RNs and licensed practical/vocational nurses function under their own licenses. Their preparation and responsibility are defined by the nurse practice act in each state. Whether they can legally take orders from an APRN is also delineated in these statutes. When prescribing drugs that others will administer, APRNs must know the nurse practice act in the state in which they practice. Medical assistants (MA) may have certification in the state that delineates their preparation, but they are generally not licensed. Their knowledge of drugs may be limited, if they have had any formal education in the area of pharmacology beyond administration. When prescribing drugs to be administered by MAs, APRNs must ensure that the MA clearly understands what they are to do; careful oversight is critical.

CANADIAN NURSE PRACTITIONER PRACTICE

There are over 3,000 APRNs in Canada (Canadian Nurses Association, 2015). As in the United States, where APRN scope of practice and regulation vary from state to state, NP scope of practice and regulation in Canada vary from province to province. NPs practice independently in most of the provinces with the exception of Prince Edward Island, where NPs must practice with a collaborating physician. The scope of practice for NPs also varies from province to province, as well as by practice setting. There are now pediatric, family practice, adult, and anesthesia NPs who can prescribe in Canada. Mental health NPs are working on prescriptive authority and currently must qualify as a prescribing NP in either adult, pediatric, or primary care.

In 2012, the Canadian federal government approved the New Classes of Practitioner Regulations (NCPR) under the Controlled Drugs and Substances Act that removed federal restrictions on NP authority to prescribe controlled substances. NCPR allows NPs to prescribe medications included in the Controlled Drugs and Substances Act when treating patients if they are authorized to do so under provincial/territorial legislation. Each individual province and territory must individually implement the NP scope of practice to include prescribing controlled substances.

CURRENT ISSUES AND TRENDS IN HEALTH CARE AND THEIR EFFECT ON PRESCRIPTIVE AUTHORITY

Autonomy and Prescriptive Authority

The growth in autonomy and prescriptive authority for NPs and other APRNs is a source of pride. APRNs have now successfully overcome the "cannot prescribe," "cannot diagnose and treat," and "cannot admit" prohibitions to practice that have required so much time and energy to overturn in the past. More states are broadening and expanding the legal, reimbursement, and prescriptive authority to practice for all APRNs, including NPs. By January 2004, all states had recognized the NP title, scope of practice, and prescriptive authority in legislation. Momentum to full autonomy is gaining, with 26 states allowing independent practice for NPs and 21 states allowing independent full prescribing as of January 2015 (National Council of State Boards of Nursing [NCSBN], 2015). APRNs in other states have also gained recognition, although the scope of practice and prescriptive authority is often more restricted.

These gains are not written in stone, however, and can be reversed. Despite continuing research studies (Newland, 2009; Pearson, 2009; Gielen, 2013) that demonstrate the effectiveness of the role of the APRN in improving patient outcomes, barriers remain. Major concerns related to prescriptive authority must continue to be addressed. Not all states have legislation that permits APRNs to prescribe independently of any required physician involvement. Turf battles continue between APRNs and physicians at national and many state levels over physician supervision requirements and co-signatures on prescriptions. The advent of the doctorate of nursing practice (DNP) degree with its comparable level of education to that of other health-care providers and a focus on independent practice may address some of these issues about supervision. However, the American Medical Association continues to stress the need for physician supervision and final authority for the patient, even for APRNs who hold the DNP (Partin, 2008; AMA, 2010, 2013). This push for physician control occurs despite data from malpractice and malfeasance ratios that clearly show that the rationale for physician supervision is unfounded (Pearson, 2009).

Interdisciplinary Teams

In a study by Kaplan and Brown (2004), the top three barriers to effective prescriptive authority for NPs all related to interactions with physicians. Among the top twelve, two related to interactions with pharmacists. It is time to put this battle behind us and work together to create teams of health-care professionals who work together to foster excellent health care for every patient. Such teams would provide care of higher quality with better patient outcomes if the strengths of each team member were fully utilized. Research and systematic reviews

comparing care given by such teams with that given by physicians alone supports this assertion (Gielen, 2013). The Institute of Medicine Committee on Health Professions Education (2003) states, "All health professionals should be educated to deliver patient-centered care as members of an interdisciplinary team, emphasizing evidence-based practice, quality improvement approaches and informatics" (p 45).

Level of Education of Team Members

One of the issues to be addressed in interdisciplinary teams is the level of education of the various providers. When the levels of education differ, issues of collegiality, collaboration, and, especially, supervision arise. Medicine has been at the practice doctorate level for more than 50 years. Pharmacists have moved the level of education to enter their profession to the practice doctorate (PharmD). APRNs are now addressing this issue. Recognizing that gaps exist between what is taught in master's-level education programs and the knowledge that is needed for practice, in 2004 the American Association of Colleges of Nurses (AACN) in collaboration with the National Organization of Nurse Practitioner Faculties (NONPF) formed a task force to develop the practice doctorate, and publish core content and competencies for such educational preparation. The title granted to the practice doctorate in nursing is the doctor of nursing practice. In 2006, the AACN organization published *The Essentials of Doctoral Education for Advanced Nursing Practice* (http://www.aacn.nche.edu). In April 2006, NONPF published the entry-level competencies for the graduate of a DNP program (http://www.nonpf.com). These competencies were replaced by NONPF in 2011/2012 with a common document that encompassed all competencies expected of NPs entering practice after graduation. Competencies related to scientific foundation, leadership, quality, practice inquiry, technology and information literacy, policy, understanding of health delivery systems, ethics, and practice are core to all NPs (NONPF, 2011/12).

A date of 2015 was set by the AACN for the educational preparation of all APRNs, including CRNAs, CNMs, CNSs, and NPs, to be at the doctoral level. A 2014 Rand study, "The DNP by 2015" (Auerbach et al., 2014), sponsored by AACN, found that of the 400 schools offering APRN education, 30 percent offered BSN to DNP programs and 58 percent had MSN to DNP programs. Barriers identified by schools that had not adopted the DNP include that the DNP is an option—not a requirement—for practice. Internal or institutional barriers included faculty resources and clinical sites.

In 2014, there were 241 DNP programs with 14,699 students enrolled (http://www.aacn.nche.edu/dnp). An additional 59 DNP programs were in the planning stages. In 2014, the AACN convened a group to evaluate the recognized variance that occurs within and across programs in order to establish more consistency in graduate outcomes and capstone projects, with the outcome not available as this text went to print. This move to the same level of education as other members of the health-care provider team will address some of the issues surrounding the interdisciplinary team. The content of this book is consistent with the recommendations of both the AACN and the NONPF related to the knowledge base in pharmacotherapeutics for DNP-prepared nurses.

Reimbursement

The passage of legislation and the adoption of regulations related to reimbursement is evolving, with the Affordable Care Act rollout creating an opportunity for APRNs to address reimbursement parity. However, the reimbursement by third-party payers continues to be a practice barrier for many nurses in advanced practice. In 2013, Oregon was the first state to pass payment parity for APRNs.

The transfer of additional accountability for Medicaid from the federal government to the states also has the potential to jeopardize the implementation of federal mandates for services and access to APRNs as providers, especially if APRNs are seen as primary care providers only to underserved populations that are financially undesirable to physicians. APRNs must be careful that they not be seen as physician-substitutes or physician-extenders but rather as APRNs who bring a different perspective and science to patient care; otherwise, the current autonomy we enjoy and the level of autonomy we hope to attain may disappear.

Private-sector and government restructuring of health care with a focus on cost control and for-profit groups has both positive and negative potential for the autonomy of the APRN. The negative aspect is that treatment options and decision making about their use are often transferred to the corporation or the government. This can limit the APRN's ability to determine treatment options, and the extra time the APRN takes to educate and counsel patients may be seen as a liability rather than as an asset. From a positive point of view, APRNs have demonstrated their ability to control costs and improve patient outcomes (Pearson, 2009). We must continue to conduct research on the ability of APRNs to provide competent, cost-effective, high-quality services to improve the health of our patients, whether in NP-only practices or in collaborative practices, and to share the findings of that research with the decision makers in the changing world of health care. Better yet, we must become decision makers.

APRNs and other providers must address these challenges and take control of their future in health care so that preferred outcomes are achieved rather than outcomes designed and implemented by others. This requires a commitment of time and energy from each APRN to work together with other providers and other nurses to deal with these issues at local, state, and national levels. Keeping current on new knowledge in pharmacology and on the latest drugs and their clinical applications is only part of the role of the health-care provider as prescriber. APRNs should join and support their professional organizations and engage in positive political activity to maintain the prescriptive authority already gained in each state and to extend autonomous prescriptive authority to all states.

REVIEW OF BASIC PRINCIPLES OF PHARMACOLOGY

Peter J. Rice

PHARMACOLOGY—THE STUDY OF DRUGS

Pharmacology is the study of drugs and their actions. Pharmacologists, those who study drugs and their actions, consider a drug to be any chemical substance that produces a measurable biological response. So drugs include not only prescription medications but also nonprescription medications, botanicals, drugs of abuse, and poisons.

As we consider the variety of drugs and the measurable responses they produce, it will be helpful to think about what we would like to see in an ideal drug (Box 2-1). There are no perfect drugs—yet. But defining what would make an ideal drug will help us understand how medicines have developed over time, and what properties to consider as we compare one drug with another to choose the best medication.

HOW NEW DRUGS ARE DEVELOPED

Drugs are developed by pharmaceutical companies to help patients and to make money. The early part of the drug development process is called the preclinical stage. Identification of promising drugs and their testing in animals occur during this stage. Pharmaceutical companies will identify a drug target, starting sometimes with ingredients isolated from a plant (or organism in the case of antibiotics) with desirable medicinal properties, sometimes with a molecular target identified in the body to produce the desired response, and sometimes with a disease in need of treatment. It is common for companies to enlist medicinal chemists, who specialize in designing and synthesizing new drugs. Medicinal chemists can provide many new chemical compounds for the preclinical process. Each drug might have a small difference in its chemical structure that will change its drug properties. Many drugs are examined as pharmaceutical companies seek the elusive perfect

drug with just the right combination of properties. Preclinical studies are performed on cells, isolated tissues and organs, and in laboratory animals to identify promising compounds.

Drugs approved by the Food and Drug Administration (FDA) must be both safe and effective and are screened by pharmacologists specializing in various aspects of drug activity. Toxicologists specialize in understanding the harmful effects of drugs and predicting as early as possible if a drug will be likely to harm patients. Ideally, drugs will produce their desired effects at dosages well below those needed to produce toxicity.

During the clinical stage of new drug development, pharmaceutical companies must establish the safety and effectiveness of new products in humans. Phase I clinical trials typically establish biological effects as well as safe dosages and pharmacokinetics in a small number of healthy patients. During phase II clinical trials, new drugs are used to treat disease in a small number of patients and to establish the potential of the drug to improve patient outcomes. If the drug still looks promising, phase III clinical trials will compare the new medication to standard therapy in a larger number of patients studied by at sites across the country. New drugs must be at least as good as, and it is hoped better than, other available therapies. Throughout the process, pharmaceutical companies work with the FDA.

After being approved by the FDA, drugs are continuously monitored through post-marketing surveillance, in which health professionals are encouraged to report adverse events, which are studied by both pharmaceutical companies and the FDA. During clinical trials, only several thousand patients receive a new drug. During the post-marketing period, a larger population of patients receives the drug, and sometimes much is learned about additional adverse effects that occur infrequently with use of the drug. Pharmacogenomics is the study of how individual variations in drug targets or metabolism affect drug therapy. Pharmacogenomic studies can identify factors that are responsible for beneficial or adverse effects in individual patients.

DRUG RESPONSES

Homeostasis is the tendency of a cell, tissue, or the body *not* to respond to drugs but instead to maintain the internal environment by adjusting physiological processes. Before a medication can produce a response, it often must overcome homeostatic mechanisms.

Drug effects depend on the amount of drug that is administered. If the dose is below that needed to produce a measurable biological effect, then no response is observed; any effects of the drug are not sufficient to overcome homeostatic capabilities. If an adequate dose is administered, there will be a measurable biological response. With an even higher dose, we may see a greater response. At some point, however, we will be unwilling to increase the dosage further, either because we have already achieved a desired or maximum response or because we are concerned about producing additional responses that might harm the patient.

Because pharmacology is the study of substances that produce biological responses, measurement of what happens when we administer medications is important. We will need ways to express and compare drug activity so that we can describe the action or effect of drugs, compare the effects of different drugs, and predict their pharmacological effects.

Dose–Response Curves

Drugs produce responses as a result of their chemical interactions with living systems. The relationship between the dose or concentration of a drug and its biological response follows the laws of chemistry. The law of mass action defines chemical interactions and forms the theoretical foundation for drug responses that occur through receptors that mediate drug responses. Simply stated, the higher the concentration of a drug at its site of action, the more the drug will bind to the receptor and the greater will be the response. With a greater number of drug molecules in the vicinity, more of them are likely to interact with the receptor.

It is simplest to think that drug responses are directly related to the fraction of receptors that are occupied, or bound, by a drug, so that 50% of the maximum response occurs at a blood level or concentration at which a drug occupies 50% of its receptors. But depending on the number of receptors in a tissue and the ability of drug binding to produce a change in the receptor conformation, far fewer receptors (less than 10%) may be needed to produce a maximum effect.

Types of Drug Responses

There are two basic types of drug responses: quantal and graded. These responses differ in how they are measured and dictate dosing decisions to achieve the desired effect.

Graded responses are biological effects that can be measured continually up to the maximum responding capacity of the biological system (Box 2-2). Most drug responses are graded. For example, changes in blood pressure are measured in millimeters of mercury (mm Hg), and patients may experience small or large changes in blood pressure following treatment with drugs. Graded responses are easier to manage clinically because we can see how each patient responds to a

particular dose of medication and, if appropriate, alter the dosage to achieve a greater or lesser response. So if a patient's blood pressure is too low or too high when a particular blood pressure medication is administered, we can adjust the dosage based on the patient's individualized response to the medication.

Quantal effects are responses that may or may not occur (Box 2-3). For example, seizures either occur or they do not. The same is true for pregnancy, sleep, and death. If we designate a response as either occurring or absent, it is a quantal response. Prediction of drug dosages or blood levels that produce quantal effects is much more reliable for a population of patients than for an individual patient. Data from a population of patients must be used to establish appropriate doses or blood levels to predict quantal effects in a large number of patients. For example, oral contraceptive doses are high enough to prevent pregnancy (a quantal response!) in over 99% of women. Note that, even with anticonvulsants or oral contraceptives, we do not achieve a 100% response. Because of natural variation in drug metabolism and responses to drugs, there may always be individuals who fail to respond, even at higher dosages. In general, responses that are far outside the typical dose or concentration range occur in patients with unusual drug metabolism or receptor mutations.

The distinction between graded and quantal responses is not always fixed. Certainly, patients are either pregnant or not and either dead or alive. However, for some other quantal responses such as seizures, you can also count the number of occurrences. This can be helpful in adjusting medications to improve patient response with fewer or shorter seizures (a graded response), even though the goal is a seizure-free (quantal response) patient. We can also make graded responses quantal by considering such issues as "Did drug therapy lower

blood pressure into the target range?" or "How many patients were headache-free?"

Expressing Drug Responses

Pharmacologists show the relationship between dose or concentration and drug effect using graphs that show the dose–response relationship, or dose–response curve. Graphs showing drug responses will show the response on the vertical axis and the concentration or dose on the horizontal axis. And for statistical reasons, because drug dosages extend over a large range, the horizontal axis is logarithmic, which means that it covers a larger dosage range and that numbers are distributed along the axis so that moving a certain distance right or left represents multiplying or dividing the dosage or blood level concentration by a fixed amount. Most dosage changes in patients are doubled or halved: a "logarithmic" adjustment.

Dose–response curves provide information on the relationship between dosage or concentration and responses for one or more drugs. To "read" a concentration–effect or dose–response curve, move from left to right along the horizontal axis; this represents an increasing dosage or concentration. At each dosage, the level of effect is shown by the vertical height of the curve. When concentration–response data are shown for two drugs or two responses on the same graph, we can compare the effects at each dose level.

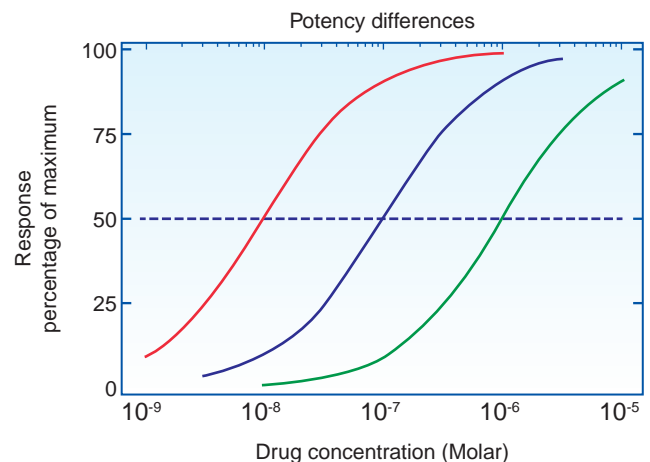
Pharmacologists compare drugs and their actions in several ways, including potency, efficacy, intrinsic activity, and selectivity. Potency is the expression of *how much* drug is needed to produce a biological response (Fig. 2-1). Potency describes the difference in concentration or dosage of different drugs required to produce a similar effect. Drugs that are more potent require a lower dosage or concentration to produce the same response. For example, compare doses of nonprescription drugs that relieve headache: 200 mg ibuprofen, 325 mg aspirin, and 50 mg ketoprofen. Because ketoprofen requires the lowest dose, it has the highest potency. Drugs


Figure 2–1. Concentration–effect curves for three drugs that differ in potency (i.e., the dose or concentration required to produce an effect). The drug concentration on the *x*-axis is expressed in molar units, representing the number of molecules in each liter of solution. The graded response is expressed as a percentage of maximum effect.

that differ in potency differ in their horizontal position on the dose–response curve.

Efficacy expresses the ability of a drug to produce a maximum effect at any dosage. Efficacy is the expression of the *maximum effect* a drug can produce. For example, consider the treatment of pain. There are many drugs that will relieve mild pain. No matter how high we increase the dosage, drugs that work well for mild to moderate pain are usually ineffective for treating more severe cancer-related pain, for example. Treatment of severe pain requires the use of stronger drugs, such as the opioid analgesics morphine or oxycodone. Morphine or oxycodone have higher efficacy for pain relief than ibuprofen. Drugs with high efficacy can produce greater effects than lower-efficacy drugs can.

Intrinsic activity is very similar to efficacy in that it represents the ability of a drug to produce a large response. Intrinsic activity, however, is used to describe the ability of a drug to produce a response once it has occupied specific receptors. Some drugs produce the maximum receptor stimulation once they occupy receptors; their response is limited by how many drug molecules occupy receptor sites. Other drugs with lower intrinsic activity can occupy the same number of receptors but will produce a lesser response. Drugs can also occupy receptors and produce no receptor stimulation; they merely block the action of neurotransmitters or other drugs.

Drug Selectivity

In clinical use, drugs produce responses that are desired and responses that are unwanted. Of course, we should be administering drugs with a goal in mind, and that goal should include a level of response, either graded or quantal. The level of unwanted response we are willing to accept typically depends on what we are treating and the type of undesired effect. Patients regularly accept all kinds of adverse effects from cancer chemotherapy when their life is on the line; cancer patients tolerate hair loss, nausea, vomiting, and generally feeling miserable because that is what goes along with killing cancer cells. Sometimes patients make surprising decisions regarding drugs that produce both desirable and undesirable effects; for example, some patients will live in severe pain rather than take an analgesic that causes constipation. For hypertension and other symptomless disease states, patients are often reluctant to accept even minor adverse effects. Patients receiving pharmacotherapy present the opportunity and challenge to adjust medications and dosages to achieve optimal results with minimal adverse effects and to educate patients to continue therapy even if minor adverse effects appear.

There are challenges to expressing drug selectivity. The most reasonable way to express *selectivity* is as a ratio of the dose or concentration producing the undesired effect to the dose or concentration producing the desired effect. This is the same as determining how many times the therapeutic dosage needs to be increased to produce the undesired effect. A medication that requires one tablet to produce the desired response and does not produce undesirable effects unless five tablets are used would have a selectivity ratio of 5. That is not a bad drug. But

many drugs produce significant undesired effects at or slightly above the therapeutic dosage.

It would be nice if we could describe drug selectivity in a way to encourage optimal drug use. Would not a medication that has high selectivity and produces only the desired effects be the treatment of choice? There are problems, though, with consistently expressing selectivity based on desired and undesired effects. Medications often have more than one effect and might be used for any of their effects, so sometimes a particular effect is desired and sometimes it is undesired. Diphenhydramine is a very nice drug that is used as an antipruritic for itching, as an antihistamine for allergies, as an anticholinergic that dries secretions, and as a sleeping aid that produces drowsiness. Desired and undesired effects can differ for each patient, and if we compare dosages, there are several selectivity ratios.

The therapeutic index is a special ratio describing drug selectivity. The therapeutic index is the ratio of the lethal dose of a drug to the therapeutic dose of a drug. There are some limitations to the therapeutic index: it uses death, a really unacceptable adverse effect, and it uses data from animal studies. But the therapeutic index provides a fixed comparison for drug safety. The therapeutic index of drugs on the market is, of course, always greater than 1; a therapeutic index of less than 1 means that the drug kills before it cures. The therapeutic index ranges from 2 for some drugs (cancer chemotherapy, lithium carbonate) to 6,000 for others (penicillin in nonallergic patients).

Drug Responses in the Real World

Pharmacotherapy in real patients is different than what has already been described. The placebo effect is a pharmacological effect that is not due to the active ingredient. Placebos are tablets or capsules that contain no active ingredient; they are sometimes called "sugar pills" because they used to be filled with sugar. It is common for drug studies to have a placebo group to see if patients are responding to the active drug or just to the act of taking a medication (Fig. 2-2). The placebo group will also be monitored for adverse effects, which establishes the level in untreated patients. Placebo effects are relatively high in some disease states, such as depression, and very low in other disease states, such as cancer.

Dose–effect relationships in the real world do not start at zero response; they start at the response associated with the placebo effect. The level of response increases as the dose increases but rarely reaches 100%. Instead, the risk of toxicity will limit the maximum dosage, or another drug will be used if there is no satisfactory effect.

Brand Versus Generic Drugs

New drugs are patented to protect the innovator company for a period during which only it can manufacture the drug. New drugs are given a generic name that anyone can use to market the drug, but innovator companies will make up a brand name that only they can use to market their drug. During the years after a drug is released, it is marketed under the
Figure 2–2. Theoretical representation of how drugs produce effects in clinical practice. Drug concentration (*x*-axis) increases from left to right. Some patients will respond at low dosages, either because of the placebo effect or sensitivity to the drug. As drug concentrations increase, greater numbers of patients will respond favorably but some will also respond adversely. At some dosage or concentration, the presence of toxic effects precludes the use of higher doses in patients.

brand name, and patients and practitioners often become familiar with the product under its brand name. Once the patent on the original drug expires, other companies can manufacture generic products that are designed to imitate the brand product. Once competition is allowed, generic manufacturers formulate similar dosage forms with the same active ingredient in the same amount.

Patients often wonder about the relationship between the effects of brand and generic preparations. Since brand and generic preparations contain the same active ingredient, the body treats the two exactly the same. Differences between brand and generic preparations can occur in the inactive ingredients of the tablet or capsule, such as coloring or filler materials.

Generic products are *supposed* to provide patients with the same dosage as brand-name products. Differences between brand and generic formulations result from differences in the time it takes for the different formulations to break apart in the stomach and dissolve prior to absorption. There are always differences in the speed, or rate, of absorption. The FDA rates generic formulations in its *Orange Book*, and products with an AB rating are considered to be similar enough to use as generic substitutes for brand-name products.

Because the differences between brand and generic products occur in the tablet/capsule disintegration and dissolution steps prior to absorption, brand and generic preparations in which the drug is already in solution, such as injectables, are similar in their rate and extent of absorption.

RECEPTORS

We can think of drug responses in a simple way. A favorite cartoon shows a mathematician solving a problem. The solution begins with an equation that states the problem, and a gap follows in which the mathematician writes "and then a miracle happens," followed by the result. If we choose to think of drug responses as the predictable miracles that follow drug administration, then pharmacology would be no more than memorizing which responses go along with which drugs. A century ago, medical schools and pharmacy schools had departments of *materia medica*, a Latin way of describing the pairing of a drug with a response without necessarily knowing what happens in between. Today, we encounter the same knowledge level for many botanicals, and patients and health professionals alike will often consult manuals that list symptoms to be treated and the plant product that can produce that action.

If we choose to actually understand drug action and why drugs produce predictable sets of responses, we need to look at the biological molecules and the chemical principles that underlie responses to drugs. Almost all drugs act through receptors. Receptors are the large molecules, usually proteins, that interact with and mediate the action of drugs. Receptors are important because they determine the relationship between dose and effect, the selectivity of drugs, and the actions of pharmacological antagonists.

Pharmacologists tend to organize drug activity based on the receptors through which individual drugs act. There are several benefits to organizing the study of pharmacology around receptors. It simplifies the amount of material that needs to be memorized. Receptors provide a theoretical framework for understanding and predicting drug actions and the relationship between dose (or concentration) and effect. Also, receptors within the same "superfamily" often share properties.

Drug targets include enzymes, ion channels, cell surface receptors, nuclear hormone receptors, transporters, and DNA. In each case, chemical interactions take place between drug and receptor molecules. Receptors act through a number of mechanisms, including those described in the following sections. Chemical energy from the drug–receptor interaction is used to change the receptor in some way that alters physiological processes to produce cellular changes that result in a measurable response.

Because chemical interactions determine the activity of a drug at a particular receptor type, changes in chemical structure result in changes in pharmacological activity. The correlation of chemical structure with pharmacological activity is called the *structure-activity relationship* (SAR). SARs can be helpful in understanding receptors and for developing new drugs. There are separate, independent SARs for different drug properties (e.g., potency, selectivity, toxicity), so the fact that any one drug property changes for the better (or worse) does not necessarily mean that the change affects the other properties of the drug.

Ion Channel Receptors

Ion channel receptors transmit signals across the cell membrane by increasing the flow of ions and altering the electrical potential or separation of charged ions across the

membrane. Ion channel receptors can produce responses with a rapid onset and short duration. For example, activation of ion channels by nicotinic receptors is responsible for muscle contraction. Muscle movement needs to start immediately and must stop at will to be effective. The nicotinic receptor consists of five subunits, which form a cylindrical structure with a hole in the center. When acetylcholine (ACh) binds to the two alpha subunits, a conformational change occurs, which momentarily opens the central channel, permitting sodium to enter and potassium to leave the cell (Fig. 2-3). Two binding sites for ACh result in a very steep concentration–effect curve, so a very small change in ACh concentration at the neuromuscular junction will produce dramatic openings in ion channels. Notice that the two ACh sites are a certain distance apart. This is important for the structure–activity relationship of drugs that blocks nicotinic receptor sites.

Ion channel receptors include receptors for ACh (nicotinic), gamma-aminobutyric acid (GABA), and excitatory amino acids (glycine, aspartate, glutamate, etc.).

Receptors Coupled to G Proteins

A number of different guanine nucleotide regulatory proteins (or G proteins) are present in cell membranes. G proteins share a similar structure in which seven regions of protein span the cell membrane to create a pocket (in which drugs can bind) and end with a receptor "tail" inside the cell (Fig. 2-4). Individual G protein receptors have the general G-protein structure but differ in their "binding site," the area that recognizes and binds to drugs, and in the intracellular portions of the G protein that control what happens after a drug is bound. Receptors are activated when specific drugs interact with the binding site, producing a conformational change, a sort of twist, in the G protein. Activation of receptors then produces intracellular changes in the binding of the G-protein receptor to other proteins that control response through other molecules called *second messengers*.
Figure 2–4. G-protein–coupled receptors are proteins that cross the cell membrane 7 times, creating a pocket in which drugs can interact. Bound drugs may stimulate the receptor to release a G protein that can interact with various effector proteins to produce physiological responses.

Second messengers include molecules such as cAMP (cyclic adenosine monophosphate), Ca^{++}, phosphoinositides, and diacylglycerols; each can be produced as a result of stimulating different G-protein–linked receptors. The conformational change in the G-protein receptor can also make intracellular parts of the receptor available for enzymes to phosphorylate. Phosphorylation, placing a phosphate group on a protein, is a way of marking it for activation or inactivation.

G proteins are made up of three major subunits (alpha [α], beta [β], gamma [γ]); minor variations (isotypes) of each subunit can result in a great deal of variation in G proteins just from different combinations of alpha, beta, and gamma subunits. Variation in G-protein subunits and receptors allows them to interact with a variety of drugs and produce different responses depending on which drug is recognized by the receptor, which subunits are involved, and which effector protein is altered. Individual cells and tissues can produce various types and amounts of G proteins. This is a homeostatic mechanism used by the body to adapt to disease states and drug treatment.

Receptors coupled to G proteins mediate the level of second messengers following the extracellular interaction of drug with the receptor. This receptor superfamily includes a large number of different receptors that recognize different drugs and activate or inhibit different second messengers. For example, beta-adrenoceptors mediate the effects of epinephrine (also called *adrenaline*) on the heart and make our hearts beat faster and stronger at scary movies.

In the prototype beta-adrenoreceptor system, interaction of epinephrine with the receptor displaces guanosine diphosphate (GDP) from the G protein, and its replacement by guanosine triphosphate (GTP) activates the G protein. The G protein uncouples from the receptor and stimulates the enzyme adenylyl cyclase to generate intracellular second messenger cAMP. Intracellular cAMP produces the pharmacological effect, such as making the heart beat stronger and faster, until the cAMP breaks down. Caffeine produces similar effects by inhibiting the breakdown of cAMP.

Figure 2–3. The nicotinic acetylcholine (ACh) receptor comprises five subunits that come together to form an ion channel receptor. When ACh binds to two sites on the receptor, the ion channel opens to let sodium (Na^+) and potassium (K^+) cross the cell membrane to initiate a response.

Changes in the number of receptors alter responsiveness to drugs. The number of available G-protein receptors decreases when the receptors are stimulated. Receptors in the cell membrane are phosphorylated at specific intracellular sites, which can lead to desensitization, or loss of receptors or responsiveness following receptor activation. These receptor changes influence drug treatment by limiting the time in which certain drugs can be used clinically and by placing patients at risk for rebound effects when certain drugs are discontinued.

Transmembrane Receptors

Transmembrane receptors consist of an extracellular hormone-binding domain and an intracellular enzyme domain that phosphorylates the amino acid tyrosine. When an active hormone binds to the extracellular binding site, the receptor conformation changes and two receptors bind to one another, activating the enzyme and sustaining the effect (Fig. 2-5). Different receptors catalyze the phosphorylation of tyrosine residues on various downstream signaling proteins.

The protein tyrosine kinase includes receptors for insulin, epidermal growth factor, and platelet-derived growth factor.

Intracellular Receptors Regulating Gene Expression

Lipid-soluble hormones can pass through the cell membrane and bind to intracellular receptors. The glucocorticoid receptor resides in the cytoplasm until it binds with a drug having glucocorticoid activity; binding of the drug displaces a stabilizing protein and permits the folding of the receptor into its active conformation. The receptor then moves to the nucleus, where it controls the transcription of genes by binding to specific DNA sequences (Fig. 2-6). Hormone receptors of this type include corticosteroids, mineralocorticoids, sex steroids, vitamin D, and thyroid hormones; these produce more sustained responses.

Figure 2–6. Steroid hormones diffuse through the cell membrane to interact with steroid receptors in the cytoplasm. The hormone–receptor pair relocates to the nucleus, where it can interact with DNA to effect RNA transcription and the synthesis of proteins.

Enzymes

Enzymes are biological molecules that encourage specific chemical reactions in the body. For example, the enzyme acetylcholinesterase breaks a chemical bond in ACh to terminate its action and make acetic acid and choline (Fig. 2-7). A different enzyme can reassemble these molecules into ACh. Drugs can act to stimulate or inhibit specific enzymes. The anticoagulant heparin binds to an enzyme called antithrombin-III and increases its inactivation of clotting factors. The anticholesterol "statin" drugs are inhibitors of the enzyme HMG-Co-A (3-hydroxy-3-methyl-glutaryl coenzyme A) reductase, which controls cholesterol synthesis in the body. Antibiotics are frequently inhibitors of enzymes that are essential for bacteria to remain alive.

Drug Action at Receptors

Drugs can do three basic things once they bind to a receptor. Agonists, or full agonists, are drugs that produce receptor stimulation and a conformational change every time they bind. Full agonists do not need all of the available receptors to produce a maximum response. Some agonists

Figure 2–5. The insulin receptor is prototypical of tyrosine kinase receptors. These receptors are brought together by extracellular drug binding (insulin in the case of the insulin receptor), which activates the intracellular enzyme tyrosine kinase. Tyrosine kinase receptors activate one another by adding a phosphorus (P) to select sites on cellular proteins, which in turn activates a physiological response.

Figure 2–7. Enzymes bind to substrates and speed up biochemical reactions. Enzymes can serve as receptors to the substrate, which binds at the active site, or to drugs that control enzyme activity through binding at a different site.

can produce their maximum response by binding to less than 10% of the available receptors. The receptors that are left over and not needed for a response are called *spare receptors.*

Antagonists are drugs that occupy receptors without stimulating them. Antagonists occupy a receptor site and prevent other molecules, such as agonists, from occupying the same site and producing a response. Antagonists produce no direct response. The response we see following administration of antagonists results from their inhibiting receptor stimulation by agonists. For example, beta blockers such as propranolol and atenolol act as antagonists at the beta-adrenoceptor. Adrenergic nerve activity can raise heart rate, and patients with high heart rates experience a significant drop in heart rate following administration of beta blockers. The same administration may have little effect on patients who lack adrenergic nerve activity and already have a lower heart rate. The effect of antagonists is dependent on the background receptor activity that it can block.

Antagonists produce a shift in the concentration–effect relationship for agonists acting at that same specific receptor as the antagonist; they make agonists for the same receptor appear less potent. The effect of an antagonist is dependent on its blood levels and its affinity for the receptor. Most antagonists in clinical use are competitive reversible antagonists, and it is possible to overcome the antagonist effects with higher concentrations of the competing agonist. A very small number of antagonist drugs (e.g., echothiophate, phenoxybenzamine) act by irreversibly binding to the receptor; their antagonism remains until new receptors can be produced by the cell.

Partial agonists are drugs that have properties in between those of full agonists and antagonists. Partial agonists bind to receptors but when they occupy the receptor sites, they stimulate only some of the receptors. This is sometimes called *intrinsic activity*. So they can act as part agonist and part antagonist. Partial agonists would require all of the available receptors to produce their full response, and the maximum response for a partial agonist is less than that for a full agonist. The beta blockers acebutolol, penbutolol, and pindolol are partial agonists. Administration can block the effects of adrenergic nerves on heart rate, but partial agonist activity keeps heart rate from falling too low, as might occur following administration of a pure beta-adrenoceptor antagonist. So beta blockers with intrinsic sympathomimetic activity control heart rate within a range that is higher than the response to an antagonist and lower than the response to an agonist.

Disease States and Receptors

Disease states or drug treatment can selectively alter the number of receptors in various tissues throughout the body. For example, hyperthyroidism upregulates, or increases, the number of beta-adrenoceptors, making hyperthyroid patients more likely to have hypertension and a rapid heart rate. Treatment with some agonist drugs can cause the receptors to downregulate, or decrease, in response to receptor stimulation; this can

limit the duration over which the drug can be clinically useful. Treatment with some antagonist drugs can cause receptors to upregulate in response to the decrease in receptor stimulation; this can produce rebound effects if the antagonist is abruptly withdrawn.

Because the maximum response to partial agonists depends on the number of receptors, an increase in receptor number will increase the response of partial agonists.

Non-receptor Mechanisms

Not all drugs act through receptors. General anesthetics, sodium bicarbonate (which neutralizes stomach acid), and chelating agents (which bind to and remove metal ions in the blood) are some examples of drugs whose action is based on their physicochemical properties rather than interaction with receptors.

PHARMACOKINETICS

Pharmacokinetics is the branch of pharmacology dealing with the absorption, distribution through the body, metabolism, and excretion of drugs. Ideally, drugs will enter the body readily, go directly to their site of action, and have a favorable combination of metabolism and excretion that will make it easy to manage patients, even in the presence of kidney or liver disease.

Absorption

Medications produce little clinical effect when they remain inside the prescription bottle. To produce a biological effect, drugs must enter the body. Once inside the body, drugs can interact with various receptor molecules to produce physiological changes that result in clinical effectiveness.

The way in which medications are presented to the body affects the speed, the extent, and the duration of drug absorption. The route of administration also affects patient compliance, that is, their willingness to follow recommendations for taking a medication (Box 2-4). So choosing the route of administration can have important implications for drug therapy, and it is not surprising that a variety of routes of administration can be chosen based on the chemical properties of an individual drug, the condition of an individual patient, and the goal of drug treatment.

There is more to it than just having a medication enter the body. Patients can swallow a poorly formulated dosage

---

BOX 2–4 EFFECTS OF ROUTE OF ADMINISTRATION

- Compliance
- Bioavailability
- Onset of action
- Duration of action

form that travels through the intestines and arrives unchanged in the toilet. There is little biological effect from these "bedpan bullets" if the active medication never reaches its site of action.

Parenteral Administration

Medications may be administered parenterally, or by injection, when immediate effect is required, when the active ingredients are destroyed or not absorbed in the gastrointestinal tract or other routes, or when the patient is unable to take an oral medication. A major limitation of parenteral administration is that it requires needles, syringes, and sterile technique.

Drug absorption is greatest for intravenous (IV) injection. IV preparations use drugs that have been dissolved in aqueous solution and are sterile and ready to enter the bloodstream. Intramuscular or subcutaneous preparations may use drugs suspended in sterile media, which is usually aqueous but occasionally oil-based. When administered by IV injection, all the drug enters the bloodstream immediately. IV administration serves as the standard to which other routes of administration are compared when we consider bioavailability, the percentage of the administered drug that is absorbed. Although there are drawbacks to needles and the need for sterility, IV administration is used for its advantages of rapid or complete absorption and immediate drug action. A major disadvantage of IV administration is that, once administered, the dosage cannot be slowed or removed. IV administration is common for emergency drugs and in the hospital setting.

Oral Administration

Oral administration is the most convenient and common route of administration. In contrast to IV administration, orally administered drugs must go through a number of steps on their way to the bloodstream. Following oral administration, dosages, as tablets, capsules, or liquid, make their way to the stomach and continue to move into and through the small and large intestines on their way to the colon. Tablets or capsules must break apart, and their drug contents must dissolve in stomach acid or intestinal fluid before the drug can be absorbed. This takes time, so orally administered drugs may not act as fast as some other routes of administration. Orally administered drugs must pass through the lining of the intestines to enter the systemic circulation. Once absorbed, orally administered drugs travel to the liver, where they may be metabolized on their way to the bloodstream.

A number of related routes of administration overcome some of the problems encountered with oral dosing. Sublingual administration (under the tongue) and buccal administration (between the cheek and gum, as with chewing tobacco) allow drugs to have a more rapid onset of action and to avoid liver metabolism as they enter the bloodstream. Nitroglycerin sublingual tablets are used to treat chest pain; they can act within a minute or two and can help stop an anginal attack and avoid an emergency room visit. Buccal administration is not very common but is used with methyltestosterone and nicotine preparations.

Some medications are destroyed by stomach acid following oral administration or are absorbed too rapidly to be convenient medications. Enteric-coated formulations protect the medication in the stomach and only disintegrate and dissolve when they reach the gentler conditions of the intestinal tract. Sustained-release preparations allow a drug to dissolve slowly in the intestines so that medication is absorbed over a period of time. It is important not to crush these preparations before administration because that would destroy the formulation and speed absorption.

The use of oral medications may be limited when patients are nauseous, vomiting, or uncooperative. Administration of suppository preparations into the rectum allows drug absorption that is similar to oral administration. While rectal administration is appropriate for some medications and is used for some pediatric medications, it is not universally welcomed by patients.

Site of Administration

Administration of medication close to where it will act has some notable theoretical advantages. When medications are administered near their site of action, higher concentrations may be achieved while minimizing unwanted effects in other parts of the body. Topical administration allows medication to be concentrated in the skin when patients need an anti-inflammatory (e.g., hydrocortisone) or an antifungal (e.g., clotrimazole) medication for a skin condition. This is particularly advantageous in that drugs pass more easily through damaged skin, so more drug is available to the areas of the skin that need the medication. Multidose inhalers and nebulizers are commonly used to administer drugs (e.g., albuterol) directly into the lungs. Ophthalmic preparations are sterile preparations suitable for administration to the eye. Because the eye is particularly sensitive, ocular medications are typically buffered and isotonic so that they do not cause discomfort when administered. Aural preparations, intended for administration into the ear canal, do not meet the buffering and isotonicity requirements for ophthalmic administration.

Bioavailability

Because not all of the administered dosage may be dissolved or absorbed or survive liver passage, only a fraction of an administered dosage makes it to the bloodstream. This percentage of the administered dose that does enter the bloodstream is called the *bioavailability* of the dosage form. Bioavailability can range from less than 10% to more than 90% for oral dosing. When the bioavailability of an oral preparation is low, a higher dose will be given so that the amounts reaching the bloodstream are similar. For example, an oral dose of 500 mg of ciprofloxacin can be substituted for a 400 mg IV dose; ciprofloxacin has about 80% oral bioavailability.

Peak Blood Levels

The speed at which drugs enter the bloodstream affects the maximum blood level that is achieved following drug administration (Fig. 2-8). Rapid absorption leads to higher peak
Figure 2–8. Blood levels for the same dose absorbed with peak-times of 20 minutes, 60 minutes, or 120 minutes. Rapid absorption results in faster effect, but blood levels are higher with a greater likelihood of toxicity.

blood levels, with a risk of greater toxicity and side effects. So rapid IV administration (e.g., "IV push") produces immediate drug effects but increases the risk of toxicity and adverse effects. For these reasons, some medications, such as aminoglycoside antibiotics, are administered by slow IV infusion over 30 to 60 minutes. This allows distribution to occur, keeps the blood level from getting too high, and minimizes toxicity.

Distribution

After a drug is absorbed, it still must reach its site of action to produce an effect. The process of drugs moving throughout the body is called *distribution*. Distribution of drugs can occur by transfer through the bloodstream and passive diffusion, or their distribution can be promoted or limited by the presence of transport systems that may selectively transport or exclude drugs based on size, charge, or chemical structure. Diffusion can influence the action of drugs; drugs can be effective only if they reach their site of action in adequate concentrations before they are metabolized.

Properties That Affect Distribution

Drugs can passively diffuse most readily when they are small and uncharged and also have the right balance between water and lipid solubility. Some of these properties will be related to the drug (e.g., molecular size and lipid:water solubility). Others will reflect drug properties as they present in an individual patient, such as pH, the acidity of the environment in which the drug finds itself. pH affects ionization of the drug. Of course, the drug may find itself in an acidic environment (pH ~2) in the stomach and more neutral environments in the intestine (pH 6–8) and blood (pH 7.4). The patient will also bring an environment that includes proteins inside the body to which the drug may bind.

Since passive diffusion represents transfer through partially permeable barriers, smaller molecules are better able to diffuse than larger molecules. Molecules with molecular weights of 500 or less are the best candidates for passive

diffusion. Molecules with molecular weights above 5,000 are expected to diffuse poorly.

Henderson–Hasselbalch Relationship

Acidity is an important property of biological environments. Acidity is measured as pH, defined as $-\log[H^-]$; lower pH is more acidic. Normal pH in the body is around 7.4; under conditions consistent with life, pH can range only about 0.3 units in either direction. Each 1 unit of pH change represents a 10-fold increase or decrease in the concentration of hydrogen ions, and each 0.3 pH unit change represents a 2-fold change in acidity.

Most drugs contain chemical functional groups, such as carboxylic acids and amines, that can exist in a neutral, uncharged form or as a charged form. The balance between the charged and uncharged forms depends on pH. At higher acidity, or lower pH, carboxylic acid groups are uncharged, but amine groups are charged. At low acidity, at higher pH under basic conditions, the amine groups are uncharged, but the carboxylic acid groups are charged. Each drug is unique, and the pH at which it exists half in the charged state and half in the uncharged state is defined as its pKa.

It is an important principle in pharmacology that passive diffusion through biological barriers occurs most readily when drugs are in the uncharged state. Since the pH of body fluids is limited to a relatively narrow range and the pKa is a fixed property for an individual drug, we can calculate the percentage of charged and uncharged molecules for a drug if we know its pKa. The pKa can be an important drug property that influences absorption, distribution, and excretion of the drug.

Passive diffusion is a process by which drugs cross some type of biological barrier, such as a cell membrane or through a layer of cells, based on the concentration difference on the two sides of the barrier. We expect that passive diffusion will proceed until the concentration of drug is equal on both sides, but that is not quite what happens. Instead, passive diffusion proceeds until the concentration of *unionized* drug is the same on both sides. As a result of this, pH differences can cause more drug to accumulate based on the fraction of unionized and ionized molecules. This is called *ion trapping*.

Protein Binding

Drugs passively diffuse and distribute when they are unbound and uncharged. Drugs can bind to a variety of proteins that are present in the bloodstream. These are often called *plasma proteins*. Many plasma proteins are produced in the liver, and their presence in the blood reflects liver function, nutritional status, and the effect of aging and disease. Albumin is a major protein in the blood and is measured as part of a typical blood analysis. Albumin has a molecular weight of 66,500 and is too large to be excreted by the kidneys in healthy patients, although in renal disease albumin is lost in the urine. Other plasma proteins include alpha-1-acid glycoprotein, cortisol-binding globulin, sex hormone–binding globulin, and lipoproteins.

Binding to plasma proteins serves several important functions. Drugs bound to plasma proteins can freely circulate in the bloodstream rather than be distributed by passive diffusion from their site of absorption, so plasma protein binding helps normalize concentrations throughout the body. Drugs that are bound to plasma protein can be protected from metabolism in the liver and from excretion by the kidneys, so plasma protein binding can extend the period of time that drugs remain in the body.

Plasma proteins can be altered by disease states. Patients with poor nutrition may not have the protein building blocks to produce adequate amounts of plasma proteins. Patients with cancer can be undernourished as the cancer cells feed off the body. Patients with liver disease may lack the cellular function to produce one or more of the plasma proteins. Plasma proteins can be affected by myocardial infarction, stress, and infection as well.

Plasma protein binding has advantages and disadvantages. As mentioned above, binding to plasma proteins can protect drugs from metabolism and excretion, extending the time the drugs remain in the body. But remember the general principle that drug action occurs through free, unbound drug. Protein binding, which may include binding to proteins that are not in the plasma, also prevents the interaction of drug molecules with their site of action. Plasma protein binding creates a reservoir of bound drug molecules that can unbind at any time to interact with drug receptors and produce responses.

Plasma protein binding occurs in the plasma and encourages retention of drug in the systemic circulation. So it may appear that blood levels of a drug are high, even if the drug is not at its active site. For example, when patients receiving digoxin, a cardiac glycoside used to slow and strengthen the heart, have clinical signs of toxicity and high blood levels, they can be given antibody fragments to digoxin (Digibind). The antibody fragments remain in the central circulation and bind to digoxin in the bloodstream, essentially pulling digoxin back into the bloodstream from its sites of action throughout the body. But since digoxin is binding to its antibody in the bloodstream, the blood concentration of digoxin rises even though there is much less free digoxin to produce pharmacological effects and toxicity. This illustrates how plasma protein binding holds drugs in the circulation and prevents their distribution to other sites in the body.

Binding to proteins is also the basis for a number of drug interactions. Drugs bound to plasma proteins cannot interact with their receptor. If a drug is very strongly bound to plasma proteins, then even a small change in the fraction that is bound can have significant pharmacological effects. Warfarin is an oral anticoagulant that is used to slow blood clotting in patients at risk for thrombosis. Warfarin is about 98% bound to plasma proteins; this means that only 2% of the drug is unbound and available to produce a pharmacological effect. What if the patient takes another drug that also binds to plasma proteins? If the binding of the second drug to plasma proteins displaces even a small fraction of warfarin, it can have a dramatic effect. If only an additional 2% of warfarin is displaced, for example, it would mean a doubling of circulating warfarin activity.

Transport Systems

Drug distribution is also influenced by transporters, membrane proteins that facilitate the movement of molecules across the cell membranes. Transport systems are often directional, and they can transport drugs into (influx) or out of (efflux) cells. In either case, the transport system can transfer molecules and can create and maintain a concentration difference between two sides of the cell membrane. For example, when some antibiotics diffuse into cancer cells, they are transported out by the multidrug resistance protein (MRP1), which maintains a concentration gradient with the drug outside the cell. The presence of MRP1 suggests that a variety of drugs that require intracellular access for activity will be ineffective because the transporter removes molecules from inside the cell as quickly as they can diffuse in.

Transport systems also form the basis for distribution into protected tissues. p-Glycoprotein, an efflux secretory transporter, is widely distributed and limits the entry of drugs into the brain, testes, intestines, and other sites. Depending on the site, inhibition of p-glycoprotein can result in increased intestinal absorption or distribution into the brain or testes.

Transport systems also affect distribution to sites of metabolism. Transport or diffusion of a drug into cells is required for intracellular metabolism, and transport systems can control how much of a drug is available to an intracellular enzyme for metabolism.

Volume of Distribution

The volume of distribution (V_D) is a hypothetical value that reflects the volume in which a drug would need to be dissolved to explain the relationship between dosage and blood levels. If we administer a dose of 100 mg and the plasma concentration is 2 mg/L, then it appears as though the drug is distributed in 50 liters. If we administer the same dose and the plasma concentration is 20 mg/L, then it appears as though the drug is distributed in a volume of 5 liters (Fig. 2-9).

Volume of distribution is important not only because it relates dosage to blood level but because it tells us something about where a drug might be distributed. Drugs that are confined to the bloodstream will have a volume of distribution equal to the blood volume. The plasma volume is really the smallest volume of distribution we will encounter, since it is not possible for drugs to confine themselves to part of the circulation volume. Plasma makes up about 4.5% of body weight, or about 3 L for an average person. Total body water is about 50% to 60% of body weight (35 to 40 L), depending on gender and body fat. Total body water is about two-thirds intracellular and one-third extracellular.

Volume of distribution is hypothetical, however, so it may also be higher than the amount of volume. For example, a volume of distribution can represent distribution into an amount of water greater than the total body volume; this suggests that much of the drug is bound somewhere outside the bloodstream.
Figure 2–9. Drug concentration in the plasma following administration depends on the volume of distribution. If a drug is confined to plasma (A), then plasma concentration will be higher compared with distribution into extracellular fluid (B) or intracellular fluid (C). Dilution in increasing volumes is shown by shading of the areas containing a drug.

Metabolism

Metabolism is an important factor in determining drug activity. When drugs are metabolized, they are chemically altered by enzymes into new molecules, called *metabolites*. Metabolism can increase or decrease the onset, duration of action, and toxicity of a medication. So it is important to know how metabolism affects drug activity and pharmacokinetics and how other drugs might interact to alter drug metabolism.

The body is a large container of enzymes that catalyze many different chemical reactions that are required to maintain life. If you think about it, one of the requirements for sustainable life is the ability to maintain a constant internal environment. All organisms are exposed to molecules that cannot be used for food or energy. If an organism cannot rid itself of a certain molecule, then that molecule can accumulate until it causes some sort of toxicity. Therefore, the human body has developed a series of enzymatic reactions directed at all sorts of molecules encountered during life. Drugs that are lipid soluble or weakly acidic or basic may not readily be excreted from the body. In general, the idea is to make these molecules more water soluble so they can be excreted by the kidneys.

Metabolism is the process of changing one chemical into another, and the process usually either creates or uses energy. Metabolism of drugs can occur in every biological tissue, but it occurs mostly in the smooth endoplasmic reticulum of cells in the liver. The liver is a major organ for drug metabolism because it contains high amounts of drug-metabolizing enzymes and because it is the first organ encountered by drugs once they are absorbed from the gastrointestinal tract. Metabolism by the liver following oral administration is called *first-pass metabolism* and is important in determining whether a drug can be orally administered.

There is a "family" of enzymes, cytochrome P450 (CYP; pronounced *sip*), that metabolizes drugs. Each of these CYP enzymes is responsible for a single type of metabolic reaction. A drug may undergo several of these biological transformations, or biotransformations, sometimes in different body tissues, before being excreted. Understanding drug metabolism through these CYPs can provide a framework for understanding metabolism in individual patients, as well as drug interactions with other medications and with food.

Phase I and Phase II Metabolism

Drug metabolism utilizes two types of reactions that prepare and tag molecules for excretion. Phase I reactions, or *nonsynthetic reactions*, involve oxidation, reduction, and hydrolysis reactions, which prepare the drug molecule for further metabolism. Phase I reactions introduce or unmask polar groups that, in general, improve water solubility and prepare drug molecules for further metabolic reactions. Phase I metabolism can result in metabolites with greater or lesser pharmacological activity. Many phase I metabolites
Figure 2–10. Metabolism of phenobarbital. Phase I metabolism adds an –OH to the molecule. A water-soluble glucuronide molecule is linked to this site during phase II metabolism.

are rapidly eliminated, whereas others go on to phase II reactions (Fig. 2-10).

Phase II reactions are called *synthetic* or *conjugation reactions* because drug molecules are metabolized and something is added to the drug to synthesize a new compound. Metabolites are linked, or conjugated, to highly polar molecules such as glucuronic acid, glycine, sulfate, or acetate by specific enzymes. Conjugation to these molecules makes metabolites more water soluble and more easily excreted by the kidneys. So the presence or activity of these enzymes can influence the pattern of drug activity and the duration of action for drugs.

Cytochrome P450

The most thoroughly studied drug metabolism reaction is the CYP P450 mixed-function oxidase reaction. This reaction catalyzes the metabolism of a large number of diverse drugs and chemicals that are highly lipid soluble. CYP transfers electrons from the oxidation of drugs to the electron transport system of the endoplasmic reticulum, a cell organelle. There are many forms of CYP that are products of separate and distinct genes and that catalyze different reactions. Over 50 human CYPs have been isolated so far. The CYPs are organized into numbered families based on their function. For example, the CYP1, CYP2, and CYP3 families metabolize a variety of drugs and steroids (Box 2-5). Subfamilies are designated by additional letters and individual enzymes by numbers. The CYP3As are the major subfamily expressed in the human liver and consist of three forms: CYP3A4, CYP3A5, and CYP3A7. The CYP3A7 enzyme is present in the fetus and appears to be discontinued after birth. CYP3A4 is a major drug-metabolizing enzyme, whereas CYP3A5 metabolizes the same drugs but is less active.

Single nucleotide polymorphisms (SNPs) are minor mutations in proteins that can result in metabolic activity changes. These alterations in DNA are sometimes associated with population groups and help explain why certain groups of patients are more or less sensitive to certain drugs. When SNP variations exist in the individual CYP enzyme, they are named by an asterisk and a number showing the order in which each SNP was identified. For example, there are several CYP2D6 isoforms: CYP2D6*1 (with no mutation), CYP2D6*3, CYP2D6*4, and up to CYP2D6*17. Metabolic activity for each isoform may be decreased, normal, or increased.

We inherit our drug-metabolizing enzymes from our parents, so it is possible to have two isoforms that differ in expression and activity. About 7% of the U.S. population lacks the CYP2D6 enzyme activity. Other patients exhibit a range of enzyme activities, with some ethnic groups having a significant percentage of ultrafast metabolizers. As you can imagine, there is the potential for a good deal of variability between individual patients.

CYP3A4 is a prominent enzyme that is responsible for metabolism of a number of drugs. It serves as an example of a CYP enzyme. Drugs that are metabolized by CYP3A4 include azole antifungals; the statin drugs that inhibit HMG-CoA (5-hydroxy-3-methylglutaryl-coenzyme A) reductase and lower cholesterol; the corticosteroids prednisone, prednisolone, and dexamethasone; the anticonvulsant carbamazepine; and many other drugs. Note the variety of drug classes and chemical structures that are metabolized by this enzyme.

Variations in CYPs and in their activity can result in marked differences in drug metabolism between individuals. Individual variation in drug metabolism contributes to drug–drug and some drug–food interactions. Enzyme induction occurs when drug treatment results in an increase in enzyme activity, usually limited to the enzymes responsible for metabolizing the drug. Enzyme induction results in an increase in metabolism that decreases the amount of drug and increases the amount of metabolite in the body.

Competition occurs when two different drugs are metabolized by the same enzyme. Often the enzyme can metabolize both drugs, but sometimes one drug will be preferentially metabolized, delaying the metabolism and extending the half-life of the competing drug.

Metabolism and Half-Life

The rate of drug metabolism depends on the blood levels of drug in relation to the affinity of the drug for its metabolism enzymes. Most drugs are present at concentrations below their K_m for metabolism (the concentration at which metabolism is half of maximum). Under these conditions, metabolism is related to drug concentration so that a fixed *fraction* of drug is metabolized per hour. This is called *first-order metabolism* and is characterized by a half-life, the time period over which the drug concentration will decrease by half. So, blood levels decrease 50% in one half-life, 75% in two half-lives, and 87.5% in three half-lives. As a general rule, drugs tend to be administered at dosing intervals that are close to their half-life.

Some drugs—ethanol is the prototype—are present at concentrations well above their K_m for metabolism. When this happens, enzymes act near to their maximal metabolic capacity and metabolize a constant *amount* of drug each hour. This is called *zero-order metabolism*.

Rarely but importantly, some drugs are present at blood concentrations that range from below to above the K_m for their metabolism. At lower doses or concentrations, they are metabolized like typical drugs, but at higher doses or concentrations their metabolism is limited. Phenytoin is a prototypical example of a drug with "mixed-order" or

CYP2D

Michelis–Menten, pharmacokinetics. Above a certain level of phenytoin dosing (about 300 mg/day in adults), dosage must be adjusted by small amounts, which can produce disproportional increases in blood levels as metabolism changes from first order to zero order.

Patterns of Metabolism

It is important to remember that metabolism can change the pharmacological activity of drugs. We typically consider that drugs are pharmacologically active and that metabolism decreases the activity and promotes excretion (Fig. 2-11), so we expect to see inactive metabolites that have short half-lives and are rapidly excreted. This is not always the case, however.

Prodrugs are inactive compounds that rely on metabolism to become active. Prodrugs have advantages and disadvantages. The advantages may be in terms of their absorption or distribution. L-DOPA is a prodrug used to treat Parkinson's disease. The problem in Parkinson's disease is a lack of dopamine in the striatum of the brain. Dopamine, however, cannot pass through the blood–brain barrier, so it cannot be used to treat the neurotransmitter shortage in the brain. L-DOPA can pass into the brain and enter into cells, where it can be converted into dopamine.

Prodrugs can also have disadvantages. Terfenadine was one of the first nonsedating antihistamines and was quite popular at one time. First-pass metabolism by CYP3A4 biotransforms terfenadine, which is cardiotoxic, into fexofenadine, an effective antihistamine. When it was realized that inhibition of CYP3A4 could result in toxicity and death in some patients, terfenadine was withdrawn and replaced with fexofenadine, its active metabolite.

The prodrug terfenadine is cardiotoxic and relies on metabolism to produce more active antihistamine that is less cardiotoxic. Other prodrugs are pharmacologically inactive and rely on biotransformation to an active metabolite. Codeine is metabolized to the 12 times more potent opioid

morphine by CYP2D6. Hydrocodone is metabolized to the more potent opioid hydromorphone by CYP2D6 as well. About 7% of the Caucasian population lack CYP2D6 activity. Administration of a prodrug requiring metabolism by CYP2D6 creates a situation in which the patient is receiving an inactive or poorly active drug. In the case of pain relievers, patients may be seeking stronger drugs, not because of abuse but because the drugs are not being biotransformed into their active metabolites. In contrast, patients with highly active CYP2D6 are at greater risk for toxicity following administration of codeine or hydrocodone.

Meperidine is an opioid analgesic that is used parenterally and orally to treat pain as well as post-operative shivering. It is metabolized by CYP2B6, 2C19, and 3A4. Meperidine remains present in the body a relatively short period of time; its half-life is 3 to 4 hours. Meperidine's metabolite, normeperidine, is more toxic and remains in the body for a much longer period of time; its half-life is 14 to 21 hours in patients with normal renal function and even longer in those with poor kidney function. This difference in half-lives creates a clinical situation in which meperidine is administered frequently and levels of normeperidine will rise until toxicity presents as irritability, tremors, delirium, and seizures in patients with poor renal function. The solution is to limit administration of meperidine so that normeperidine does not accumulate and to avoid meperidine use in at-risk patients.

Drug Interactions

Alterations in biotransformation are responsible for many drug–drug and drug–food interactions. There are a limited number of drug-metabolizing enzymes, and these enzymes can metabolize only one drug molecule at a time. Compounds compete for enzymes based on their chemical affinity; chemicals with higher affinity for a particular CYP or drug metabolism enzyme will be preferentially metabolized. So a drug that can be metabolized by multiple enzymes will be biotransformed by each enzyme in proportion to the affinity. When several drugs are metabolized by a single enzyme, each of the drugs will be metabolized in proportion to the affinity of each of the drug–enzyme interactions. If one drug monopolizes the enzyme, then it can block the biotransformation of other drugs, extending their time in the body and contributing to toxicity. So when we look for drug interactions, we often look for drugs that are metabolized by the same CYPs.

CYP3A4 is particularly problematic because it metabolizes so many different drugs. Consequently, there is a greater likelihood of interference with metabolism when a patient receives a number of drugs. In addition to other sites in the body, such as the liver, CYP3A4 activity is present in the cells lining the gastrointestinal tract and can be influenced by food as well as drugs. Grapefruit juice contains a substance that inhibits CYP3A4 and can sometimes markedly increase blood levels of drug in patients consuming grapefruit juice. Surprisingly, this interaction extends to patients consuming grapefruit juice within about a day prior to drug administration. This interaction can affect a number of drugs, such as
Figure 2–11. Typical effect of metabolism (solid arrows) on drug activity. Prodrugs are metabolized to active drugs that can undergo phase I and phase II metabolism, with metabolites varying in activity, compared with the parent drug, and in solubility, which increases the likelihood of renal elimination. Sometimes metabolism produces unusual effects (dashed arrows), such as drug metabolites that retain drug activity or accumulate in the body.

several older statin drugs that have increased blood levels in the presence of grapefruit juice. Higher blood levels are not always bad, but it is appropriate to counsel patients to avoid potential toxicity resulting from CYP3A4 interactions and inhibition.

Some drugs increase the expression of drug-metabolizing enzymes; this is called *enzyme induction*. Induction can be due to either increased enzyme synthesis or decreased enzyme degradation. Pharmacotherapy with phenobarbital, for example, effectively induces CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, and CYP3A4. Induction increases the biotransformation of drugs and can encourage variations in metabolism and generally increase the removal of drugs by metabolism.

In clinical practice, transport systems and metabolic enzymes work together in the biotransformation of drugs. Drugs are transported into cells where they can be metabolized. Patients can have genetic differences in their ability to transport drugs through cell membranes, leading to additional variation in metabolism and drug response.

We generally assume that metabolism of drugs results in a product that has less pharmacological activity and is more likely to leave the body. Metabolism, or biotransformation, can actually result in either an inactive or an active metabolite. Metabolites are generally excreted more rapidly, but sometimes metabolite excretion is delayed. Drugs may interact with more than one CYP enzyme to produce multiple metabolites with different levels of activity and excretion.

Excretion

Excretion is the process in which drugs are transferred from inside the body to outside the body. This makes excretion or elimination the opposite of absorption. Just as drugs pass a biological boundary between inside and outside for absorption, so they must pass in the opposite direction, though not necessarily in the same location, for elimination.

The locations at which drugs can pass from inside the body to outside include some sites that are familiar as sites of absorption, such as lung, skin, and intestines. There are also some unique sites where drugs are excreted but not absorbed. These include the kidney and the gallbladder. The principal organs for drug elimination are considered to be the kidneys, lung, biliary system, and intestines. Any individual drug may rely on one or more of these sites for elimination or on a different site, such as skin excretion or excretion into saliva or breast milk.

Renal Excretion

The kidney is the primary organ of excretion for most drugs. The general theme of metabolism is to produce drug metabolites that are more water soluble and more easily removed by the kidneys. The kidney can then remove these substances from the plasma and excrete them in the urine.

The kidney is a complex organ with several important functions, including excretion of waste products and maintenance of fluid and electrolyte balance in the body. The

strategy of the kidney is to allow removal of a large volume of plasma and then to take back the substances that the body needs. The result is urine. There are also transport mechanisms that can secrete substances into the urine. We will consider how drugs manage to end up in the urine.

Production of urine begins in the glomerulus of the kidney. The operational unit of the kidney is the nephron, and each of the approximately 1 million nephrons begins with a glomerulus (Fig. 2-12). The glomerulus is a specialized area of the nephron adapted for ultrafiltration, a process in which substances in the plasma pass through small holes, or pores, in the glomerular capillary membrane based on their size and charge. The structure of the glomerular capillary membrane permits filtration of smaller molecules while restricting the passage of compounds with larger molecular weights. As blood flows through the kidney and encounters the glomerulus, much of the fluid portion of the blood is filtered into the lumen, or center, of the nephron. The kidney is exceptionally efficient at what it does. Approximately 125 mL of blood flows through the glomeruli in the kidneys per minute, the glomerular filtration rate (GFR), and it is an important measure of renal function.

Glomerular filtration is the first step toward production of urine containing excreted drug. Filtration preserves plasma proteins while removing free drugs and other waste products from the plasma. The large volume of fluid filtered through the glomerulus is an ideal vehicle for drug removal. As the ultrafiltrate is formed, drugs that are free in the plasma and not bound to plasma proteins or blood cells are filtered. Filtration may be slower for drugs that are large because of the size of the pores through which filtration occurs; very large drugs may not be filtered at all. The pores of the glomerulus contain a fixed negative charge, so filtration may also be affected by drug charge.
Figure 2–12. Diagram of the nephron, the functional unit of the kidney. Blood vessels flowing into the glomerulus provide blood, which is filtered into the lumen, the inner opening of the nephron. As fluid passes along the nephron, transporters can either reabsorb drugs (dark arrow) back into the blood or secrete (light arrow) drugs from blood into the lumen.

The glomerular filtrate in the nephron contains a variety of smaller molecules, including excreted drug and metabolites. As the filtrate moves through the lumen of the nephron, molecules are reabsorbed from the lumen into the blood. The extent to which a drug diffuses back across the nephron to reenter the circulation is one of the factors that determine urinary excretion of drug. The passive diffusion of substances back into the circulation is encouraged by the reabsorption of water that occurs along most of the nephron, creating a concentration gradient promoting reabsorption if the lipid solubility and ionization of the drug are appropriate.

The unionized or uncharged form of the drug will diffuse more readily, and the acidity of urine can influence the ionization and reabsorption of drugs. Acidification of the urine creates a situation that favors the excretion of basic drugs and metabolites, whereas basic urine encourages the excretion of acidic drugs and metabolites. Effects of urine acidity on drug elimination can have important clinical implications. Urine can be made acidic by administration of ammonium chloride and can be made basic by administration of sodium bicarbonate.

Tubular Reabsorption

In addition to reabsorption by passive diffusion, some substances filtered at the glomerulus are reabsorbed by active transport systems located primarily in the proximal tubule of the nephron. Active transport is important for endogenous substances that the body needs to recover from the glomerular filtrate, such as ions, amino acids, and glucose. The active transport systems are located on the luminal cell surface and transport substances into the cell, where they are passively transported into the plasma.

A small number of drugs may be actively reabsorbed. It is more common that drugs acting on tubular secretion do so by inhibiting active transport. Uricosuric agents such as probenecid and sulfinpyrazone inhibit the active reabsorption of uric acid. Substances that are actively reabsorbed can also be actively secreted and drugs may inhibit both processes. For example, low doses of salicylates, such as aspirin, inhibit tubular secretion and decrease total urate excretion, whereas higher doses inhibit tubular reabsorption and result in increased excretion of uric acid.

Tubular Secretion

The nephron also contains active secretory systems that transport drugs from the blood into the lumen of the nephron. There is a transport system that secretes organic anions and a transport system that secretes organic cations. The transporters are present on the plasma side of the tubular cells of the nephron, where they actively pump anions or cations into the cell. The substances then pass into the lumen by passive transport. The secretory capacity of these transporters can be saturated so that less drug is excreted at high drug concentrations. When two drugs are substrates for the same transporter, they compete with one another and decrease the rate at which each is excreted.

Active secretory systems for anions and cations are important because charged anions and cations are often strongly bound to plasma proteins and may not be readily excreted by glomerular filtration. Tubular secretion often contributes to the renal elimination of drugs that have short half-lives. Hydrochlorothiazide, furosemide, penicillin G, and salicylates are among the substrates for the organic anion transport system. The organic cation transport system actively secretes atropine, cimetidine, morphine, and quinine.

Renal Excretion of Drugs

The rate at which a drug is excreted by the kidneys depends on several factors. Renal blood flow influences the GFR, which is how much plasma is filtered per minute by the glomerulus. Filtration in the glomerulus depends on the molecular size, the charge, and the degree of protein binding, each of which influences how much drug passes through the glomerular basement membrane. Tubular acidity will influence the degree of reabsorption. Active reabsorption or active secretion into the urine may also influence excretion rate.

Renal excretion of drugs is typically well characterized. What is variable, however, is the level of renal function in an individual patient receiving a renally excreted medication. It is common to monitor renal function of patients in the clinical setting and to adjust dosages based on renal function and the renal contribution to drug excretion. Renal function is typically assessed from patient serum creatinine along with height, weight, age, and gender.

Biliary Excretion

In addition to metabolizing many drugs, the liver secretes about a liter of bile each day. Drugs can enter the bile and be excreted into the intestinal tract when bile is released to help digest food. Only small amounts of drug enter the bile by diffusion; instead, biliary excretion contributes to removal of some drugs. The biliary system includes three types of active transport. Organic cation and organic anion transporters are similar to those found in the renal tubules. The additional system is the bile acid transport system. Conjugated metabolites of drugs generally have enhanced biliary excretion. Cardiac glycosides, such as digoxin, are an example of drugs secreted into the bile.

Some drugs that are excreted in bile can be reabsorbed in the intestine. This creates a phenomenon called *enterohepatic cycling,* in which drug is excreted in the bile, absorbed from the intestines, and then excreted in the bile again. Enterohepatic cycling decreases the amount of drug that is actually excreted and extends the time that a drug remains in the body.

Other Sites of Excretion

Drug excretion is not limited to the kidneys and liver. Drugs can diffuse out of the body at various sites, and while these excretion sites are typically not major, they can be important for forensic or clinical reasons.

Pulmonary excretion can occur for any volatile material present in the body. Pulmonary excretion is important for anesthetic gases, such as nitrous oxide. Pulmonary excretion

is also important following alcohol consumption. Ethanol distributes throughout the body and is readily excreted each time we breathe. Because the amount of ethanol exhaled in each breath is proportional to blood level, the Breathalyzer can be used to estimate blood levels of ethanol. Pulmonary excretion is also important for volatile ketones, which are produced in diabetic patients who are poorly controlled; the smell of ketones on a patient's breath can be an important clue that the patient may have diabetes and be at risk for diabetic ketoacidosis.

Substances can be excreted through the skin, although this is often a minor route of elimination. The skin has a large surface area through which excretion can occur; drugs may be incorporated into the hair and can be excreted through the sweat glands. Excretion of drugs into sweat and saliva is of minor importance for most drugs and depends on the diffusion of uncharged drug across the epithelial cells of sweat and salivary glands. Excretion into hair, sweat, and saliva is quantitatively unimportant but can be used to non-invasively detect drugs in the body. Interestingly, some drugs excreted into saliva can produce changes in taste. Excretion into saliva might help explain part of the pharmacological action of certain drugs, such as antibiotic erythromycin, in throat infections.

Drugs can also be excreted into the breast milk of nursing mothers. The concentration in the breast milk depends on drug properties such as lipid solubility and the degree of ionization and on patient properties such as the extent of active secretion into breast milk and the blood level of the drug in the mother. Low-molecular-weight drugs that are unionized can passively diffuse across the epithelial cells of the mammary gland and enter the breast milk. Because breast milk is more acidic than plasma, it tends to accumulate basic drugs.

Infants can be exposed to drugs through breast milk. The risk to the infant from drug exposure in breast milk depends on the amount and type of drug involved and the ability of the infant to metabolize the drug. Breastfeeding is discouraged when there is a potential for drug toxicity in the infant.

SUMMARY

The rational use of drugs is based on a foundation of chemical and physiological principles. Drugs interact with specific sites, called receptors, according to chemical laws; higher concentrations of drug produce more interactions and greater effects. How rapidly a drug is absorbed, distributed, metabolized, and excreted dictates local concentrations of drug that produce effects. The onset and duration of a drug effect reflect the pharmacokinetics of the drug and the properties of the receptor. Sound therapeutic decisions draw upon the unifying foundational principles of pharmacology.

RATIONAL DRUG SELECTION

Teri Moser Woo

The process of prescribing medication requires a thoughtful, evidence-based approach to drug selection. The World Health Organization (WHO) definition of rational drug selection is that "patients receive medications appropriate to their clinical needs, in doses that meet their own individual requirements, for an adequate period of time, and at the lowest cost to them and their community" (WHO, 2013). WHO states that irrational use of medication is a "major problem" worldwide, with an estimated 50% of drugs prescribed, dispensed, or sold inappropriately (2013). Examples of irrational medication use outlined by the WHO include: polypharmacy, inappropriate prescribing of antimicrobials, overuse of injections versus oral preparations, and failure to follow guidelines when prescribing (2013). This chapter discusses the process of rational drug selection and the drug factors that influence drug selection as well as influences on rational prescribing.

THE PROCESS OF RATIONAL DRUG PRESCRIBING

Thoughtful prescribing requires a systematic process that is used every time a prescription is written. The WHO model for rational drug prescribing is one approach a provider can use (de Vries, Henning, Hogerzeil, & Fresle, 1994). The first step in the WHO process is an accurate diagnosis and a determination of the therapeutic objective, for example, treating an infection. The appropriate treatment is chosen with these factors in mind. It is critical that the provider collaborates with and educates the patient regarding the therapy. The chosen therapy then needs to be monitored to determine the effectiveness of the regimen (Box 3-1).

Define the Patient's Problem

The process of prescribing begins with the assessment of the patient and formulation of a working diagnosis and possible differential diagnosis. Early screening of high-risk patients maximizes the benefits of pharmacological treatment (WHO, 2012). Once the diagnosis is made the provider develops a plan of care. Is there a clear indication for drug therapy? What drugs are effective in treating this disorder? Differential diagnosis is not within the scope of this book, but the reader will find the diagnostic criteria and pathophysiology of common diseases treated with medications discussed in the chapters in Unit III.

Specify the Therapeutic Objective

Before deciding what medication to prescribe, it is important to clarify the therapeutic objective (de Vries et al, 1994). Is the goal to cure the disease? Relieve symptoms of disease? Replace deficiencies (i.e., insulin or iron)? Long-term prevention? Or is the goal treating the combination of two outcomes such as treating pain and inflammation. Sometimes the goal is to make the patient comfortable with palliative therapy. Maxwell suggests that the provider clarify whether the treatment goals are curative, symptom relieving, or preventive (2009). The WHO model recommends that the provider include the patient in this stage of the process so the patient is a partner in the treatment regimen (de Vries et al, 1994). Eliciting patient beliefs and preferences regarding the drug therapy is essential to successful drug therapy, especially in chronic diseases, such as diabetes, that require long-term drug treatment (Latter et al, 2010). When the goal is long-term therapy for a chronic disease, it is necessary to look at costs and how well the drug fits into the patient's lifestyle.

Choose the Treatment

Determining the drug treatment is actually a two-step process of first determining what would be the appropriate therapy based on evidence-based guidelines, then individualizing the drug choice for the specific patient (Richir, Tichelaar, Geijtemann, & de Vries, 2007). Individualizing the drug choice includes consideration of other drugs that the patient may be taking and potential interactions with the drug treatment choice being made. Richir and colleagues (2007) describe two types of reasoning used when choosing drug therapy: analytical and nonanalytical. Novice providers use an analytical approach, which is slow, time-consuming, systematic, and evidence-based. More experienced providers use their experience and pattern recognition to carry out a nonanalytical process in a faster, subconscious manner (Richir et al, 2007). When experienced

providers are confronted with a complex patient situation, they will use a more analytical, systematic approach to prescribing. Bissessur et al (2009) propose a model of therapeutic reasoning that incorporates these analytical or non-analytical processes used to develop a course of treatment (Fig. 3.1).

Individualizing drug therapy requires examining the suitability of the drug for the patient. WHO recommends that the provider examine the drug and the dose, the dosage schedule, duration of treatment, effectiveness, and safety (de Vries et al, 1994). The criteria for examining a drug for appropriate prescribing are discussed later in this chapter. A mnemonic that new prescribers can use when learning to prescribe is proposed by Iglar, Kennie, and Bajcar (2007) and is summarized in Box 3-2. Table 3-1 provides an example of the use of the mnemonic.

Start the Treatment

Once the appropriate drug has been chosen, a prescription is written, and the patient must have the prescription dispensed at a pharmacy. The legal requirements for writing a prescription are discussed in Chapter 4.

Care should be taken when writing a prescription to make sure that the drug, dose, and schedule are accurate. At the time of writing the prescription, drug costs need to be

Figure 3–1. Hypothetical model of therapeutic reasoning. *Bissessur et al, 2009.*

Table 3–1 Example of the Use of the 'I Can PresCribE a Drug' Mnemonic

Case: A 23-yr-old female presents to the clinic with symptoms of a urinary tract infection (UTI). Urine analysis confirms initial diagnosis of UTI and a urine culture is pending.	
Indication	Antibiotics are indicated in UTI treatment. Treatment guidelines for UTIs are found in Chapter 47. Sulfamethoxazole and trimethoprim (SMZ-TMP, Septra, Bactrim) is the recommended first-line drug in most patients.
Contraindications	SMZ-TMP is contraindicated in patients who are allergic or who have allergies to drugs with known cross-sensitivity to sulfa drugs (discussed in Chapter 24), porphyria, megaloblastic anemia due to folate deficiency.
Precautions	SMZ-TMP is Pregnancy Category C. Use cautiously in patients with G-6-PD deficiency, impaired renal function, or hepatic function. Potential drug–drug interactions should be evaluated.
Cost/**C**ompliance	SMZ-TMP is on the $4 list of many retail pharmacies. It is dosed twice a day for 3 d for UTI. Fewer doses and shorter treatment length have higher compliance.
Efficacy	*E. coli* is the most common pathogen in UTI and is usually sensitive to SMZ-TMP. Culture results will need to be followed to determine sensitivity.
Adverse effects	Adverse effects of SMZ-TMP are discussed in Chapter 24.
Dose/**D**uration/**D**irection	Dose: 1 double-strength tablet twice a day. Duration: 3 d Direction: Drink plenty of fluids while taking SMZ-TMP.

addressed with the patient. If patients cannot afford to fill the prescription, they will not take the medication, regardless of how appropriate the drug is for the disease process. The pharmacoeconomic aspects of prescribing are discussed in depth in Chapter 12.

Educate the Patient

Up to 50% of patients do not take their medications as prescribed or they do not take them at all (Cohen, 2012). Poor medication adherence leads to worsening disease and death, as well as increased health-care costs; 33% to 69% of medication-related hospital admissions are related to poor adherence, at a cost of $100 billion per year (Osterberg & Blaschke, 2005). Patient education regarding the purpose of the medication, instructions for administration, and potential adverse drug effects will improve adherence to the medication regimen. Patient education should be tailored to the patient and presented in plain language (fifth- or sixth-grade reading level), with an understanding that nine out of 10 adults have difficulty reading health information (Centers for Disease Control and Prevention [CDC], 2013). Appropriate patient education is discussed for each drug category in the chapters in Unit II.

Monitor Effectiveness

Once the patient begins taking the prescribed medication, the chosen drug needs to be monitored for effectiveness. The WHO model describes two types of monitoring: passive and active (de Vries et al, 1994). Passive monitoring occurs when the patient is educated on the expected outcome of the drug therapy and is instructed to contact the provider if the treatment is not effective or if adverse drug effects occur. This is common when short-term treatment, such as an antibiotic, is prescribed, and no test of cure is required. Active monitoring occurs when the provider schedules a follow-up examination to determine the effectiveness of the drug therapy (de Vries et al, 1994). Active monitoring may include evaluating therapeutic blood levels and making dosage adjustments, as is necessary in anticoagulant therapy or patients taking an antiseizure medication. Active monitoring may also include adding or subtracting medications from the treatment regimen based on the effectiveness of the treatment. Monitoring parameters are often published for a drug but may need to be adjusted based on age or concurrent disease processes.

> **CLINICAL PEARL**
>
> Drugs don't work in patients who don't take them.
> —C. Everett Koop, MD

At the follow-up visit, the provider will determine whether to continue the medication. If the treatment has been effective and the disease has been cured, the drug can be stopped. The treatment can also be effective but not curative, as in the case of chronic disease management. If the drug is working well for the patient, then it should be continued. If the medication is not effective or if the patient experiences significant adverse effects, the drug may need to be changed. Even an appropriately chosen medication will not work in every patient; therefore, evaluating the effectiveness of therapy and making adjustments as needed are essential.

DRUG FACTORS INFLUENCING DRUG SELECTION

Evidence-based guidelines are the gold standard for initial drug selection, but providers need to examine the drugs recommended in the guideline for their clinical utility with the individual patient. Selecting the appropriate drug treatment requires that the provider consider multiple factors regarding the drug and the patient who will be receiving the medication: pharmacokinetics, pharmacodynamics, therapeutic issues, safety, and cost (Spector & Vesell, 2002). Additionally, individual patient and provider factors may influence drug choice. The nurse practitioner should review and consider all seven of these criteria prior to prescribing (Spector & Vesell, 2002).

Pharmacodynamic Factors

The pharmacodynamics of a drug must be specific and selective to the target tissues affected by the disease to have the greatest therapeutic effect with the least adverse effects (Spector & Vesell, 2002). The ease of titration is influenced by the dose–response curve of the drug (Maxwell, 2009). The relationship between a drug's desired therapeutic effects and its adverse effects is called its *therapeutic index* (see Chap. 2). Drugs with a low or narrow therapeutic index may require close monitoring for toxicity or adverse effects, whereas drugs with a wide therapeutic index are fairly safe and require less monitoring. Antibiotics, for example, tend to have fairly wide therapeutic indices. Propranolol (Inderal) has such a wide therapeutic index that doses safely range from 20 mg to 320 mg.

Pharmacokinetic Factors

When deciding what drug in a class to prescribe, the pharmacokinetic properties of a drug may influence drug selection. For example, the bioavailability (BA) of different formulations may influence prescribing (Maxwell, 2009). The bioavailability of digoxin, for instance, varies between 60% and 100% depending on the formulation used. Because this drug has a very narrow therapeutic index, this difference in BA is critical in formulation choice. Another consideration is metabolism. Different drugs in a class may use different cytochrome P450 (CYP450) enzymes, which may influence metabolism or drug interactions. Drugs that are excreted almost exclusively by the kidney may not be appropriate for a patient with decreased renal function, such as the older adult. Therefore, a patient's renal function and the pharmacokinetics of the drug need to be evaluated during the drug selection process. Additionally, the dose–concentration curve and half-life will determine the dosing schedule, with fewer doses per day encouraging adherence to the drug regimen (Maxwell, 2009; Spector & Vesell, 2002). Pharmacokinetics are discussed in depth in Chapter 2.

Therapeutic Factors

The therapeutic impact of a drug is reviewed in the literature and observed in the individual patient. A nurse practitioner examines the evidence for the therapeutic impact of a selected drug, using evidence from clinical trials, clinical practice guidelines, and systematic reviews (including *Cochrane Reviews* or *Clinical Evidence Reviews*) to determine the impact of a drug. The effect of a drug on decreasing morbidity, mortality, and hospitalization is examined (Spector & Vesell, 2002) as well as the drug's ability to relieve symptoms and treat the disease process (Maxwell, 2009). Extrapolating results from randomized controlled trials (RCTs) should be done with caution because RCTs usually recruit patients who are relatively healthy with few comorbidities, whereas most patients are more complex (Maxwell, 2009).

Safety

The safety profile of a drug is taken into consideration and weighed against other factors when prescribing. Safety is initially determined in clinical trials and is outlined in the precautions and contraindications in the drug monograph. Safety may vary with the population. For example, a drug may be safe in a healthy elder but also be a teratogen; thus, it would be unsafe in pregnant women (Iglar et al, 2007). Safety may also vary with the disease process; for example, some drugs pose safety concerns in patients with liver or renal dysfunction. Contraindications to a drug in a specific patient population or allergy to the drug eliminate it from the potential drugs that can be prescribed for the patient.

The U.S. Food and Drug Administration (FDA) collects information on and monitors the safety of drugs via postmarketing surveillance by the MedWatch program (http://www.fda.gov/Safety/Medwatch). The FDA has a tiered system of safety announcements to promote drug safety. The agency gathers initial reports via MedWatch, then it issues an early communication about an "Ongoing Safety Review" while it collects and analyzes data (http://www.fda.gov). The FDA issues a "Public Health Advisory" when there is drug safety information that needs to be conveyed to patients or caregivers. When new drug information affects safe prescribing, the FDA may issue a "Letter to Health Care Professionals" or an "Information for Health Care Professionals" information sheet to provide specifics about the safety issue and factors to consider when making treatment decisions. When drugs are determined by the FDA to have serious safety issues, particularly ones that may lead to serious injury or death, the FDA may require a warning to be displayed prominently on the drug monograph, often referred to as a "Black Box" warning. Prescribers are responsible for keeping up-to-date on the latest drug safety information.

Cost

When prescribing, the nurse practitioner must consider the costs to the patient and the cost to the health-care system or to society at large. The cost to patients may be so high that they cannot afford prescriptions, and cost then becomes a barrier to adherence. Many insurance policies do not cover the cost of drugs, and patients must therefore pay out of

pocket for their medications. Medicare patients with Part D coverage may reach the "donut hole," the coverage gap in drug costs where the proportion of out-of-pocket costs goes up to 50%. This coverage gap will slowly be decreased to 25% for generic drugs by 2020, but Medicare patients will still pay 50% of brand-name drug costs while in the coverage gap.

Increasingly, as soon as the patent on a brand-name drug expires, that drug may be made in a generic form. Prescribing generics when possible and knowing what drugs are on the $4 retail pharmacy prescription lists assists in keeping costs reasonable for the patient. For example, albuterol nebulizer solution (20 mL) is on the Walmart $4 list, whereas generic albuterol nebulizer solution (20 mL bottle) may cost $20. Knowing the approximate costs of medications and discussing with clients their out-of-pocket costs will improve adherence. Drug costs are shown in the Available Dosage Forms tables for each drug category in the chapters in Unit II.

Prescription drug spending has increased significantly over the past few years, from $239.9 billion in 2004 to $307.4 billion in 2010 (IMS Health, 2012). Although the out-of-pocket costs to patients may be acceptable to them, providers still need to consider the actual costs of the medications to the health system. Each prescriber plays a part in controlling prescription drug expenditures through thoughtful prescribing of the most cost-effective drug for the patient. The pharmacoeconomics of prescribing are discussed in depth in Chapter 12.

Patient Factors

Patient factors that may affect prescribing include drug adverse effects that influence adherence, health beliefs, values, and current drug therapy that may interfere with the new drug (Maxwell, 2009; Spector & Vesell, 2002). In addition to interference with the new drug, unnecessary duplications with other drugs being taken may occur. Any time a regimen can be simplified by reducing duplication, adherence is more likely. Other patient factors that affect prescribing are the patient's age (children and older adults), pregnancy, mental health diagnosis, or another disease. Beta blockers, for example, have adverse drug reactions (ADRs) that include anxiety, depression, and mental status changes. The drugs in this class that have higher central nervous system (CNS) penetration are more likely to have these ADRs. If a beta blocker is to be prescribed for a patient with a mental health diagnosis, it is best to use the ones that are less lipophilic because this subset of the drug class is less likely to exhibit these ADRs.

Previous Adverse Drug Reactions

ADRs can be a significant factor in nonadherence. Some patients, such as those with renal dysfunction, are at higher risk of experiencing ADRs. Exploration of previous experiences with medications will identify those at risk for ADRs (Maxwell, 2009). Listening to the patient and noting unusual responses is a proactive approach to prescribing. Remembering that each patient's response to a medication may differ and taking the time to carefully choose a medication that has

the fewest ADRs will promote adherence. Chapter 5 provides an extensive discussion of ADRs.

Health Beliefs

Health beliefs and patient attitudes both affect the medication regimen. Patients who believe the medication is going to help them feel better or prevent long-term harm are more likely to adhere to the drug regimen and to have positive outcomes from taking the drug. Belief that one does not have asthma when symptoms are absent is more common among older asthmatics with poor health literacy, leading to nonadherence in use of asthma medications (Federman, Wisnivesky, Wolf, Leventhal, & Halm, 2010). Assessment of beliefs and attitudes is critical to medication adherence.

Current Drug Therapy

A patient's current drug therapy may affect the drug selected or the dosage prescribed because of the potential for drug interactions (Maxwell, 2009). Throughout this text potential drug interactions are listed for each drug category, with suggested alterations in therapy if needed. If a patient is on a complex medication regimen, consultation with a pharmacist or PharmD who has access to drug interaction software is warranted for patient safety.

Patient Age

Patients at the extremes of age, either the very young or the very old, have developmental pharmacokinetic differences that warrant careful prescribing. Infants have immature liver and renal functions that place them at risk for toxicity and ADRs and may require dosage adjustments based on age. Likewise, the elderly population has decreased liver and renal functions related to the physiological changes associated with aging, placing them at risk for increased ADRs. Prescribing for children is discussed in Chapter 50 and prescribing for geriatric patients is discussed in Chapter 51.

Pregnancy

Pregnant patients pose a challenge to the prescriber. Early in pregnancy, there is a risk for drugs being teratogenic to the fetus. The FDA has historically assigned a pregnancy category to prescription drugs, rating them as Pregnancy Category C, D, or X, known to cause fetal harm (U.S. Food and Drug Administration, 2009). The FDA has proposed a change in labeling to incorporate a pregnancy risk summary and clinical considerations to the drug label (U.S. Food and Drug Administration, 2011). Later in pregnancy, drugs may cause fetal adverse effects, such as tachycardia or stroke, or may cause the fetus to abort during premature labor. The National Library of Medicine TOXNET Developmental and Reproductive Toxicology Database (DART) is a Web-based databank of the latest information on the developmental and reproductive effects of drugs (http://toxnet.nlm.nih.gov). Drugs in pregnancy are discussed in the Precautions and Contraindications sections for each drug class and in Chapter 49.

Provider Factors

Ease of Prescribing or Monitoring

Providers often develop a personal formulary of drugs with which they are familiar and that they are comfortable prescribing (Maxwell, 2009). Unfamiliar medications require providers to research the drug and educate themselves in order to prescribe the drug safely. The amount of provider follow-up required, whether it is titrating doses or therapeutic monitoring, may influence prescribing decisions (Maxwell, 2009; Spector & Vesell, 2002).

Formularies

Many health insurance plans have restricted formularies; the provider must prescribe from the formulary or the patient may have significant additional out-of-pocket costs. The restricted formulary of many health plans requires that nurse practitioners move away from their personal formulary. Nurse practitioners need to be familiar with the formulary of medications they are allowed to prescribe from and to keep themselves updated as formularies change (Spector & Vesell, 2002).

INFLUENCES ON RATIONAL PRESCRIBING

Pharmaceutical Promotion

The pharmaceutical industry consistently ranks among the most profitable industries (Spitz & Wickham, 2012). Pharmaceutical companies fund many academic research studies, and there have been reports that some of these studies do not publish negative results of industry-sponsored clinical trials (Institute of Medicine, 2009). Pharmaceutical companies also offer free dinners, gifts, and free drug samples to providers to raise awareness of their products and to influence prescribing (Austed, Avorn, & Kesselheim, 2011). Gifts range from small items such as pens and coffee mugs to medical textbooks and equipment. The Institute of Medicine issued a report in 2009 regarding the conflicts of interest and noted the influence of meals and gifts on physician prescribing; the report stated, "Data suggest that these relationships may influence physicians to prescribe a company's medicines even when evidence indicates another drug would be more beneficial" (p 3).

There has been little research regarding the influence of pharmaceutical marketing on nurse practitioner (NP) prescribing practice. Blunt (2005) surveyed NPs ($N = 393$) regarding the influence of pharmaceutical company education and gifts, and 80% of respondents reported that they changed their prescribing practices after pharmaceutical company education or interaction with a drug representative. Ladd, Mahoney, and Emani (2010) surveyed NPs nationwide ($N = 263$) and found 90% believed it was acceptable to attend a lunch or dinner sponsored by the pharmaceutical industry, with 48% indicating they were more likely to prescribe a drug that was featured in the sponsored event. In focus groups exploring prescriptive decision making of geriatric nurse practitioners (GNPs), the GNPs reported skepticism regarding the information provided by pharmaceutical representatives. They noted that the studies presented to them often excluded geriatric patients from the sample, thus making the information provided of little use for their practice (Mahoney & Ladd, 2010). Mahoney and Ladd noted that the participants of their focus groups felt their nursing background influenced their prescribing and that GNPs have a more holistic approach to prescribing than do physicians. More research is needed regarding the influence of pharmaceutical marketing and education on NP prescribing.

In light of the influence that pharmaceutical marketing has on prescribing, professional organizations have issued statements regarding such marketing. The Institute of Medicine recommends that conflicts of interest and financial relationships be disclosed by those providing education and that providers limit the distribution of drug samples to patients who do not have financial access to medication (Institute of Medicine, 2009). The Pharmaceutical Research and Manufacturers of America (PhRMA) has developed its Code on Interactions with Healthcare Professionals, stating a commitment to high ethical standards in the marketing of pharmaceutical products (PhRMA, 2010). NP prescribers need to be aware of the influences of all aspects of pharmaceutical marketing on their prescribing.

When Prescribing Recommendations Change

The approach of expert providers may serve them well most of the time, but when guidelines change or new evidence becomes available, expert providers may need to be coached or reeducated regarding appropriate prescribing. Prior to the 1990s, antibiotics were widely prescribed for upper respiratory infections. The excessive and inappropriate use of anti-infective agents became a major factor in drug resistance (Bishai, Morris, & Scanland, 2004; CDC, 2009; Linares, Ardanuy, Pallares, & Fenoll, 2010).

The emergence of antibiotic resistance due to antibiotic overprescribing led to a need to shift attitudes and prescribing patterns. The CDC developed the "Get Smart" campaign, and a similar STAR (Stemming the Tide of Antibiotic Resistance) campaign was conducted in the United Kingdom (Bekkers et al, 2010; CDC, 2009). The CDC employed an intervention involving collaboration with the medical professional organizations and intensive education regarding appropriate prescribing of antibiotics. The STAR program used Social Learning Theory, online learning, and context-bound learning to change attitudes about prescribing antibiotics (Bekkers et al, 2010; Simpson et al, 2009). Changing ingrained prescribing behavior is essential to reducing antibiotic resistance, and each prescriber is responsible for the thoughtful prescribing of antibiotics to prevent resistance.

The changing recommendations regarding prescribing antibiotics is just one example of how prescribing recommendations may change and of the necessity for prescribers to keep up-to-date on the current guidelines for prescribing.

LEGAL AND PROFESSIONAL ISSUES IN PRESCRIBING

Tracy Klein

FEDERAL DRUG LAW

History

The Food, Drug, and Cosmetic Act of 1906 was the first federal law designed to protect the public by restricting the manufacture and distribution of drugs. The law designated that drugs must meet official standards for strength and purity and prohibited "the manufacture of adulterated or misbranded or poisonous or deleterious foods, drugs, medicines, and liquors" (U.S. Food and Drug Administration [FDA], 2010). Focusing primarily on how drugs were ultimately labeled or branded, it did not broadly prevent the manufacturing of unsafe or ineffective medications.

In 1937, a manufacturer marketed an elixir of sulfanilamide that used diethylene glycol as a solvent for the new antibiotic. Because its pharmacological effects were not tested, its toxicity went unnoticed until reports of more than 100 patient deaths were collected.

The public outcry for new laws resulted in the federal Food, Drug, and Cosmetic Act of 1938 (FDA, 2010). This act has three basic principles that restrict drug adulteration, misbranding, and the interstate commerce of an unapproved drug. It also created the FDA. As a regulatory agency, the FDA was initially charged with enforcing new laws requiring that drugs be checked before they went to market. From 1938 to 1962, the approval of new drugs was based on safety. In the early 1960s, the use of thalidomide by women in the early stages of pregnancy resulted in the birth of hundreds of deformed babies in Europe. A tragedy of this scale was avoided in the United States because the drug was not approved for marketing here. This situation spurred the passage of the Kefauver-Harris amendments in 1962 (FDA, 2010). These amendments required that both the safety and efficacy of a drug be proven before it is marketed. In addition, the act required that all drugs marketed from 1938 to 1962 be evaluated for efficacy. This study was performed by the National

Academy of Sciences/National Research Council and called the Drug Efficacy Study Implementation (DESI). Thousands of drugs were studied and ineffective drugs were withdrawn from the market.

Two additional acts have had considerable influence on improving drug availability and benefiting patients with rare diseases. The Orphan Drug Act of 1983 fosters orphan drug development for diseases so rare that the usual approval process would take decades to complete (FDA, 2010). The Drug Price Competition and Patent Term Restoration Act of 1984 expanded the number of generic drugs suitable for an abbreviated new drug application (ANDA). This makes it possible for generic drug companies to market generic versions of drugs by proving bioequivalence rather than duplicating the clinical trials needed for initial drug approval.

Another significant legislative act was the Pediatric Research Equity Act passed in 2003 (FDA, 2010). This act, referred to as the "Pediatric Rule," authorized the FDA to request pediatric studies of already marketed drugs or to require studies by others if the manufacturer refuses. Since the passage of the Pediatric Rule, several drugs in common use for children were removed from the market because their safety and efficacy had never been tested in pediatric subjects.

U.S. Food and Drug Administration Regulatory Jurisdiction

The FDA regulatory jurisdiction over drugs encompasses the standardization of nomenclature, the approval process for new drugs and new indications, official labeling, surveillance of adverse drug events, and methods of manufacture and distribution (FDA, 2012). The classification of a drug as a prescription or nonprescription medication is a matter of federal law. Products labeled with the legend "Caution: Federal law prohibits dispensing without a prescription" are regulated by the FDA and are referred to as *legend drugs.*

The FDA also regulates medical and electronic devices that meet criteria under the 1976 Medical Devices Amendment of the Food, Drug, and Cosmetic Act (FDA, 2012). Examples of medical and electronic devices include ultrasound imaging equipment, artificial joints, and HIV testing kits.

Prior to 1997, the FDA strictly limited direct-to-consumer advertisements (FDA, 2010). However, such advertising is now commonplace, and studies show it increasingly influences consumer and prescriber decision making regarding medications. The federal Food, Drug, and Cosmetic Act provides that the advertising of prescription drugs must conform to the labeling. Any advertisement that describes a drug's use must contain the generic name and amount of active ingredient, the name and address of the manufacturer, and a brief summary of the prescribing information. A prescription drug advertisement that implies incorrectly that a drug is the treatment of choice or is useful for an off-labeled indication is unlawful. Drug manufacturers are increasingly marketing prescription drugs to patients through print and electronic media, which has increased the demand on practitioners to prescribe advertised drug products.

The New Drug Approval Process

The U.S. system of new drug approvals is perhaps the most rigorous in the world. On average, it costs a company approximately $2.6 billion to get one new medicine from the laboratory to the pharmacist's shelf, according to a 2014 Tufts University analysis for its Center for the Study of Drug Development, which included costs for drugs that were never marketed as well as post-marketing research (DiMasi, Grabowski, & Hansen, 2014). As illustrated in Figure 4-1, it takes 8.5 years on average for an experimental drug to travel from laboratory preclinical trials to FDA approval (Duke Clinical Research Institute, 2010).

Preclinical Research

The process of synthesis and extraction identifies new molecules with the potential to produce a desired change in a biological system (e.g., to inhibit or stimulate an important enzyme, to alter a metabolic pathway, or to change cellular structure). The process may require research on the fundamental mechanisms of disease or biological processes, research on the action of known therapeutic agents, or random selection and broad biological screening. New molecules can be produced through artificial synthesis or extracted from natural sources (plant, mineral, or animal). The number of active pharmaceutical ingredients that can be produced based on the same general chemical structure runs into the hundreds of millions.

Biological screening and pharmacological testing use nonhuman studies to explore the pharmacological activity and therapeutic potential of compounds. These tests involve the use of animals, isolated cell cultures and tissues, enzymes, and cloned receptor sites, as well as computer models. If the results of the tests suggest potential beneficial activity, related compounds are tested to see which version of the molecule produces the highest level of pharmacological activity and demonstrates the most therapeutic promise, with the smallest number of potentially harmful biological properties.

Pharmaceutical dosage formulation and stability testing make up the process of turning an active compound into a form and strength suitable for human use. A pharmaceutical product can take any one of a number of dosage forms (e.g., liquid, tablets, capsules, ointments, sprays, patches) and dosage strengths.

Toxicology and safety testing determines the potential risk a compound poses to people and the environment. These studies use animals, tissue cultures, and other test systems to examine the relationship between factors such as dose level, frequency of administration, and duration of exposure to both the short- and the long-term survival of living organisms. Tests provide information on the dose–response pattern of the compound and its toxic effects. Most toxicology and safety testing is conducted on new molecular entities

prior to their human introduction, but companies can choose to delay long-term toxicity testing until after the therapeutic potential of the product is established.

Clinical Studies

An investigational new drug (IND) application is filed with the FDA prior to human testing. The IND application is a compilation of all known information about the compound. It also includes a description of the clinical research plan for the product and the specific protocol for phase I study. Unless the FDA says no, clinical tests can begin 30 calendar days after submission. The FDA has formulated IND regulations for the clinical study of a new drug's safety and efficacy and has divided this evaluation into three phases:

1. Phase I clinical evaluation is the first testing of a new compound in subjects, for the purpose of establishing the tolerance of healthy human subjects at different doses; defining its pharmacological effects at anticipated therapeutic levels; and studying its absorption, distribution, metabolism, and excretion patterns in humans.

2. Phase II clinical evaluation is controlled studies performed on patients with the target disease or disorder to determine a compound's potential usefulness and short-term risks. A relatively small number of patients, usually no more than several hundred subjects, are enrolled in phase II studies.

3. Phase III trials are controlled and uncontrolled clinical trials of a drug's safety and efficacy in hospital and outpatient settings. Phase III studies gather precise information on the drug's efficacy for specific indications, determine whether the drug produces a broader range of adverse effects than those exhibited in the small study populations of phases I and II studies, and identify the best way of administering and using the drug for the purpose intended. If the drug is approved, this information forms the basis for deciding the content of the product label. Phase III trials verify that the acceptable risk/benefit ratio seen in phase II persists under conditions of anticipated usage and in groups of patients large enough to identify statistically and clinically significant responses.

Conferences between the sponsor and the FDA are held during all three phases of development. While an IND is in effect, the sponsor must report in writing to the FDA within 10 working days any serious and unexpected adverse reactions that may be drug related. The treatment IND program is part of the FDA's efforts to facilitate the development of significant new therapies. Under this program, treatment protocols using an investigational drug can be approved for life-threatening illnesses for which there is no comparable alternative therapy. Information on the availability of an investigational drug under a treatment IND is published in the

Journal of the American Medical Association and other public sources. Patients and families can learn about clinical trials and access to investigational drugs for cancer treatment through the National Cancer Institute's PDQ database available online. The National Institute of Health Clinical Center (NIH CC) also sponsors an extensive database of clinical trials for a wide range of medical conditions, which can be accessed online at http://clinicalstudies.info.nih.gov/.

Bioavailability Studies

Healthy volunteers are used to document the rate of absorption and excretion from the body of a compound's active ingredients. Companies conduct bioavailability studies both at the beginning of human testing and just prior to marketing to show that the formulation used to demonstrate safety and efficacy in clinical trials is equivalent to the product that will be distributed for sale. Companies also conduct bioavailability studies on marketed products whenever they change the method used to administer the drug (e.g., from injection or oral dose form), the composition of the drug, the concentration of the active ingredient, or the manufacturing process used to produce the drug.

Regulatory Review: New Drug Application

To market a new drug for human use, a manufacturer must have a new drug application (NDA) approved by the FDA. All information about the drug gathered during the drug discovery and development process is assembled in the NDA. During the review period, the FDA may ask the company for additional information about the product or seek clarification of the data contained in the application. The FDA has 60 days to determine whether the NDA will be filed for review. Once the FDA files the NDA, a team is assigned to review the drug sponsor's research on the safety and effectiveness of the drug. Usually, the FDA requests additional information, and the manufacturer needs from 1 to 5 years to complete any additional well-controlled trials necessary to support the claimed indications or prove the drug's safety.

Accelerated Approval of a New Drug Application

The timely availability of new drugs remains the subject of considerable debate. In December 1991, the FDA published new regulations to accelerate approval of certain new drugs that provide therapeutic benefit to patients with serious or life-threatening illnesses (FDA, 2010). The FDA can approve these drugs based on well-controlled clinical trials establishing that the product has an effect on a therapeutic endpoint that is likely to predict clinical benefit. The applicant is required to conduct post-marketing studies.

Postapproval Research

Clinical experience with a new drug may include no more than 1,000 to 2,000 patients. The detection of rare (less than 1 in 1,000) adverse drug reactions is not reliable until hundreds of thousands of patients have taken the drug. Clinical trials conducted after a drug is marketed (referred to as phase IV studies in the United States) are an important source of information on as-yet undetected adverse outcomes, especially in populations not included in the premarketing trials (e.g., children, the elderly, pregnant women), and the drug's long-term morbidity and mortality profile. Regulatory authorities can require companies to conduct phase IV studies as a condition of market approval.

An important source of postapproval information is data collected and submitted by practitioners in the field through programs such as MedWatch, the FDA's safety and adverse-effect reporting system (http://www.fda.gov/Safety/MedWatch). Although the MedWatch system is voluntary, it is relied on to obtain post-marketing information that may lead to further trials, modification in use recommendations (i.e., Black Box warning), or even withdrawal of the drug from the market.

Official Labeling

The legal distinction between a legend drug and an over-the-counter (OTC) drug is not founded on relative safety per se but rather involves a regulatory decision on whether adequate directions for the drug's proper use can be written for the layperson. If the FDA determines that adequate directions can be written, the manufacturer is not allowed to identify the drug with a prescription legend.

Conversely, for a prescription drug, the manufacturer's directions or FDA-approved labeling (the package insert) is intended for the prescriber, pharmacist, or nurse and provides a summary of information about the chemical and physical nature of the product, pharmacological indications and contraindications, means of administration, dosages, side effects and adverse reactions, how the drug is supplied, and any other information pertinent to safe and effective use. This summary, or official labeling, is developed through discussion between the FDA and the drug manufacturer. The material in the *Physician's Desk Reference* (PDR) is a verbatim presentation of the official labeling.

The FDA's jurisdiction over the uses of marketed drugs and doses extends only to what the manufacturer may recommend and must disclose in its labeling. The FDA is not charged with dictating how a prescriber should practice. The FDA is concerned with the marketing and availability of drugs that have demonstrated substantial evidence of an acceptable risk/benefit ratio for labeled indications. *The proper and efficacious therapeutic use of these drugs is the responsibility of the prescriber.*

Off-Label Use

The prescription of an FDA-approved drug for an off-label (unlabeled) indication may be initiated by patient need. Off-label use includes use of an FDA-approved drug in a dose or route for which it was not approved or for a clinical indication other than the FDA-approved use. Clinical support can be demonstrated for off-label use if the proposed use is based on rational scientific theory or controlled clinical studies. The FDA has made it clear that it neither has nor wants the

authority to compel prescribers to adhere to FDA-approved use in all clinical situations. An example of off-label use is that of trazodone, which is an antidepressant, for sleep. In this example, a side effect of the medication (drowsiness) has been shown to have clinical efficacy for patients with difficulty sleeping whether or not they are clinically depressed. Although not FDA approved for insomnia, trazodone is commonly prescribed for this indication.

Nurse practitioners (NPs) are responsible for knowing the FDA indication and approval status of any drug they prescribe. However, a prescribing decision on how to use a drug must be based on what is best for the patient and then supported by available evidence. In professional liability suits, FDA-approved drug labeling may have evidentiary weight, but drug labeling is not intended to set the sole standard for what is good clinical practice. NPs must also be aware that Medicare and other insurers rarely cover off-label prescriptions and that consequently the patient may bear greater cost. Off-label prescribing can also result in increased or unknown risk to the patient (Gillick, 2009).

Controlled Substance Laws

The most comprehensive federal drug legislation is the Controlled Substances Act of 1970 (FDA, 2010). This law was designed to improve regulation of the manufacturing, distribution, and dispensing of drugs identified as "controlled" drugs by providing a closed system for legitimate providers of these substances. Every person who manufactures, distributes, prescribes, procures, or dispenses any controlled substance must register and obtain a registration number with the U.S. Drug Enforcement Administration (DEA). The *Practitioner's Manual: An Informational Outline of the Controlled Substances Act,* published in 2006, outlines regulations and requirements for controlled-drug prescribing. This pamphlet is available from the DEA or can be viewed online (http://www.deadiversion.usdoj.gov/pubs/manuals/pract/index.html). All those who regularly dispense and administer controlled substances during the course of their practice must maintain and keep on file for a minimum of 2 years accurate records of controlled drugs they purchase, distribute, administer, and dispense.

Many states have controlled substance acts patterned after federal law. Because differences are allowed in the scheduling of drugs among states (a state may be more restrictive but not less restrictive), NPs must become acquainted with the provisions of the regulations in the state in which they are licensed. NPs wanting authority to prescribe controlled substances must apply for state prescriptive authority prior to application for a federal DEA number. Applications for a DEA number may be obtained online through the DEA or though the state regional office. Before applying, it is important to verify with the state board of nursing or pharmacy if a state-issued prescribing number or certificate is also issued separately from the NP license.

For many years the DEA number was inappropriately used for other than controlled substances by pharmacies, primarily to bill insurance or track medications under a provider-unique identifier. Concern over this as well as the plethora of separate numbers used for Medicaid and Medicare billing led to the development and use of the National Provider Identifier number (NPI). The NP should obtain an NPI as soon as it is feasible. Application is free and available online. This number is unique to the provider and is used for all prescriptions that are billed through insurance, as well as for other billing services.

In an effort to control drug distribution, a classification system was developed to categorize drugs as "controlled" based on their potential for abuse, accepted medical use, and diversion potential. NPs must know the different classifications and schedules of controlled drugs as well as the associated prescribing rules and regulations. Controlled drugs are listed in five different schedules— I, II, III, IV, and V—to which different regulations apply. Controlled substance authority for NPs varies from state to state according to ability and autonomy of practice.

Table 4-1 presents the schedules, controls required, and examples of drugs.

Controlled Substance Prescribing Precautions

Prescribers should take precautions with controlled drug prescription pads and information included on the controlled substance prescription to minimize the chance for fraud and diversion of these drugs. The prescription pad (or prescription printer paper) should be stored in a locked area or locked drawer on the printer. Prescriptions should never be signed in advance or used as notepads. The prescriber's name, NPI number, address, and telephone number should be printed on the pads to allow verification by the dispensing pharmacist. Some states also require that the NP's license number appear on the prescription in addition to that of any supervising/collaborating practitioner. The DEA registration number must be designated on all controlled substance prescriptions, though individual states may permit a pharmacist to write in the DEA number if it is not initially provided. The prescription should be dated on the day it is written, indicating any authorized refills as allowed and clinically appropriate. It is helpful to spell out the quantity dispensed as well, using an Arabic numeral (e.g., "forty [40]") to discourage alterations in the intended quantity.

A prescription for a controlled substance may be directly faxed to the pharmacy as an additional precaution, with the exception of Schedule II controlled substances. A fax cannot be considered the original for Schedule II drugs unless the drug in question is (1) for a nursing home, (2) for a hospice, or (3) for parenteral medication for home IV administration.

As of 2009, tamper-proof prescription pads are required for prescriptions written for patients under Medicaid payment plans. State law incorporates the federal guidelines for what constitutes a tamper-proof prescription into any additional state-specific requirements for controlled substances, such as duplicate prescription pads. A practitioner may find

Table 4–1 **Controlled Drug Schedules**

Schedule	Controls Required	Drug Examples
I	No accepted medical use No legal use permitted For registered research facilities only	Heroin, LSD, mescaline, peyote, marijuana*
II	No refills permitted No telephone orders unless true emergency and followed up by written prescription within 7 days Electronic prescribing permitted as of 2011 with specific software and secure identification processes	Narcotics (morphine, codeine, meperidine, opium, hydromorphone, oxycodone, oxymorphone, methadone, fentanyl) Stimulants (cocaine, amphetamine, methylphenidate) Depressants (pentobarbital, secobarbital)
III	Prescription must be rewritten after 6 mo or 5 refills Telephone or fax prescription okay	Narcotics (codeine in combination with non-narcotic ingredients not to exceed 90 mg/tab; hydrocodone not to exceed 15 mg/tab) Stimulants (benzphetamine, chlorpheniramine, diethylpropion) Depressants (butabarbital) Anabolic steroids, testosterone
IV	Same as Schedule III Penalties for illegal possession are different	Pentazocine, phentermine, benzodiazepines, meprobamate
V	Same as all prescription drugs May be dispensed without a prescription unless regulated by the state	Loperamide, diphenoxylate Cough medications with less than 200 mg/100 mL Pregabalin

*Marijuana may be classified under individual state law as a Schedule II drug and used for medical purposes. It may not be "prescribed," however.

the use of tamper-proof prescription pads or paper to be advisable for all written prescriptions, because many drugs that have abuse potential are not currently federally controlled. Such drugs include tramadol, carisoprodol, and pseudoephedrine.

A few medications have such high abuse potential or potential for serious adverse effects that they should be prescribed very cautiously and with increased monitoring. The medications with high abuse potential that fall into this category include methadone, amphetamine, and scheduled appetite suppressants. Medications with especially problematic adverse-effect profiles include meperidine and butalbital. Medications with exceptionally narrow safety margins include secobarbital, pentobarbital, meprobamate, methadone, and ethchlorvynol. Medications with little established efficacy include carisoprodol, butalbital, and scheduled appetite suppressants.

Opioids such as morphine have legitimate clinical usefulness, and the practitioner should not hesitate to prescribe them when indicated for patients who require analgesia or symptomatic relief not provided by other analgesics. Methadone is also used for chronic pain management due to its cost and long half-life. However, methadone also has an extremely variable half-life (7 to 60 or more hours) that differs for individuals based on their metabolism. It therefore should not be a first-line therapy for pain management, especially for the less experienced practitioner. Buprenorphine is another long-acting opioid used for pain management. Both buprenorphine and methadone are legal to prescribe for pain management provided that an NP has his or her own Schedule II authority. However, it is not legal for an NP to prescribe methadone or buprenorphine for narcotic addiction, and such patients should be referred

to an MD or a state-registered clinic that specializes in addiction treatment.

A specific clinical challenge regarding controlled drug prescribing is the patient who has a history of drug or alcohol abuse or dependence and who needs management of pain, anxiety, and insomnia. Special attention should be given to patients with current dependence on opioids or other central nervous system depressants such as benzodiazepines. If a genuine symptomatic need is established by adequate diagnostic confirmation, evaluation, and periodic reevaluation and other analgesics or nondrug treatments are ineffective, then it is the practitioner's responsibility to prescribe appropriate pain control or refer to a specialized pain management clinic. When prescribing opioids, evaluation must be made of the patient using clinically available tools that have been validated, such as SOAPP (Screener and Opioid Assessment for Patients in Pain) or SOAPP-R (Screener and Opioid Assessment for Patients in Pain—Revised) (Butler, Fernandez, Benoit, Budman, & Jamison, 2008). In developing a pain treatment plan, it is important to consider that the effective dose will vary according to the degree of tolerance that the patient has developed.

For any patient, abrupt discontinuation can precipitate a withdrawal syndrome if the patient undergoes major surgical or medical trauma while dependent on the drug. Patients can be instructed in planned withdrawal or taper in conjunction with their surgical or hospital team. Withdrawal or taper of benzodiazapines requires particular clinical expertise and supervision. Unlike opioids, benzodiazapine withdrawal can result in seizures and significant mortality if managed improperly.

The practitioner must caution any patient for whom an antianxiety or hypnotic is prescribed about the potentiating effects of alcohol and other drugs. Practitioners should also

be aware that benzodiazepines in particular have associated cautions due to their clinical effects and potential for abuse that contraindicate them for patients on methadone or with a current substance use disorder.

CONTROLLED SUBSTANCE MISUSE: PRESCRIBER EDUCATION

In standard clinical practice there are many opportunities for individuals to obtain excessive quantities of controlled drugs, either intentionally or as a result of duplicate prescribing, often by different prescribers. The problems and costs associated with misuse of controlled prescription drugs may have an impact on patients and their prescribers.

Principles for prescribers related to prescription drug misuse assessment include the following:

1. Acquisition and wide use of chemical dependence screening skills.

---

2. Early and firm limit setting regarding indications for controlled drug prescribing.
3. Careful documentation of a confirmed diagnosis and the ruling out of chemical dependence before initiating a controlled prescription or drug subject to misuse.
4. Practice in "just saying no" and feeling comfortable in being firm without escalating the discussion into an argument with the patient.

Further discussion of pain medication abuse is found in Chapter 52.

Behavioral Red Flags

Almost every practice experiences the chemically dependent patient who uses dishonest mechanisms to obtain increasing supplies of controlled prescriptions. There are certain behaviors that are "red flags" for identifying patients who may be addicted or diverting their controlled medications. Passik and colleagues (1998) have listed behaviors that providers should be aware of that are predictive of addiction (Table 4-2).

Once a scam has worked in a given practice, that scam will continue to surface periodically in that office practice until the provider ceases to reinforce the scam. Drug enforcement investigators and patients who abuse prescription drugs commonly observe that the greater the ease of practicing scams and drug-seeking behavior in a provider's practice, the higher the prevalence of drug-abusing patients there will be in that practice. Dealing with scams consists of the following steps:

1. Learning to recognize the common scams.
2. Refusing to give in to scammers.
3. Practicing the skill of turning the tables on the scammer.

Scams are generally conducted to obtain more medications, more potent or higher-dosage formulations, higher street-value brands of drugs, a controlled drug without a chart or visit note, or to avoid noncontrolled alternatives. Most scams produce discomfort in providers, and patients using scams are often willing to push the practitioner if they encounter resistance to the scam. Patient-generated pressure to prescribe in the face of clinician hesitancy is one classic sign of a scam. Patients rarely argue pharmacology with providers unless the issue of prescribing

---

Table 4–2 Behaviors More and Less Predictive of Addiction

Probably More Predictive	Probably Less Predictive
Prescription forgery	Drug hoarding during periods of reduced symptoms
Selling prescription drugs	Aggressive complaining about need for higher doses
Stealing or borrowing another patient's drugs	Requesting specific drugs
Injecting oral formulation	Unapproved use of drug to treat another symptom
Obtaining prescription drugs from nonmedical sources	Obtaining similar drugs from other medical sources
Concurrent use of illicit drugs	Reporting psychic effects not intended by the provider
Unsanctioned dose escalations	Unsanctioned dose escalations one or two times
Recurrent prescription losses	Resistance to change in therapy associated with tolerable adverse effects, with expressions of anxiety related to return to severe symptoms
Evidence of deterioration in the ability to function at work, in the family, or socially, which appears to be related to drug use	
Repeated resistance to changes in therapy despite clear evidence of adverse physical or psychological effects from the drug	

Passik et al (2006).

controlled drugs is being contested. The clinical phenomenon of an initial no (refusal to prescribe by the practitioner) becoming a yes (eventual willingness to prescribe) if the patient brings the right pressure to bear on the practitioner is pathognomonic of prescription drug misuse.

Prescription altering and forging are a frequently encountered scam. Variations include stealing prescriptions, forging blank prescriptions, photocopying prescriptions, and rewriting prescriptions. Additional common prescription alteration strategies include changing the strength of a prescribed drug, the number of pills prescribed, the number of refills indicated, or the date of the prescription. Patients and staff members who have substance misuse issues may also call in prescriptions with the NP's DEA number, as current law permits phoned-in prescriptions for Schedules III–V.

Pressure to Prescribe

Another factor that increases the demand for controlled substances is the pressure to prescribe at every visit and the expectation that patients deserve a prescription for something at each visit or for each symptom offered. This process results in two well-known adverse situations: (1) overprescribing of antibiotics and resulting antibiotic resistance and (2) polypharmacy, especially of the elderly. It also may result in a tendency on the part of practitioners to prescribe higher-potency noncontrolled substances and then ultimately controlled drugs when patients persist with vague somatic complaints.

Enabling

Enabling refers to the powerful instinct in practitioners to do anything medically possible to enable patients with present or potential disability to live at a higher level of function. Unfortunately, the disease of chemical dependence has a bottomless appetite for enabling, also defined as behaviors on the part of a friend, family member, or health-care provider that shelter the chemically dependent individual from the adverse consequences of the disease. When the practitioners' enabling instincts interact with chemically dependent patients, the patients are often able to manipulate the practitioners to avoid the consequences of their disease process, thus permitting that disease to progress to further, more pathological levels. This is especially true when controlled drug prescribing is involved. A common statement from practitioners who have been manipulated into enabling and overprescribing to patients is "I was only trying to help." Chemical dependence is one disease process in which practitioners must strive against enabling tendencies, especially when prescribing controlled drugs.

When You Suspect a Patient Is Misusing Medications

Communication Barriers

Curricula in training programs over the past two decades have come to emphasize the clinical interview and practitioner–patient relationship-building skills. Skill building involves active learning strategies in the areas of verbal and nonverbal communication, empathy, and rapport building. Nursing socialization further emphasizes therapeutic patient advocacy, sometimes without the counterbalance of coaching nurses on how to say no and enforce boundary limitations. Therefore, many NPs feel acutely uncomfortable with conflict and interpersonal confrontation. It is obvious how the practitioners' fear and avoidance of confrontation play into the hands of chemically dependent patients, who have a stronger relationship with the prescription than they do with the practitioners.

Communication Skills

Practitioners must be able to identify common scams and defuse them efficiently and effectively. One strategy is to just say no and mean it. Chemically dependent patients have learned that the practitioners' enabling instincts and confrontation discomfort are so great that when NPs initially say no, it usually ultimately can be turned into a yes if enough pressure is applied. Thus, it is important to be able to mean no and to stick with it. A higher-level clinical skill is initially to say no and then to turn the tables on a patient who demands the prescription. This strategy is based on the clinical fact that patients who demand controlled drugs generally have a pathological relationship with that prescription because of underlying chemical dependence. By making the statement "I am feeling pressured by you to write a prescription today that is not clinically indicated. Because of this I am really concerned about you, and we need to talk about your use of alcohol or other substances," the NP can often effectively turn the tables and shift the discomfort to the patient while still refusing to prescribe.

Systemic Solutions to Problems of Controlled Substance Prescribing

Law enforcement and legislative efforts have produced few solutions to the problem of imbalance in controlled drug prescribing. Until recently, these approaches have targeted diversion of drugs and overprescribing. Results of duplicate and triplicate prescription policies, as well as stricter investigation and enforcement, led to decreased prescribing of controlled drugs across the board, even to patients in need of them for legitimate medical reasons. The development of more permissive policies and pain management guidelines by state legislatures and health regulatory boards increased prescribing for pain management; however, a concurrent 65% increase in hospitalizations in the United States for poisonings from prescription drugs (opioids, sedatives, and tranquilizers) ensued from 1999 to 2006 (Coben et al, 2010). Coben and colleagues report a 400% increase in admissions for methadone overdose. This increase is possibly due to inappropriate dosing and use of methadone for pain management, as well as by diversion of legitimately prescribed medications from the patient for whom it was originally prescribed.

Careful charting and documentation habits are essential for prescribing controlled drugs. Document clearly in a

progress note (1) physical evaluation of the patient, (2) the diagnosis, (3) the clinical indications for treatment, (4) the written treatment plan, (5) the expected symptom outcomes, (6) informed consent and agreement for treatment from the patient, and (7) consultation and/or collaboration necessary to meet treatment goals and objectives. These strategies reduce, but do not eliminate, the risk of controlled drug diversion from one's practice.

● PRESCRIBING TIPS ●

A few prescribing tips can help the practitioner reduce environmental facilitation of prescription misuse. First, collect and document a complete history and examination before prescribing controlled substances. Do not rely on patient-supplied history, x-rays, or medical records to confirm your assessment—obtain this information directly from the primary source. Passik and Weinreb (2000) advise use of the four "A's" to guide initial and ongoing assessment of medication efficacy: (1) analgesia measurement by use of pain scales or other assessment tools, (2) activities of daily living (ADLs) as measured by levels of physical and psychological functioning, (3) adverse effects, and (4) abuse issues.

Prescribe limited quantities without refills on a first visit, allowing additional time for patient assessment and confirmatory documentation. Educate medical and assistive staff in reinforcement of consistent clinic policies and procedures related to scheduling, forms, urine drug screening, records review and release, and refills. It is not uncommon for patients who do misuse substances to quickly identify the "weak link" among the treatment team and focus their energies on this person or process. Standardize expectations regarding after-hours calls, use of multiple providers, and weekend or early refills and post them where they are readily available.

Patients covered by insurance plans, including Medicaid and Medicare, can be limited to one pharmacy or one prescriber through their payment plan. Case managers can often be utilized to help review and manage medication use and advocate for access to additional options for pain management and control. Other tips include prescribing generic, longer-acting formulations of drugs that have less street value and writing out the quantity prescribed rather than using only numerals, which can be altered.

Medication Agreements

One tool for defining and implementing treatment objectives is the medication agreement. This written tool can be incorporated into treatment of chronic pain, particularly if long-term management with opioids is indicated. The agreement is not limited to opioid prescribing practice, however. A medication agreement can be used for treatment of pain or other conditions with medications that are not opioids but still have potential for patient misuse, such as benzodiazepines, tramadol, or other adjunctive medications. Formats can be found in the links at the end of this chapter and

in Chapter 52. These may be modified for individual clinic settings and client populations.

It is advisable to treat medication agreements under a "universal precaution" model of care, meaning that the NP develops and uses agreements that are expected of all patients requiring ongoing use of medications with potential for misuse. It is inequitable and a potential legal liability to pick and choose patients who will be asked to sign a medication agreement based on their age, income status, use of other controlled or illicit substances, or other personal characteristics. NPs are advised to familiarize themselves with urine drug and alcohol screens and their availability, cost, sensitivity, and specificity. In-office rapid screenings are now available that can be done quickly and without prior notice in order to confirm adherence to medication agreement criteria. An example of a pain medication use agreement is found in Chapter 52.

Prescription Drug Monitoring Programs

As of 2012, all but one state (Missouri) have an active or legislatively enabled Prescription Drug Monitoring Program (PDMP). A PDMP enables practitioners to query a confidential database of controlled substances statewide to evaluate whether a patient is currently receiving a prescription elsewhere. Some states also have regulations that permit cross-state sharing of this information, which has reduced the ability of patients who misuse controlled substances to obtain multiple prescriptions from multiple providers. For more information regarding these programs and how to access them, contact the local DEA office or state board of pharmacy or the Alliance of States with Prescription Drug Monitoring Programs (http://www.pmpalliance.org/).

STATE LAW

Jurisdiction

Federal law establishes whether a drug requires a prescription but does not dictate who may prescribe. The authority to prescribe is a function of state law. Unlike the uniform nature of federal law, prescriptive authority varies from state to state. The states have the authority to license health-care professionals. Although a state may sign a compact agreement permitting cross-state practice, as is the case with the Nurse Licensure Compact, there are no currently implemented cross-state agreements that cover NP practice.

Regulation of nursing education and practice is relatively recent. The NP role originated in the 1960s as an extension of the registered nurse (RN) role. States thereafter implemented a variety of methods for recognizing NP practice. Although the National Council of State Boards of Nursing recommends licensure as the appropriate level of regulation for the autonomy and authority of the NP role, some states still recognize NPs with certification, endorsement, or through delegated authority from a physician. States have authority under the states' "police power" to take regulatory action to protect public health, welfare, and safety, including emergency suspension or revocation of practice authority. The courts have consistently upheld professional licensing

laws as legitimate use of this power. The purpose of these laws is to ensure that those who provide health-care services for a fee have demonstrated a minimum level of competency.

A license is always required for practice as an NP. The state Nurse Practice Act specifies the exact title that must be used for practice and on a prescription. NPs working in federal facilities such as the Veterans Administration or Indian Health Services need to have a state-based license that governs their scope of practice in that facility but may practice in a facility different from the state of origin under the same license. Persons practicing in a federal facility are also exempt from fees for DEA registration.

Each state has practice acts that set forth licensing requirements for health professionals, define the scope of practice, and prohibit unauthorized practice. These laws usually provide for a state board that governs each profession and establishes administrative rules of conduct for each profession. Prescriptive authority may be granted to a variety of types of health-care providers in a state, including optometrists, naturopaths, and clinical psychologists. Some states grant prescriptive authority to NPs solely through the board of nursing (plenary authority), whereas others require a joint process through a board of medicine or pharmacy. Some states require involvement of a board or authority other than the board of nursing only when controlled substances will be part of prescriptive authority.

Prescriptive authority exists as dependent and independent authority. Independent authority permits the prescriber to exert autonomous judgment. Dependent authority exists when the primary prescriber delegates the authority to another through a collaborative or supervisory agreement. These agreements usually involve written guidelines and/or a protocol for treatment. Some states limit authority by restricting prescribing to a written formulary. Other restrictions may apply, including limits on the geographic locations of the clinical site or limits on the number of doses or refills that may be authorized, or requiring written agreements with a practicing NP that spell out the scope of the prescribing authority. Dispensing, which means the release of a prescription from other than a pharmacy for a patient to take home, is an authority that some states grant with varying degrees of requirements to prescribing practitioners. All states permit NPs some degree of prescribing and all permit dispensing of samples with appropriate prescriptive authority.

Chapter 1 discusses the laws across states. Each year, the January issues of *Nurse Practitioner* and *The Journal for Nurse Practitioners* contains a review of the current state laws regarding prescriptive authority for advanced practice nurses. This review is useful in determining the current status of prescribing in each state.

Writing and Transmitting the Prescription

The Prescription Format

A number of directions need to be communicated in writing or verbally to the dispensing pharmacist to complete a prescription properly. Tools such as the Institute for Safe

Medication Practice's (ISMP) *List of Error-Prone Abbreviations, Symbols and Dose Designations* (2012) can help prescribers decrease transmission errors. The following are suggestions to provide a complete, safe prescription:

1. Use preprinted prescription pads/electronic templates that contain the name, address, and telephone number and NPI number of the prescriber. This will allow the pharmacist to contact the prescriber if there are any questions about the prescription.
2. Designate the complete drug name, strength, dosage, and form.
3. Indicate the date of the prescription.
4. Use metric units of measure, such as milligrams and milliliters; avoid apothecary units of measure.
5. Avoid abbreviations.
6. Avoid the use of "as directed" or "as needed."
7. Include the general indication, such as "for infection."
8. Indicate "Dispense as Written" if generic substitution is not desired.
9. Include the patient weight, especially if pediatric or elderly.
10. Indicate if a safety cap is not required, as medications will be dispensed with them by default.

Examples of prescriptions are found in Figures 4-2 and 4-3.

As of April 1, 2008, all written prescriptions for covered outpatient drugs paid for by Medicaid must be designated on tamper-proof prescription paper. The required elements are adopted into state pharmacy law and include specific inks and papers. Contact the state board directly regarding state-specific prescription requirements.

The appropriate amount of drug and the refill authorization benefit the patient in terms of convenience and may reduce the cost of therapy. For acute therapies, the amount prescribed should be enough to cure the illness or maintain therapy until the next patient visit. Overprescribing is costly, permits inappropriate self-treatment with leftover doses, and contributes to the risk of accidental overdose. Patients cannot return unused drugs to the pharmacy for credit or disposal. Conversely, for the treatment of chronic illness, it is more economical to obtain a supply of medication for 90 days

instead of repeated refills of smaller quantities. Mail-order pharmacies and insurance plans may require that a 90-day supply be dispensed with each prescription. It is judicious to prescribe small initial trial supplies until patient dosage and compliance can be determined, followed by larger refill quantities for chronic therapy.

Schedule II drugs may not be refilled and require a new prescription for each dispensed quantity. However, it is legal and acceptable to write 3 months' worth of prescriptions at one visit for established and stable patients. This is done by writing three separate prescriptions, each with the current visit date, and a statement "do not fill until__." The dates for the next 2- and 3-month refills can be filled in on each prescription, and these can be given to the patient in one visit, mailed, or left for pick up and signature.

What May Be Prescribed

Prescriptions are required for the majority of controlled drugs (state laws may permit the sale of Schedule V controlled substances without a prescription in limited quantities). They are also required for some medical devices, home-health and home-testing equipment, durable medical equipment, needles and syringes, and sometimes for Medicaid or Medicare coverage of OTC medications that are required for patient health. Prescriptions are required in order to compound medications for patient administration in strengths or formulas not otherwise available.

State-Specific Elements

State pharmacy law determines the required format for a prescription. A few states require duplicate or triplicate copy pads for controlled substances. NPs who prescribe in a state with mandated collaboration or supervision may need to indicate the name and information of this person on their prescriptions. A state can also designate that a drug is controlled and requires a DEA number or other special authority, even if the federal government does not. This is becoming true of pseudoephedrine, which is used for methamphetamine man-

ufacturing. A state may pass laws regarding medications that are more restrictive but may not pass laws more permissive than federal law. NPs must verify prescribing laws through their state board of nursing and pharmacy. Less commonly, a board of medicine may also be legally involved in an NP's prescribing practices and regulations.

Electronic Prescribing and Secure Prescribing

The days of "writing" a prescription may soon be over. Electronic prescribing is enjoying support and institutional funding as a method for decreasing medication error and increasing drug tracking and accountability. Electronic prescribing has been implicated, however, in medication errors as well. Prescribers may become exceedingly reliant on pre-populated protocols and dosages that may not apply to the individual patient's clinical circumstances. Most electronic health record systems have override features that are easy to implement, and this can be a benefit, but it can also be a danger in the wrong hands. It is critical that NPs who prescribe take responsibility for individually verifying appropriate doses and treatments. If in doubt, a pharmacist may be consulted directly, and many large universities run free consulting services for this purpose.

As of June 1, 2010, the DEA's revised "Electronic Prescriptions for Controlled Substances" regulation provides practitioners with the option of writing prescriptions for controlled substances electronically (DEA, 2010). The DEA outlines a certifying process required in order for prescribers and pharmacies to transmit electronic prescriptions for controlled substances. NPs will need to be aware of this issue, carefully follow state and federal legislation related to the area of electronic prescribing, and follow all DEA instructions regarding availability of prescribing software that is state-approved for electronic prescribing of controlled substances.

ETHICAL ASPECTS OF PRESCRIBING

Informed Consent

The notion of informed consent is shorthand for the doctrine of informed decision making, which proposes that patients have the right to make informed decisions about those things that will affect them. Although some question whether consent to medical procedures can ever be truly informed, the doctrine has been assimilated into American society's concept of what clinical practice should include. Informed consent should be obtained from a patient before all medical interventions, diagnostic as well as therapeutic. A patient may either agree to or refuse a proposed intervention; in both situations, the patient is making her or his own informed decision.

The provider who performs a specific service is responsible for obtaining consent to that specific service. The consent usually is given to the identified provider, as well as others working with him or her to perform the specific procedure or associated procedures. In general, a referring provider is not responsible for getting consent for a procedure performed by another provider. Some exceptions may apply,

however, and practitioners who send patients for tests or consultations should inform them generally about the procedure and their clinical recommendations for requiring it.

Informed consent has four critical features: (1) a competent patient (2) who is provided adequate information with which to make a decision (3) and who voluntarily (4) consents to a proposed intervention. Although legal opinions tend to merge the concepts, it is helpful to consider competence as two related but distinct areas: legal competence and clinical competence. A patient must be both legally and clinically competent to give informed consent. In general, an adult is presumed to be legally competent unless declared incompetent in formal legal proceedings. To be clinically competent for medical decision making, a patient must be able to comprehend information that is provided, formulate a decision about a proposed intervention, and communicate that decision to the health-care team. Patients may be deemed legally competent to make certain types of decisions or give consent but not legally responsible for all decision making.

Clinical competence is also not an all-or-none phenomenon. A patient may be competent to make some choices but not others. Clinical competence may vary over time and is affected by the course of an individual's illness and therapies currently in use. Assistive devices and environmental modification may be important to maintaining and enhancing clinical competence. Hearing aids, interpreters, and communication boards may be key assistive devices to certain patients. Examples of environmental factors that affect clinical competence include sedative medications, presence of background noise for a patient with a hearing disability, and the side of approach to a patient with a visual field loss.

A medication agreement, as discussed in this chapter, may also outline informed consent for initial and ongoing treatment with medications that have the potential for side effects and habituation. Mental health medications have specific consent regulations due to the vulnerability of their target population. Other areas that may have specific consent procedures include prescribing medications for elderly or minor patients. Parental or partner involvement in prescribing determinations related to sexually transmitted infections, family planning, and birth control may be limited under specific state law, and a minor may give informed consent for some surgical or medical procedures even if a parent is not informed. These are sensitive areas of law that require specific study. Advice of an attorney may be required.

Prescribing for Self, Family, or Friends

State law varies regarding whether an NP can prescribe for family or friends. In order for a prescription to be clinically legitimate, a patient must be assessed and there must be a record of his or her assessment. It is clearly unethical to prescribe for oneself, and many states punish this with significant fines or board action. Although it may be technically legal to prescribe for family or friends, an NP needs to consider whether it is ethical. If the clinical circumstance requires a controlled substance, the judicious prescriber will refer a friend or family member to a colleague for confidential assessment and treatment. It is never considered ethical for a mental health provider to engage a family member or close friend in a clinically therapeutic relationship, whether or not prescribing is involved.

Sale of Pharmaceuticals and Supplements

It is illegal to sell pharmaceuticals that are designated as samples and provided to a clinic for free distribution to patients. Depending on the dispensing laws of the state, it may be permissible to stock and sell limited amounts of commonly prescribed medications within the practice setting. It may also be permissible to sell supplements such as prenatal vitamins or fish oil, especially if the prescriber is able to order them at a discount and pass the savings on to the patient. It may not be technically illegal but can be ethically questionable if the prescriber is selling medications with a broad profit margin to patients perceived as vulnerable.

NURSE PRACTITIONER ROLE OUTSIDE THE UNITED STATES

The NP role is expanding to health systems outside of the United States. As an example, in 2004–2006 the Canadian government funded the Nurse Practitioner Initiative to promote recognition, education, and utilization of NPs as primary care providers. Similar to U.S. states, Canadian provinces have individual practice acts that designate the parameters and autonomy of prescriptive authority. Prior to legislative recognition of the NP role, many provinces, such as Ontario, had provisions for a class of RN with expanded or extended practice permitting limited diagnosis and prescribing.

One significant difference in Canada, which is also true of the UK and its Nurse Practitioner movement, is that prescribing is supported by a national pharmacy system. Nationally adopted core competencies outlined in *The Canadian Nurse Practitioner Core Competency Framework* (Canadian Nurses Association, 2010) clearly articulate preparation of an NP who will be competent to select, prescribe, monitor, and dispense prescription medications. A national expert advisory committee (CEDAC) reviews and recommends drugs for provincial formularies based on efficacy and evidence-based review. Provinces develop formularies for prescribing, which may be further modified based on scope of practice for individual health professions. A provincial pharmacy network, known as PharmaNet, records all community prescriptions in a central database, which facilitates checking for duplication, contraindications, and interactions.

NPs have controlled substance prescribing ability in many Canadian provinces. They may also order laboratory tests, blood products, and other therapeutic interventions and diagnostics. Both NPs and pharmacists in the UK have prescribing ability, based on formularies or standards adopted based on national guidelines.

The NP role is expanding in other countries, such as Australia and New Zealand, to address primary care needs. In 2010, nurse practitioners in Australia gained approval to prescribe medicines designated by an "NP" on the Pharmaceutical Benefits Scheme (PBS) list of medications. In 2011, the Australian Controlled Substances Act was amended to allow prescribing of scheduled drugs. In 2013, the number of endorsed NPs in Australia passed 1,000. New Zealand has followed a similar pattern, with NPs gaining prescribing authority in 2013 and the ability to prescribe controlled substances in 2014.

ADVERSE DRUG REACTIONS

Connie A. Valdez • Anne E. Morgan • Peter J. Rice

According to the U.S. Food and Drug Administration (FDA), over 2 million serious adverse drug reactions (ADRs) occur annually, resulting in emergency room visits, hospital admissions, and an estimated 100,000 deaths (FDA, 2009). It is estimated that 3% to 6% of all hospital admissions annually are for treatment of ADRs and that 10% to 15% of hospitalized patients experience an ADR (Gomes & Demoly, 2005). The total cost associated with ADRs has been estimated to range from $3.5 to $136 billion per year (Centers for Disease Control and Prevention [CDC], 2012; FDA, 2009;). In order to reduce morbidity and mortality associated with ADRs, it is important for practitioners to understand the causes and mechanisms of ADRs and develop practices to predict and prevent their occurrence.

An ADR is any undesirable or unintended effect following administration of a medical product, whether or not the effect is considered related to the medical product (FDA, 1995, 2009). Although ADRs are common, most are not severe and usually resolve when the drug is discontinued or the dose reduced, or they diminish as the body adjusts to the drug. For example, dry mouth from amitriptyline is a mild reaction that will resolve once the medication has been discontinued; dizziness from lisinopril is generally considered to be a common reaction that can be minimized by reducing the dose; an individual using diphenhydramine will notice that the sedative effects will diminish after about 2 to 3 weeks of consistent use. Unfortunately, some ADRs may be serious and/or persist for a significant duration of time even after the drug is discontinued. For example, isotretinoin can cause birth defects when used before or during pregnancy, and antipsychotics can cause tardive dyskinesia that endures after discontinuation of the medication. Since ADRs manifest in many forms, it is helpful to categorize the reactions based on type, onset, and severity.

MECHANISTIC CLASSIFICATION OF ADRS

There are two basic types of ADRs: pharmacological and idiosyncratic (Aronson & Ferner, 2003; Pirmohamed, Breckenridge, Kitteringham, & Park, 1998). A pharmacological reaction (Table 5-1) is often predictable based on the drug's mechanism of action and is typically dose-related (Aronson & Ferner, 2003; Edwards & Aronson, 2000; Pirmohamed et al, 1998). Idiosyncratic reactions are unpredictable and may be more likely to result in mortality (Aronson & Ferner; Edwards & Aronson; Pirmohamed et al, 1998).

Pharmacological ADRs are more common and comprise approximately 85% to 90% of reported ADRs (Pirmohamed et al, 1998). These reactions are often an exaggerated physiological response related to the pharmacology of the drug,

Table 5–1   Pharmacological Adverse Drug Reactions

85%–90%	Predictable and dose-dependent
10%–15%	Idiosyncratic: unpredictable and not dose-related

Table 5–2   Immune-Mediated Adverse Drug Reactions

Type I	IgE-mediated, immediate-type hypersensitivity Example: angioedema and anaphylaxis
Type II	Antibody-dependent cytotoxicity Example: heparin-induced thrombocytopenia
Type III	Immune complex hypersensitivity Example: Arthus reaction to tetanus vaccine
Type IV	Cell-mediated or delayed hypersensivity Example: Drug Rash, Eosinophilia and Systemic Syndrome

for example, hypotension from the beta blocker metoprolol, diarrhea from the fat-blocking drug orlistat, and insomnia from the stimulant methylphenidate. These adverse reactions are often managed by withdrawing the medication or reducing the dose. Pharmacological ADRs may also occur based on secondary pharmacology, such as weight gain from the atypical antipsychotic olanzapine, flatulence from the fiber supplement psyllium, or myopathy from the HMG Co-A reductase drug simvastatin. Because there is an interest in reducing adverse effects, preclinical trials are now focusing attention on secondary adverse effects to predict what may occur when the drug is administered to humans.

Idiosyncratic reactions are concerning because they are unpredictable, often serious, and may result in death (Pirmohamed et al, 1998). Idiosyncratic reactions are mediated by the immune system, receptor abnormalities, drug–drug interactions, abnormalities in drug metabolism, pharmaceutical variations, or unmasking of an abnormal biological system. Most commonly, idiosyncratic reactions are mediated by the immune system when a drug molecule is recognized as a foreign substance (Aronson & Ferner, 2003; Edwards & Aronson, 2000; Pirmohamed et al, 1998).

The hapten hypothesis describes how drugs may cause an immune-mediated hypersensitivity reaction. The hypothesis suggests that drugs are haptens, that is, low-molecular-weight chemicals that can become antigenic when they covalently bind to a carrier molecule, which is usually a protein (Chipinda, Hettick, & Siegel, 2011). Through this mechanism, individual patterns of metabolism may generate reactive metabolites that act as haptens to elicit an immune-mediated reaction. Penicillin is an example of a hapten with a low molecular weight that is able to bind to a protein and result in a Type I hypersensitivity (anaphylaxis) reaction.

Medications that are not haptens are also able to elicit an immune-mediated reaction through a different mechanism identified as the "pharmacologic interaction with immune receptors." For example, lidocaine, sulfamethoxazole, mepivacaine, celecoxib, carbamazepine, lamotrigine, and ciprofloxacin are chemically inert drugs, unable to covalently bind to proteins. However, these medications are able to "fit" into major histocompatibility complex (a set of surface molecules) and the T-cell receptor sandwich. This elicits a hypersensitivity reaction (Chipinda et al, 2011). Immune-mediated reactions can be further defined as Type I, II, III, or IV hypersensitivity reactions as described in Table 5-2 (Janeway, Travers, Walport, et al, 2001).

Type I immune-mediated reactions (IgE-mediated, immediate-type hypersensitivity) are provoked by reexposure to an antigen. A Type I reaction is an acute hypersensitivity reaction that may be local or systemic, involving the skin, bronchopulmonary system, nasopharynx tract, eyes, and/or gastrointestinal tract. It is caused by inducing the release of mediators (i.e., histamine, leukotrienes, and prostaglandins) from mast cells, basophils, and recruited inflammatory cells following antigen exposure, which then activates IgE. Although most cases are mild, symptoms may vary from mild to severe (allergic conjunctivitis, rhinitis, bronchospasm, urticaria, atopic dermatitis) and can be life-threatening (angioedema, anaphylactic shock). Symptoms may occur immediately, within minutes, or have a delayed onset where it may take several hours for symptoms to present following exposure to the provoking medication or antigen. For example, acute anaphylaxis may occur following the exposure to antibiotics (penicillin, cephalosporins, sulfonamides), neuromuscular blockers (suxamethonium, alcuronium, vecuronium, pancuronium, atracurium), and some chemotherapeutic agents (carboplatin, oxaliplatin) and monoclonal antibodies (cetuximab, rituximab). Management of Type I reactions usually involves administration of epinephrine, antihistamines, and corticosteroids.

Type II hypersensitivity reactions (antibody-dependent cytotoxicity) may affect a variety of organs and tissues. In the bloodstream and on the surface of cells, antibodies unite with antigens or haptens and induce destruction of cells and tissues through activation of the complement system or through removal by macrophages. Immune-mediated thrombocytopenia, also called *drug-induced immune thrombocytopenia* (DITP), is generally caused by medications but may also be caused by foods or herbal products. Most DITP reactions are associated with the formation of drug-dependent antibodies that bind to glycoprotein and cause an antibody–platelet reaction resulting in thrombocytopenia. Examples of medications with a risk of DITP include abciximab, argatroban, beta-lactam antibiotics, carbamazepine, eptifibatide, linezolid, phenytoin, quinine, quinidine, sulfonamide, rifampin, ranitidine, tirofiban, trimethoprim-sulfamethoxazole, valproic acid, and vancomycin (Aster, Curtis, McFarland, & Bougie, 2009; Burgess, Lopez, Gaudry, & Chong, 2000; Dihmess, et al,

2012; Gentilini, Curtis, & Aster, 1998; George et al, 1998; Kaufman et al, 1993; Nguyen, Reese, & George, 2011; Patel et al, 2010; Pedersen-Bjergaard, Andersen, & Hansen, 1996; Pedersen-Bjergaard, Andersen, & Hansen, 1997; Pedersen-Bjergaard, Andersen, & Hansen, 1998; Pereira et al, 2000; ten Berg et al, 2006; Von Drygalski et al, 2007).

DITP can also occur when heparin binds to platelet factor 4 (PF4) proteins resulting in the formation of an antigenic complex where IgG antibodies bind to the platelet. The antibody-coated platelets are viewed by the body as foreign and the body destroys the platelets via complement activation, causing thrombocytopenia. Hemolytic anemia and neutropenia occur by a similar mechanism. Hemolytic anemia occurs when a drug binds to antigens on the surface of red blood cells, resulting in complement activation and cell lysis. Examples of medications that cause hemolytic anemia include cephalosporins (e.g., cefotetan, ceftriaxone), penicillin and penicillin derivatives, NSAIDs, quinidine, quinine, and trimethoprim-sulfamethoxazole. Neutropenia or agranulocytosis can occur when antibodies unite with antigens on the surface of neutrophils. The reaction time generally occurs within minutes to hours following drug administration. Examples of common drugs that cause neutropenia or agranulocytosis include clozapine, antithyroid medications (e.g., methimazole, carbimazole), sulfasalazine, clomipramine, trimethoprim-sulfamethoxazole, ACE inhibitors, and H2 receptor antagonists (Alvir, Lieberman, Safferman, Schwimmer, & Schaaf, 1993; Casato et al, 1995; van der Klauw et al, 1999; Yunis, Lieberman, & Yunis, 1992). Treatment involves anti-inflammatory and immunosuppressive agents.

Type III hypersensitivity reactions (immune complex hypersensitivity) occur when aggregates of antigens and IgG and IgM antibodies create insoluble immune complexes in vessels or the blood that may be deposited in tissues (e.g., joints, kidneys). The reaction generally takes a week or more to occur and may present as serum sickness, drug fever, or vasculitis. The Arthus reaction is a local vasculitis reaction that causes severe pain, swelling, edema, induration, hemorrhage, and possibly necrosis, which can occur following tetanus/diphtheria toxoid (Td) vaccination. The risk of the Arthus reaction from the Td vaccine is elevated when a patient receives vaccination more frequently than every 10 years. The risk of developing more antibody–antigen immune complexes is higher if revaccination occurs when there is a high concentration of circulating tetanus antibodies. This is because the Arthus reaction results from deposition of immune complexes and complement activation. For this reason, it is recommended that individuals who have experienced an Arthus reaction following vaccination with tetanus toxoid do not receive Td more frequently than every 10 years, even if the vaccine is part of a protocol for wound management. The Arthus reaction can also occur with the 23 valent pneumococcal vaccine, and should this occur following the initial dose, revaccination is contraindicated (CDC MMRW, 1997). Other medications and treatments that can cause type III

hypersensivity reactions include streptokinase, monoclonal antibodies (e.g., rituximab, infliximab, alemtuzumab, omalizumab, natalizumab), rabies vaccine, antivenom, and other antitoxins. These reactions are treated with antihistamines and anti-inflammatory agents (NSAIDS and corticosteroids).

Type IV hypersensitivity reactions (cell-mediated or delayed-type hypersensitivity) are unlike other hypersensitivity reactions because they are not an antibody-mediated reaction but rather, a cell-mediated response that results in activation and proliferation of T cells. Type IV hypersensitivity reactions are the result of autoimmune and infectious diseases or contact dermatitis. These reactions generally occur within 2 to 3 days but may take days to weeks to occur. Following rechallenge, the reaction may occur within 24 hours.

The reaction may be in the form of contact dermatitis, morbilliform or maculopapular eruptions, Stevens–Johnson syndrome, toxic epidermal necrolysis, or drug-induced hypersensitivity syndrome. Drug-induced hypersensitivity syndrome (DiHS) is a severe reaction that not only causes rash but is frequently associated with fever (38° to 40°C), eosinophilia, and organ failure (i.e., lungs, kidney, liver, heart). DiHS is also known as DRESS (Drug Rash, Eosinophilia and Systemic Symptoms) (Ben m'rad et al, 2009; Cacoub et al, 2011; Peyrière et al, 2006). Examples of drugs that may cause DRESS include abacavir, allopurinol, carbamazepine, dapsone, minocycline, nevirapine, and phenobarbital. Corticosteroids and other immunosuppressive agents are used in treatment.

ADRs have also been categorized as Types A–F. Type A reactions are equivalent to pharmacological reactions, account for 85% to 90% of ADRs, are dose-dependent, and are predictable, whereas Type B reactions are idiosyncratic, account for 10% to 15% of ADRs, are not dose-dependent, and are not predictable (Rawlins, 1981). Adverse reactions have been further stratified by letters C through F. Type C reactions result from chronic medication use, Type D reactions are delayed, Type E reactions are from drug–drug interactions, and Type F reactions result from treatment failures.

TIME-RELATED CLASSIFICATION OF ADRS

One distinguishing feature of drug reactions is the correlation between administration and tissue exposure to onset of the reaction. The World Allergy Organization classifies immunological reactions as immediate or delayed. Symptom presentation that occurs within 1 hour following exposure is classified as an immediate reaction, whereas a delayed reaction occurs more than an hour following exposure (Johansson et al, 2004). Time-related reactions can be further categorized as rapid, first dose, early, intermediate, late, and delayed.

Rapid reactions occur during or immediately following the administration of a medication. These unintended

adverse reactions generally occur when medications are administered improperly and are not necessarily related to being the first dose. For example, vancomycin can cause an adverse reaction known as red man syndrome when administered too rapidly (Aronson & Ferner, 2003). Phenytoin can cause can adverse reaction known as purple glove syndrome (blood vessel irritation and inflammation) when administered peripherally (Earnest, Marx, & Drury, 1983). Skin or tissue necrosis secondary to extravasation may occur with administration of chemotherapeutic agents. For example, hand-foot syndrome may occur when extravasation of chemotherapy occurs and damages the surrounding tissues in the hands and feet, causing redness, swelling, burning, blisters, ulcers, peeling skin, and difficulty when walking (Yokomichi et al, 2013). For these reasons, it is important for practitioners to be familiar with the proper administration technique of medications to avoid precipitation of these adverse reactions.

First-dose reactions occur following the first dose of a medication. For example, orthostatic hypotension is a common reaction that occurs following the first dose of doxazosin, which generally does not occur with repeated doses. Cytokine release syndrome can occur following the first dose of orthoclone OKT3. Patient education and monitoring are essential when administering medications that are known to have a first-dose reaction, especially to ensure continued adherence, as the reaction is unlikely to persist.

Early reactions occur early in treatment and generally resolve with continued treatment as the patient develops tolerance. These reactions typically do not require discontinuation of the drug but may simply require patients to adapt to the medications. It is often useful to initiate drugs likely to cause early reactions with low starting doses and sequentially titrate the dose upward to mitigate the severity and duration of side effects. Examples include gastrointestinal upset following the initiation of metformin or selective serotonin reuptake inhibitors. Immune hypersensitivities may occur following the first or subsequent dose. These reactions, however, often do require immediate discontinuation of the drug and possibly further medical attention, such as in the case of anaphylaxis resulting from administration of penicillin or its derivatives.

Intermediate reactions occur following repeated exposure to a medication. Examples include hyperuricemia from furosemide, hemolytic anemia from ceftriaxone, interstitial nephritis from penicillin G, and contact dermatitis from neomycin. Intermediate reactions are difficult to predict but should be monitored. Patients with predisposing factors or increased susceptibility for adverse reactions should be followed vigilantly while on therapy for occurrence of these reactions.

Late reactions occur after prolonged exposure to an offending agent. Examples include osteoporosis or thinning of the skin due to prolonged corticosteroid use or hypogonadism following prolonged use of opioids (Brennan, 2013). It may be possible to symptomatically treat late adverse drug reactions, but most are predictable and occur following repeated exposures. Thus, it is often recommended to remove the offending agent before the reaction is predicted to occur in order to manage this type of adverse effect. Late reactions also include reactions that occur when a dose of a chronic medication is reduced or withdrawn. For example, rapid discontinuation of oxycodone can cause the patient to experience symptoms of withdrawal (i.e., anxiety, insomnia, rhinorrhea, diaphoresis, tremor, vomiting, diarrhea, and/or tachycardia). A patient who takes clonidine or propranolol may experience rebound hypertension following withdrawal of the medication. These types of adverse drug reactions are relatively common and can often be avoided by thoughtful tapering of the drug, as they are a predictable extension of the drug's therapeutic effect.

Delayed reactions occur at variable time points following drug exposure and can even occur after the discontinuation of a drug. For example, drug-induced tardive dyskinesia may occur following prolonged exposure to antipsychotics or metoclopramide, with symptoms persisting for months to years following discontinuation of the precipitating drug (Tarsy & Baldessarini, 1984). Polyalkylimide implant injection (cosmetic filler) can cause swelling and tender nodules near the injection site as well as other symptoms (fever, arthritis, xerostomia) up to 12 months following the injection.

DOSE-RELATED ADRS

Adverse drug reactions may also be dose-related. This could be from administering an excessive dose or failing to adjust doses properly for age and organ function (i.e., renal insufficiency or liver failure). For example, a person with diabetes may become hypoglycemic after administering an excessive dose of insulin. An individual patient could experience lithium toxicity upon development of acute renal failure with no adjustment of the lithium dose.

SEVERITY OF ADRS

The severity of an adverse drug reaction varies based on the clinical effect and the outcome. The FDA defines serious ADRs as those that result in death, are life-threatening, result in hospitalization (new or prolonged), are disabling or incapacitating, produce congenital abnormality or birth defect, or require an intervention to prevent one of these outcomes. Any ADR that meets FDA criteria should be reported to the FDA MedWatch program (FDA, 2013).

In this chapter, the severity of ADRs will be further categorized as mild, moderate, and severe. Mild adverse events can typically be managed by dose reduction, discontinuation of the drug, or with no intervention if the reaction subsides following development of tolerance by the patient (Aronson & Ferner, 2003; FDA, 2013;). Moderate adverse events often require discontinuation of the drug and minimal medical intervention but typically do not

cause permanent harm. An example of a moderate adverse reaction is drug-induced sunburn requiring an analgesic to treat the pain. Severe ADRs may be life-threatening and result in hospitalization, disability, birth defects, or even death and will require intensive medical intervention (FDA, 2013).

COMMON CAUSES OF ADRS

It is important for practitioners to realize that many ADRs are preventable. Approximately one-third result from medication errors and up to one-third from allergic reactions (Budnitz et al, 2006). Practitioners can reduce ADRs by being aware of specific drugs and drug classes that have a high incidence of ADRs. Budnitz and others evaluated ADRs that led to an emergency department visit. One single drug or drug class was the suspected cause in 94% of those cases. The top five drug classes responsible included insulins, opioid-containing analgesics, anticoagulants, amoxicillin-containing medications, and antihistamines or cold remedies. Additionally, the top five drug classes implicated in precipitating hospitalizations following admission to the emergency department included anticoagulants, insulins, opioid-containing analgesics, oral hypoglycemic medications, and antineoplastic agents. In the elderly population, one-third of all ADRs requiring treatment in the emergency department were due to only three medications: warfarin, insulin, and digoxin (Budnitz et al, 2006). In addition to the above medications, practitioners should be aware that antibiotics, sedatives, antipsychotics, and chemotherapeutic agents are also drug classes that have a high rate of ADRs (Bates et al, 1995; Evans, Lloyd, Stoddard, Nebeker, & Samore, 2005; Gurwitz et al, 2005; Woolcott et al, 2009).

One of the most common manifestations of ADRs is in the form of cutaneous skin reactions, ranging from mild skin rashes to life-threatening Stevens–Johnson syndrome. Out of the top 10 drugs linked to skin reactions, the majority are antibiotics. Specifically, the top 10 drugs linked to skin reactions are, in order, amoxicillin, trimethoprim-sulfamethoxazole, ampicillin, iopodate, blood products, cephalosporins, erythromycin, dihydralazine hydrochloride, penicillin G, and cyanocobalamin (vitamin B$_{12}$) (Roujeau & Stern, 1994).

RISK FACTORS

Multiple patient characteristics can increase an individual's risk of experiencing an adverse drug reaction (Aronson & Ferner, 2003). Risk factors for ADRs include genetic abnormalities, age, sex, polypharmacy (increasing the risk for drug–drug interactions), and concomitant medical conditions (increasing the chance for drug–disease interactions). Not all drug classes are susceptible to these risks, but an assessment should be made for all patients when starting or stopping medications to determine the relevance.

Genetics

Genetic features that affect the body's ability to metabolize medications can contribute to pharmacological and idiosyncratic reactions (FDA, 2009; Pirmohamed et al, 1998). Although rare, some people have DNA mutations that predispose them to develop adverse drug reactions. For example, if an individual has an alteration in liver enzyme activity secondary to a gene mutation, the rate at which affected medications are metabolized may be increased or decreased, thus altering the concentration of active, inactive, and potentially toxic drug products in the circulation. If drugs are not metabolized appropriately, patients can accumulate toxic or reactive metabolites, leading to adverse drug reactions, as is the case with acetaminophen. Malignant hyperthermia following administration of general anesthetics is an example of a receptor abnormality (mutations encoding for abnormal RYR1 or DHP receptors), which results in sustained muscle contraction from the unregulated movement of calcium from the sarcoplasmic reticulum into the intracellular space. Genetic factors can also increase the likelihood of a hapten-induced hypersensitivity reaction (Pichler, Naisbitt, & Park, 2011).

A common mediator for these immune responses is variation in the *HLA-B* alleles. For example, patients who express the *HLA-B*5701* allele are at a significantly increased risk of severe T-cell–mediated hypersensitivity reactions to the HIV medication abacavir. Additionally, the Han Chinese, who express *HLA-B*1502* or *HLA-B*5801* alleles, are at higher risk of hypersensitivity reactions to carbamazepine and allopurinol, respectively. For this reason, it is recommended that all patients receive genetic testing to confirm the presence or absence of the specific *HLA-B* allele prior to initiation of known high-risk medications (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013; Pichler et al, 2011).

Age

Children and the elderly are at higher risk of experiencing an ADR (Budnitz et al, 2006; Kongkaew, Novce, & Ashcroft, 2008). Children are at higher risk primarily because medication dosages must be tailored to their specific weight or body mass index. Inattention to weight-based dosing may cause harm. The very young may additionally have immature organ function, which further complicates dosing and increases the risk for an ADR (Kaushal et al, 2001).

Predictable underlying concerns in patients over 65 include taking more medications and taking them more often than younger patients. Also, elderly patients have decreased renal and hepatic function, resulting in decreased metabolism and clearance and causing an elevated drug concentration and risk of drug accumulation and toxicity. Patients over the age of 65 required hospitalization for treatment of ADRs 7 times more often than patients under the age of 65 (Budnitz et al, 2006). Hospitalizations in this age group due to ADRs were most commonly a result of unintentional overdoses (Budnitz et al, 2006). More than half of ADRs in

hospitalized patients 70 years of age and older are considered to be preventable (Gray, Sager, Lestico, & Jalaluddin, 1998). Therefore, all prescribers working with these populations should take care to minimize polypharmacy, unless clinically necessary, to reduce the risk of drug–drug interactions, confusion between medications, and drug accumulation with insufficient renal and hepatic function. In addition, it has been shown that four out of five ADRs can be prevented by using prescriber computer order entry with clinical decision support and clinical pharmacist consultation in high-risk populations (Kaushal et al, 2001).

Gender

Women have more ADRs than men in part due to differences in body composition (impacting drug distribution, pharmacokinetic properties of medications, and hormonal fluctuation). Furthermore, ADRs may be related to pregnancy and lactation.

Drug Interactions

Similar to genetic differences in metabolism, drug–drug interactions can also affect the rate at which individuals metabolize medications. Some medications bind to certain enzymes in the liver and either speed up (induction) or slow down (inhibition) the rate of metabolism and clearance of drugs that flow through the same enzyme pathway. Both scenarios can cause problems, but most commonly drug inhibition leads to accumulation of drug and higher-than-desired concentrations in the circulation, often leading to ADRs. An additional interaction is the potential for two drugs to compete for metabolism, which increases the concentration of both medications and the risk of side effects.

Most drug interactions can be identified by reviewing patient medication profiles and using a drug interaction checker, such as Micromedex, Online Facts and Comparisons, or Lexicomp. These resources also provide recommendations based on the severity of the interaction. A review of therapy should be performed prior to the initiation of new medications. There is also the potential for foods to interact and affect metabolism. The best example of food–drug interactions is grapefruit reducing the clearance of simvastatin and increasing the risk of myopathy, or herbal products such as St. John's wort reducing clearance of cyclosporine (Aronson & Ferner, 2003; FDA, 2009).

Some drug–drug interactions can manifest rapidly (within 1 to 2 days). For example, when trimethoprim-sulfamethoxazole is added to warfarin, an anticoagulant, warfarin metabolism is reduced, resulting in an increase in the INR and prothrombin time. Ultimately, this increases the risk of bleeding and should be avoided, if possible, or adjustments should be made in monitoring warfarin frequency and dose. Many interactions, however, may take longer to present. For example, when the antiarrhythmic amiodarone is added to digoxin, amiodarone inhibits the metabolism of digoxin. This interaction can take weeks to months before the full extent of the effect precipitates due to the long half-life of amiodarone. It requires diligence to appropriately adjust the digoxin dose and monitor serum concentrations. Although not all interactions are significant, clinicians should evaluate each interaction and determine clinical importance.

Medical Conditions

Many disease states alter the physiology of the body and affect drug metabolism, increasing the risk of ADRs (FDA, 2009). Liver and renal disease can decrease the metabolism and clearance of medications, resulting in increased serum concentrations. Medications that are extensively cleared from the body through the kidneys have specific dosage adjustments based on creatinine clearance. These recommendations should be followed to prevent drug accumulation. Heart failure decreases liver and kidney perfusion and can reduce metabolism and clearance. Similarly, thyroid dysfunction can alter drug metabolism; decreased thyroid function will reduce metabolic activity and increased function is likely to induce a faster metabolic rate. Additionally, other medical conditions, such as pregnancy, can create temporary changes in physiology that require dose adjustments or avoidance to prevent adverse reactions for the mother and/or child. Practitioners should be aware that medications can also affect various medical conditions. For example, indomethacin can precipitate an exacerbation of heart failure, aggravate gastroesophageal reflux, or worsen renal function in a patient with kidney disease. For these reasons, patients should always be assessed for past medical history and concomitant medical conditions upon initiation and/or changes of drug therapy.

DETECTION AND ASSESSMENT OF ADRS

Drugs or drug combinations suspected of producing adverse reactions will frequently be identified through drug interaction screening by pharmacists. It is important to remember that most (~90%) of identified drug interactions will not have clinical consequences for an individual patient but do represent a warning to monitor an individual patient for a potential problem. A smaller number (perhaps 2%) of identified drug interactions will have profound clinical consequences. The clinical challenge is that individual adverse reactions can present in patients without warning. It is appropriate for prescribers to work closely with pharmacists and other members of the health-care team to identify potential problems and monitor patients closely to optimize patient medications.

It can be difficult to determine causality between a drug and a potential adverse drug reaction. To aid in this distinction, several important elements should be considered. The presence of a temporal relationship between drug exposure and a reaction is often the first clue for causality

(Field, Furwitz, Harrold, Rothschild, Debellis, Seger et al, 2004). Some reactions, such as hypersensitivity reactions, occur almost immediately upon administration and can be easily linked to the drug being administered. This is more common with IV medications because they are directly administered into the bloodstream. Pharmacological and hypersensitivity reactions to oral medications are likely to present early but may subside after persistent exposure. Assuming no other changes in medications or health status, adverse reactions that present temporally with administration of a new drug can often be attributed to the drug in question.

Adverse reactions due to drug–drug or drug–disease interactions may be more difficult to discern because the interactions may not follow the timeline for initiation of the offending agent but may be more closely related to changes in disease status or alterations in interacting medications.

Responding to ADRs and Warnings

Many drugs suspected of causing an ADR are promptly discontinued and should be if the offending drug can be safely stopped, if the event is life-threatening or intolerable, if continuing the medication would worsen the patient's condition, and if there is a reasonable alternative medication. Drugs responsible for an adverse drug reaction may be continued in a patient if the drug is medically necessary and there is no acceptable alternative drug or if the problems are tolerable and reversible. Most adverse reactions that are related to dose and pharmacological effects will respond favorably to dosage adjustment.

If the ADR resolves following discontinuation of the medication, then the adverse event was likely caused by the discontinued medication. The only definitive indicator for causality is the recurrence of an adverse event following readministration of a potential drug offender. As long as no other medication changes are made and no change in the patient's health status occurs, the reappearance of an ADR following a rechallenge confirms causality.

Rechallenge is not a common practice and is generally not appropriate, especially for life-threatening ADRs. Also, patients are often reluctant to retry something that potentially caused an ADR. Therefore, although rechallenge is the gold standard for ADR detection, causality is often presumed based on temporal relationships, patient risk factors, and/or disappearance of the ADR following removal of the drug.

Assessing the causality of an adverse drug reaction involves consideration of several parameters relative to the reaction. Prior history of an ADR to the same or similar medications, literature reports, or a relationship in time between drug administration and the onset and resolution of the ADR support causality by an individual drug. The presence of alternative etiologies or absence of a relationship between dosing and the ADR support alternative explanations for the adverse reaction.

Naranjo ADR Probability Scale

Naranjo et al (1981) developed a framework for assessing the probability that an adverse reaction is related to administration of a particular drug. The Naranjo protocol, based on timing, prior history and reports, rechallenge, alternative causes, dose dependency, and objective evidence, defines the relationship between drug and adverse reaction as definite, probable, possible, or doubtful based on scoring. The Naranjo protocol is shown in Table 5-3.

ADR REPORTING

As drugs progress through preclinical and clinical trials, potential problems are identified based on the drug's pharmacology, toxicology, and pharmacokinetics. Exposure of patients to drugs during clinical trials identifies many adverse effects and their frequency. By the time a drug reaches the market,

Table 5–3   Naranjo Adverse Drug Reaction Scoring

Naranjo Adverse Drug Reaction Scoring	Yes	No	Not Known	Score
1. Are there previous *conclusive* reports on this reaction?	+1	0	0	
2. Did the adverse event appear after the suspected drug was administered?	+2	−1	0	
3. Did the adverse reaction improve when the drug was discontinued or a *specific* antagonist was administered?	+1	0	0	
4. Did the adverse reaction reappear when the drug was readministered?	+2	−1	0	
5. Are there alternative causes (other than the drug) that could on their own have caused the reaction?	−1	+2	0	
6. Did the reaction reappear when a placebo was given?	−1	+1	0	
7. Was the drug detected in the blood (or other fluids) in concentrations known to be toxic?	+1	0	0	
8. Was the reaction more severe when the dose was increased, or less severe when the dose was decreased?	+1	0	0	
9. Did the patient have a similar reaction to the same or similar drugs in any previous exposure?	+1	0	0	
10. Was the adverse event confirmed by any objective evidence?	+1	0	0	
			Naranjo Score (Total)	

Definite	>8
Probable	5–8
Possible	1–4
Doubtful	<1

however, it may have been studied in only several thousand patients. Because of this, it is likely that adverse events occurring in fewer than 1% of patients are not fully characterized.

Post-marketing surveillance becomes an important safety strategy. FDA post-marketing reporting programs seek to identify problems not identified prior to approval as well as any problems that may arise related to drug labeling or manufacturing. The FDA maintains a computerized database of adverse events for approved drugs and biologicals, the FDA Adverse Event Reporting System (FAERS). MedWatch is the FDA's safety information and adverse event reporting program that provides health-care professionals with medical product information on prescription and nonprescription drugs, biologics, medical devices, and nutritional products.

As health professionals, we have an obligation to provide data to allow the FDA to monitor medication and vaccine safety. MedWatch allows health-care professionals and consumers to report adverse events and serious problems caused by FDA-regulated products. The Vaccine Adverse Events Reporting System (VAERS) is a separate program used to report adverse events related to vaccinations and like MedWatch allows voluntary reporting on adverse events by both health-care professionals and consumers. The FDA monitors adverse events and can respond with safety announcements, alerts, and/or removal from the market. The FDA publishes alerts in MedWatch (Fig. 5-1) and consumer publications.

To ensure a favorable balance between benefits and risks for certain drugs or biologicals, the FDA requires manufacturers

> ## BOX 5–1 COMMON DRUGS WITH REMS
>
> - Isotretinoin
> - Extended-release and long-acting opioid analgesics
> - Rosiglitazone
> - Testosterone
> - Verenicline
> - Metoclopramide
> - Mifepristone
> - Buprenorphine and naloxone
> - Naltrexone

to implement a Risk Evaluation and Mitigation Strategy (REMS). A REMS protocol is composed of various actions (called ETASU: elements to assure safe use), including letters to prescribers; additional patient information; and required patient, prescriber, and/or pharmacy registration and training. REMS are required for many drugs, including those listed in Box 5-1.

SUMMARY

Adverse drug reactions are an unavoidable reality with pharmacotherapy. Fortunately, many ADRs respond well to dosage adjustment or discontinuation of the offending agent. Strategies such as drug-interaction screening and conscientious monitoring and reporting of adverse responses can identify at-risk patients and help minimize the incidence of ADRs.

FACTORS THAT FOSTER POSITIVE OUTCOMES

Marylou V. Robinson • Teri Moser Woo

The goal of health-care providers is to help patients become healthier. When the patient does not or cannot follow recommendations or instructions that lead to this goal, the provider may become frustrated. Multiple clinical studies have revealed that even though providers expect adherence and positive outcomes, in reality these often do not happen. A change of perspective toward patient-centered care and patient participation in setting health-care goals may foster a positive change for adherence and positive outcomes.

Many questions arise when discussing adherence. Why do patients not adhere to instructions about taking their medications? What occurs outside the office setting to sabotage the best of intentions? What is the patient's responsibility, and what is the provider's? This chapter discusses the major issues in adherence and ways to foster positive outcomes.

OVERVIEW OF NONADHERENCE

The problem of poor adherence to drug therapy is widespread around the world (Brown & Bussell, 2011). In the United States, it is estimated that less than 50% of patients adhere to their drug regimen (New England Healthcare Institute [NEHI], 2009). Other studies report similar data (Brown & Bussell, 2011; Osterberg & Blaschke, 2005) with chronic disease patients more likely to have spotty adherence (NEHI, 2009). Those at highest risk include patients who have asymptomatic conditions, chronic conditions (Hayes, McCahon, Panahi, Hamre, & Pohlman, 2008; Mahat, Scoloveno, & Donnelly, 2007), cognitive impairment, psychiatric illness, or disorders requiring significant lifestyle changes (e.g., smoking cessation) (Myung, McDonnell, Kazinets, Seo, & Moskowitz, 2009) and those who are on complex regimens with multiple daily dosing and significant adverse reactions (Luthy, Peterson, & Wilkinson, 2008; Sarver & Murphy, 2009). When patients' interactions with the provider include poor communication (Zagaria, 2008), the risk of nonadherence is even higher. Wheeler, Roberts, and Neiheisel (2014) have synthetized much of the literature on adherence with much research left to be done on the multiple variables associated with whether medications are taken or not.

The health-care provider–patient relationship is not a parent–child relationship; it is one of setting and working toward realistic mutual goals. Providers cannot expect compliance unless patients have participated in realistic goal setting, including validating their belief they can follow the plan and identifying barriers that will impede those goals. Compliance implies an involuntary act of submission and provider-centric decision making. Adherence implies a voluntary act of negotiation and joint acceptance of a treatment regimen. Horne (2004) points out that "typically, over 30% of patients harbor strong concerns" about the need for their medication and the risk involved in taking it. What is more, the patient tends to overestimate the risk. If these issues are not addressed by open communication, surreptitious nonadherence is likely to result. This shift in attitude from compliance to adherence highlights the providers' essential focus upon their responsibility to educate patients about their diseases and drugs.

Nonadherence to pharmacological regimens can lead to failure to reach the desired treatment goal, which may be very costly. Patients who stop using their drugs have more complications from their disease, which results in total increased cost for themselves and the health-care system. The health-care system itself creates barriers to adherence by limiting access to health care; using restricted formularies; and having prohibitively high drug costs, co-payments, or both. Over $290 billion in unnecessary emergency room and health-care costs related to adherence issues are estimated to occur in the United States every year (NEHI, 2009). Mortality rates double for cardiovascular and diabetic patients who do not follow their treatment plans. Increasing insurance rates and co-pays contribute to this. The Affordable Care Act (ACA) is intended to remove some of these system barriers. Payment reform with an emphasis on quality outcomes is anticipated to also foster more prescriber attention to adherence factors.

Intentional Versus Nonintentional Nonadherence

Taking or not taking medications may be intentional or inadvertent. Unintentional nonadherence can be attributed to forgetfulness (especially if it is a side effect of a drug), dementia, mental health problems, simple procrastination, or an overextended lifestyle. Not perceiving the usefulness of a medication for symptom resolution is one source of intentional nonadherence. Whether people believe the medication is effective, are unaware of the subtlety of its actions, or become frustrated with a "lack of cure" can contribute to whether they take medications as prescribed. Drug cost may also be a factor in intentional nonadherence.

ADVERSE DRUG REACTIONS

Real or perceived adverse reactions directly affect the outcome of a prescribed drug regimen. If a patient reports a prescribed drug is causing a reaction, then the provider should explore alternative options to treating the problem. This response assures patients that the provider is willing to listen and work with them until the right drug or right dosage is prescribed. Patients might think that their skepticism about a drug will be interpreted as lack of confidence in the provider (Horne, 2004). It may be difficult for patients to tell providers that they have a different view of the drug. Encouraging open communication about these concerns and perceptions is important. Communication is discussed further below.

Certain adverse reactions are more likely to produce nonadherence than others. Oddly enough, serious adverse reactions such as severe hypotension or anaphylaxis are not among them. The ones most likely to produce nonadherence are the "irritating" ones that interfere with the patient's ability to carry out activities of daily living, including what he or she may do for a living. These reactions include headache, dizziness, anorexia, nausea and vomiting, constipation, sexual dysfunction, and diarrhea. Unfortunately, these are also the most common adverse reactions. What is a problematic adverse reaction for one person may not be for another. When looking for potential nonadherence, it is important to look for the adverse reactions that commonly cause nonadherence and talk to patients about them, but it is also important to ask which ones would be a problem for the individual patient and take these into consideration in making a drug choice.

ASYMPTOMATIC CONDITIONS

A variety of disease states are essentially asymptomatic until their later stages. Some of these can be treated with drugs in their early stages to prevent their progression. However, it

may be difficult to convince a patient that he or she has a serious disease when there is no overt indication of the disorder except the provider's word. It is even more problematic when the drugs given to treat this "invisible" disorder produce "disease symptoms" themselves. One of the most common of these asymptomatic disorders is hypertension.

Uncontrolled hypertension contributes to increased risk for cardiovascular disease, including stroke, ischemic heart disease, and heart failure, yet adherence to antihypertensive medications is often poor (Rajpura & Nayak, 2013). Rajpura and Nayak report that 66% of elderly patients with hypertension did not take their medication as prescribed, with the reasons for not taking the medication including the patient's perception regarding the seriousness of the illness and beliefs or concerns about the medication. Beliefs about the benefits of the medication can outweigh cost as a reason for nonadherence.

Patients may realize through education that control of hypertension is very important to their health but may not adhere to the regimen secondary to the adverse reactions they experience to the drugs given to treat this disease. Antihypertensive drugs that have a rapid onset and short duration of action are not very desirable in long-term therapy secondary to possible large variations in blood pressure. If the patient misses one dose, the antihypertensive effect disappears, creating a possible rebound or adverse reaction. Since many of the drugs used to treat hypertension have these effects, nonadherence (including missed doses) is likely. Selecting a more "forgiving" drug that either does not depend on half-life or has a longer half-life will produce limited effect on the efficacy of the drug if doses are delayed or missed (Osterberg & Blaschke, 2005). Antihypertensives that require several dose titrations (e.g., alpha-adrenergic blockers) can be particularly troublesome (e.g., severe orthostatic hypotension) if the patient misses some doses and then restarts the drug, even if it is not at the full dose.

Erectile dysfunction (ED) is a highly publicized medical problem that may have as its root cause an adverse reaction to medications. Antihypertensives and psychotropic drugs have been implicated as the cause of ED. The provider must explore a change in medication if a patient is experiencing ED, anorgasmia, loss of libido, or other changes in sexual health.

Predicting probable adverse reactions of certain medications provides a basis for making an alternative treatment plan for individuals experiencing side effects. The provider looks at the tolerability profile of each drug and discusses it in selecting drugs for a particular patient. Tolerability is directly linked to patient adherence for both short- and long-term therapy and ultimately to the overall success of treatment.

CHRONIC CONDITIONS

One out of every two Americans has at least one chronic condition (Centers for Disease Control and Prevention [CDC], 2010). Chronic diseases account for three-fourths of the nation's 1.4 trillion dollars in medical care costs and one-third of the years of potential life lost before age 65 (CDC, 2010). Many variables, such as increased individual risk factors, a lack of health-care resources for the poor and underserved, and environmental conditions that do not support the adoption and sustainability of healthy eating and physical activity impact chronic care onset and medication adherence. These factors may clinically express themselves differently from one person to another. As a result, the prescriber and members of a multidisciplinary health team must use a variety of approaches to positively intervene for persons living with chronic illness.

Ideally, the patient develops a pattern of taking drugs consistent with her or his activities of daily living; for example, taking the white pill before breakfast and the blue one at dinner. Weekends, vacations, visiting family, and unexpected events alter the pattern, leading to missed doses. Discuss methods for remembering how to take medication, such as calendars, phone or watch alarms, or day-of-the week pill organizers to assist patients in managing their medication regimen.

Building support mechanisms and setting up monitoring of drug taking for patients with chronic disease is critical to their adherence to their regimens. Kutzleb and Reiner (2006), for example, found significantly improved symptom control and disease self-management in patients with heart failure who received weekly telephone follow-up by nurse practitioners. Early phone contacts enable the provider to determine if the information shared in the clinic has been clearly understood and is being followed. Similar results were found with Web-based collaborative care for type 2 diabetes patients (Ralston et al, 2009). Such follow-up contacts not only help with adherence but also contribute to building a stronger patient–provider relationship. Factors influencing adherence in chronic illness are summarized in Table 6-1.

KNOWLEDGE DEFICIT AND PATIENT PERCEPTION

Understanding the disease state and the treatment regimen plays a role in adherence. Providing educational material alone, written or oral, cannot ensure that the patient will not

Table 6–1 **Factors Contributing to Medication Adherence With Chronic Illness**

Understanding treatment regimen	Beliefs in effectiveness
Fitting with current routine	Cultural relevancy (see Chap. 7)
Having the skills to carry out the regimen	The staging of disease and level of wellness
Fear of side effects	The ability to control side effects
Remembering to take the medications	Mental health
Family/caregiver support	Interaction with street drugs
Personal views of health	Trust in provider

Adapted from Frank, L., & Miramontes, H. (1998). *Health care provider adherence curriculum.* Pittsburgh, PA: AIDS Education and Training Centers Program.

have a knowledge deficit regarding the drug regimen or that she or he will be adherent. Today, providers feel pressured into having shorter visits with the patient, but more time spent with a patient is not the only component related to increased patient adherence. The quality of the communication and interaction that occur during that time is most important. Patients report greater adherence to a drug regimen if they feel that their concerns and specific points of knowledge deficit are addressed during the encounter. Post-encounter contacts by the office staff nurse, group visits, and tele-health may all be part of the solution to shorter encounters.

Keys to Patient Education

To be effective, patient education must:

- Be simple and focus on the critical points. What does the patient need to know to take this drug safely?
- Use language that is clear and understandable to the patient. This does not just mean "English versus Spanish," for example; it means reduced "medicaleze." It is important not to talk down to people who do understand the medical terms; however, never assume patients do or do not understand terms used. Likewise do not assume that a fellow health-care worker does not have knowledge deficits.
- Be in a form the patient can refer to as needed after the contact with the provider, such as an after-visit summary. Zagaria (2008) found many prepackaged materials are written at the 12th-grade reading level at least. Most patients read medical information at or below the 6th-grade reading level, and some do not read at all and are too embarrassed to tell the provider.
- Be in the order of use or preparation if steps therapy is used.
- Be inclusive of the family and caregivers. Health behaviors are learned and reinforced with the family, so a family-centered approach (Mahat et al, 2007; Tyler & Horner, 2008) that engages and supports parents and children has a better chance of improving adherence.

Patients may understand what you taught but not be able to follow through even when they want to do so.

Health and Cultural Beliefs

Other influences regarding a patient's knowledge deficit include culturally based health beliefs (see Chapter 7) and the relationship between the patient and the provider (Castro & Ruiz, 2009). Some patients do not want to share in the decision-making process. Their beliefs about health or their cultural beliefs may influence how they perceive their role in their care, and they may believe they need to do what the health-care provider tells them to do. To some others, the idea of having to share the control of taking care of themselves is foreign. Those patients who expect the provider to tell them what to do may perceive that the decision-sharing provider does not know what she or he is doing and may not return to that provider. Conversely, a mismatch can also occur between the patient who wants to be in control and a provider who presents information in an authoritarian manner.

Medical Terminology Literacy

Nearly 9 out of 10 adults have difficulty understanding health information (CDC, 2011). Certain populations are especially at risk for low health literacy. They include adults 65 years of age and older, minority populations, low-income individuals (who may read below the 5th-grade level), and immigrant populations whose English proficiency may be limited (U.S. Department of Health and Human Services, 2010; Zagaria, 2008). Using plain language makes it easier for patients to understand and use health information (CDC, 2012). Avoid using medical jargon and biomedical terminology when explaining disease processes and treatment plans. When in doubt as to whether the patient understood the information, ask the patient to repeat the information back to you in his or her own words. Remember that health literacy is not only about accessing and understanding the information but then being able to apply it to one's own personal health-care plan (Sakraida & Robinson, 2009).

Resources that may help the provider understand and address health literacy in their practice include the following:

- The Centers for Disease Control and Prevention health literacy Web site. http://www.cdc.gov/healthliteracy/.
- National Patient Safety Foundation. http://www.npsf.org/for-healthcare-professionals/programs/ask-me-3/.
- University of Arizona has a self-learning module for older adults with health literacy problems. http://www.healthlit.fcm.arizona.edu.

Written Handouts

The National Institutes of Health (NIH) has implemented the Clear Communication initiative to focus attention on health education materials that are accessible to specific audiences based on cultural competence and that incorporate plain language (NIH, 2013). Do not give patients written material without taking the time to explain it. Check all patient education materials to make sure they are written in plain language and meet the CDC and NIH recommendations for health education materials. Patient materials such as a drug insert may not be understood by the patient and may make patients anxious as they read how many adverse reactions may occur. The provider and pharmacist must work closely together to provide patients with plain-language information regarding their medication. Having open communication with patients and using plain language can enhance the positive outcomes from the drug regimen. Enhanced, clear communication forms a positive relationship between patient and provider. In an atmo-sphere of shared values, shared language (Castro & Ruiz, 2009), and mutual respect, adherence and positive patient outcomes occur.

COGNITIVE IMPAIRMENT AND PSYCHIATRIC ILLNESS

Communicating effectively with patients who have cognitive impairments (e.g., Alzheimer's disease) can be a challenge. Providers need to be able to count on the patient's ability to understand and remember education presented about the drug if adherence is to occur. Each person with cognitive impairment is unique, having a different constellation of abilities and needs for support in understanding and remembering. Assessing the abilities of each patient is important to maximizing adherence. This may involve working with a caregiver or guardian (see later).

Patients with psychiatric illnesses may have difficulty adhering to their drug regimen. Half of the patients with major depression for whom antidepressants are prescribed will not be taking the drugs 3 months after the initiation of therapy (Osterberg & Blaschke, 2005). Rates of adherence among patients with schizophrenia are between 50% and 60% (Lacro, Dunn, Dolder, Leckbane, & Jeste, 2002; Perkins, 2002), and among those with bipolar disorder, the rates are as low as 35% (Colom, et al, 2000). Three major factors are involved here. (1) Psychiatric illness has a social stigma. (2) The presence of symptoms may result in thoughts and behaviors that do not foster adherence—for example, paranoia, agitation, or depression. Finally, (3) the adverse effects with psychotropics—for example, dizziness, orthostatic hypotension, blurred vision, decreased central processing, and confusion—are effects commonly associated with nonadherence.

Longer-Acting Drugs

As with hypertension, selecting drugs with longer half-lives may reduce the likelihood of drug withdrawal symptoms and the return of illness. For example, fluoxetine (Prozac), a serotonin reuptake inhibitor used to treat depression, has a 2-week duration of action so that missing doses or stopping the drug altogether produces a long taper and gives the provider time to discover the problem and work to correct it. Fluphenazine (Prolixin) is a parenteral antipsychotic that also lasts 2 weeks and is very helpful in patients with schizophrenia. Other drugs are also being developed in depot formulations that are long acting and can be given intramuscularly. These agents combine better efficacy and tolerability with improved adherence.

Use of Reinforcements

Osterberg and Blaschke (2005) suggest the use of reinforcements such as monetary rewards or vouchers, frequent contact with the patient, and personalized reminders. Educational approaches appear to be most effective when combined with behavioral techniques and supportive services, including reinforcements. Regardless of the diagnosis, mental health patients require careful monitoring related to their adherence to drug therapy that may include help from family, friends, and other providers. Other patient groups also greatly benefit from the attention and support.

CAREGIVER'S ROLES

When the patient is a child, an adult with cognitive deficits or disabilities, or a person with mental illness, the patient's caregiver must be involved in the educational process. The caregiver can provide valuable information regarding the patient's responses to drugs or difficulties in adhering to the prescribed medication regimen, including adverse reactions. If the provider detects that the caregiver may be having difficulty in adhering to the drug regimen, it is possible that the caregiver may need to be provided one-on-one interventions to help foster positive outcomes for the patient.

The Pediatric Patient

Achieving full adherence in pediatric patients requires the cooperation not only of the child but also of a devoted, persistent, and adherent parent or caregiver (Mahat et al, 2007; Tyler & Horner, 2008). Adolescent patients create even more challenges, given the unique developmental, psychosocial, and lifestyle issues implicit in adolescence. Adherence rates in children and adolescents are similar to those seen in adults, with rates of adherence to drug regimens averaging about 50%. Special interventions for children are discussed in the chapter on pediatric patients (Chapter 51).

Caregiver's Quality of Life

The caregiver's quality of life may have a huge impact on the patient's quality of life. By exploring with the caregiver the psychological, physical, and social impact of giving care, the provider is acknowledging the difficulties the caregiver must face every day. Helping the caregiver find ways to "take a break" for herself or himself and showing concern for the caregiver as well as the patient will foster a positive relationship with the provider. Greater adherence and positive outcomes can be achieved by understanding the impact caregivers have on their patient and providing positive regard for their efforts.

Behavioral Therapy

Behavioral therapy can empower the caregiver to provide appropriate interventions. Discuss situations in which the patient does not cooperate with his or her care, including drug therapy. Help the caregiver to remember the times the patient did cooperate, and try to determine what the characteristics of the situation were that elicited that cooperation. Techniques to elicit cooperation can then become part of the routine care. An interdisciplinary approach is the best intervention for caregivers of patients having a multitude of consulting providers.

COMPLEXITY OF DRUG REGIMEN AND POLYPHARMACY

The number of drugs used to manage multiple complex disease processes increases the possibility of nonadherence, adverse reactions, and the chances of a decreased positive outcome for the patient. Thirty-two million Americans take three or more medications to treat a variety of ailments. Of Medicare-eligible patients, 51% take more than five medications, and more than half of these patients admit they take less medication than prescribed (PhRMA, 2011). Deciding what to do and when to do it can be complex and frustrating for all involved, patient and provider alike.

Collaborative management is an important method of encouraging adherence to a complex health-care regimen. Collaborative management is care that "strengthens and supports self-care in chronic illness while assuring that effective medical, preventive, and health maintenance interventions can take place" (von Korff, 1997, p 1097). The process of collaborative management is both dynamic and continuous. Collaborative management:

1. Begins with dialogue and mutual respect between the patient and the health-care team.
2. Is a starting point for care in chronic illness that includes choosing desirable and obtainable goals that provide direction for care management.
3. Is flexible in nature to enhance care and communication.
4. Does not end with regimen selection but progresses through stages in the direction of improving adherence, optimal health, and survival (Jani Stewart, Nolen, & Tavel, 2002, p 84).

Moreover, von Korff (1997, p 1098) further outlines the essential elements of health care central to such collaborative management. These essential elements are the following:

1. Collaborative definition of problems.
2. Targeting, goal setting, and planning.
3. Creating a continuum of self-management training and support services.
4. Active and sustained follow-up.

These four elements provide a unique manner for addressing not only medication adherence issues but also chronic illness care in general. For example, patients and providers may define problems differently. Patients may focus on functionality, subjective complaints, and lifestyle choices; providers may focus on disease prevention, medication therapy, nonadherence to recommendations, and risk factors related to prognosis. It is imperative that patients and providers have a mutual understanding of problems and understand one another's points of view (von Korff, 1997).

Personalized Drug Schedules

Education for the patient, written and oral, regarding the importance of following a daily schedule is the gold standard. Helping patients set up a personalized drug schedule devised only for them is one possible solution. Working with nursing staff at the clinic, a matrix of activities of daily living can be devised into which drug schedules can fit. Because the schedule is specific to that individual patient's life, it is easier for the patient and/or caregiver to follow and to remember.

Smartphones are used by 7 of 10 U.S. adults for symptom tracking or health-care monitoring (Pew Research Center, 2013). These high-tech "diaries" involve the patient in their own care and help provide an individualized method of refining medication plans.

Simplifying the Regimen

Multiple studies have been done relating adherence to the number of times a drug must be taken each day and the total number of drugs being taken daily. One study of diabetics (Morris, Brennan, MacDonald, & Donnan, 2000) found that for each increase in daily dosing frequency, there was a 22% decrease in adherence. Likewise, liver transplant patients were more adherent to once-daily dosing of the immunosuppressant tacrolimus than twice-daily dosing (Eberlin, 2013). A systematic review of 38 hypertension drug adherence trials involving 15,519 patients (Schroeder, Fahey, & Ebrahim, 2004) found that simplification of dosing regimens improved adherence between 8% and 19.6%. A literature review of 76 publications by Claxton, Cramer, and Pierce (2001) showed that adherence to once-daily dosing was 79%, twice a day was 69%, three times a day was 65%, and four times a day was 51%. The data on short-term use of antibiotics for respiratory infections are even more impressive, with nearly 100% adherence for once-daily dosing. When given an antibiotic dosing schedule of twice daily, at least one-third of patients missed one or more doses. As the number of doses increased, so did the nonadherence (Carlson, Stool, & Stutman, 2005). The ideal drug, it appears, would be taken once daily.

The combination of several medications into one tablet, a poly pill, helps adherence even in the population that is not mentally challenged (Thom, 2013). A meta-analysis of studies regarding the use of fixed-dose combination medications available for hypertension, tuberculosis, and HIV found a 24% to 26% decrease in noncompliance when combination medications are prescribed (Bangalore, Kamalakkannan, Parker, & Messerli, 2007). Consideration of whether the increased cost of fixed-dose combination medication is offset by better disease management due to increased adherence is part of the decision-making process when prescribing.

Sensory or Mobility Challenges

Patients need to be able to read the label and open pill bottles to easily self-administer medications. Large-print labels can increase safety for those with visual impairment. Easy-open lids and pillboxes increase ease of administration when a person has arthritis or impaired coordination or mobility. Prescribers need to anticipate sensory or mobility problems that affect self-administration of medications.

Cues as Reminders

There are multiple methods that can be employed to provide cues to remember to take medications. Some patients

use a simple visual cue, such as putting their morning medication near the coffee pot to remind themselves to take their medication when they make the coffee. Pill containers can be purchased with compartments from once-daily to multiple times/day dosing and from weekly to monthly schedules. These containers not only serve as cues to take a drug but also help to monitor when a drug is or is not taken. Daily calendars with sections for each hour of the day can be marked with the name of the drug to be taken. Monthly calendars are sometimes needed for drugs not taken on a daily basis. Electronic technologies include reminders through mobile phones, personal digital assistants, and pillboxes with paging systems. Elders appear to profit the most from having multiple cues (Boron et al, 2013). A Cochrane review of the use of mobile phone messaging in the self-management of chronic disease demonstrated increased medication compliance (de Jongh, et al, 2012). For pediatric patients, stickers, which can be applied to a reminder board or chart, are also helpful. Keeping antihypertensive medications with the home blood pressure cuff may foster both medication adherence as well as self-monitoring of medication effect.

Scheduling Visits for Medication Follow-Up

Patients who miss appointments are often those who need the most help in improving their ability to adhere to a drug regimen. Such patients often benefit from clinical scheduling that matches their drug regimen. If a drug is prescribed for 2 weeks, the next appointment should be on the day after the drug should be completed. For chronic illness, clinic scheduling around the time for any laboratory work or doing physical assessments such as blood pressure can also include consideration for the time to fill the prescriptions. Matching the timing of refill intervals with appointment schedules is also patient-centered.

One-stop-shopping for medical care and prescription refills is a potential adherence strategy. Larger clinics with on-site pharmacies or even pharmacy-based convenience care clinics may provide the bonus of overcoming barriers to filling and refilling medications. Worksites with primary care clinics have nearly 10% better adherence rates (Sherman, et al, 2009).

FINANCIAL IMPACTS

Pharmacological interventions may be costly. Cost can have an impact on the ability and willingness of the patient to adhere to drug regimens. Even if the patient has access to financial assistance (e.g., Medicaid, insurance coverage for drugs), this does not ensure that the patient will view drugs as a primary financial need. Basic needs (e.g., food, housing) may take precedence over drugs in planning a monthly budget. This is especially true for older adults, who are frequently on fixed incomes and yet are the highest users of prescription and over-the-counter drugs. Over 50% of Medicare patients do not keep to their therapeutic regimens (Gould & Mitty, 2010).

Cost Versus Complications

Sipkoff (2005) reported a 3-year study that measured the medical effect of nonadherence on 8,000 people with chronic conditions, including hypertension, diabetes, and depression. Researchers found that study subjects who said they cut back on their prescriptions because of cost were 75% more likely to have suffered a significant decline in their overall health, and 50% were more likely to have had a heart attack, stroke, or chest pain episode than those who filled their prescriptions.

For newly diagnosed patients with chronic illnesses, high cost-sharing—that is, having a large co-payment for each prescription or having to pay up to a certain dollar amount before insurance pays the rest—has been shown to delay the initiation and continuation of drug therapy. A study of patients with hypertension found that 54.8% of the patients delayed initiating therapy when cost-sharing was doubled (Solomon, Goldman, Joyce, & Escarce, 2009).

Out-of-Pocket Versus Insurance

Having insurance that partially covers the cost of medications does not in itself guarantee appropriate utilization of this benefit. From a sample of 27,057 patients with type 2 diabetes, Dor and Encinosa (2004) estimated that the business cost saved by increasing a drug co-payment by as little as $6 would also increase the cost of diabetic complications related to increased nonadherence by $360 million per year, far exceeding the business savings of $31.2 million incurred by the co-payment increase (Lozada, 2005).

An increasing number of patients are either uninsured or underinsured. The hope is that the ACA will assist with this issue. Frustratingly, though, the Veteran's Administration has found that cheap or even free medication refills do not always produce adherence to treatment regimens. Mail-order pharmacy prescription refills are typically cheaper than monthly pickups at local pharmacy windows. Use of mail-order supplies had a higher adherence rate than those from retail agencies (Iyengar et al, 2013).

Family Versus Self

Patients who have several family members to support may view taking drugs for themselves as somehow being selfish. The child who has a chronic disease also affects the financial stability of the family, which may cause resentment from parents or siblings.

Generic Versus "New and Improved" Brand Name

Many patients see new drugs advertised on TV and the provider hears about them from the drug representative: "This new drug is so much better than the old one" or "This brand-name drug is so much better than a generic." There are times when a new drug has characteristics that make it better than anything else on the market, and generic drugs that are not

bioequivalent may not be as effective as a brand-name drug. However, choosing a new or nongeneric formulation that is very expensive requires careful consideration. A brand-name drug may cost *hundreds* of times as much as the generic. Providers need to consider cost before prescribing a drug, even if the patient or the insurance provider appears to be able to cover the cost.

Public and Private Assistance

The issue of public assistance is certainly a complex and difficult one. Being aware of possible public programs available to assist financially is only a part of the whole picture. The provider also has to have knowledge of the patient and whether that patient will accept public assistance. Public assistance may not be an alternative if the patient or family views it as a social or cultural stigma that is unacceptable.

Prescribers should keep contact information on hand for large pharmaceutical companies that offer coupon reductions and home-delivery options. Many companies have need-based programs that result in no-cost medications for patients in temporary or even permanent financial crisis. During times of disaster, larger pharmacy chains provide rapid refills and low-cost substitutes for medications lost during floods, fires, and wind storms.

COMMUNICATION DIFFICULTIES

Finding common terminology is not the only communication difficulty. There are also speech, hearing, and language barriers. Communication barriers can create safety concerns, as well as frustration for the provider and patient.

Non–English Speakers and Interpreters

Language barriers may create difficulty in adhering to a drug regimen. Federal law requires that clinics provide an interpreter if the primary language is different from the provider's. Clinics are able to contact interpreters for a number of different languages via interpreter services or phone interpretation. The difficulty that arises is whether the interpreter is repeating exactly what the provider is saying and, in return, whether the interpreter is saying exactly what the patient is saying.

Professional certified medical interpreters are preferable. A patient may not want to share certain information with the family member who is the interpreter, and the family interpreter may not wish to give the provider certain information about the patient. Cultural norms play a major role here. When a professional interpreter is not accessible, every effort must be made to find a reliable interpreter. The provider can be held liable for poor outcomes if a lay interpreter is used and incorrect information is given to the patient.

Speech and Hearing Issues

Patients with hearing or speech difficulties should not be automatically classified as individuals who will have adherence problems. Patients with hearing difficulties may have learned to compensate by reading lips. If this is the case, the provider must stand directly in front of the patient and speak clearly, looking directly at the patient's face. Presbycusis (hearing loss due to age) is commonly associated with decreased ability to hear higher-pitched tones, often those within the range of the human voice. Speaking in low tones or finding a provider with a lower voice may improve the patient's ability to understand. Written instructions are necessary to ensure accurate information is conveyed to the patient.

Patients with speech difficulties include those who are deaf and those who have had strokes or laryngectomies that reduce their ability to produce speech. Sometimes, these patients have learned coping mechanisms or had speech therapy to enable them to communicate. The provider must discover what tools the patient uses/needs to communicate and use these to the patient's advantage. An interpreter should be provided for patients who use American Sign Language. Patients using speech-enhancing devices usually bring such items with them. In any case, special attention should be paid to ensure that these patients communicate effectively with the provider, and vice versa.

COMMUNICATION BETWEEN PROVIDERS

It can be challenging to coordinate health care for a patient who sees several different providers. Open lines of communication are a must between the patient and his or her provider(s) and among health-care providers. If a patient sees a specialist for whatever reason, ask the patient to request that the records of each visit be sent to the coordinating primary care provider. However, the patient or the specialist's staff does not always follow through on this request. A congenial call by the primary care provider will do much to secure these reports; coordinate care, regimens, and appointments; let patients know the provider thinks they are important; and let the specialists know who the primary care provider is, thus also enhancing the visibility and credibility of primary care practice.

Patients who see several health-care providers or who do not consistently have the same provider experience greater problems in adhering to treatment therapy. Encouraging repeat visits to the same provider increases communication and knowledge between the patient and the provider.

PATIENT'S RESPONSIBILITIES

Providers are responsible for determining the best plan of care for a patient and for working with the patient to actualize

that plan of care. However, the plan of care should be mutually arrived at with the patient, and the patient carries some of the responsibility for its actualization. Not taking a drug, not taking it as prescribed, or premature discontinuance of a drug are common forms of nonadherence. Failure to fill or refill the prescription is another form of nonadherence. All of these are within the control and responsibility of the patient. Chronic illnesses create some of the greatest problems for the patient who has to adhere to ongoing therapy. Time, finances, and a desire to be perceived as healthy appear to have the greatest impact on compliance.

Self-monitoring has been shown to have positive effects on outcomes of drug regimens. For the patient with asthma, self-monitoring of peak expiratory flow rates can improve disease awareness and predict asthma flare-ups (see Chapter 31). Patients demonstrated better adherence after the first follow-up visits but gradually tapered off unless the importance of using the drugs was reiterated in follow-up visits. This technique can be utilized with other chronic diseases (e.g., diabetes, chronic obstructive pulmonary disease, cardiac disease, hypertension, depression) by reviewing whatever device is utilized for home management. Sarver and Murphy (2009) stress the importance of patient-centered versus disease-centered management strategies that include comprehensive patient and caregiver education and "solid partnerships between healthcare providers and patients."

Do not assume that the patient with a history of homelessness or substance abuse will not follow a treatment plan or that the well-educated, affluent patient will. The provider must find out if the patient actually wants to take the drug and is committed to adhering to a drug regimen. Patients have the responsibility to try to adhere to pharmacotherapeutics, but it is also the provider's responsibility to attempt to discover the barriers that are impeding a positive outcome.

MEASURING ADHERENCE

Adherence can rarely be measured by only one method. Methods that may be used include patient reports, clinical outcomes, pill counts, refill records, biological and chemical markers, and medication adherence tools.

Patient Reports

Patient reports are the easiest monitoring tool, but caution must be used when determining if the patient is actually pseudocompliant, telling the provider what the provider wants to hear rather than revealing the reality of nonadherence. Patients do not want to be scolded or chastised when nonadherence is discovered. Asking the "why" behind not taking meds helps to understand previously unknown or new barriers to adherence. Have the patient keep a drug diary to help him or her answer the following questions honestly:

- Did you fill your prescription?
- How often have you taken your drug in the past [number of days or weeks]?

- Have you missed any scheduled times to take the drug? If so, what was the reason? The answer to this question may give the provider insight into ways to improve adherence by removing barriers to it.
- Are there things we could do together to help you take your drugs?

Clinical Outcomes

In most cases, there is a clear clinical outcome being attempted by the use of drugs. Did the drug actually lower blood pressure or blood glucose? Did the patient have fewer asthma attacks or trips to the emergency room? Graphs or flow charts demonstrate the trajectory of outcomes and can be very convincing. If the clinical outcome was not met, adherence may be part of the problem, but remember, it is rarely the whole answer.

Pill Counts

Pill counts can be helpful in determining if the correct number of pills was taken between visits. Some new technologies dispense only one pill at a time, thereby reducing the risk that the patient may pour out pills to avoid being "caught." This type of dispensing can also be tied to reminders to take the pills. Bubble packs are cheap pill-counting methods that do not require fancy technology. If the patient has a caregiver, the caregiver can do the pill counts.

Refill Records

Records of refills can be monitored in the electronic health record or can be obtained from the pharmacy if the patient uses only one pharmacy to refill his or her prescriptions. Having clinic staff monitor whether refills are ordered as expected during the check in process can alert the provider to potential issues of adherence. Completing medication reconciliation as part of each patient encounter will uncover drugs not currently in use or duplication of prescriptions and may bring to light conflicting prescriptions from other providers.

Biological and Chemical Markers

Biological and chemical markers usually are laboratory tests or other diagnostic markers. Serum drug levels are mostly limited to measuring recent activity. Other biomarkers, such as Hb A1c, may be used to determine if a patient is taking the medication and whether the medication is effective.

Medication Adherence Scales

There are several medication adherence scales in the literature. None is considered the gold standard. The reader is directed to the literature for several scales currently in use. A review of four common scales is a good starting point

(Lavsa, Holzworth, & Ansani, 2011). The fastest to administer is the Medication Adherence Questionnaire (MAQ, also known as the Morisky 4), which is presented in Box 6-1. Because there are few questions and it is very easy to score, it is a popular tool to try to get to the source of adherence issues, including adverse drug effect and memory issues. The psychometrics include a reliability coefficient of $\alpha = 0.61$ (Lavsa, 2011). The addition of measuring self-efficacy is found in the Self-Efficacy for Appropriate Medication Use Scale (SEAMS), which has an alpha value of 0.89. Both the MAQ and the SEAMS have been validated in low-literacy populations.

PREDICTORS OF ADHERENCE

There is no end to the variety of factors that impact medication adherence. Wheeler, Roberts. and Neiheisel (2014) propose a model identifying predictors of medication adherence, which includes social, disease, financial, and health system factors that may influence medication adherence. There are additional elements that may influence adherence, including personal elements such as self-efficacy or health beliefs, and biomedical influences such as functional impact of the disease. While multiple elements influence adherence, each individual patient has unique elements that more greatly influence adherence at different points

of time (Fig. 6-1). The elements that influence adherence may be grouped into spheres of influence with elements of potential positive and/or negative contribution within those spheres. Determining which factors are impacting adherence at any point in time requires the advanced practice prescriber to conduct a complete nursing database concerning the elements that are playing into the current picture of adherence. These influences are not static; the elements are constantly in motion, with the importance of particular spheres of influence or several elements coming and going in duration and degree of impact on adherence to the therapeutic regimen. Every sphere plays a role in every patient's choices, abilities, and capabilities for self-care. A particular sphere or factor that may have played a key role previously can become more or less powerful in its influence. When previously reliable prescription adherence changes, the prescriber in tandem with the patient must return to the database to determine what new spheres and elements of influence might be at work.

Providers are encouraged to consider social factors and financial and health system factors when planning treatments in concert with patients. Planning must go beyond the disease factors that direct selection of therapeutic agents based on standard severity and degree of complexity of physiological effects. In concordance with the patient, the prescriber must weigh the pros and cons of different options, regimen complexity, and any concurrent medication or lifestyle challenges that may impact the patient's ability to adhere to the regimen. The relationship between prescriber and patient can make the difference in whether adherence is achieved or the issues previously discussed overshadow the plan and result in poor adherence. Predicting potential issues and exploring methods to overcome any objections are critical to promoting adherence.

SUMMARY

Patient education, enhanced communication between patient and provider and between providers, and consideration of multiple complicating social factors all contribute to fostering adherence and positive outcomes. Identifying patients at risk for nonadherence or those who actually are nonadherent, determining the cause of the nonadherence, facilitating the removal of the cause or barriers to adherence, and developing partnerships with patients to produce adherence and positive clinical outcomes are important roles for the prescribing provider. Table 6-2 provides a summary of adherence factors.

BOX 6–1 MORISKY SIMPLIFIED SELF-REPORT MEASURE OF ADHERENCE

Scoring: 0 = High Adherence; 1–2 Medium Adherence; 3–4 Low Adherence

1. Do you ever forget to take your medicine?
2. Are you careless at times about taking your medicine?
3. When you feel better do you sometimes stop taking your medicine?
4. Sometimes if you feel worse when you take your medication, do you stop taking it?

Five spheres of influence and multiple factors that impact adherence and self-management. M. Robinson, 2015.

Personal Influences
Psychological well-being
Self-efficacy
Health beliefs
Spiritual beliefs
Prior success
Willingness
Ability to trust

Health System Influences
Access to care
Availability of specialty care
Self-management support
Continuity of care providers
Continuity of insurance plan coverage
Wait times
Insurance coverage for medications
Pharmacy access
Automatic renewals
Personalize messaging
concerning adherence

Biomedical Influences
Timing of diagnosis
Duration of impact
Degree of physical impact
Comorbidities
Polypharmacy
Functional impact
Anticipated trajectory of impact
Frequency of dosing
Drug-to-drug interactions

Patient

Socioeconomic Influences
Occupational support
Occupational demands
Financial stability
Educational level
Impact of costs on prior lifestyle
Impact of costs on other family members
Cost of medications
Transportation access
Cultural barriers and considerations
Religious barriers and considerations
Rural locations
Living arrangements
Housing stability
Legal status
Formal dependency status

Interpersonal Influences
General external social support
Familial support
Familiarity with others
with similar circumstances
Changes in above factors
after diagnosis
Language barriers
Patient provider relationship
Patient provider stability

Figure 6–1. Five spheres of influence and multiple factors that impact adherence and self-management. *Robinson, M. (2015). Derived from Wheeler, K. J., Roberts, M. E., & Neiheisel, M. B. (2014). Medication adherence part two: Predictors of nonadherence and adherence.* Journal of the American Association of Nurse Practitioners,26*(4), 225–232.*

Table 6–2 Factors Influencing Adherence

General Health Status	Medical History, Nutritional Assessment, and Comorbidities
Life goals	To understand deeper issues such as • what gives meaning to a patient's life • the context of illness and treatment on a patient's life • the patient's definition of quality of life • a patient's attitudes and motivations based on one's self-perception
Medication history	Past experience, current regimens, and side effects from all medications
Comorbidities	Psychiatric, substance use, and medical illnesses
Social stability	Housing status, food resources, transportation needs, financial status, and insurance status
Employment status	Type of job, constraints, and disclosure issues
Health beliefs & cultural background	Language and perceptions toward illness and chronic illness, diagnosis, prognosis, role of medications, understanding of consequences of medication nonadherence, and spiritual/religious orientation in reference to one's life and health goals
Family & social support	Identification of personalized medication facilitator and network of social support
Educational background	Educational level, literacy level, baseline knowledge regarding specific chronic illness, medications, and importance of adherence

CULTURAL AND ETHNIC INFLUENCES IN PHARMACOTHERAPEUTICS

Lorena C. Guerrero • Leila M. Jones

The United States has been described as a melting pot of races and cultures. Its total population in 2010 was 308,745,538, and data indicate that the U.S. population is 72.4% white, 16.3% Hispanic, 12.6% black or African American, 4.8% Asian, 0.9% American Indian or Alaska Native, 0.2% Native Hawaiian or other Pacific Islander, 6.2% other race, and 2.9% of two or more races (U.S. Census Bureau, 2010a). With over 43.9% of our population being ethnic or racial minorities, the health-care provider must be versed in pharmacotherapeutic and other health topics that affect the health and well-being of diverse and growing segments of the population.

U.S. DEMOGRAPHICS

The U.S. Census Bureau (2012a) predicts that by 2060 the United States will become an equally diverse nation; that is, although the white non-Hispanic population will remain the largest group, other ethnic groups will also represent a large portion of the population. In fact, the U.S. census data show five states with "minority-majority" populations in 2012. These include Hawaii (77.2% minority), the District of Columbia (64.5%), California (60.6%), New Mexico (60.2%), and Texas (55.5%) (U.S. Census Bureau, 2013a). Projections for minority groups (one race/ethnic group only and not

mixed in with other ethnic groups) show significant growth. By 2060, the Hispanic population will represent 31% of the population, African American 15%, Asian 8.2%, two or more races 6.4%, American Indian/Alaska Native 1.5%, and Native Hawaiian/Pacific Islander 0.3% (U.S. Census Bureau, 2012b). In addition, a growing percentage of the total American population, 13%, are those born in another country. Among the foreign-born population, people born in Latin America and the Caribbean represent the majority, with 53.1%, followed by Asians at 28.2% (U.S. Census Bureau, 2012c).

Consistent with the growth of the foreign-born population is the growth in the number of people who have limited English proficiency (LEP), defined by the U.S. Census Bureau as any person age 5 and over who reported speaking English "less than very well." As of 2010, 9% of the U.S. population (over 25.2 million people) are in this category. Of these individuals, 65.5% speak Spanish, followed by Chinese (6.1%). States with over 1 million or more LEP persons are California (27.3%), Texas (13.3%), New York (9.7%), Florida (8.4%), Illinois (4.6%), and New Jersey (4.1%) (Pandya, Batalova, & McHugh, 2011).

Being in the LEP category and having minority status have been shown to be risk factors for low health literacy. These factors make it difficult for patients to understand English and result in confusion over medical language, difficulty in completing forms, and/or possibly limited access to health-care providers. All of these factors create barriers in the health-care interaction, which can exacerbate communication errors between the patient and the provider (U.S. Department of Health and Human Services, 2013). Health literacy and English language proficiency have been shown to be strong factors in the delivery of high-quality health care. Prescribers have a duty to ensure that patients understand how to take medication. Masland, Kang, and Ma (2011) found that the odds of Chinese, Korean, Mexican, and Central American patients living in California experiencing difficulty in understanding prescription labels were 3 and 4 times those of their white American counterparts. Other patient factors that increased these odds were a history of disability, low education level, low income, and recent immigration (Masland et al, 2011).

This chapter presents relevant information about these fast-growing minority groups that practitioners in the United States need to consider when making prescribing decisions for people who may have cultural origins different from the prescriber's. The shifting of the U.S. population away from a Western European racial majority impacts every decision the provider makes when caring for a more heterogeneous group of patients. Health-care providers must be knowledgeable about specific racial and ethnic factors that may influence health disparities and adapt their practice to meet the health-care needs of a diverse populace.

U.S. Demographic Groupings

The American Anthropological Society (AAS) has raised several pertinent issues related to both racial and cultural heritage in the United States. Although the U.S. Census Bureau collects data based on seven distinct groupings, the AAS states that the United States is home to at least 26 different and distinct racial and cultural groupings; the U.S. Census Bureau lists 184 ethnic groups. It is not possible within this chapter to delineate all of these groupings, so we have used the 7 that are delineated by the census. Readers should understand, however, that these are artificial groupings and that people listed within a specific group may be very different from one another; for example, Japanese, Chinese, Vietnamese, Filipinos, and Asian Indians are all grouped under the umbrella category "Asian," yet within these ethnic groups there are differences in the manner in which they metabolize certain drugs (Purnell, 2013).

Health Disparities in the United States

The Centers for Disease Control and Prevention (CDC) defines health disparities as "differences in health outcomes and their determinants between segments of the population, as defined by social, demographic, environmental, and geographic attributes" (CDC, 2011, p 11). In addition to the diversity among racial groups are the existing health disparities that continue to affect racial and ethnic minorities. Long-standing inequalities in the medical treatment of ethnic and racial minority groups by the health-care system, as identified by the Institute of Medicine (IOM), are on the increase (IOM, 2012). Other current research documents significant gaps in health between segments of our society—among racial and ethnic minorities in particular.

The IOM identifies several factors that have an influence on these differences, such as socio-political-historical background; social policies that influence individual health-care interactions; financial and organizational structures in the health-care system that promote illness and poorly controlled chronic diseases instead of prevention; the settings in which health care is delivered, which focus mainly on acute care versus promoting the health of communities and populations; and the nature of the health-care workforce, which at this time does not reflect the current racial and ethnic minority makeup of the United States. Together, these factors contribute to the continuation of health disparities. Health-care practitioners must be aware of local, state, and national statistics that describe health disparities and work toward the reduction, and ultimately the elimination, of these disparities with the goal of improving the overall health of patients, the communities they live in, the nation, and the world.

Cultural Influences on Care

Equally important to understanding health disparities is having knowledge of cultural factors that may impact the well-being of patients. Knowing who makes the decisions in the family about health care and if this person supports the use of the prescribed drug and the plan of care, how the patient and family members view health and illness and their views on the management plan, and cultural factors that may

create challenges in adhering to the treatment plan are all important to helping clients improve and/or maintain their health. Although each person with a specific cultural heritage is unique and may not subscribe to all or even most of the health beliefs and health practices of that cultural group, it is important to know what is common to members of the group and in particular what risk factors the group shares. Cultural heritage plays an important role in helping to explain values, attitudes, beliefs, customs, language preferences, and behaviors that influence health practices (Giger, 2013). Socioeconomic factors also influence prescription choices and they may supersede cultural and racial differences. For this reason, we discuss the cultural factors to be taken into account, including background socioeconomic data, such as current demographics, median income, education, and employment (since many patients obtain health insurance through their employment) as well as LEP status, percent foreign-born (if applicable), and health-care utilization.

This chapter focuses on both cultural and ethnopharmacological factors that influence the practioner's choice of drugs. Pharmacogenetics, described in Chapter 8, also influences prescription choice. The data provided here are based on evidence derived from drug research and on the pharmacokinetics of those drugs most likely to exhibit differences. In using this information, it is important to keep in mind that most Americans are not of any "pure" cultural or racial background and that patients must be treated as unique individuals.

The United States is a constantly changing and evolving cultural mosaic made up of individuals who represent a variety of ethnic and racial backgrounds, each having its own culture and beliefs that influence health. How much of the material presented in this chapter on the cultural values, beliefs, and practices of different ethnic and racial minority groups continues to be valid in the 21st century is unknown. There is little empirical research to support the information on cultural beliefs and practices presented here, although every effort has been made to locate current evidence-based research. The reader should understand that the majority of our sources are found in cultural and anthropological texts that do not clearly state where the information originated or if it is still relevant to today's health-care consumer. Thus, we caution readers that our descriptions may be outdated and may not apply to all members of that particular group. Further research is needed to discover whether the long-reported cultural values, beliefs, and practices continue to represent the majority of the ethnic and minority populations discussed. The reader should acknowledge that culture is a living concept that is evolving and changing and that patients may represent a kaleidoscope of these ever-changing cultural beliefs and practices (Purnell, 2013).

TRANSCULTURAL NURSING CARE THEORIES

Cultural awareness allows the provider to be aware of and open to the differences between patients, regardless of their culture. Madeleine Leininger, in her Culture Care Sunrise model, focuses on assessing the patient in his or her environmental context, which includes seven major areas: technological, religious, social and kinship, cultural value, political/legal, and economic and educational factors (Leininger, 2004). Purnell (2013) expands this model to other factors, including health-care practices, attitudes toward health-care practitioners, high-risk health behaviors, and knowledge about current health disparities for diverse ethnic and cultural groups. The provider should consider all of these factors in planning and implementing treatment regimens that are unique to each patient—regardless of racial or ethnic minority group. For example, the provider would assess the patient's economic resources and education as well as culture before planning care. Several studies have shown that patients do not adhere to medications for several reasons, such as economic factors (high co-payments or lack of prescription coverage from health insurance), prescriptions delivered electronically, and new prescriptions (Shrank et al, 2010). This is especially true of ethnic minorities who lack prescription benefits; they have been reported to be more likely than whites to not take prescribed medications because of cost (Jacobs, Shepard, Suaya, & Stone, 2004).

In providing transcultural care, Leininger states that the provider must decide which preservation/maintenance, accommodation/negotiation, or repatterning/restructuring actions should be undertaken. For example, when a Hispanic patient is newly diagnosed with diabetes, the provider structures care to preserve relevant values that are important to the patient while negotiating changes in behavior, such as food choices and other lifestyle modifications. The client will need to change or greatly modify some behaviors in order to have optimal health outcomes. Practitioners should use frameworks such as those presented by Leininger or Purnell that allow them to provide evidence-based, individualized, and culturally appropriate care regardless of the ethnic or cultural group to which the patient belongs.

STANDARDS OF CULTURAL COMPETENCY

According to the Institute of Medicine (2012), the main factor affecting health disparities is the cultural competence of the health practitioner. The National Standards for Culturally and Linguistically Appropriate Services in Health and Health Care (referred to as the enhanced National CLAS Standards) were developed as a way to address and correct the inequities that exist in the delivery of health care to culturally and ethnically diverse populations. These standards offer a blueprint for health-care professionals and organizations to implement culturally and linguistically appropriate services (Office of Minority Health, 2013b).

National CLAS Standards were originally published in the Federal Registry in 2000 by the U.S. Office of Minority Health in response to a 1994 federal law mandating CLAS Standards for all organizations receiving federal funds, such as Medicaid

and Medicare. Recently, the National CLAS Standards have undergone a revision, referred to as the Enhanced National CLAS Standards. These standards were further revised in response to research on health and health-care disparities and changing demographics, as well as legal and accreditation requirements. National CLAS Standards have gained recognition as an important way to help health-care professionals and organizations address the persistent health disparities that plague our nation's diverse communities by improving access and advancing health equity (Office of Minority Health, 2013b).

The new focus on national accreditation standards for professional licensure in the fields of medicine and nursing, as well as health-care policies recently passed by Congress, such as the Affordable Care Act, have also added to the importance of cultural and linguistic competency as part of high-quality health care and services in hopes of decreasing and eradicating health disparities (Putsch, SenGupta, Sampson, & Tervalon, 2003).

A notable change in the new 2013 version of the Enhanced National CLAS Standards is the definition of culture as "the integrated pattern of thoughts, communications, actions, customs, beliefs, values, and institutions associated, wholly or partially, with racial, ethnic, or linguistic groups, as well as with religious, spiritual, biological, geographical, or sociological characteristics" (Office of Minority Health, 2013b). Culture is further defined as a dynamic concept in which individuals may self-identify with more than one culture over the course of their lifetimes. For the first time, the Enhanced National CLAS Standards also include an explicit definition of health, as encompassing "many aspects, including physical, mental, social, and spiritual well-being and occurring along a continuum that can range from poor to excellent " (Office of Minority Health, 2013b). And finally, the Enhanced National CLAS Standards include not only a discussion on how the standards can lead to health equity for all individuals but are also specifically aimed at those of diverse racial, ethnic, and cultural backgrounds (Office of Minority Health, 2013b). The Enhanced National CLAS Standards add a broader definition of culture and health that is in line with nursing's view of health.

The Enhanced National CLAS Standards were developed to reach a broader audience, including patients, consumers, clients, recipients of care, families, caregivers, and even communities. The standards mandate language access services and organizational supports for cultural competence, which are included under culturally competent care. Three types of standards—mandates, guidelines, and recommendations—help providers meet the varied needs of culturally and linguistically diverse populations. These standards call for the provision of professional language assistance services for translation rather than ad hoc interpreters such as family and friends. The standards encourage the education and training of staff members and the provision of culturally appropriate and easily understood teaching materials, including those for adults with low literacy levels. They encourage collaboration with the communities served by the organization and stringent

assessment practices. Other organizations have approved strategies for CLAS implementation. In 2009, the Joint Commission, an organization that accredits health-care organizations such as hospitals and clinics, implemented requirements that help address communication, cultural competence, and patient- and family-centered care (Joint Commission, 2013).

Key to the understanding of the treatment plan is the patient's ability to understand what the health-care provider wishes to communicate through oral and written methods. Not only does the federal government and the Joint Commission require that cultural and linguistic standards be met and followed according to the CLAS Standards, but it is the duty of the prescriber to ensure that the correct information is elicited in order to make a proper diagnosis and that the patient is educated about the agreed-upon treatment plan. This is particularly important when providers care for people with LEP.

Although the majority of the U.S. population speaks English, many speak languages other than English. Immigrants have increased the number of people who are categorized as LEP. Prescribers must be aware of how well these groups are able to participate in the health-care visit, understand written and verbal instructions, and interact with the English-speaking majority. The Census Bureau determines LEP by asking three questions on its yearly American Community Survey and the decennial census: (1) whether there is someone in the household who speaks a language other than English, (2) what the foreign language is (write-in response), and (3) degree of English-speaking ability (self-rated as *very well, well, not well,* and *not at all*). Respondents who self-identify themselves as anything other than "very well" are required to have an interpreter.

As of 2010, 21% of the population (ages 5 and over) in the United States spoke a language other than English (but did not necessarily describe themselves as LEP); 62% reported speaking Spanish, 4.8% percent spoke Chinese, 2.6% spoke Tagalog, 2.3% spoke Vietnamese, and 2.1% spoke French (U.S. Census Bureau, 2010). As previously reported, over 25.2 million people are considered LEP; the primary language of the majority of these is Spanish (65.5%), followed by Chinese (6.1%). On further analysis, only 25.9% of the Spanish-speaking population reported speaking English *not well* and *not at all*, and 29.6% of the Chinese-speaking population, 7.2% of the Tagalog-speaking population, 33.1% of the Vietnamese-speaking population, and 6.5% of the French-speaking population describe their English skills as in the same manner. In fact, the percentages of other Asian groups who report speaking English *not well* and *not at all* are 28.4% for Korean speakers, 29.5% for Mon-Khmer/Cambodian speakers, and 27% for Laotian speakers. Providers must familiarize themselves with changing trends in their local service areas to be able to meet the needs of LEP patients and fully understand and communicate all pertinent information regarding the treatment plan (Pandya et al, 2011).

Providers must ensure that proper interpreter services are used to meet the CLAS Standards or risk losing Medicaid and Medicare funding. LEP patients who utilize interpreter services, rather than ad hoc interpreters such as family members,

engage in more recommended preventive health services, make additional office visits, and fill more prescriptions (Jacobs et al, 2004). The importance of ensuring proper communication and understanding among LEP patients cannot be overemphasized and is an important factor that affects the health-care visit and patient adherence.

In order to meet the changing needs of diverse populations, prescribers must become culturally competent. According to Purnell (2013), cultural competence in health care is "having the knowledge, abilities, and skills to deliver care congruent with the patient's cultural beliefs and practices" (p 7). Becoming culturally competent involves having not only an understanding of the patient's culture but also knowledge of one's own culture and personal values and the ability to detach from preconceived ideas and beliefs that can influence attitudes and behaviors toward patients from diverse backgrounds (Purnell, 2013). Ethnocentrism can influence the relationship between the patient and the prescriber by creating barriers to providing culturally competent care. Although the Human Genome Project (2003) showed that only one-tenth of a percent of genetic variations are responsible for differences among humans, Purnell (2013) states that these differences may be significant when conducting health assessments and prescribing medications.

Accreditation bodies like the American Association of Colleges of Nursing (AACN) have also called for cultural competence in nursing education. The Essentials of Doctoral, Master's and Baccalaureate Education for Professional Nursing Practice (AACN, 2006, 2008, 2010) urges the integration of cultural competence standards in both undergraduate and graduate nursing education with the aim of supporting patient-centered care that addresses patient differences in values, preferences, and expressed needs, which may influence health outcomes. According to the AACN, nursing professionals should understand the interrelationship among the concepts of social justice, a commitment to the health of vulnerable populations, and the elimination of health disparities through an understanding of cultural, physiological, ecological, pharmacological, and genetic factors that affect people. In particular the AACN document (2006, 2008) calls for nursing professionals to be able to discuss the effect of drugs on specific ethnic and racial groups.

ELIMINATING HEALTH DISPARITIES

Since the inception of the Healthy People 10-year national objectives initiative in 1979, the focus of national health goals has moved toward improving the health of all Americans. The program has also identified the significant problem of health disparities that affect a disproportionate amount of our ethnic and minority populations. Although health indicators such as life expectancy and infant mortality (markers that are often used as proxy measures to compare the health and well-being of populations across and within countries) have improved for the majority of nonminority Americans, ethnic and racial minorities continue to experience a disproportionate burden of preventable diseases, death, and disability (CDC, 2013a).

Even though the United States spends $2.5 trillion annually on health care (CDC, 2012a), it consistently falls short of other industrialized Western countries in infant mortality rankings. As of 2011, the United States failed to meet the *Healthy People 2020* goal of fewer than 6.0 infant deaths per 1,000 live births (U.S. Department of Health and Human Services, 2013). Other countries that spend much less on health care per capita, such as Cuba and Singapore, have continued to report lower infant mortality rates than the United States (Central Intelligence Agency, 2012). Contributing to this poor standing is the rate of African American infant mortality, which is 2.3 times the rate for the white non-Hispanic population (Office of Minority Health, 2013a). Another example is the age-adjusted asthma mortality rate, which is significantly higher among non-Hispanic blacks (3.3 deaths per 100,000 persons) compared to non-Hispanic whites (1.1 deaths per 100,000 persons) (National Center for Health Statistics, 2010). Non-Hispanic blacks are more likely to have severe asthma, have more asthma control problems, and visit the emergency department more often, all of which influence asthma morbidity and mortality (Mosen et al, 2010).

The U.S. Department of Health and Human Services urges health practitioners to understand issues related to social justice and globalization that impact health care so that they can make a conscious effort to work toward eliminating health disparities. In order to positively influence the health of patients, and ultimately populations, health-care practitioners must be aware of socioeconomic, personal, and cultural factors that may affect adherence to treatments. The World Health Organization and the CDC recognize several factors, called *determinants of health*, that influence health disparities and contribute to a person's current health status: (1) biology and genetics, (2) individual behavior, (3) social environment, (4) physical environment, and (5) health services (CDC, 2013). The interrelationship of these factors requires practitioners to be aware of physical, psychological, spiritual, cultural, and environmental factors, as well as to be conscious of the social and political context in which health can be optimized and/or threatened.

ETHNOPHARMACOLOGY

A factor only recently being incorporated into pharmacotherapeutic decision making is that of ethnopharmacology—the study of racial differences in drug metabolism and response. Practitioners may be aware and guidelines may sometimes specify that certain drugs are less or more efficacious or may have different side effects with certain racial groups. As the cost of gene sequencing decreases, more research has been done that demonstrates the underlying genetic reasons for these differences in efficacy. Large studies are being conducted that include gene mapping of global populations and determining pharmacogenomically relevant markers of drug response, which provide evidence for predicting variations in drug response based on ethnic background (Ramos et al, 2014). Research implicates multiple cytochrome enzyme systems (CYP450, CYP 2D9, and others) in the differences in

drug metabolism and response, but these enzymes are not the only sources of racial differences. The expectation is that more information will be gained in the area of ethnic differences in drug pharmacokinetics because of the National Institutes of Health's (NIH) mandate for inclusion of women and minorities in funded clinical research (NIH, 2013).

The pharmacokinetic factors that can be expected to potentially exhibit racial differences are (1) bioavailability for drugs that undergo gut or hepatic first-pass metabolism, (2) protein binding, (3) volume of distribution, (4) hepatic metabolism, and (5) renal tubular secretion. Absorption, filtration at the glomerulus, and passive tubular reabsorption would not be expected to exhibit such differences. Because there is little research evidence on racial differences for relatively few drugs, it is often necessary to conjecture whether these differences might exist. For example, a drug that is eliminated entirely by the kidney through filtration and reabsorption and is not highly protein bound is very unlikely to exhibit racial differences. Conversely, a drug that undergoes significant hepatic first-pass metabolism and is highly protein bound is more likely to exhibit pharmacokinetic differences between racial groups.

This chapter will identify and discuss cultural and ethnic influences on pharmacotherapeutics that play a role in influencing the health outcomes of the patients who trust their care and well-being to the health-care practitioner.

AFRICAN AMERICANS

Cultural Factors

Demographics

According to the U.S. Census Bureau, in 2011 those who designated themselves as African American alone and/or in combination with another race made up 13.6% of the population, and their numbers are increasing faster than the overall growth of the population (CDC, 2011a). The U.S. Census Bureau predicts that by 2060, African Americans will make up 18.4% of the population (CDC, 2011a). As a group, African Americans are young (33.9% under age 20) and more likely to be unmarried (68.8%) and female (53.1%). The majority of African Americans (55%) live in the South. The proportion below the poverty line in 2011 was 27.6%, and the mean household income was $32,329 (CDC, 2011a; U.S. Census Bureau, 2011a).

Education and Employment

In 2011, 82.5% of those who identify as African American have a high school diploma or equivalent, 13.3% have a bachelor's degree, and 6.8% hold an advanced degree (U.S. Census Bureau, 2011a). More African American women than African American men earn a bachelor's degree or higher (respectively, 21.6% compared to 18.2%). According to the U.S. Department of Labor (2012a), the unemployment rate is more than twice that of white Americans (15.8% versus 7.9%) and higher than that of any other ethnic group. In this group, men are more likely than women to be unemployed, at a rate

of 16.7% compared to 13.2%. Additionally, African Americans earn less than their white counterparts, with a median weekly salary of $653, approximately $200 less than the median weekly salary for white Americans. African Americans (along with other minority populations) are more likely to be employed in hazardous occupations (CDC, 2011a). A significantly higher number of households have non-Hispanic black women designated as female head of household (27.5%) than do non-Hispanic Asian (7.8%), non-Hispanic white (9.0%), and non-Hispanic Native Hawaiian/Other Pacific Islander (10.5%) households (U.S. Census Bureau, 2013b). These data support the potential for a difficult reality for many African American families as they continue to face socioeconomic challenges that other racial and ethnic minorities may not.

Family Relationships

Although over half of African Americans are raised in single-parent homes, a strong kinship bond among family members exists. The female is the dominant family force, and the grandmother is often the major decision maker. Sickness can bring families together, and extended and nuclear family members take care of one another (Purnell, 2013). Ever alert for signs of discrimination, they may see health-care providers as "outsiders" in health decisions.

Research has shown that family dynamics affect the course of psychiatric illnesses such as schizophrenia and are as well a factor in contributing to poor outcomes, which vary by race and ethnicity. For example, Lawson (2008) describes family behaviors (such as high emotionality, family intrusiveness, and critical comments) that are normally identified as "toxic" and causing poor outcomes among European American families are instead thought of as protective factors in African American families. African American patients experiencing schizophrenia will view their families as supportive, and therefore the practitioner may wish to continue family involvement in the therapeutic treatment plan to maximize compliance.

Health-Care Utilization

In 2011, 46.7% of African Americans, compared to 65.8% of whites, had employer-sponsored health insurance; and 18.8% of African Americans, compared to 11.1% of non-Hispanic whites, were uninsured (CDC, 2011d, 2012a). Beal, Doty, Hernandez, Shea, and Davis (2007) found that more African Americans (21%) than whites had no usual source of health care and that cost considerations for prescription drugs are especially important in this group. African Americans use hospital clinics and emergency rooms as their care providers more than any other ethnic group, perhaps in part because of their urban residence (Purnell, 2013).

Health-care utilization is also influenced by the types of jobs that people hold. African American males are twice as likely as non-Hispanic white males to work in service-related occupations, such as laborers, fabricators, and operators. These occupations result in higher injury rates (approximately by a third) among African American males and females when compared to white non-Hispanic workers (CDC, 2011c).

In addition to lacking health insurance, many African Americans have a long-standing distrust of the modern health-care system, in part due to the Tuskegee experiment with syphilis conducted by the U.S. Public Health Service from 1932 to 1972. This study withheld treatment from the African American patients it enrolled long after 1947, when treatment with penicillin became the drug of choice, only for the sole purpose of learning more about the long-term effects of syphilis on the body (CDC, 2013b). Despite public apologies from the U.S. government by President Bill Clinton and the Surgeon General in 1997, many African Americans still harbor a suspicion of government-provided health care. This also has implications for recruiting African Americans for research studies, because this population may choose to abstain from participation (CDC, 2013b; Soto, Dawson-Andoh, & BeLue, 2011). Prescribers should familiarize themselves with published clinical studies and evaluate whether they meet the NIH requirements that NIH-sponsored research adequately address its inclusion guidelines concerning recruitment of women, minorities, and children.

Additional factors that may influence health-care utilization is a shortage of African American providers, a belief that pain is inevitable and should be endured, the use of folk practitioners instead of traditional Western medicine, and the view that nurses are less important than physicians (Purnell, 2013).

Health Status and Other Biological Variables

The gap in life expectancy between African Americans and white Americans is narrowing but still exists. African Americans' life expectancy is shorter than the average American's by 4.7 years (National Center for Health Statistics, 2010).

This population continues to experience significant health disparities in the rate of preterm birth, low birth weight, and infant mortality. According to the U.S. Office of Minority Health, maternal mortality rates are over twice (2.3 times) those of other ethnic groups, such as non-Hispanic whites (2013c). In 2004, Sudden Infant Death Syndrome (SIDS) was the third leading cause of death for African American infants under the age of 12 months (111.5 versus 48.8 per 100,000), a rate that is 2.3 times greater than that of non-Hispanic whites. Researchers believe that factors influencing SIDS rates among this population include low rates of acceptance of current guidelines, which call for infants to be put "Back to Sleep"; continuation of myths passed down through generations, often by well-meaning mothers and grandmothers, that infants sleep better in a prone position; and the continued reluctance by this population to follow current research demonstrating that placing infants on their backs decreases the rate of SIDS by 50% (American Lung Association, 2007). Practitioners can help African American mothers make informed choices by offering clear instructions, addressing these myths, and offering research-based education whenever possible on the positive results of the "Back to Sleep" program.

African American women experience preterm birth (described as a birth before 37 weeks gestational age) at a rate

of 17.4 per 1,000 births (compared to 10.9 per 1,000 for white non-Hispanics) and deliver an infant classified as low birth weight (a birth that is less than 2,500 grams) at almost twice the rate of the non-Hispanic white population (13.6% versus 7.2%). Some Southern states with high African American populations, such as Alabama, Louisiana, and Mississippi, have some of the highest premature rates of the nation: 14.9%, 15.6%, and 16.9%, respectively (March of Dimes, 2013). In addition, the African American population has the second-highest pregnancy rates in the nation for females ages 15 to 19 (47.3 versus 21.7 per 1,000 for white non-Hispanics) (Office of Adolescent Health, 2013).

The patterns of illness in the African American population include a higher prevalence of coronary heart disease, hypertension, stroke, obesity, type 2 diabetes mellitus, and HIV infection. When compared to their non-Hispanic white counterparts, the prevalence and age-adjusted mortality rate for diabetes and hypertension are 2 times higher, with an overall risk of being diagnosed with diabetes that is 77% higher than the risk for the general population, and a risk for stroke that is 1.7 times higher (Purnell, 2013). In 2011, the percentage of African Americans of all ages who reported their health as fair or poor was 14.2% (CDC, 2011a), versus 9.9% for the non-Hispanic white population (CDC, 2011b). These statistics demonstrate that the African American population may present with more chronic health problems that prescribers must address effectively.

Several risk factors for chronic health problems like coronary artery disease exist in the African American population: cigarette smoking, obesity, and poor dietary choices. The prevalence of cigarette smoking, a risk factor for heart disease, is similar in the African American and non-Hispanic white populations; 19.4% of blacks smoke as do 20.6% of non-Hispanic whites. However, while the non-Hispanic white population has seen a decrease in the number of smokers, this is not true for the African American population, where there has been no significant decline in the overall smoking rate from 2005 to 2011. In particular, black men make up 24.2% of smokers, versus 21.6% overall for male smokers in the general U.S. population (CDC, 2013c). In an 8-year study, Haiman et al (2006) found that African American and Native Hawaiian smokers (smoking 20 cigarettes or less per day) had a significantly higher risk of developing lung cancer when compared with white, Japanese American, and Latino smokers with similar smoking rates. The authors suggest that this may be related to smoking behavior (such as African Americans tending to inhale more nicotine than whites) and/or susceptibility to tobacco carcinogens.

Another cardiovascular risk factor, obesity, is more prevalent in the African American population, affecting 37.6% of men and 54.2% of women. Purnell (2013) believes that the reason for this is due to the African American diet, which contains more animal fat, less fiber, and fewer fruits and vegetables and includes traditional items like chitterlings, fried okra, ham hocks, corn, mustard, collard and kale greens, which are often cooked with pork fat. Foods are often prepared by frying or barbecuing and are often accompanied

by gravies and sauces, which may add calories, fat, and salt. Practitioners need to understand that changing cooking and eating habits may be difficult, for the negative view of obesity that predominates in the American culture may not be shared by African Americans: a bigger body habitus is often viewed as a healthy body—particularly in women (Purnell, 2013).

Diets high in fat, cholesterol, and salt may also contribute to the increase in hypertension. For example, approximately 37% of African American men and 44% of women have hypertension (CDC, 2011a). When compared to other ethnic groups, hypertension in the African American population is normally more severe, is often resistant to treatment, occurs earlier in life, and leads to significantly worse target organ damage (Purnell, 2013).

African Americans also have the lowest immunization rates for infections like tetanus and the second-lowest rates after Hispanics for influenza and pneumococcus infections (CDC, 2008). These low vaccination rates may contribute to lower-respiratory infections and be the reason for such infections being the seventh leading cause of death for this population. On a positive note, the African American population has greater bone density than other ethnicities and therefore suffers less osteoporosis (National Center for Health Statistic, 2010).

Health data clearly demonstrate disparities in HIV in both new infections and death rates for the African American population. Although this population accounts for 12.6% of the U.S. population, it accounts for 44% of new HIV cases. In particular, young, gay, bisexual, and other African American men who have sex with men (MSM) are affected disproportionately. For 2010, African American MSM accounted for 70% percent of the black men newly diagnosed with HIV. This rate is 7 times higher than that for whites, 2 times higher than the rate for Hispanic men, and almost 3 times as high as the rate for black women (CDC, 2011a). More than two-thirds of black men who reported engaging in MSM sexual behavior in a low-income, high-HIV-prevalence community identified themselves as heterosexual (43%) or bisexual (24%), and over 71% of MSM reported having sex with women. Therefore, providers must have greater tolerance and acceptance of sexual diversity, provide health promotion education, and focus on HIV screening among the African American population.

Another disparity between African Americans and the general population involves susceptibility to pain. Interestingly, research indicates that African American and Hispanic patients experience pain differently than their non-Hispanic white counterparts. Rahim-Williams et al (2007) found that both racial groups had lower pain tolerance levels for contact heat and cold; however, there was no difference between minority and non-Hispanic white populations' tolerance of ischemic pain (pain experienced from an application of a tourniquet). Additionally, there was no difference in pain threshold (defined as the pressure level at which pressure pain was felt) between the racial groups. This may have implications for achieving adequate pain management goals.

Prescribers may need to keep these differences in mind when treating African American and Hispanic patients.

African Americans also have an increased risk (as high as 4 times that of European Americans and Latinos) of being diagnosed with schizophrenia (Blow et al, 2004). This increased risk may be due to a possible genetic predisposition as well as to environmental risk factors. Lawson (2008) proposes that polymorphisms of the synapsin III and NOTCH 4 genes found in African Americans with schizophrenia, but not as yet identified in European Americans, as well as environmental factors may increase the risk for schizophrenia. Another difference between these populations is that African Americans respond differently than whites to alcohol, psychotropic drugs, and caffeine: they reach higher blood levels, have a faster therapeutic response, and a higher rate of extrapyramidal effects than do non-Hispanic whites (Purnell, 2013).

Blacks have a higher number of asthma visits to the emergency department, 18.6 per 100,000 versus 5.6 for whites, and also experience a higher asthma-related death rate of 2.7 per 10,000 versus 1.4 for whites. But prescribers are falling short of the Healthy People 2020 target in providing black patients with key asthma education and management strategies, such as proper use of an inhaler (Alkinbami, Moorman, & Liu, 2011).

The U.S. Office of Minority Health attributes the poor health outcomes for African Americans to, among other things, "discrimination, cultural barriers, and lack of access to health care" (National Center for Health Statistics, 2010, p 2). In addition, a large body of literature, including Johnson (2006) and Soto and colleagues (2011), attributes psychopathology among the African American population to stress arising from racism, unequal treatment, and anxiety over experiences of racism, which may lead to poorer health status from the continued overactivation of the stress response and poorer overall health.

Health Beliefs and Practices

For a significant portion of the African American population, health is a gift from God, and illness and suffering are God's will or are caused by evil influences. Because God's will is the source of the illness, African Americans rely heavily on the healing powers of religious ritual and the advice of their religious leaders. They take their religion seriously and engage in prayer for many reasons. Folk healers and folk medicine—such as cod liver oil to prevent colds, sulfur and molasses in the spring to promote health, and copper or silver bracelets to protect from harm—are often used as are herbal remedies. Allopathic health care is not considered for prevention (Purnell, 2013).

Regional differences are often a factor in attitudes toward health issues for all ethnic groups, including African Americans. Those who were raised in the southeastern part of the United States are more likely to subscribe to health beliefs and practices common to that region than are African Americans raised elsewhere. Prescribers should become familiar with regional differences and assess each

patient's unique attitudes in order to meet the health-care needs of that particular patient.

Racial Differences in Drug Pharmacokinetics and Response

African Americans appear to have been studied more than other ethnic groups in relation to ethnopharmacology, which has resulted in a larger body of knowledge about racial differences in pharmacokinetics for this group. This intense interest in ethnic pharmacology led to the first drug being approved by the U.S. Food and Drug Administration (FDA) in 2005 specifically for adjunctive treatment of heart failure in patients who self-identify as African American. BiDil is a fixed-dose combination of two generic drugs, hydralazine and isosorbide dinitrate, the first drug labeled exclusively for a specific race (Brody & Hunt, 2006). In an extensive review of ethnic variation and the significance of CYP 2C9 and CYP 2C19, Rosemary and Adithan (2007) discovered that the presence of CYP 2C9 *2 and *3 alleles required a 29% reduction in warfarin dose in African Americans.

Some black persons may be ultrarapid metabolizers of substrates of CYP 2D6. The prevalence of ultrarapid CYP 2D6 metabolizers among the African American population is 3.4%, similar to Caucasians, but the prevalence of ultrarapid CYP 2D6 metabolizers among Africans of Ethiopian descent is 29% (U.S. Food and Drug Administration [FDA], 2012). The impact of ethnic differences is seen in the case of codeine metabolism, where codeine is metabolized into morphine at a more rapid pace, leading to higher serum morphine levels and risk for morphine toxicity. Differences have also been demonstrated between African Americans and whites in plasma protein binding (Johnson & Livingston, 1997). This study found increased unbound fractions of drugs bound to albumin, a common binding site for many drugs. The researchers were careful to point out, however, that differences in protein concentrations might also explain the racial differences. At the time of this publication, no more recent research was found, indicating that further study is needed in this area. A large number of drugs could be affected by this racial difference if the findings can be replicated.

Hypertension has a high prevalence in African Americans. One reason behind this phenomenon appears to be salt sensitivity (Weinberger, 1993), which is often cited as the reason to use diuretics as first-line therapy for this ethnic group. In a study looking at the use of beta-adrenergic blockers to treat hypertension in African Americans, Prisant and Mensah (1996) found that not all African Americans are salt sensitive. When salt sensitivity was controlled for, there was no racial difference in efficacy when beta-adrenergic blockers were used with diuretics as combination therapy for hypertension. This study suggests that beta-adrenergic blockers should be given to some African Americans for certain indications, such as myocardial infarction prophylaxis.

To further confuse the issue of beta-adrenergic blockers, studies have been done related to racial differences in nucleotide-mediated smooth muscle relaxation (vasodilation) in response to nitric oxide. Studies by Cardillo, Kilcoyne, Cannon, and Panza (1998, 1999) support a difference between African Americans and whites in vasodilation response. The vasodilation effect of beta-adrenergic blockers stems from the combination of direct smooth muscle stimulation and endothelial nitric oxide release. Specifically, variations on a gene that codes for nitric oxide synthase, NOS3, has been found to correlate with left ventricular remodeling in African Americans with heart failure (McNamara et al, 2009). A variation on a similar gene, *eNOS4*, appears to influence the relationship between plasma nitric oxide levels and blood pressure (Li et al, 2004). Other drugs dependent on nitric oxide for their action include the nitrates. Both drug classes may not be efficacious or may require dosage alterations to achieve efficacy in African Americans.

The utilization of beta-adrenergic blockers in African Americans with heart failure is supported by Yancy, Laskar, and Eichhorn (2004) and Shekelle, et al (2003). Following a review of the literature, the authors recommended that, barring specific contraindications, beta-andrenergic blockers be used for any patient with left ventricular dysfunction in heart failure. Additionally, beta-adrenergic blockers used in conjunction with angiotensin converting enzyme (ACE) inhibitors in African Americans can be effective in treating heart failure (Yancy et al, 2004).

A study by Weir and colleagues (1998) also demonstrated that controlling for salt sensitivity affected response to two other classes of drugs (ACE inhibitors and calcium channel blockers). Calcium channel blockers are recommended second-line therapy for African Americans. African Americans who were salt sensitive had more lowering of blood pressure with isradipine (a calcium channel blocker) than with enalapril (also a calcium channel blocker). Therefore, differences appear to be not only between drug classes but also within them.

ACE inhibitors are also useful in treating hypertension, but African Americans appear to have less renin-dependent hypertension, and these drugs are less useful with that group. A study by Mitchell and colleagues (1997) confirmed racial differences in the renal hemodynamic response to chronic use of ACE inhibition that was independent of diuretic use and the magnitude of blood pressure lowering. More recent research into the use of ACE inhibitors in African Americans found that those homozygous for a variation at gene *G12269A* exhibited faster response to the ACE inhibitor Ramipril than those who were heterozygous (Bhatnagar et al, 2007). In this case, the authors are careful to stress that this area should be further researched before the information is utilized in clinical practice.

A serious adverse reaction to ACE inhibitors that contraindicates their use is angioedema. It is thought to be related to the reduced breakdown of bradykinin in patients taking this class of drugs. A study by Gainer, Nadeau, Ryder, and Brown (1996) concluded that African Americans show racial differences in the kallikrein-kinin system and are more sensitive to bradykinin, placing them at increased risk of ACE inhibitor–associated angioedema, independent of dose or concurrent drugs.

Diabetes mellitus has a higher prevalence in African Americans. The Bogalusa Heart Study Twentieth Anniversary Symposium (1995) suggested that elevated insulin levels observed in African American adolescents, especially girls, may be attributed to their decreased hepatic insulin clearance. This suggests consideration of drugs that affect hepatic insulin clearance (e.g., metformin [Glucophage]) for treating African Americans with type 2 diabetes. Stephens, Gillaspy, Clyne, Mejia, and Pollack (1990) also found racial differences in the incidence of end-stage renal disease associated with diabetes, which suggests that more aggressive management may be needed to prevent this complication.

Cryer and Feldman (1996) studied racial differences in gastric function between African Americans and whites. Gastric bicarbonate secretion was significantly higher in African Americans, making their gastric pH also higher. This might be a factor in the absorption of drugs that require highly acidic media for absorption. In the same study, mucosal biopsies demonstrated a much higher prevalence of *Helicobacter pylori* infection and chronic active superficial gastritis in African Americans. Even those who were negative for this infection had differences in gastric bicarbonate secretion.

As previously mentioned, African Americans are more likely to develop lung cancer when compared with European Americans (Haiman, et al., 2006). Berg, Mason, Boettcher, Hatsukami, and Murphy (2010) found that African Americans using a nicotine patch and abstaining from smoking metabolized nicotine differently from European Americans, as evidenced by lower urine excretion levels of nicotine and cotinine (a metabolic derivative of nicotine). This may have implications for African Americans who are quitting smoking using a nicotine patch.

Current biological evidence regarding psychotherapy agents points to decreasing the dosages of psychotropic medications and when possible prescribing atypical antypsychotics when formulating treatment plans for African American patients. In particular, Lawson (2008) describes that first-generation antipsychotics metabolized by the CYP450 2D6 isoenzyme show ethnic variation. African Americans (as well as European, Asian, and Hispanic Americans) demonstrate a reduced activity of this enzyme, which results in slower drug metabolism. Patients with this variation may experience increased extrapyramidal side effects when given a standard dose. Newer second-generation antipsychotic agents are not mainly metabolized through the CYP450 1A2 isoenzyme system, with CYP450 2D6 as a minor pathway. Thus, the adage of "start low, and go slow" applies to the treatment of African Americans when prescribing and choosing antipsychotics (Lawson, 2008).

Finally, a study by Carmel (1999) looked at racial differences in cobalamin and homocysteine levels between African Americans and whites. The study raised concern about potential underreporting and undertreatment of pernicious anemia because African Americans have significantly higher serum cobalamin levels than do whites. They also have significantly lower homocysteine levels, metabolize homocysteine more efficiently, and do not show the same benefit from vitamin therapy in treating this anemia. A further question raised related to the prescription of folate: "Given their lower rate of neural tube defects, possibly lower homocysteine levels, more efficient homocysteine metabolism, and lesser impact of vitamin therapy on it, does the untargeted promotion of high folate intake provide less benefit to blacks than to whites while exposing them to an equal risk for adverse effects because of unrecognized pernicious anemia?" (Carmel, 1999, p 90).

AMERICAN INDIAN/ALASKA NATIVE GROUPS

Cultural Factors

Demographics

American Indian and Alaska Native (AI/AN) peoples are a diverse group; more than 560 different tribes are recognized by the federal or state governments and, in addition, there are others that are not so recognized. Including individuals who identified as AI/AN in combination with another race, the U.S. Census in 2011 found that this group represents 1.6% of the population and that its numbers are increasing faster than the growth in the overall population (26.7% versus 9.7%, respectively) in part due to higher fertility rates than other racial/ethnic groups and living arrangements that include extended families (U.S. Census Bureau, 2012d). One problem in reporting the accurate size of the American Indian population is the tendency of this group to count members as part of an AI/AN tribal group by a blood quorum; that is, an individual must be at least a certain percentage American Indian or Alaska Native in order to be recorded and counted. Membership in the tribe would qualify the individual for health-care services provided by the Indian Health Service. Interracial marriages are also common, and the children are often documented as being of the race of the non-Indian parent. However, a shift toward recognition and taking pride in American Indian heritage has occurred (Purnell, 2013). The 2000 census permitted individuals to list more than one race, allowing children of mixed-race couples to avoid having to choose to be identified as one race or another.

As a group, the AI/AN are young (30.5% of the population is under the age of 18), undereducated (17.3% of those 25 years and older have a bachelor's degree or higher), and poorer than the rest of the U.S. population (median household income is $37,095, and 26.4% live below the federal poverty level (U.S. Census Bureau, 2012d). In addition, the AI/AN population is divided in residence, with 60% living in urban areas and fewer than a quarter living on the reservation and tribal lands (Office of Minority Health, 2012a).

Education and Employment

Over 81% of American Indian and Alaska Native adults (25 years of age or older) have at least a high school diploma or equivalency, 11.2% have a bachelor's degree, and 6.1% have achieved a graduate degree (U.S. Census Bureau, 2012d).

Overall, 17.3% of American Indians and Alaska Natives have a bachelor's degree or higher, compared with 34.5% of non-Hispanic white Americans (National Center for Education Statistics, 2012; U.S. Census Bureau, 2011b). In 2011, the unemployment rate among this population group was at 14.6%, the second-highest of any racial group in the United States (the highest being African Americans, unemployed at a rate of 15.8%, and significantly higher than the non-Hispanic white unemployment rate of 7.9%). The U.S. Department of Labor explains that higher levels of education tend to lead toward higher levels of employment for a racial group, which may help to explain the large unemployment rate among Native Americans and Alaska Natives (U.S. Department of Labor, 2012).

Family Relationships

The average American Indian family household has four to five members, making it the largest family size of any of the ethnic minority groups. Women head 25% of the households and the nuclear family is often comprised of extended relatives living under one roof, including relatives from both parental sides. Elder members usually assume leadership and decision-making roles. Some tribal groups are matriarchal while some are patriarchal, with the leadership and the health decision making coming from the sex that matches the leadership orientation, often with the help of spiritual leaders or medicine people (Purnell, 2013).

Many tribes have an established clan system whereby members of the tribe help to rear children, participate in general family life and customs of the tribe, and help make decisions for members of the clan. Marriage definitions in the AI/AN population may also not follow the traditions governing marriage and having children "out-of-wedlock" that exist in the predominant American culture. For example, 58.4% of births occur to women who have never been married versus 33.2% in the general population, yet these women may have a strong cultural identity and support from numerous clan members (National Healthy Marriage Resource Center, 2008). Prescribers should try to determine the unique histories, environments, and cultural beliefs of the specific tribal groups from which their patients originate in order to understand the family structure, decision making, and leadership style of AI/AN patients so as to ensure optimal treatment plans.

Health-Care Utilization

In 1824, the Bureau of Indian Affairs (BIA) was given the responsibility to "enhance the quality of life, to promote economic opportunity, and to carry out the responsibility to protect and improve the trust assets of American Indians, Indian tribes and Alaska Natives" (U.S. Department of the Interior, 2012, p 1). Numerous treaties, laws, Supreme Court decisions, and Executive Orders have assured the provision of health-care services for the 566 federally recognized tribes and their descendants.

Since 1954, the U.S. Department of Health, Education and Welfare, known today as the U.S. Department of Health and Human Services, has been responsible for providing no-cost comprehensive health-care services to American Indians and Alaska Natives under the direction of the Indian Health Service (IHS). Unfortunately, the IHS is severely underfunded when compared to other government health-care agencies. The IHS receives only $2,130 per person (pp) compared with $3,985/pp for the Bureau of Prisons, $5,010/pp for Medicaid, $5,234/pp for the Veterans Administration, and $7,631/pp for Medicare (Wilner, 2008). Approximately 70% of all members of the group who claim American Indian heritage receive IHS funded care.

Some tribes have chosen to take over the provision of health care from the IHS under the provisions of the 1975 Indian Self-Determination and Education Assistance Act, often because of the long-held deep suspicion of the federal government. In addition, only 22% of AI/AN live on the reservations or trust lands and an overwhelming 60% live in metropolitan areas away from IHS sites. Since 1972, the IHS has expanded its funding of health-related activities in off-reservation settings to help meet the needs of patients living away from reservations or trust lands. According to the IHS, 41% of AI/AN reported having private health insurance coverage, 36.7% relied on Medicaid coverage, and 29.2% had no health insurance coverage in 2010 (Office of Minority Health, 2012a); the percentage of non-Hispanic whites who had no health insurance in the same year was 16.3% (U.S. Census, 2013d).

Health Status and Other Biological Variables

Health disparities are prevalent in this minority group as demonstrated by the high rates of alcoholism (552% higher), diabetes (182% higher), unintentional injuries (138% higher), homicide (83% higher), and suicide (74% higher), when compared to the Caucasian population (IHS, 2013a, b). Among young males age 15–34, suicide is the second leading cause of death, which is 2.5 times higher than the national average for the same age group (CDC, 2012b). The infant mortality rate is 65% higher than that of whites, and the rate of sudden infant death syndrome is 2.4 times that of whites. Additionally, AI/AN infants have 2.3 times the rate of death from accidental injuries (MacDorman & Matthews, 2011).

These statistics ultimately influence the overall life expectancy of American Indians and Alaska Natives, which at 73.6 years is 4.1 years less than the overall U.S life expectancy for all races; life expectancy is 78.9 years for non-Hispanic whites (IHS, 2013a; Kaiser Family Foundation, 2013). Life expectancy within Arizona's American Indian population is 54.7 years (Wilner, 2008). The five top causes of mortality in 2009 were heart disease, cancer, injury, diabetes, and chronic liver disease/cirrhosis. Other causes, in descending order, are chronic lower respiratory diseases, cerebrovascular diseases, suicide, pneumonia and influenza, and kidney diseases (Kochanek, Xu, Murphy, Miniño, & Kung, 2011).

The higher a person's percentage of American Indian or Alaska Native genetic heritage, the more likely that individual is to manifest diabetes, almost exclusively type 2. The rate of type 2 diabetes is greatest in a subset of American Indians,

the Pima Indians (Knowles, Saad, Pettitt, Nelson, & Bennett, 1993). Within this group, research has shown that genetic variants in the *PYY-Y2R* pathway were correlated with obesity among full-heritage Pima Indian men, which may relate to the increased rate of diabetes in this group. (Ma et al, 2005). Additional research on Pima Indians and Old Order Amish patients found that two variants of the *MBL2* gene, which encodes for mannose-binding lectin, are associated with a higher risk for type 2 diabetes (Muller et al, 2010). As more research is done regarding genetics, obesity, and type 2 diabetes in the Indian population, there will be an ever-increasing level of evidence to guide the care of this population. In order to address this health disparity, Congress has allocated over $150 million to the Special Diabetes Program for Indians (SDPI). This program has had a huge impact in the improvement of diabetes health outcomes in the AI/AN population. One of the most important improvements was a 10.8% decrease in the mean hemoglobin A1c level of AI/AN diagnosed with diabetes, which has resulted in a 40% reduction in diabetes complications (IHS, 2013b).

Navajo Neuropathy is a fatal autosomal recessive genetic disorder present in the Navajo population. Those with the illness display weakness, metabolic acidosis, neuropathy, and liver failure (Hodgins & Hodgins, 2013). Karadimas and colleagues (2006) examined incidences of Navajo Neuropathy and found that a mutation on the *MPV17* gene is associated with disease development. The authors suggest that this finding can be used in genetic testing.

Lactose intolerance is very common among American Indians, with between 79% and 100% of the population affected (Giger, 2013; Swagerty, Walling, & Klein, 2002). The NIH (2010) explains that actual percentages are difficult to determine, as much of the present data relies solely on self-report. Further research needs to be done in this field to determine more accurate statistics as well as investigate the cause of the variance between this group and Northern European whites, who have an estimated lactose intolerance prevalence of 2% to 15% (Swagerty et al, 2002).

Alcohol abuse is also prevalent among American Indians (Hodgins & Hodgins, 2013). A 2003 study conducted by Wall, Carr, and Ehlers (2003) found the rate of alcoholism among Mission Indians to be 60%, with men being more affected than women (72% versus 53%, respectively). Of this population, the percentage of Native American heritage was found to be important—those with more than 50% Native American heritage were more likely to be alcoholic when compared to those with less than 50% heritage. Additionally, they found that certain variations of *ADH2*, a gene for alcohol dehydrogenase, was a protective factor for alcoholism.

The AI/AN population has a higher prevalence of current smoking rates than any other minority or racial group. Only 20.6% of whites in the United States smoke cigarettes, but 31.5% of AI/AN use tobacco products, with men engaging in smoking behaviors more often than women (34.4% versus 29.1%, respectively). Unfortunately, there has been no significant documented change in the prevalence of smoking among the AI/AN compared to among the non-Hispanic white and black populations (CDC, 2013c). Therefore, prescribers should focus on discussing proven evidence-based interventions aimed at tobacco cessation with this population.

Health Beliefs and Practices

Practitioners must understand that the AI/AN population is characterized by a wide variance in cultural values, beliefs, and practices; the environments that they live in; and their socio-economic circumstances. The AI/AN population's high-risk behaviors, such as alcoholism and higher smoking rates, may be due to alcohol metabolism issues and long-held sacred cultural traditions involving tobacco, which include the use of tobacco products for prayer, protection, respect, and healing (Cimino, Sayers, & Roods, 1999). For these populations, health is harmony with nature and oneself. Illness is disharmony and may be caused by a supernatural force or by violation of a restriction or prohibition. The illness is seen as an imbalance of mind, body, and spirit. Because the cause of the illness is external, illness-prevention practices that relate the cause of illness to the behavior of the patient are questioned. This is an interesting conflict, because self-control is considered to be a central attribute to maintaining harmony, and each person is accountable for his or her own health.

Many AI/AN maintain traditional beliefs regarding spiritual activities and their relationship to health (Giger, 2013). Traditional beliefs and Western medicine are often interwoven (Moghaddam & Momper, 2011). Western medicine is accepted but not seen as able to heal except when used in conjunction with native healing practices. Because the hospital is considered the place to die, the patient may resist hospitalization. Pain is supposed to be borne, so AI/AN may not request pain medication when needed. Practitioners should be mindful about educating the AI/AN community on the positive aspects of healing in regard to adequate pain control.

A belief in a Great Spirit pervades AI/AN views regarding life and their association in the natural world, where their focus is on the importance of balancing and achieving harmony with people, animals, plants, nature, weather, and supernatural forces (Giger, 2013). Giger (2013) describes an important philosophy among the Navajo called Blessing Way, a ceremonial song complex which attempts to restore harmony through stories, songs, rituals, prayers, symbols, and sand paintings. Medicine bags, which may contain medicine bundles—symbolic and sacral items such as corn pollen, feathers, stones, and arrowheads—and other instruments are used for healing and blessings. These bags may be worn or carried to protect a person from evil spirits or to promote wellness and harmony. The medicine person may also use negative powers, but only against the sick person's enemies. Native American/Alaska Native healing ceremonies that may include singing are often part of the healing ritual. Traditional care may be sought from a member of the family or a medicine man/woman who has the ability to use his or her powers of healing in conjunction with herbs and other rituals (Giger, 2013). Providers need to determine which herbal remedies a patient is using before prescribing modern medicines.

Racial Differences in Drug Pharmacokinetics and Response

Although a large portion of this ethnic group has health care provided by the U.S. Indian Health Service, little research has been done related to racial considerations in pharmacokinetics or other therapies. In the past, a few studies in the literature, which were found to be contradictory, were related to metabolism of alcohol (Bennion & Li, 1976; Chan, 1986). More recently, Gizer, Edenberg, Gilder, Wilhelmsen, and Ehlers (2011) investigated traits related to chromosome 4q near a cluster of alcohol dehydrogenase (ADH) genes. These genes encode enzymes of alcohol metabolism and may be responsible for variants in the *ADH1B* and *ADH4* genes, which may protect against the development of commonly seen symptoms associated with alcohol dependence in other ethnic/racial groups (Gizer et al, 2011). Another study, involving lipoproteins (Harris-Hooker & Sanford, 1994), reported that American Indians have a lower prevalence of coronary heart disease related to lower low-density lipoprotein (LDL) cholesterol and higher high-density lipoprotein (HDL) cholesterol levels. There may also be significant ethnic differences in the response to morphine in ventilated patients. Cepeda and colleagues (2001) found that despite higher levels of serum M6G levels in Caucasians, Native Indians were more susceptible to morphine depression of the ventilatory response than Caucasians. Providers should use caution when medicating this group to avoid an exaggerated response in the respiratory system.

Although research with the AI/AN groups has expanded since the last edition of this text, more research is needed to identify further racial/ethnic differences in drug pharmacokinetics in this ethnic group.

ASIAN AMERICANS

Cultural Factors

Demographics

The Asian cultural group is the most diverse of all the minority groups, encompassing over 50 distinct racial/ethnic subgroupings with over 30 different languages. Asians have many countries of origin (spanning East Asia, Southeast Asia, and South Asia), religious/spiritual affiliations, cultural backgrounds, health-care beliefs and practices, and immigration experiences. The top six Asian subgroups in the United States are Chinese, Filipino, Asian Indian, Vietnamese, Korean, and Japanese (U.S. Census Bureau, 2012c). In fact, in recognition of this diversity, the 2000 census divided this subgroup into two—one the "Asian American" group and the other the "Hawaiian and Other Pacific Islanders" group. Therefore, we discuss these two in separate sections in this edition of the text.

In the 2010 U.S. census, 5.6% of the population identified themselves as Asian, either alone or in combination with other races (U.S. Census Bureau, 2012a). This group includes people originating from the Far East, Southeast Asia, or the Indian subcontinent. The number of Asians, either alone or in combination with one or more other races, increased by 45.6% from 2000 to 2010 (U.S. Census, 2012b), and they have surpassed Hispanics as the fastest-growing ethnic minority immigrant group (PEW Research Center, 2013). This may be due to the changing national sociopolitical climate that has imposed more restrictions on southern border crossings and to changes in state laws (e.g., Arizona) that aim to verify the immigration status of Hispanics (PEW Research, 2010).

In the 2011 census study the median household income for those identifying as Asian American alone was $67,885, which is the highest of all minority groups in the United States, and the percentage of the population living in poverty was 12.8%, the lowest of all minority groups (U.S. Census Bureau, 2011b). However, as a reminder of the diversity of this group, the poverty levels ranged from low (among those of Indian, Japanese, and Filipino descent) to high (among those of Korean, Vietnamese, and Chinese descent). And although the averages give a positive picture, this group includes both extremes of health and socioeconomic indicators (PEW Research, 2012).

A high percentage (76.9%) of this population, age 5 and older, does not speak English at home, and large percentages are not fluent in English: 55% of Vietnamese, 46% of Chinese, 22% of Filipino, and 22% of Asian Indian (Pandya et al, 2011). Therefore, prescribers will need to have interpreter services available if their community has non-English–speaking Asian populations.

Education and Employment

Asian Americans as a group are better educated and better paid than the general U.S. population. The unemployment rate is lower than that of the general population and of each individual racial group, with 7% of Asians unemployed in the 2011 census, compared with an overall unemployment rate of 8.9% (U.S. Department of Labor, 2012a). About 49% were employed in managerial, professional, or other higher-paying jobs compared to 35% of white Americans (U.S. Department of Labor, 2012a).

In 2011, 85.1% of Asian American adults had at least a high school diploma, which is similar to the total population (85.9%), but 50% of Asian Americans compared to 28.5% of the total American population had at least a bachelor's degree. Additionally, 20.7% achieved a graduate degree or higher, compared with 10.6% of all Americans (U.S. Census Bureau, 2013a). These statistics demonstrate that as a whole, the Asian population is more affluent than other racial/ethnic minorities and in some instances may not be considered an at-risk group when they seek entry into higher education.

Family Relationships

Family relationships are strong, with extended (often multigenerational) families and an expectation of family loyalty from all members. Families are a source of strength. In Japanese families, the father is away from the home on business a great deal of the time, so the mother–eldest son relationship is very strong. Before the eldest son is of age, the mother is

the dominant person in the home. Both nuclear and extended families are involved in decision making. In all Asian American groups, males are more "valued" than females, females are submissive to males, and respect for elders is taught at an early age. Individuals' wishes and needs are subordinated to the needs of the group. Spector (2004) says that adherence to Buddhism, Confucianism, and Taoism leads these Asian American families to avoid admitting physical or mental illness. Conflicts are handled within the family, and there is kinship solidarity in which the individual is expected to seek the input of elders in the family and from kin.

Health-Care Utilization

Researchers have found that there are substantial differences by country of birth in health-care access and utilization among Asian Americans. Recent Asian immigrants are less likely to have health-care coverage, which may result in less frequent visits to health-care providers. Asian groups overall, however, are well insured, with only 15.4% of U.S. Asians uninsured in 2011 (U.S. Census Bureau, 2013a). Asian Americans over age 65 make about half as many visits to health-care providers as their non-Hispanic white counterparts (Ye, Mack, Fry-Johnson, & Parker, 2012).

Health Status and Other Biological Variables

As a homogenous group, the health status of Asian Americans as a whole is excellent. They have a longer life expectancy and lower death rates from all causes than does the general population (Asian women have a life expectancy of 85.5 years—the largest of any other racial/ethnic minority group) (Office of Minority Health, 2012b). The illnesses that are experienced at higher levels than those in the general population include tuberculosis, stomach/colorectal cancer (among Japanese), and suicide (among elderly Chinese women). Southeast Asian refugees have a higher incidence of intestinal parasites, tuberculosis, and presence of hepatitis B antigen and more anemia than other Asian Americans or the general population. Overall, the leading causes of death are cancer, heart disease, stroke, accidents, and diabetes. Asian Americans have the highest rate of TB of any cultural group and twice the rate of the hepatitis B virus than white Americans (although this is decreasing). Sudden infant death syndrome is the fourth leading cause of infant mortality. Asian Americans also have a high rate of chronic obstructive pulmonary disease (Office of Minority Health, 2012b; Purnell, 2013).

Although Asian Americans have the lowest percentage of smoking rates among all of the racial/ethnic groups, 9.9% versus 20.6% for non-Hispanic whites, there exist marked differences among Asian subgroups. Asians of Korean and Vietnamese descent have the highest smoking rates among all of the Asian subgroups, 26.6% and 21.5%, respectively. The lowest smoking rates among the Asian population are found in the Chinese (8.8%), Asian Indian (11.9%), Japanese (12.1%), and Filipino (16.7%) populations. Gender differences for smoking rates also exist among the Asian subgroup populations. Women of Asian Indian descent have the lowest smoking rates (3.5%) and Korean

women have the highest rates (20.1%). Among men, those of Chinese ancestry have the lowest smoking rates (13.9%) while Korean men continue to have some of the highest smoking rates (37.4%) (CDC, 2013c).

Also important to note is that pneumonia/influenza is the fourth leading cause of death among Asians aged 65 and over and that case rates for tuberculosis (TB) (25.8 cases per 100,000) are the highest among any other ethnic/minority group, with Asians having the highest percentage of new TB cases among foreign-born persons living in the United States. However, recent research suggests that Asians may have a genetic component that somehow reduces their risk of chronic obstructive pulmonary disease (COPD) regardless of their smoking habits. In fact, rates of COPD are low in mainland China even though approximately one-third of that population smokes. In the United States, Asians are 60% less likely to be hospitalized for COPD than non-Hispanic whites (American Lung Association, 2007). These data clearly show that more research to further explore these differences among the different ethnic/minority groups is needed. In addition, practitioners should screen the Asian population for TB to help slow the spread of the disease.

Health Beliefs and Practices

Health beliefs and practices vary among different Asian American subgroups. Chinese and Vietnamese people have a fatalistic attitude and believe that health is a result of forces that rule the world: yin (cold) and yang (hot). Illness results when there is an imbalance in these forces. Illness is diagnosed by pulses (there are seven different ones), color and texture of the tongue, and other means not commonly used by allopathic medicine. Treatment is provided with the opposing force to achieve balance. For example, a "cold" illness (e.g., colic, diarrhea, or edema) is treated with "hot" herbs and foods. "Hot" illnesses (e.g., hypertension, blood diseases, or a cough) are treated with "cold" herbs and foods. Healers within the group are skilled at diagnosis and prescription of therapy. Such therapy may include acupuncture, acupressure, tai chi, moxibustion, or medicinal herbs.

Chapter 10 discusses herbal therapy, with the important caveat that one must understand and subscribe to a totally different view of health and illness to prescribe these herbs appropriately. "Chi" is innate energy, and lack of it results in fatigue and long illnesses. Asians may call on their ancestors for help, and the Vietnamese may use cupping with a heated cup or glass jar that is placed on the skin to create a vacuum. This practice leaves bruising and may be misinterpreted in children as child abuse. Asian populations may believe that mental illness and physical disabilities should be hidden. Women usually seek care from female providers. Older clients may appear willing to comply with prescribed therapies but then don't follow them; their respect for the provider prohibits them from discussing their unwillingness to follow the regimen.

Japanese beliefs are influenced by Shinto, a religious orientation. They believe that humans are inherently good and that evil is caused by outside spirits. Both Japanese and Vietnamese

people believe that pleasing good spirits and avoiding evil ones help to maintain harmony and health. Evil is removed by purification rituals. Mental illness is taboo and often translates into acceptable somatic symptoms, and addictions are shameful (Purnell, 2013). Alcoholism and family violence are hidden but serious problems.

Filipinos also subscribe to the concept of yin and yang but believe that God's will and supernatural forces govern the universe and determine health and illness. Illness is punishment for violations of God's will. Amulets and religious medals may be worn as a shield from witchcraft or as a good-luck charm. Filipinos often engage in healing rituals and may perform sacrifices. The "evil eye" may be considered the reason for illness in infants and children. Filipinos are the most likely of the Asian American groups to be obese. They have high alcohol consumption and smoking rates.

All of these groups use combinations of allopathic and ethnically defined health and illness care. The allopathic approach, however, is often chosen last or to supplement ethnically defined care. In a study of college students who identified themselves as having an Asian or European background, Asian students had more negative views of medications than European students. Asian students were more likely to view medicines as "intrinsically harmful, addictive substances" and were less likely to believe in the benefits of modern medicine. All the students viewed taking prescribed medications more favorably if they had taken prescribed medications before (Horne et al, 2004, p 1307).

Racial Differences in Drug Pharmacokinetics and Response

Bertilsson (1995) first compared Asian Americans and whites on the basis of drug metabolism by the CYP450 2D6 and 2C19 isoenzyme systems. The CYP 2D6 isoenzyme system is responsible for metabolism of antiarrhythmics, antidepressants, and neuroleptics, among others. The mean activity of CYP 2D6 extensive metabolizers is lower in Asians and is the molecular genetic basis for slower metabolism of antidepressants and neuroleptics in Asians. This difference in metabolism requires lower doses of these drugs. The CYP 2C19 system is involved in the metabolism of acids (e.g., mephenytoin), bases (e.g., imipramine and omeprazole), and neutral drugs (e.g., diazepam). Diazepam (Valium) is partially demethylated by CYP 2C19, and the high frequency of mutated alleles in Asians is probably the reason that such populations have slower metabolism and are treated with lower doses of diazepam than are whites. Although other drugs in this same class have not been studied, it is likely that they have similar metabolic fates as diazepam. Omeprazole (Prilosec) is hydroxylated to a major extent by CYP 2C19, and there is an approximately 4-fold difference in oral clearance between Asians and whites. Hence, a lower dose for this drug is required for Asians (Vaz-da-Silva et al, 2005). Interestingly, when treating *H. pylori* in Chinese patients, success of a triple-drug therapy using a regimen of either esomeprazole or rabeprazole was not related to differences in the CYP2C19 gene (Lee et al, 2010).

Brooks, Enoch, Goldman, Li, and Yokoyama (2009) explained that those of East Asian descent (Japanese, Chinese, and Korean) have a propensity toward an aldehyde dehydrogenase-2 (ALDH2) deficiency, causing a "flush" to occur after drinking alcohol. This may occur despite the amount of alcohol ingested being minimal (O'Hara & Zhan, 2004). Chan (1986) also reported this "atypical" dehydrogenase, which he stated is present in 85% to 90% of Asian Americans. The deficiency in ALDH2 is caused by a genetic variance in the ALDH2 gene and can increase the patient's risk for developing esophogeal cancer (Brooks et al, 2009).

O'Hara and Zhan state that Asians have also been described as "fast acetylators." Recent studies have determined that Asian subgroups that originate in eastern Asia (Bangladesh, Thailand, Malaysia, China, Hong Kong, Korea, and Japan) have a higher percentage of fast acetylators than those from western Asia (Turkey, Russia, and Saudi Arabia). Researchers have determined an East–West geographic longitude, termed the Asian "fast acetylator longitude," that allows for prediction of acetylator status (Zaid et al, 2004). Hepatic acetylation is responsible for metabolism of many drugs, including cardiac and psychotropic drugs, and 78% to 93% of Asians are "fast acetylators" (Lin, Poland, Smith, Strickland, & Mendoza, 1991). This faster metabolism may require a more frequent or higher dose of drugs metabolized by acetylation to achieve efficacy.

Warfarin, a common anticoagulant, has a narrow window of therapeutic efficacy—too high a dose can cause excess bleeding, and too low a dose will not be effective as an anticoagulant. Moyer and colleagues (2009) conducted a literature review of articles exploring the genetic foundations of warfarin sensitivity. They found that among the two genes associated with sensitivity, Asians had a lower incidence of variance of the CYP 2C9 gene and increased variance of the *VKORC1* gene when compared to whites. The decrease in CYP 2C9 variance indicates a more "normal" warfarin metabolism, whereas the increase in *VKORC1* variance can mean an increased or a decreased sensitivity to warfarin (depending on the allele). A similar study found that a high occurrence of *VKORC1* variance led to prescribing lower doses of warfarin to achieve optimal results in Chinese patients when compared to New Zealand Europeans (Gladding et al, 2010).

For almost 50 years researchers have been aware of racial differences in response to antipsychotic drugs (Frackiewicz et al, 1997). An extensive review by Arranz and de Leon (2007) indicates Han Chinese may have enhanced response to atypical antipsychotics (risperdone) and no difference from Caucasians in their response to clozapine. Lee, Yang, and Hu (1998) found a lack of racial differences in lithium pharmacokinetics between Taiwanese Chinese bipolar patients and whites. In a study of antidepressant use, ethnic Chinese required significantly lower doses of sertraline (Zoloft) to achieve clinical efficacy than white patients (Hong Ng et al, 2006). "Despite controlling for weight, gender and dietary factors (alcohol, nicotine and caffeine) because of their possible influence on the metabolism of sertraline, the difference observed between ethnic groups remained statistically significant [$F(2,34) = 4.15$, $P < 0.05$]" (Hong Ng et al,

2006). These studies may indicate that atypical antipsychotics and selective serotonin reuptake inhibitors need to be dosed lower in Asian patients. Filipinos require lower doses of dopaminergics (levodopa) than do whites, and they develop dyskinesia more readily at comparable doses. This difference appears to be related to racial differences in erythrocyte catechol-o-methyltransferase (Rivera-Calimlim & Reilly, 1984).

Studies regarding the impact of pharmacogenetics on hypertension and response to antihypertensives were first published 20 years ago. In comparing Asian American children with African American, Hispanic, and white children, Liu and Levinson (1996) found a higher prevalence of elevated blood pressure in Asian Americans. Early studies supported the need for lower doses of beta-adrenergic blockers in Asians (Hui & Pasic, 1997; Matthews, 1995) and also ACE inhibitors and calcium channel blockers (Hui & Pasic, 1997), based in part on increased adverse drug reactions at doses used for whites. For example, Asian populations have an increased risk of a coughing side effect from angiotensin-converting enzyme inhibitors (Dikewicz, 2004). Interestingly, valsartan, an angiotensin II receptor blocker (ARB), has been shown to be equivalent to ACE inhibitor use in Indonesian and Taiwanese patients with hypertension (Black, Bailey, Zappe, & Samuel, 2009). Pharmacogenomic influences on the effectiveness of antihypertensive medications has become a focus of research in order to determine ethnic and individual response to medications (Johnson, 2010).

After organ transplant, patients are often given immunosuppressant medications to prevent organ rejection. One such medication is tacrolimus, a calcineurin inhibitor, which is metabolized by the protein products of the CYP 3A enzyme gene. Two single-neucleotide polymorphisms (SNPs) within CYP 3A, CYP 3A4*18B and CYP 3A5*3, are common in the Asian population. Among Chinese men, a combined genotype of CYP 3A4*1/*1- 9CYP3A5*3/*3 was associated with a change in the pharmacokinetics of tacrolimus (Shi et al, 2011). Patients with this genotype "may require lower [tacrolimus] doses to achieve target concentration levels" (Shi et al, 2011, p 621).

Of note is the fact there are ethnic differences among the Asian populations and ethnic minorities within the major Asian groups, with each having their own pharmacogenomic variant. For example, the Kyrgyz population in northwest China has three important pharmacogenetic variants from the Han Chinese, which are the majority ethnic group in China (Yunus et al., 2013). The drug-metabolizing enzyme activity of the Vietnamese differs from the Chinese (*CYP2A6*4* and *CYP2A6*5* differ), Koreans (*CYP2A6*5* and *CYP2A6*6*), Japanese (*CYP2A6*6*), and Malaysians (*CYP2A6*5*) (Viega et al, 2009).

NATIVE HAWAIIAN AND PACIFIC ISLANDERS

Cultural Factors

Demographics

According to the 2010 U.S. Census, the Native Hawaiian and Pacific Islander (NH/PI) population alone and in combination has seen incredible growth and has surpassed the rate of growth of the U.S. population by over 3 times, increasing by 35% from 399,000 to 540,000. This growth is especially evident for the NH/PI combination population rates because more than half (56%) of the NH/PI population declared a mixed combination with other racial groups, making up 0.4% of the total U.S. population. This is the second-fastest-growing racial group in the country after the Asian-alone or Asian-combination population. In addition, the NH/PI population is relatively young: 30% of NH/PI are under the age of 18 versus 23.5% of the U.S. population (U.S. Census Bureau, 2012e). The NH/PI population describes a wide array of people and customs whose origins may be Native Hawaiian, Guamanian or Chamorro, Samoan, or other Pacific Islander; Polynesian, such as Tahitian, Tongan, and Tokelauan; Micronesian, such as Marshallese, Palauan, and Chuukese; and Melanesian, such as Fijian, Guinean, and Solomon Islander.

The rulers of the Hawaiian islands were overthrown by a coup d'etat and the islands were subsequently annexed as a U.S. territory at the turn of the 20th century; Hawaii eventually became a state in 1959. It is important to note that although NH/PI originate from native lands, NH/PI have not been granted the same reparations, assistance, or group rights that have been afforded to other groups like American Indians and Alaska Natives and thus have significant health disparities.

Although traditionally the largest proportion of the NH/PI population has resided in the West (over 52% live in Hawaii and California), other parts of the United States have seen a tremendous growth in this population, particularly in the South and several Western states. In the southern states of Arkansas, Alabama, Delaware, North Carolina, Tennessee, Florida, Texas, Kentucky, Georgia, Oklahoma, Maryland, South Carolina, Virginia, and Louisiana, the NH/PI population grew by more than 50%. In the West, states such as Nevada, Alaska, Arizona, Idaho, Wyoming, Utah, Washington, Oregon, Montana, and New Mexico have also seen a 50% growth in the NH/PI population (U.S. Census Bureau, 2012e). Other localities that showed rapid growth include the District of Columbia, with a 68% growth rate, and counties in northern Alabama and northwest Arkansas, northern Utah, southern Nevada, Arizona, northern Georgia, Tennessee, North Carolina, and parts of Maryland, Virginia, and Texas, all of which experienced rapid growth of the NH/PI population (U.S. Census Bureau, 2012e).

There are significant economic disparities that must be addressed when formulating treatment plans for the NH/PI population. In 2011, the NH/PI poverty rate was 21.5% and the median income was $49,378, versus 13% and $55,305, respectively, for the non-Hispanic white population (U.S. Census Bureau, 2012e).

Education and Employment

The NH/PI attainment of a high school degree is similar to that of the non-Hispanic white population (85.1% versus 85.9%). However, only half continue on to college (14.5% versus 28.5%) or complete bachelor's degrees, and even fewer,

4.3%, of NH/PI, have completed a graduate/professional degree (versus 10.6% of non-Hispanic whites).

The average NH/PI family median income was $59,521 in 2010, versus $67,892 for non-Hispanic white families in the mainland United States, and 17% of NH/PI families, in comparison to 10.6% of non-Hispanic whites, were living at the poverty level during the 2010 census (Office of Minority Health, 2012c). The unemployment rate for this population in 2012 was 14%, considerably higher than the 7.9% rate for the non-Hispanic white population and 8.9% for the whole United States (U.S. Census Bureau, 2011a; U.S. Department of Labor, 2012a).

Family Relationships

The average family size for Hawaiian/Pacific Islanders is four and its organization is matriarchal with a belief in placing children in a position of prominence within the family (Liu & Almeda, 2011). Although there exists much diversity within the NH/PI populations in terms of family relationships, research describes four key pan-family values, beliefs, and practices that are commonly found in family practices across NH/PI subgroups.

The family interdependence is of utmost importance when forming a caring relationship with a patient from a NH/PI group. This interdependence is based on collectivism, relational orientation, familism, and family obligation. Collectivism is described as a predisposition to place group goals above those of the individual; relational orientation is defining the self as interdependent with others in the family unit; familism describes a family hierarchical system that includes extended family members as the basic social unit; and family obligation includes attitudes and behaviors expected of children. Children are expected to show respect and affection for older family members; seek their advice on important matters and accept their decisions; and maintain physical proximity, kinship, psychological and financial assistance, and emotional ties with parents, native Hawaiian elders (called *na kapuna*), and the extended family across the life span. These four cultural values, beliefs, and practices should influence the development of treatment plans that are culturally congruent with the NH/PI beliefs surrounding family relationships (Browne, Mokuau, & Braun, 2009; Yee, Debaryshe, Yuen, Kim, & McCubbin, 2013).

Health-Care Utilization

Data in the research literature on Native Hawaiian and Pacific Islanders is often limited due to a tendency to group this population with Asians and Pacific Islanders. Here we have attempted to distinguish among these groups because they often have different patterns of health risk and should not be viewed as homogeneous. For example, the Asian and Pacific Islander group's life expectancy is often reported as 80.3 years for the group as a whole (a level that is over 5 years higher than that of the total U.S. population), and this statistic includes the Japanese subgroup, which has one of the highest life expectancy rates—82.1 years (Kaiser Family Foundation,

2013). However, Native Hawaiians have one of the lowest life expectancy rates—68.3 years. For this reason, we have decided to treat this group separately from the Asian group in this edition.

Johnson, Oyama, LeMarchand, and Wilkens (2004) note that native Hawaiians die younger than Hawaiian residents of other ethnic groups. For example, in 2000, the age-adjusted death rates for Native Hawaiians due to heart disease, cancers, strokes, and diabetes were higher than for the general population in the state of Hawaii as a whole. In particular, diabetes age-adjusted death rates per 100,000 persons for the state of Hawaii were 16.3 versus 38.0 for Native Hawaiians and 155.8 versus 208.6 per 100,000 for cancer. McCubbin and Antonio (2012) state that the native Hawaiian population continues to have the highest rates of morbidity and mortality and chronic health conditions such as hypertension, diabetes, and asthma than other ethnic groups and have higher rates of smoking and drinking and more risk factors, such as overweight and obesity (Johnson et al, 2004).

Native Hawaiian children and adolescents also face significant health disparities: exposure to prenatal alcohol and tobacco use, late or no prenatal care, macrosomia as well as low birth rates, low rates of exclusive breastfeeding at 6 months, high rates of infant mortality, and high rates of obesity and physical, mental and sexual abuse (Liu & Almeda, 2011).

The leading causes of death in American Samoa, Guam, and the Federated States of Micronesia are similar to those in the United States, but patients must often travel long distances to Hawaii to obtain adequate treatment (Tseng, Omphroy, Cruz, Naval, & Haddock, 2004). The Pacific islands affiliated with the United States, such as Guam, have reported an increase in the number of chronic diseases. For example, diabetes was diagnosed in 9.1% of the population of Guam in 2009 (Ichiho, Gillan, & Aitaoto, 2013). Ichiho and colleagues describe risk factors for the leading causes of death in Guam (heart disease, cancer, and cerebrovascular accidents) to include poor diet, lack of physical activity, and lifestyle behaviors that are associated with overweight and obesity. These authors contend that significant advancements and the development of a territory-wide health plan and standards of care are needed to help address the prevention and control of such diseases.

Other areas in the Pacific, such as the Republic of Palau, reported cardiac arrest and respiratory arrest as the leading causes of death (Wong, Taoka, Kuartei, Demei, & Soaladaob, 2004), and in the Marshall Islands the leading cause of death was sepsis (Kroon, 2004).

Health Status and Other Biological Variations

There is limited data on the health status of Native Hawaiians and Pacific Islanders alone because many studies have small sample sizes and often include this group in a category labeled "Other Races," or results are often presented in conjunction with the Asian and the Native American group (American Lung Association, 2007). The NH/PI population has the second-highest tuberculosis rate after the Asian population

(15.9 per 100,000). In 2007, the TB rate was 21 times higher than that for white teenagers (American Lung Association, 2007; Office of Minority Health, 2012c). This population also has a high infant mortality rate.

Health Beliefs and Practices

In the Polynesian cultures, a Hawaiian philosophy called *Huna* is an important concept. One of the tenets of *Huna* is the seeking of harmony, love, and positive energy flow. The energy flow is believed to tap into the Universal Power that the Hawaiians call *mana*. The secret for attaining true health, happiness, prosperity, and success is the loving use of the power of *mana*. One of the ways that this can be achieved is through a Hawaiian massage, *lomi lomi*, that is delivered by a trained traditional healer. *Lomi lomi* is performed in a rhythmic and fluid motion that uses the practitioner's forearms as well as the hands to change the energy toward a positive flow. *Lomi lomi* is sometimes described as feeling like gentle waves moving over the body and is meant to relieve stress, stimulate blood and lymph flow, and assist in the elimination of wastes in the body (Lakainapali, 2013).

The cause of illness may be attributed to the stress of anger, guilt, recriminations, and lack of forgiveness. Families and individuals are encouraged to participate in *Ho'oponopono*, an ancient Hawaiian practice that leads to forgiveness and reconciliation. In other Polynesian cultures, illness may be attributed to a person's mistakes or errors, which may anger the gods. *Ho'oponopono* are family conferences in which interpersonal family relationships can be corrected through prayer, discussion, confession, repentance, and mutual restitution and forgiveness (Lakainapali, 2013).

The Native Hawaiian family, *'ohana*, is the core social unit within which the individual lives and interacts. It should be taken into account during the health-care transaction in order to aid NH/PI patients to meet their health-care goals (McGregor et al, 2003).

Racial Differences in Drug Pharmacokinetics and Response

Much current research on racial differences in pharmacokinetics has combined the Asian and NH/PI groups. However, Gladding and colleagues (2010) found in studying warfarin dosage in Chinese patients separately from Pacific Islanders that Chinese patients required lower doses of warfarin to achieve optimal results when compared to New Zealand Europeans and that Pacific Islanders had very few variants along the *CYP2C9* gene, requiring higher doses of warfarin (see Asian American section for further discussion of warfarin genetic variants).

HISPANIC AMERICANS

Cultural Factors

Demographics

The federal government considers race and ethnicity to be two separate constructs. Therefore, an individual can be of any race and self-identify as Hispanic. Individuals of Hispanic descent are not a homogeneous group. In fact, the group includes individuals who can trace their heritage to over 20 different Spanish-speaking countries of origin worldwide (Lopez, Gonzales-Barrera, & Cuddington, 2013). Hispanics are the largest minority group and make up 16.3% of the U.S. population (U.S. Census Bureau, 2010a), a figure that does not include the over 4 million residents of Puerto Rico. The Hispanic population is projected to more than double by 2060, from 53.3 million in 2012 to 128.8 million (U.S. Census Bureau, 2012a).

The majority of the Hispanic population is born in the United States (62.9%); only 37.1% is foreign-born, a 3% decrease since 2000 (PEW Research, 2012) that may be due to tougher border-crossing laws and enforcement of laws requiring official documents to cross the U.S. border. Although in 2008 the State Department implemented the use of passport cards, which are a less expensive and a more portable alternative to a passport for border crossings, the cards may still be a considerable expense for large Hispanic families, and some families may not qualify due to their undocumented status. Although the cards offer a lower-cost alternative to the traditional passport ($110), each card may cost from $40 to $55 for children and adults, respectively (U.S. Passport Cards, 2012).

In the United States, Hispanics include those of Mexican descent (63%), Puerto Ricans (9.2%), Cubans (3.5%), and people from Central and South America (CDC, 2012). The Hispanic population as a group is young, with 37.1% under age 20 compared to 22.4% for whites (U.S. Census Bureau, 2012a). Many Hispanic Americans live in the southwestern states, with over 50% living in California, Florida, and Texas (U.S. Census Bureau, 2010a). According to Lopez (2014), by March 2014, California will become the second state (behind New Mexico) where the Hispanic population is projected to become a plurality, meaning not that they are more than half of the population but make up the largest percentage of any other racial/ethnic group, surpassing the non-Hispanic white population.

Much heated debate has occurred recently regarding the unauthorized immigrant population in the United States. The majority (58%) of the 11.2 million unauthorized immigrants in 2010 were from Mexico. Of this population, approximately 5.5 million are children of unauthorized immigrants; 1 million of these children are foreign-born and 4.5 million are U.S.-born. It is important to note that the population of U.S.-born Hispanic children more than doubled from 2.1 million in 2000 (PEW, 2011).

Education and Employment

Hispanic subgroups differ in terms of socioeconomic data. For example, Hispanics of Mexican origin have a drastically lower college attainment rate (8%) than Hispanics from Cuba and South America (30% and 28%, respectively) (National Center for Education Statistics, 2010). As well, prescribers should be aware that there may be differences between U.S.-born Hispanics and Hispanic immigrants and Hispanic immigrants from different countries of origin. Hispanic patients may also

display diverse levels of acculturation, even within the same family unit (Askim-Lovseth & Aldana, 2010). These factors add to the complexity of understanding and making treatment recommendations for this group.

Hispanics as a whole have lower socioeconomic status than that of the predominant white population. For example, as a group, the median household income in 2011 was $39,589 (compared to $55,305 for non-Hispanic whites), and the percentage of families below the poverty line was 25.8% compared to 11% for non-Hispanic whites. However, not all Hispanic subgroups have the same socioeconomic risk factors. For example, the national poverty rates ranged from a low of 16.2% for Cubans to a high of 26.3% for Dominicans. Among Hispanics, 74.3% of those age 5 and older spoke Spanish at home in 2011 (U.S. Census Bureau, 2011b).

In 2007, 61% of Hispanic adults compared to 89% of the total population had a high school education, 12.5% of Hispanic adults compared to 30.5% of the total population had at least a bachelor's degree, and 3.8% had advanced degrees (Office of Minority Health, 2013a). The unemployment rate for Hispanics in 2011 was 11.5%, the second-highest unemployment rate after African Americans. Within Hispanic subgroups, the unemployment rate for Hispanics from Puerto Rico was the highest (14.1%) and the rate for Cubans was slightly lower than the overall average (U.S. Department of Labor, 2012b). This statistic may not accurately reflect the migrant farm worker population nor the undocumented workers currently living in the United States, who do not qualify for unemployment benefits (U.S. Department of Labor, 2006).

Family Relationships

Familismo, the social structure in which the needs of the family as a group are viewed as more important than the needs of an individual family member, is the predominant social structure among Hispanic families. Strong kinship bonds often extend outside blood and marriage lines and include godparents, called *padrinos/compadres*, who are often established by ritual kinship. Thus, the family roles and titles of brother, sister, aunt, and uncle may not necessarily designate a true blood relative (Purnell, 2013). Hispanic families are often larger (average household size is 3.53 versus 2.55 for non-Hispanic whites) and made up of extended family members (U.S. Census Bureau, 2010b). Higher household size is due to higher fertility rates, continued migration, and the presence of other family members living in the home. This arrangement increases the resources that are available to benefit the family as a whole and serves as a major source of support in helping families mitigate socioeconomic stressors through the pooling of limited individual resources (Purnell, 2013).

Respect for parents and elders is taught early. Family is the major source of support for all its members and food is used to maintain family ties. There is respect for the elderly and infirm and for collective rather than individual achievement (Giger & Davidhizar, 2008). Religious leaders are also a source of support. Males and females have clearly differentiated roles. The father is the main decision maker in the family, but

women, who are considered the primary healers in the group, decide health-related issues and provide health advice and remedies. Native healers (*curanderas/curanderos*) may be women or men (Giger, 2013; Purnell, 2013).

Health-Care Utilization

The combination of unemployment and undocumented workers means that this group has the highest percentage of people without health insurance (between 30% and 33% in 2008) and therefore lacks access to preventive care and health promotion (National Center for Health Statistics, 2010). Public health clinics and emergency departments are often used as the sites for primary health care.

Contrary to public belief, foreign-born Hispanics (specifically, the undocumented sector of the population) utilize fewer medical services and contribute less to health-care costs than the U.S.-born Hispanic population (Goldman, Smith, & Sood, 2006). Researchers attribute this to the Hispanic paradox, in which the foreign-born Hispanic population shares a better health status than the U.S.-born population despite having socioeconomic risk factors similar to those of other racial/ethnic groups and no health insurance (Goldman, Smith, & Sood). Recent debates in Washington, DC, have focused on undocumented, foreign-born Hispanic immigrants. However, empirical research does not support the case being made for the fiscal liabilities of providing care to this population. Researchers (Goldman, Smith & Sood; Hunt, Schneider, & Comer, 2004) have called for a dialogue on immigration that is based on empirical facts and looks at all sides of the immigration question, including both the positive and negative benefits of our mainly Hispanic immigrant population.

Health Status and Other Biological Variations

The National Center for Health Statistics (2008) data indicate that in 2008, 9.5% of Hispanics/Latinos were reported to be in fair or poor health. Obesity is a significant problem in the Hispanic population, with 69% of women and 70% of men over age 20 self-reporting as being overweight (National Center for Health Statistics, 2006b). Obtaining accurate health statistics on Hispanics is difficult because their data are often included with those of whites or go unreported owing to an undocumented status.

According to a National Health Interview Survey performed by the U.S. Department of Health and Human Services (2011), 11.8% of adults who identified as Hispanic reported having diabetes, which is greater than the 7.1% in adults who identified as non-Hispanic white. Specifically, Mexican adults reported having diabetes at a rate of 13.4%. Haffner and colleagues (1996), working with data from the Insulin Resistance Atherosclerosis Study (IRAS), studied racial differences in insulin resistance and insulin secretion and found that Hispanic patients had higher levels of insulin resistance and lower levels of insulin sensitivity when compared to non-Hispanic white patients. More recently, Hispanic Americans were found to demonstrate less insulin secretion yet be more insulin sensitive when compared with African Americans (Palmer et al, 2008).

Like African Americans, Hispanic patients experience pain differently than their non-Hispanic white counterparts. Rahim-Williams and colleagues (2007) found that both racial groups had lower levels of tolerance for contact heat and cold pain; however, there was no difference between minority and non-Hispanic white populations' tolerance of ischemic pain. Additionally, there was no difference in pain threshold for any of the three measures.

The leading causes of mortality for Hispanics are cardiovascular disease, cancer, accidents, stroke, and diabetes (CDC, 2008). Hispanics have higher rates of obesity; in 2006–2008, the age-adjusted estimated prevalence of obesity in Hispanic adults overall was 28.7% (versus 35.7% among non-Hispanic blacks and 23.7% for non-Hispanic whites). The obesity and overweight problem is also noted among Hispanic children. According to Singh and Kogan (2010), from 2006 to 2008, 43.3% of Hispanic children ages 6 to 17 were overweight (versus 39.6% of non-Hispanic blacks and 34% of non-Hispanic white children). Obesity rates are also highest among the Hispanic group, at 23.9%, versus 23.5% and 17.9% for non-Hispanic blacks and non-Hispanic whites, respectively. These data can have implications for metabolism and absorption of certain drugs.

The majority of Hispanics identify with the Roman Catholic Church. During an illness, Hispanic patients may use prayer, lighting of candles, and visiting shrines in order to influence a positive outcome (Giger, 2013). Even though there may be a strong religious tradition and connection with the Church, foreign-born Hispanics may choose to use contraception, but methods that are often less reliable, such as the rhythm method and condoms (Rocca & Harper, 2012), instead of more permanent methods, such as female sterilization, which Shih, Vittinghoff, Steinauer, and Dehlendorf (2011) found were used more often among U.S.-born Hispanics in California. However, Rocca and Harper (2012) state that this is due to lack of education regarding effectiveness rates among methods rather than religious beliefs. These data may have an influence on the higher birth and fertility rates seen among this population. In 2011, the birth rate for Central and South Americans was the highest of all Hispanic subgroups at 23 per 1,000 births, followed by Mexican (16.9), Puerto Rican (13.7), and Cuban (9.1) rates (per 1,000 births). In comparison, the non-Hispanic white birth rate was 10.7 and the black rate was 14.6 per 1,000 births (Martin, Hamilton, Osterman, Curtin, & Mathews, 2013).

Other health disparities include an increase in HIV/AIDS and the highest rate of diabetes among Puerto Ricans; a low rate of individuals who receive the flu vaccine; and more than twice the death rate from asthma than is seen in whites (CDC, 2008). Many pregnant Hispanic women do not seek prenatal care until late in their pregnancy; however, the rate of low birth weight is lower than that of whites except for a high rate among Puerto Ricans (OMH, 2010). Puerto Ricans also have low rates of prostate and breast cancer but a high rate of stomach and liver cancer.

Health disparities exist even within the Hispanic ethnic group. For example, 16.6% of Puerto Ricans suffer from asthma while only 4.9% of Hispanics of Mexican origin do (compared to 7.8% for non-Hispanic whites) (Akinbami et al, 2011). In the area of asthma prevention education, the data demonstrate that Hispanics of Mexican origin are least likely to have been given an asthma management plan, taught how to recognize early signs and symptoms of an asthma episode, advised on environmental controls, and taught how to properly respond to an asthma exacerbation (Akinbami et al, 2011). These data support the need for continued teaching by all health-care providers regarding known asthma education and management strategies that have been proven to decrease asthma morbidity and mortality.

Health Beliefs and Practices

The continued use of traditional medicine/folk medicine and traditional folk practitioners (*curanderos/curanderas*) is one of the most important variables leading to underutilization of Western medical care by many groups, including Hispanics (Ericksen, 2006). Patients may choose these traditional practices because they are often more accessible and affordable and have been used for many generations; patients also believe that traditional medicine and treatments are somehow gentler on the body (World Health Organization, 2002).

The prevalence of traditional medicine/complementary and alternative medicine (TM/CAM) has been documented to vary from 50% to 90% (Ortiz, Shields, Clauson, & Clay, 2010). Several studies have documented TM/CAM practices used by all subgroups of Hispanics, among which are medicinal herbs/teas (Factor-Litvak, Cushman, Kronenberg, Wade, & Kalmuss, 2001; Kronenberg, et al, 2006; Lagana, 2003); spiritual healing, religion, and prayer modalities and other traditional remedies (Palinkas & Kabongo, 2000; Upchurch & Chyu, 2005; Upchurch, et al, 2007); and visits to nutritionists and chiropractors (Factor-Litvak, Cushman, Kronenberg, Wade, & Kalmuss, 2001) . Several modalities of TM/CAM may be unfamiliar to prescribers. Ortiz, Shields, Clauson, and Clay (2010) report several studies described linden, sapodilla, and star anise as commonly used.

Hispanics are also more likely to engage in prayer as a form of TC/CAM, especially when feeling frustrated by lack of information regarding their disease processes and treatment options (Reyes-Ortiz, Rodriguez, & Markides, 2009). Prescribers should be prepared to ask Hispanic patients if they are engaging in TM/CAM practices and attempt to adequately assess for any potential drug interactions with other substances the patient may be taking or applying.

At the time that Spain was settling the New World, Spanish medicine was grounded in the humoral beliefs, that is, that the body was made up of four fluids: blood, phlegm, yellow bile, and black bile. These humors were further subdivided into the dualities of "wet and dry" and "hot and cold," which are classifications still used by many Hispanics to describe illness and wellness (Avila & Parker, 1999; Galanti, 2003). Diseases and illnesses, which can result from an imbalance of these forces, are either hot or cold and need to be treated with these concepts in mind. Illness may also be caused by several

cultural ideas, such as *envidia* (jealousy), *mal ojo* (evil eye), *mal aire* (bad air), *nervios* (restlessness/anxiety), *caida de mollera* (fallen fontanel), and *susto* (magical freight), that can affect patients with physiological and/or psychological symptoms that vary in intensity and can be severe and life-threatening (Giger, 2013). For example, *caida de mollera* (fallen fontanel) may signal severe dehydration in an infant and requires medical treatment, and *mal ojo* (evil eye) is believed to be a condition that affects infants and children as a result of an individual thought to possess special powers who purposefully or involuntarily causes an illness by looking at or admiring but not touching a child. Practitioners can avoid being considered as inadvertently causing *mal ojo* by touching the child during the health-care visit (Giger, 2013). However, health-care providers can still be suspected of giving this look inadvertently. Although, several recently published texts (Giger, 2013; Romero, 2008) continue to state that these beliefs are common among the Hispanic population, providers should understand that few current empirical research studies give credence to their continuation among the Hispanic population living in the United States; also the beliefs may differ based on the acculturation level of the individual.

Health beliefs often have a strong religious association, with health being a gift from God as a reward for good behavior. Eating proper foods, working the proper amount of time, wearing religious medals, and sleeping with relics in the home are thought to prevent illness. Hispanics typically consult both traditional healers and allopathic providers and may or may not follow the modern medicine prescribed. For example, in one study only 53% percent of Hispanics with high blood pressure were taking antihypertensive medications. Hispanics also underuse preventive services and health promotion activities (Fordyce, 2003); in 2006, 43% of Hispanics had no medical home compared to 15% of whites (Beal, Doty, Hernandez, Shea, & Davis, 2007). When prescribing other drugs, understanding that *curanderas/curanderos* (traditional folk healers) treat illness with a variety of herbs and teas as well as recommend visits to shrines, medals, the use of candles, and promises to God to change behavior will reduce the risk for drug interactions. As with Asian medicinal therapies, it is important to understand that illness conditions are defined differently and that there are illnesses that have no correlate in allopathic medicine.

Racial Differences in Drug Pharmacokinetics and Response

A study that investigated the dose requirements using published warfarin dosing algorithms (derived from a mainly non-Hispanic white group) and genetic influences of warfarin in Hispanic versus non-Hispanic whites showed no pharmacokinetic differences in response. Specifically, researchers looked at the contribution of cytochrome *P450 2C9* (*CYP2C9*) and vitamin K epoxide reductase complex-1 (*VKORC1*) genotypes and their associated clinical factors to warfarin dose requirements. This study results suggests that factors influencing warfarin dose requirements in Hispanic

Caucasians are similar to those previously described in European Americans and that presently published dosing algorithms derived from non-Hispanic Caucasian cohorts are applicable to Hispanics living in the United States (Cavallari et al, 2011).

Asthma is the most common chronic illness among all children, with around 10% of all children afflicted. But Puerto Ricans have a much higher rate of asthma, with more than 20% afflicted compared with non-Hispanic whites. Conversely, only approximately 8% of Mexican American children are reported to have asthma. Similar statistics apply to Puerto Rican and Mexican adults in the United States (National Center for Health Statistics, 2002). This difference may be due to genetic differences between Puerto Ricans and Mexican Hispanics. Choudhry and colleagues (2005) studied the differences between Puerto Ricans and Mexicans with asthma in response to the drug albuterol and found there was a very strong association between the *Arg16* genotype and greater bronchodilator responsiveness for Puerto Ricans with baseline forced expiratory volume at 1 second (FEV$_1$) less than 80% of predicted, but not in those with FEV$_1$ greater than 80%. This association was not seen in the Mexican study participants, indicating that not all Hispanics respond to asthma medications in a similar fashion.

The *CYP2D6* gene is involved in metabolism of different medications, including dextromethorphan (a common cough suppressant). Research indicates that differing alleles on *CYP2D6* affect the rate of metabolism; however, research within the Mexican population is inconclusive. Mendoza and colleagues (2001) found that the *CYP2D6*4* variation occurs less often in Mexican Americans when compared to non-Hispanic whites and may be the cause of the lower rate of poor metabolism of drugs in Mexican Americans. Conversely, Alanis-Banuelos and colleagues (2006) found no difference in the rate of allele variation between the Mextizos of Durango, Mexico, and non-Hispanic whites. Further research needs to be completed in this area to provide conclusions.

Despite preliminary evidence of racial differences in insulin secretion and glucose metabolism and in factors associated with cardiovascular risk, evidence of differences within the Hispanic population in terms of drug pharmacokinetics and response to drugs is lacking. This may be related to the genetic variability among persons classified as Hispanic or to a lack of studies that focus on these differences.

NON-HISPANIC WHITES

Little discussion is needed of this segment of the population because most allopathic health care is currently directed at this group. Within this group, however, are some subgroups that require some discussion.

Whites of various ethnic backgrounds may hold beliefs in the "evil eye" and the curative powers of folk medicine. German, Polish, and Italian Americans also see stress and environmental changes as sources of illness. Along with Irish Americans, they have strong family ties, with the male as the dominant force and decision maker. Polish and Italian Americans may use folk

remedies and native healers. All four groups have strong religious ties, with Polish, Irish, and Italian Americans being mainly Roman Catholics. Religious medals and rituals are often used to promote health, prevent illness, and heal. Overall, an increasing percentage of the U.S. population is seeking alternative sources of health care or is self-medicating with herbal remedies; this is discussed in Chapter 10.

One interesting study by Gaskin, Spencer, Richard, Anderson, and Powe (2008) seems to defy the widely held belief that in the United States minorities receive poorer care than white Americans. Gaskin and colleagues found that "when whites and minorities were admitted to the hospital for the same reason or to receive the same hospital procedure, they receive the same quality of care."

SUMMARY

Consideration of demographic, socioeconomic, and cultural factors and recognition of the potential for drug interactions with herbs or foods that may be used in culture-specific healing practices are important in order to prescribe drugs for patients appropriately. Becoming culturally sensitive requires recognizing that cultural diversity exists, identifying and exploring one's own cultural beliefs, and being willing to modify health-care delivery to be more congruent with the patient's cultural background.

As can be seen from the research and other data discussed here, ethnopharmacology studies often present conflicting data. It is incumbent on prescribers to keep current in the literature and to take the time to review research studies for the validity and reliability of the methods and statistics used in the research and for its appropriateness to their patients. Box 7-1 describes sources of information for providers. Studies that report differences without stating a specific metabolic or biochemical relationship should be especially suspect. It is also important to focus on articles in journals with reputations for peer review and careful selection of research reports.

One quick way to review the literature in ethnopharmacology is to use a Web site (http://www.pharmgkb.org/aboutUs.jsp) sponsored by Stanford University Department of Genetics. It includes a full discussion of clinical information, including dosing guidelines and drug labels and potentially clinically actionable gene–drug associations and genotype–phenotype relationships, along with the research used to arrive at these conclusions.

AN INTRODUCTION TO PHARMACOGENOMICS

Ashim Malhotra

Advances in health care have led to a significant improvement in patient survival in the past three decades. The introduction of more selective and potent therapeutic agents and optimal patient-care services have affected patient survival and quality of life significantly, with life expectancy rising from 70.9 years in 1970 (U.S. Department of Health, Education, and Welfare, 1974) to 77.7 years in 2006 (Arias, 2010). Drug therapy is often the most challenging aspect of care. Optimal drug treatment requires selection of the best possible agents with close monitoring of pharmacokinetics, pharmacodynamics, adverse drug reactions, and the cost of different agents. This chapter focuses on the pharmacogenomic influences on drug therapy. Adverse drug reactions (ADRs) are discussed in depth in Chapter 5, although this chapter will also discuss ADRs related to genetic polymorphisms.

Pharmacogenomics is the branch of science concerned with the identification of the genetic attributes of an individual that lead to variable responses to drugs. Interestingly, the science has evolved to also consider patterns of inherited alterations in defined populations, such as specific ethnicities, that account for variability in pharmacotherapeutic responses. For the purposes of this chapter, the term *pharmacogenomics* is used more generally to refer to genetic polymorphisms that occur in a patient population—for instance, in an ethnic group—as opposed to individual patients.

Until recently, the ultimate goal of pharmacogenomics had been the development of prediction models to forecast debilitating adverse events in specific individuals and, more recently, across populations based on similarities in age, gender, or more commonly, race or ethnicity, as contrasted with the rest of the population. However, in spite of this newer usage, pharmacogenomics may predict the extreme deviation of some patients from predictable pharmacokinetic and pharmacodynamic responses: the idiosyncratic response.

In recent practice, pharmacogenomic tools coupled with proteomics and other advanced molecular diagnostics are emerging as the cornerstone of individualized patient therapy, especially when differential genetic responses to xenobiotics are considered across specific ethnicities. For instance, a 2010 *New York Times* article described the cutting-edge genetic characterization of a patient's cells to identify the specific aberrant oncogenes responsible for cancer in this individual, who was subsequently administered chemotherapy specific to the identified altered molecular pathway (Kolata, 2012). This is the new and changing face of pharmacogenomics in the present century—enabling patient-centered and patient-specific pharmaceutical care.

Pharmacogenomics seeks to identify patterns of genetic variation that are subsequently employed to guide the design of optimal medication regimens for individual patients. Historically,

the approach to drug therapy has been largely empiric and based on clinical studies that determined the maximally tolerated dose and reasonable toxicity in a narrowly defined population. This approach typically leads to the safe and effective administration of drugs for most individuals. However, with empiric therapy, interindividual (allotypic) variation in drug response occurs—with patient outcomes varying from a complete absence of therapeutic response to potentially life-threatening adverse drug reactions (ADRs).

Genetic differences may account in part for some of the well-documented variability in response to drug therapy. Obviously, many factors other than genetics—such as age, sex, other drugs administered, and underlying disease states—also contribute to variation in drug response. However, inherited differences in the metabolism and disposition of drugs and genetic polymorphisms in the targets of drug therapy (e.g., metabolizing enzymes or protein receptors) can have an even greater influence on the efficacy and toxicity of medications. Interestingly, age, gender, and endemic geographical differences may themselves emerge as phenotypic consequences of differential epigenetic control. This implies that heterogeneity in the control of gene expression based upon age, gender, and geographic location is itself a life-long changing process that is under the control of molecular "epigenetic" switches that either activate or inhibit groups of genes as a unit. Specific identification of these epigenetic controls in special populations, for instance differences in pediatric or geriatric protein expression in immune cells when compared to the general adult population, can provide valuable clues to how special populations based on age, gender, pregnancy, and even geographical location respond differentially to specific drugs. This information can then be incorporated in optimal therapeutic design.

With the publication in 2001 of Lander's and Venter's description of their groundbreaking effort to map the entire human genome, the Human Genome Project (HGP), about 95% of the sequence of all human DNA was established, resulting in the identification of Open Reading Frames (ORF) for many human proteins. A more recent development has been the discovery of single-nucleotide polymorphisms (SNPs), genetic differences that account for allotypic phenotype variations. About 1.4 million SNPs in humans have been identified through a mass effort by the SNP Consortium, which was funded by multiple pharmaceutical companies. The existence of the SNP Consortium is an excellent reminder of the significance of SNPs to drug companies, since SNPs may account for some of the differences in drug responses seen in pharmacotherapy in the population at large (Howe, 2009). With the identification of the individual SNPs, our understanding of pharmacogenetics and pharmacogenomics has exploded.

A study published in 2011 by Li, Zhang, Zhou, Stoneking, and Tang on the heterogeneity in drug-metabolizing genes in globally defined populations has provided profound insights and ever stronger evidence for the significance and relevance of SNP-induced variation in drug metabolism. This study compared differences in 283 drug-metabolizing enzymes and transporter genes across 62 globally distributed ethnic groups and demonstrated that patterns of emergence of SNPs in specific populations spread out across the world indicate positive selection at work and that these differences in SNPs importantly account for the differential drugs response in any given population (Li et al, 2011). Not only does this work support and explain the origin of genetic polymorphism in drug-metabolizing enzymes, it purports to provide an evolutionary rationale for such differences across ethnicities.

GENETICS REVISITED

An individual's genetic makeup (or genotype) is derived as a result of genetic recombination or "mixing" of genes from that individual's parents. All the DNA contained in any individual cell is known as the *genome* of the individual, a word formed by the combination of "gene" and "chromosome," and thus represents all the genes that individual can express. Interestingly, even though two unrelated people share about 99.9% of the same DNA sequences, the less than 0.1% difference between them translates into a difference of 3 million nucleotides. These variants, introduced above, are the SNPs (pronounced "snips") (Howe, 2009). The variability of the genome at these various SNPs accounts for nearly all of the phenotypic differences we see in each other.

The Human Genome Project has sought not only to identify and correlate SNPs with phenotypic differences but also to record and map haplotypes as well (Nebert, Zhang, & Vesell, 2008). Haplotypes are large portions of genetic material (around 25,000 base pairs) that tend to travel together. Understanding how SNPs and haplotypes make humans genetically unique is the current focus of much genetic research (Nebert et al, 2008). The completion of the Human Genome Project, as well as the mapping of SNPs and haplotypes, has allowed the field of pharmacogenomics to understand the variability of drug metabolism seen across individuals and populations. Box 8-1

BOX 8–1 **DEFINITIONS**

Genetic polymorphism: multiple differences of a DNA sequence found in at least 1% of the population

Genetics: the study of heredity and its variations

Genomics: the study of the complete set of genetic information present in a cell, an organism, or species

Pharmacogenetics: the study of the influence of hereditary factors on the response of individual organisms to drugs (Venes, 2005); the study of variations of DNA and RNA characteristics as related to drug response (U.S. Food and Drug Administration, 2010b)

Pharmacogenomics: the study of the effects of genetic differences among people and the impact that these differences have on the uptake, effectiveness, toxicity, and metabolism of drugs

SNP: single-nucleotide polymorphism

Source: Venes, D. (2005). *Taber's cyclopedic medical dictionary* (21st ed.). Philadelphia: FA Davis; U.S. Food and Administration. (2010b). Table of valid genomic biomarkers in the context of approved drug labels. Retrieved from http://www.fda.gov/RegulatoryInformation/Guidances/ucm129286.htm

provides definitions of terms used in pharmacogenetics and pharmacogenomics.

Another interesting aspect of this discussion is the frequency with which the "mutant" gene copy is expressed. If the variant copy of a gene, such as is common for genes encoding Drug Metabolizing Enzymes (DME), is expressed in the equivalent of 1% or more of the population, the genetic variation is referred to as a polymorphic variation.

Standard adopted nomenclature is used in pharmacogenomics and pharmacogenetics. Of the various mutant variants of a specific gene, each variant is numerically and sequentially named starting with the "wild-type" or normal or nonmutated copy of the gene. Thus, for instance,*CYP2D6* written in italics refers to the normal copy of the gene, whereas *CYP2D6*1* (pronounced "star 1") refers to the first identified natural variant (mutant) copy of this gene.

HISTORY OF PHARMACOGENETICS

The Greek philosopher and mathematician Pythagoras recorded the first interindividual difference of drug administration in 510 BCE when he noted that some patients developed hemolytic anemia after ingesting the fava bean (Nebert et al, 2008). The term *pharmacogenetics* was first coined by Vogel in 1959, but not until1962 was pharmacogenetics defined as the study of heredity and the response to drugs by Kalow (Nebert et al, 2008). Since 1962, the term has been used to refer to the effects of genetic differences on a person's response to drugs.

Interest in pharmacogenetics emerged in the 1950s in response to the discovery of an abnormal butyrylcholinesterase enzyme in psychiatric patients who exhibited prolonged muscular paralysis after administration of succinylcholine before electroconvulsive therapy (Meyer, 2004). Also in the 1950s a connection was established between the development of hemolysis in African American males treated for malaria with primaquine and glucose-6-phosphate dehydrogenase deficiency (Beutler, 1959). Other seminal pharmacogenetic findings include the identification of the proportion of slow acetylators in certain ethnic groups, including 10% of the Japanese and Eskimos; 20% of the Chinese; and 60% Caucasians, blacks, and South Indians (Ellard, 1976), and attribution of peripheral neuropathy to slow acetylation of isoniazid in some patients treated for tuberculosis due to genetic diversity in the enzyme *N*-acetyltransferase (Fig. 8-1) (Yamamoto, Subue, Mukoyama, Matsuoka, & Mitsuma, 1999). The rate of acetylation of a drug such as isoniazid is clinically relevant because it determines the rate of elimination of the drug from the body. Thus, individuals known as slow acetylators will metabolize the drug slowly, allowing greater residence time in the body and enhanced toxicity. It is a pharmacogenomic variation, which is responsible for slow or fast acetylators as explained below.

PHARMACOGENOMICS

The ultimate promise of pharmacogenomics is the possibility that knowledge of the patient's DNA sequence might be used to enhance drug therapy to maximize efficacy, to target drugs only to those patients who are likely to respond, and to avoid ADRs. Increasing the number of patients who respond to a therapeutic regimen with a concomitant decrease in the incidence of ADRs is the promise of pharmacogenomic information. The long-term expected benefits of pharmacogenomics are selective and potent drugs, more accurate methods of determining appropriate drug dosages, advanced screening for disease, and a decrease in the overall cost to the health-care system in the United States caused by ineffective drug therapy.

GENETIC DIFFERENCES IN DRUG METABOLISM

Genetic differences in metabolism were first realized by the observation that sometimes very low or very high concentrations of drug were found in some patients despite their having been given the same amount of drug. Most genetic differences in drug metabolism have been found to be "monogenic" genetic polymorphisms, meaning that they arise from the variation in one gene (Nebert et al, 2008).

Genetic Polymorphism

A genetic polymorphism occurs when a difference in the allele(s) responsible for the variation is a common occurrence. An allele is an alternative form of a gene. A gene is called polymorphic when allelic variations occur throughout a given population at a stable rate of less than 1% (Howe, 2009). Under such circumstances, mutant genes will exist somewhat frequently alongside wild-type genes. The mutant genes will encode for the production of mutant proteins in these populations. The mutant proteins will, in turn, interact with drugs in different manners, sometimes slight, sometimes significant. Monogenic traits by themselves cannot explain the complexity of drug metabolism (Nebert et al, 2008). Genes interact on a complex level, yielding different responses depending on which genes are wild-type and which show mutant phenotypes. Sometimes these interactions can be very difficult to elucidate and may in fact be the source of seemingly unexplainable drug reactions. Figure 8-1 illustrates the relationship between genetic polymorphisms in drug metabolism and at drug receptors.

Four different phenotypes categorize the effects that genetic polymorphisms have on individuals: poor metabolizers (PMs) lack a working enzyme; intermediate metabolizers (IMs) are heterogeneous for one working, wild-type allele and one mutant allele (or two reduced-function alleles); extensive metabolizers (EMs) have two normally functioning alleles; and ultrarapid metabolizers (UMs) have more than one functioning copy of a certain enzyme (Belle & Singh, 2008). See Table 8-1 for the clinical implications of genetic polymorphisms.

Phase I and Phase II Metabolism

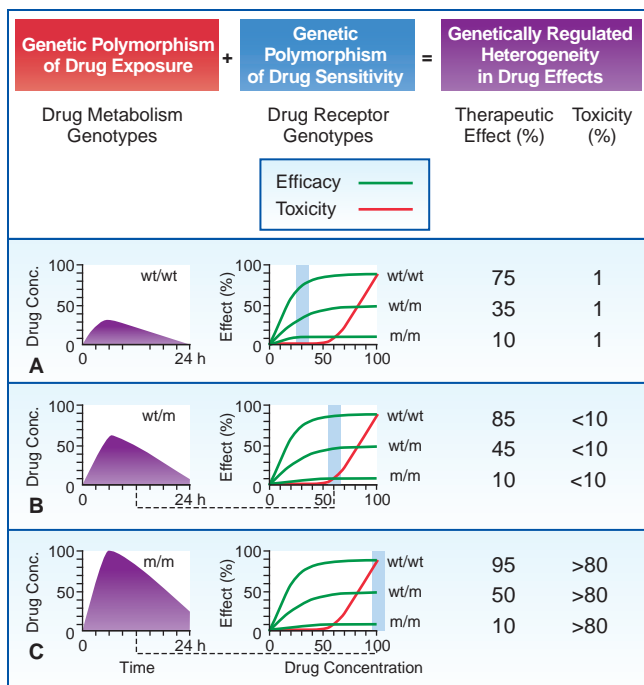
Drug metabolism generally involves the conversion of lipophilic substances and metabolites into more easily excretable water-soluble forms. Drug metabolism takes place


Figure 8–1. Genetic polymorphisms and drug metabolism/receptors.

Table 8–1   Clinical Implications of Genetic Polymorphisms

Metabolizer Phenotype	Effect on Drug Metabolism	Clinical Implications
Poor to intermediate metabolizers	Slow	Prodrug will be metabolized slowly into active drug metabolite. May have accumulation of prodrug. Active drug will be metabolized slowly into inactive metabolite. Potential for accumulation of active drug. Patient requires lower dosage of medication.
Ultrarapid metabolizers	Fast	Prodrug rapidly metabolized into active drug. No dosage adjustment needed. Active drug rapidly metabolized into inactive metabolites leading to potential therapeutic failure. Patient requires higher dosage of active drug.

mostly in the liver and is divided into two major categories, phase I (oxidation, reduction, and hydrolysis reactions) and phase II metabolism (conjugation reactions). A hallmark experiment in pharmacogenomics, diagrammed in Figure 8-2, illustrates how differences in the rates of the phase II metabolizing enzyme N-acetyltransferase (NAT-2) can affect the half-life and plasma concentration of drugs that are subject to NAT-2 metabolism (Meyer, 2004).
Figure 8–2. Pharmacogenomics of acetylation in isoniazid. Plasma isoniazid concentrations in 267 patients measured 6 hours post-dose. The bimodal distribution shows the effect of an *NAT-2* genetic polymorphism.

Phase I metabolism enzymes are responsible for approximately 59% of the adverse drug reactions cited in the literature (Phillips, Veenstra, Oren, Lee, & Sadee, 2001). In terms of evolution, the cytochrome P450 (CYP450) enzyme system was one of the first biocatalytic machineries to emerge on earth. These ubiquitous enzymes contain an iron-porphyrin ring center that is essential to the chemical reaction they catalyze. During this oxygenation reaction, the oxidative state of iron in the porphyrin ring changes, resulting in spectrophotometric absorption maxima observed at 450 nm, which contributed to their naming.

CYPs are generally located in the endoplasmic reticulum (ER) and the mitochondria in human cells, of which the ER isoforms are of particular importance to the field of drug metabolism. In terms of their organ distribution, they are found in greater amounts in the liver and the intestine and to a somewhat lesser extent in other organs, such as the skin, brain, lungs, and kidneys. Hepatic, renal, and intestinal ER CYPs are involved in the biotransformation of a plethora of drugs and endogenous substrates in humans mainly by oxygenation of the target substrate molecule and mediated by differential oxidation states of the central iron atom in the enzyme. Due to this oxygenation reaction, CYPs are classified as monooxygenases. The high genetic variability of the cytochrome *P450* enzymes constitutes the most important of the phase I metabolizing enzymes, with a total of 57 genes encoding for CYP450 enzymes. Of these, CYP2D6, CYP2C9, and CYP2C19 are highly polymorphic and account for upward of about 40% of hepatic phase I metabolism (Phillips et al, 2001) (Fig. 8-3 and Table 8-2).

Specific CYP450 Enzymes
CYP2D6

Up to 25% of drugs are metabolized via CYP2D6 (Belle & Singh, 2008). Phenotypic variations between some enzymes can have an astounding outcome on drug therapy. For example, a 1,000-fold difference has been observed in the rate of
Figure 8–3. Proportion of drugs metabolized by CYP450 isoenzymes.

metabolism of some substrates due to differences in CYP2D6 isozymes. Figure 8-4 illustrates this difference within the European population for the CYP2D6 substrate nortriptyline.

Pharmacogenomic Variance of *CYP2D6*

CYP2D6 is a well-studied instance of a drug-metabolizing enzyme (DME) coding gene that exhibits polymorphism. The CYP2D6 gene product acts on many xenobiotics, including many common prescription drugs (Table 8-3) such as the selective serotonin reuptake inhibitors (SSRIs) fluoxetine, tricyclic antidepressants (TCAs), beta blockers (metoprolol), calcium channel blockers (diltiazem), theophylline (Phillips et al, 2001), and tamoxifen. Research has shown that while approximately 10% of Caucasians, up to 7% of

African Americans, and 4.8% of Asians have the "poor metabolizer" (PM) phenotype, 5% of Caucasians and 4.9% of African Americans have the "ultrarapid metabolizer" (UM) phenotype. For Asians, the percentage of CYP2D6 ultrarapid metabolizers shoots up to 21%, perhaps leading to the therapeutic failure of or the need for increased therapeutic dosages of drugs such as SSRIs in these target populations (Belle & Singh, 2008). Thirty-five percent of the population carries a nonfunctional 2D6 allele. This nonfunctional allele may increase the risk of ADRs, especially in patients with polypharmacy. Interestingly, of the 43 alleles of the CYP2D6 gene, about 5 alleles account for the poor metabolic phenotype.

Among the many reasons for genetic variations, an interesting one that specifically applies to CYP2D6 is gene duplication. As the name suggests, in some ethnicities duplication of the allele coding for 2D6 may result in increased protein expression and therefore ultrarapid metabolism and markedly reduced activity of some drugs. The percentage of population that shows gene duplication for CYP2D6 across different countries is shown in Figure 8-5.

CYP2D6 and Tamoxifen

Recently, the ameliorative effects that variable isoforms of CYP2D6 have on the metabolism and therapeutic efficacy of tamoxifen in some patients have received much attention. With reference to tamoxifen, the role of CYP2D6 is not so much the metabolism of this drug as it is to activate it by conversion to endoxifen inside the cell. Pharmacogenetic variation in CYP2D6 has been shown in clinical trials conducted in the United Kingdom and Germany to lead to variable therapeutic outcomes to tamoxifen treatment of estrogen-sensitive cancers (Schroth et al, 2009, 2010; Thompson et al, 2011).

Table 8–2   Medications and Their Receptors

Gene	Medications	Drug Effect Linked to Polymorphism
Drug-Metabolizing Enzymes		
CYP2C9	Tolbutamide, warfarin, phenytoin, NSAIDS	Anticoagulant effect of warfarin
CYP2D6	Beta blockers, antidepressants, antipsychotics, codeine, debrisoquine, dextromethorphan, encainide, flecainide, guanoxan, methoxyamphetamine, *N*-propylamaline, perhexiline, phenacetin, phenformin, propafenone, sparteine	Tardive dyskinesia from antipsychotics; narcotic side effects, efficacy, and dependence: imipramine dose requirement; beta blocker effect
Dihydropyrimidine dehydrogenase	Fluorouracil	Fluorouracil neurotoxicity
Thiopurine methyltransferase	Mercaptopurine, thioguanine, azathioprine	Thiopurine toxicity and efficacy; risk of second cancers
Drug Targets		
ACE	Enalapril, lisinopril, captopril	Renoprotective effects, cardiac indices, blood pressure, immunoglobulin A nephropathy
Potassium channels	Quinidine	Drug-induced long QT syndrome
HERG	Cisapride	Drug-induced torsade de pointes
KvLQT1	Terfenadine, disopyramide, mefloquine	Drug-induced long QT syndrome
hKCNE2	Clarithromycin	Drug-induced arrhythmia
Figure 8–4. European population and the *CYP2D6* substrate nortriptyline.

Table 8–3 *CYP2D6*

Substrate	Inhibitors	Inducers
Codeine	Amiodarone	Carbamazepine
Dextromethorphan	Fluoxetine	Phenytoin
Metoprolol	Labetalol	Phenobarbital
Paroxetine	Paroxetine	Rifampin
Haloperidol	Propafenone	
Propranolol	Quinidine	
Risperidone	Sertraline	
Timolol	Cimetidine	
Amitriptyline		
Nortriptyline		
Clozapine		
Morphine		
Methadone		

CYP2D6 and Opioid Analgesics (Codeine)

Opioid analgesics such as codeine rely on CYP2D6 enzymes to convert them to their active form, morphine (Belle & Singh, 2008). Genetic polymorphisms of the CYP2D6 enzyme can greatly alter the effect that codeine has on patients who are PM or UM types. UM types may not experience the analgesic effects of the drug at normal therapeutic doses, and PMs may not be able to convert codeine to its active metabolite morphine, thus experiencing little or no clinical benefit. Other narcotics that are active when administered to patients may produce the effects of excess drug at even the lower end of therapeutic dosing. See Table 8-3.

A recent area where CYP2D6 polymorphism has generated interest is the effects of its pharmacogenomic variation on infants who are breastfed milk by UM mothers on codeine. In UMs, excessive codeine activation to morphine may cause fatal respiratory depression. Since the active metabolite, morphine, is lipophilic and may be found in breast milk, severe respiratory depression could result in infants who have not yet been weaned. However, a study published in 2012 demonstrated that the main concern in this scenario is CNS depression in UM mothers on codeine, which was found to be a significant risk factor when compared with CNS depression as measured by sleepiness and lethargy in the infants being fed breast milk by the same mothers (Sistonen et al, 2012).

In addition, fatalities have been observed in some pediatric patients following the administration of codeine for postoperative pain management after tonsillectomy and/or adenoidectomy procedures. In August 2012, the Food and Drug Administration (FDA) acknowledged that it was considering the lethal effects of codeine in some pediatric patients and estimated that "the number of "ultrarapid metabolizers" is generally 1 to 7 per 100 people, but may be as high as 28 per 100 people in some ethnic groups." Consequently, as recently as February 2013, the FDA issued a Black-Box Warning for the cautious use of codeine in children, particularly for pain management following surgery.

Genetic Testing for CYP2D6 Polymorphisms

There are commercially available tests that can provide immensely helpful information. One such test called the Tag-It system is described at the end of the chapter.

CYP2C9

CYP2C9 is the primary route of metabolism for about a hundred different drugs in humans. While some CYP2C9 substrates are the more common drugs, such as phenytoin, glipizide, and losartan, other drug substrates include those that evince a narrow therapeutic index, such as the coumarin-related anticoagulant agents warfarin and acenocoumarol.

CYP2C9 and Warfarin

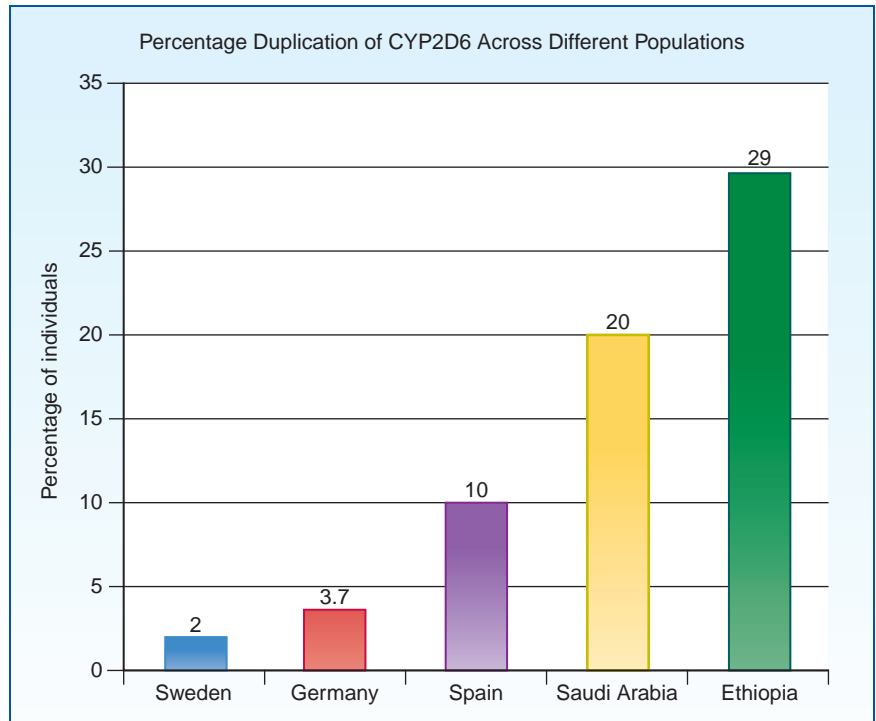
Warfarin is one of the most effective, cheapest, and widely prescribed anticoagulant drugs that act by inhibiting the enzyme vitamin K epoxide reductase, which prevents the formation of functional vitamin K. This action in turn inhibits the activation of clotting factors in the liver, causing the anticoagulant effect. Warfarin is available as a racemic mixture, of which the *S*-enantiomer, which is the more bioactive form, is metabolized by CYP2C9. The presence of CYP2C9 mutations is associated with a reduction in the metabolism of *S*-warfarin. Clinically, warfarin maintenance dosing requirements are lower in patients with CYP2C9*2 polymorphisms and further reduced in patients with CYP2C9*3 variants (Gulseth, Grice, & Dager, 2009), making these two the most common "reduced function variants" for the CYP gene in terms of its effect on warfarin. The CYP2C9*2 variant evinces a 30% and the CYP2C9*3 variant a 90% reduction in warfarin clearance (Rettie,


Figure 8–5. Percentage distribution of individuals across countries showing a duplication of an allele of CYP2D6. The figure explains the exaggerated metabolism of some drugs in the specified percentage of individuals belonging to certain ethnic backgrounds (generously assuming ethnic homogeneity in some countries) due to increased 2D6 activity.

Haining, Bajpai, & Levy, 1999), resulting in adjusted dose requirements in these patients compared with noncarriers.

In addition, patients with homozygous presentation of a CYP2C9 mutation appear to have a greater reduction in dosing requirement than do heterozygotes. Approximately one-third of the population carries at least one allele for the slow-metabolizing form of CYP2C9 (U.S. Food and Drug Administration, 2009). The clinical implications of altered warfarin metabolism can be significant; the clinical implications of pharmacogenomic variants are found later in this chapter. See Table 8-4.

In spite of the information outlined above, controversy exists in the field of pharmacogenetic testing over initiation or

Table 8–4 *CYP2C (9 and 19)*

Substrate	Inhibitors	Inducers
S-warfarin	Amiodarone	Carbamazepine
Losartan	Cimetidine	Phenytoin
Diazepam	Chloramphenicol	Rifampin
Imipramine	Fluconazole	
Amitriptyline	Isoniazid	
Phenytoin	Ketoconazole	
Rosiglitazone	Zafirlukast	
	Fluoxetine	
	Fluvoxamine	
	Sertraline	
	Rosiglitazone	

maintenance of anticoagulant therapy following an adverse cardiovascular event, in part due to some conflicting reports in the literature about the clinical effectiveness and relevance of pharmacogenomic variability in warfarin drug metabolism. However, recent studies on the pharmacogenomics of warfarin have included an analysis of the effects of polymorphism of CYP2C9 and vitamin K epoxide reductase (VKORC1) across populations in Europe, Asia, and elsewhere. Polymorphisms in these two genes account for nearly 40% of the differences in warfarin therapy across populations (Yip & Pirmohamed, 2013). Taken together, the data from these pharmacogenomic studies indicate a strong connection between the variant effects of CYP2C9 polymorphism and the metabolism and therapeutic efficacy of warfarin and acenocoumaral. CYP2C9 variation was reported to be important for the maintenance therapy of warfarin in a genome-wide association analysis in the Swedish and Japanese population (Cha et al, 2010).

Data from disparate research resources need to be organized to obtain clinically relevant information that assists in guiding the therapeutic rationale for the use of warfarin in special populations. One such approach would be to analyze studies on the frequency of allelic variation of the three drug-metabolizing genes for warfarin in selected populations. Thus, for the CYP2C9 gene, the frequency of allelic variation for CYP2C9*2 is about 10% in Caucasians, compared to less than 1% in Africans and Asians, while the frequency of allelic variation for CYP2C9*3 is about 6% in Caucasians, 4% in Asians, and less than 1% in Africans (Fig. 8-6). The frequency of allelic variation of the VKORC1 gene is substantially higher in all the three ethnicities compared with the mutational frequency of CYP2C9. For the specific VKORC1 (-1639) mutation, allelic frequency is 98% for Africans, 60% for Caucasians, and 2% for Asians; see Figure 8-7 (Voora & Ginsburg, 2012).

Figure 8–6. Percentage distribution of individuals across ethnicities exhibiting polymorphism in *CYP2C9.*

Figure 8–7. Percentage distribution of individuals across ethnicities showing variation in *VKORC1.*

The wealth of scientific data documenting evidence of *CYP2C9*2, CYP2C9*3,* and VKORC1 (-1639 G > A) polymorphisms affecting dose response to warfarin in different populations resulted in the FDA updating the label of the drug in 2007 and then again in 2010 (Finkelman et al,

2011). A number of algorithms have been published to help physicians in making a decision about warfarin dosing after pharmacogenetic testing, of which two prominent examples are the Gage algorithm and the International Warfarin Pharmacogenetics Consortium (IWPC) algorithm.

Interestingly, the nonsteroidal anti-inflammatory drugs (NSAIDs) celecoxib and flubiprofen have received "use with caution" in PM label warnings from the FDA owing to CYP2C9 polymorphism.

CYP3A4

The CYP3A group of isoenzymes is responsible for up to 50% of drug metabolism (Howe, 2009). CYP3A4 isoenzyme is responsible for metabolism of several important classes of drugs that are commonly used in primary care (see Table 8-1). Examples of these classes include azole antifungals, calcium channel blockers, antihistamines, anticonvulsants, antimicrobials, and corticosteroids. Both drug-related induction or inhibition of CYP450 3A4 isoenzyme may complicate drug therapy in patients (Howe, 2009). Predicting the onset and offset of these effects is very difficult. The time to onset and offset of drug–drug interactions is closely related to each drug's half-life and the half-life of enzyme production. Clinically significant drug interactions in this setting may increase the risk of toxicity. For example, amiodarone has a half-life of close to 60 days and requires months to reach steady state and inhibit the CYP450 enzyme system effectively (Table 8-5). Conversely,

Table 8–5 *CYP3A4*

Substrate	Inhibitors	Inducers
Cyclosporine, FK 506	Erythromycin	Carbamazepine
Corticosteroids	Clarithromycin	Phenobarbital
Erythromycin	Diltiazem	Rifampin
Felodipine, isradipine	Ketoconazole	Rifabutin
Nifedipine	Fluconazole	Phenytoin
Nisoldipine	Itraconazole	Corticosteroids
Nitrendipine	Quinidine	INH
Digoxin, quinidine	Grapefruit juice	St. John's wort
Verapamil	Cimetidine	
Warfarin	Indinavir	
Sildenafil	Fluoxetine	
Astemizole	Zileuton, zafirlukast	
Terfenadine	Verapamil	
Pioglitazone	Amiodarone	
R-warfarin	Corticosteroids	
	Fluvoxamine	

it takes less than 2 days for rifampin, which is a nonspecific CYP450 inducer with a shorter half-life, to decrease blood concentrations of many drugs to a subtherapeutic level and significantly increase the risk of therapeutic failure. Close monitoring is required when prescribing drugs that induce or inhibit CYP3A4 enzymes. See Table 8-5 for further information.

P-GLYCOPROTEIN

P-glycoprotein (Pgp) is a membrane-bound, ATP-dependent transport system responsible for the efflux of a variety of xenobiotics from cells to the extracellular fluid. This includes the ejection of drugs from cells, usually against their concentration gradients. Pgp, also known as multidrug resistance (MDR1) protein, is the product of the *ABCB1* and *ABCB4* genes and is a member of adenosine triphosphate (ATP)-binding family of proteins. Differential expression of Pgp may explain tissue-specific and temporal variations in efflux efficiency in different cells. In fact, chemoresistance in cancer therapeutics has been strongly linked with Pgp expression—the more Pgp protein expressed by the cell, the greater the efflux potential of xenobiotics such as anticancer drugs. In addition to differences in protein expression, polymorphic variation of the Pgp genes may also dynamically affect intracellular and plasma drug concentration. Over 50 SNPs within the *ABCB1* gene have been identified, which may lead to variability in drug responses (Reed & Parissenti, 2011).

Pharmaceutically relevant examples of this include the variation in drug response to agents such as antiepileptic drugs, select cardiovascular agents, and so on. Interestingly, P-glycoprotein at the site of the gastrointestinal (GI) tract effluxes hydrophilic drugs out of the cell and inhibits drug absorption through the GI tract (Howe, 2009). As drugs passively diffuse through the GI tract, Pgp pumps move drugs from cytoplasmic areas to extracellular fluid. Some examples of substrates of P-glycoprotein include carvedilol, diltiazem, and digoxin (Howe, 2009). Several antiepileptic drugs such as phenytoin, carbamezapine, lamotrizine, phenobarbital, valproic acid, and gabapentin are substrates or inhibitors of Pgp, but there is considerable controversy in the literature regarding these. In the case of digoxin, Pgp affects the level of digoxin available for absorption and elimination (Howe, 2009). P-glycoprotein inhibitors include verapamil, quinidine, cyclosporine, and ketoconazole (Howe, 2009). If an inhibitor of P-glycoprotein is administered, then blood levels of substrates will rise, as seen if quinidine is administered with digoxin.

Drugs can be categorized as reversible or suicidal inhibitors or P-glycoproteins. For example, calcium channel blockers and high-dose steroids are considered as reversible inhibitors of both P-glycoproteins and CYP450. However, grapefruit and ritonavir are suicidal agents for both P-glycoprotein and CYP450, meaning the effect of grapefruit juice will be prolonged, perhaps up to 24 hours. See Figure 8-8.
Figure 8–8. Drug–metabolism interactions.

CLINICAL IMPLICATIONS OF PHARMACOGENOMICS

Adverse Drug Reactions

One benefit of understanding pharmacogenomics is the possibility of a decrease in the number of ADRs. The CYPP450 enzymes in families 1 to 3 mediate 78% to 80% of all phase I–dependent metabolism of clinically used drugs (Spatzenegger & Jaeger, 1995). The polymorphic forms of CYPP450s are responsible for the development of idiosyncratic ADRs (Kalgutkar, Obach, & Maurer, 2007). According to Phillips and Van Bebber (2005), 56% of drugs cited in ADR studies are metabolized by polymorphic phase I enzymes, of which 86% are P450s.

Warfarin

In 2008, the package insert for warfarin was updated by the U.S. Food and Drug Administration to include application of pharmacogenomics to the dosing of warfarin. Previous work had identified variable metabolism by CYP2C9 as a major contributor to the variable response to the drug. In 2004, coding-region mutations in VCORC1, encoding a subunit of the vitamin K epoxide reductase complex (the pharmacological target for the drug), were found to cause a rare syndrome of warfarin resistance. Subsequently, the variants in VCORC1 have been found to account for a much greater fraction of variability in warfarin response (21%) than do variations in CYP2C9 (6%) (Gulseth et al, 2009). Although genetic testing prior to prescribing has not yet been required by the FDA, numerous warfarin dosing calculators exist on the Web where a clinician can insert clinical information about the patient, including genetic test results and indications, and a dosing regimen will be calculated or "individualized" for that patient (http://www.warfarindosing.com; http://www.globalrph .com/warfarin.htm).

Pharmacogenetic Testing Prior to Prescribing

The FDA now requires additional pharmacogenomic information on several drug package inserts (Table 8-6). Within the anticoagulant drug class, warfarin is a drug with

Table 8–6 U.S. Food and Drug Administration Positions on Necessity of Pharmacogenetic Testing as Indicated on Drug Labeling

Pharmacogenetic Biomarker	Drug
Test Required	
EGFR expression	Cetuximab
HER2/NEU overexpression	Trastuzumab
CCR-5-tropic HIV-1	Maraviroc
Presence of Philadelphia chromosome	Dasatinib
Test Recommended	
HLA-B*1502	Carbamazepine
HLA-B*5701	Abacavir
CYP2C9 variants	Warfarin
VKORC1 variants	Warfarin
Protein C deficiency	Warfarin
TPMT variants	Azathioprine, mercaptopurine, thioguanine
UGT1A1 variants	Irinotecan
G6PD deficiency	Rasburicase
Urea cycle disorders	Valproic acid
Information Only	
c-KIT expression	Imatinib
CYP2C19 variants	Voriconazole
CYP2C9 variants	Celecoxib
CYP2D6 variants	Atomoxetine, tamoxifen, fluoxetine
DPD deficiency	Capecitabine, fluorouracil
EGFR expression	Erlotinib
G6PD deficiency	Rasburicase, primaquine
NAT variants	Isoniazid, rifampin
Philadelphia chromosome	Busulfandeficiency
PML/RAR gene expression	Tretinoin

EGFR = epidermal growth factor receptor; *HER2/NEU* = v-erb-b2 erythroblastic leukemia viral oncogene homolog 2; *CCR-5* = chemokine C-C motif receptor; HLA = human leukocyte antigen; *CYP2C9* = cytochrome P-450 isoenzyme 2C9; *VKORC1* = vitamin K epoxide reductase complex subunit 1; TPMT = thiopurine *S*-methyltransferase; *UGT1A1* = uridine diphosphate-glucuronosyltransferase 1A1; *c-KIT* = v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog; *CYP2C19* = cytochrome P-450 2C19; *CYP2D6* = cytochrome P-450 isoenzyme 2D6; DPD deficiency = dihydropyrimidine dehydrogenase; G6PD = glucose-6-phosphate dehydrogenase; *NAT* = *N*-acetyltransferase; *PML/RAR* = promyelocytic leukemia/retinoic acid receptor.cytochrome P-450 isoenzyme 2D6; DPD deficiency = dihydropyrimidine dehydrogenase; G6PD = glucose-6-phosphate dehydrogenase. *Source*: Derived from U.S. Food and Drug Administration. (2010b). Table of valid genomic biomarkers in the context of approved drug labels. Retrieved from http://www.fda.gov/Drugs/ScienceResearch/ResearchAreas/Pharmacogenetics/ucm083378.htm

a narrow therapeutic index. In 2007, the FDA recommended an important label update suggesting genetic testing to prevent possibly fatal bleeding in patients with polymorphic variants of CYP2C9, the metabolizing enzyme, and VKORC1, the target enzyme of warfarin. Patients with CYP2C9 variations require more time to achieve the International Normalized Ratio, or INR, and are at an increased risk for bleeding (Sconce, 2005); they may also require lower doses of warfarin to achieve and maintain therapeutic INR (Limdi, 2007). Thus, if there are indications of inherited differences in these genes, the patient should be genotyped. However, monitoring INR is still as much of a requirement while dosing warfarin as before. While the FDA did not explicitly require genetic testing in patients prior to prescribing warfarin, the package labeling did show changes in dosage amounts. There is an FDA-approved genetic testing kit available, but others may also be used. Generally, cell samples are collected from the mouth or from blood. However, it should be emphasized that genetic testing is not the sole consideration, since patient-related factors such as age, sex, body weight, and some other parameters may need to be considered with the genetic results. A variety of online algorithms can aid physicians and hospital staff in making these dosage adjustments, as presented, for example, at www.warfarindosing.org.

The pharmacogenetic tests mentioned on drug labels can be classified as "test required," "test recommended," and "information only." Currently, four drugs are required to have pharmacogenetic testing performed before they are prescribed: cetuximab, trastuzumab, maraviroc, and dasatinib. Cetuximab treatment needs a confirmation of epidermal growth factor receptor *(EGFR)* expression. Trastuzumab therapy requires testing for HER2/NEU overexpression. Infection with *CCR-5*-tropic HIV-1 should be confirmed before initiation of therapy with maraviroc (an antiretroviral). Dasatinib is used for the treatment of patients with Philadelphia chromosome-positive acute lymphoblastic leukemia resistant to or intolerant of prior therapy (U.S. Food and Drug Administration, 2010b).

In December 2007, the FDA added a Black-Box Warning on the carbamazepine label, recommending testing for the HLA-B*1502 allele in patients with Asian ancestry before initiating carbamazepine therapy because these patients are at high risk of developing carbamazepine-induced Stevens–Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN). Interestingly, although Asians or patients with Asian ancestry have been reported to have a strikingly high frequency (10 times higher than whites) of carbamazepine-induced SJS or TEN if they carry an HLA-B*1502 allele, other races carrying the allele do not seem to have the increased risk (U.S. Food and Drug Administration, 2007).

The anticancer agent irinotecan is a prodrug used for the treatment of colorectal cancer, small-cell lung cancer, and other solid tumors. The active metabolite of irinotecan is SN-38, a topoisomerase I inhibitor, and uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1) plays a critical role in inactivating SN-38 (McLeod & Hoskins, 2007).

The low activity of the UGT1A1 enzyme may increase the risk for adverse events associated with irinotecan therapy (e.g., neutropenia) by increasing serum concentrations of the active metabolite. A polymorphism in the promoter region of the UGT1A1 gene determines patient exposure to SN-38 (McLeod & Hoskins, 2007). Patients homozygous for the polymorphism (UGT1A1*28) are at a 5-fold greater risk of irinotecan-related toxicity compared with patients with one or two normal alleles. Additionally, the FDA has approved a test for detection of the UGT1A1*28 genotype for irinotecan dosing. Additional genotype tests approved by the FDA and their implications are summarized in Table 8-7.

SUMMARY

We live in remarkable times, in which multiple therapeutic options are available for most common diseases. However, the selection of the optimal medication for an individual patient is still problematic. Practitioners still pick the "right" initial medication only half the time and ADRs are still unpredictable. In addition, the expense of new biological agents is such that even wealthy countries like the United States cannot afford to treat all patients.

The completion of the Human Genome Project has enabled the development of clinical tools for patient evaluation. Pharmacogenomics may allow identification of patients most likely to benefit from a given therapy and those patients for whom the cost and risk outweigh the benefits. Both the safety and efficacy of drug therapy may improve. In the future, genotyping may be used to personalize drug treatment for vast numbers of patients, decreasing the cost of drug treatment and increasing the efficacy of drugs and health in general.

Table 8–7 FDA-Approved Diagnostic Test Commercially Available for Commonly Prescribed Pharmacologic Therapies

Genetic Test	Drug	Benefit of Genetic Test
CYP2C9/ VCORC1	Warfarin	Reduce time to target INR; possibly decrease bleeding episodes
CYP2D6	Tamoxifen	Reduce therapeutic failure
	Codeine	Reduce GI toxicities/ improve pain control
	Oxycodone	Reduce GI toxicities/ improve pain control
	Tricyclic antidepressants	Reduce therapeutic failure
TMPT	Azathiaprine	Reduce myelosuppression
	6-mecaptopurine	Reduce myelosuppression
UGT1A1	Irinotecan	Reduce neutropenia

NUTRITION AND NUTRACEUTICALS

Teri Moser Woo

Eating is a part of daily life. The use of nutrition as therapy is beginning to take its rightful place in health promotion, disease prevention, and disease treatment because we now have significant knowledge about the importance of nutrition in these areas. We know that nutrition therapy can provide effective and efficient treatment when the medical condition affects nutritional needs or the diet affects the medical condition. When nutritional considerations are part of the plan of care, the health-care provider helps patients feel better; improves management of their health-care problems; and avoids complications that affect quality of life, productivity, and health-care costs. This chapter examines the role nutrition plays in pharmacotherapy, including the role of food intake on drug pharmacokinetics and the use of nutraceuticals (foods that claim to have a medicinal effect).

NUTRIENT–DRUG INTERACTIONS

Drugs do not create new bodily functions but rather interact with cellular function. Key to adequate cell function is the supply of needed nutrients. Because drugs are designed to improve altered cell function, it seems logical to conclude that nutritional factors can, in turn, affect pharmacological therapy. Clinically, health-care providers are concerned about the effect of drugs on the absorption, transport, metabolism, cellular uptake, and excretion of nutrients and the effect of nutrients on the pharmacokinetics of drugs. Additionally, some foods contain chemicals that may directly compete with medications; for example,

foods high in vitamin K compete with warfarin. Therefore, drug–nutrient interactions must be considered to utilize drugs effectively in the prevention and treatment of disease. Patient education must be provided about drug–food interactions, especially if there is a potential for adverse patient outcomes.

Influence of Diet on the Pharmacokinetics of Drugs

Drug Absorption

The most frequent type of drug–food interaction is the effect that food has on the gastrointestinal (GI) absorption of drugs. Drug absorption can be decreased, delayed, accelerated, or increased by food (Singh & Malhotra, 2004; Cvijic, Parojcic, & Langguth, 2014; Varum, Hatton, & Basit, 2013). Drug absorption takes place across the mucosa of the GI tract. The proximal part of the small intestine plays a significant role in drug and nutrient absorption, secondary to its large surface area. Drugs utilize the same transport mechanisms as nutrients: passive and facilitated diffusion, endocytosis, and active transport.

Several physiological factors affect drug absorption during the transport process: bioavailability—the percentage of drug available to produce a pharmacological effect—presystemic metabolism, gastric emptying time, concentration gradient, and absorptive surface area. Food in the GI tract at the time of drug administration affects absorption and bioavailability of the drug by changing the gastric emptying time through interaction within the GI lumen and by competitive inhibition.

The absorption of drugs can be increased or decreased, depending on the presence of food (Varum et al, 2013). Food decreases the amount of fluid in the GI tract, thus slowing down drug dissolution. Lack of food for an extended period—fasting for a day, for example—can decrease absorption secondary to vasoconstriction. Gastric emptying time also can influence drug absorption. However, the effect varies, depending on the type of drug preparation and the need for presystemic metabolism or dissolution. A drug that requires interaction in the stomach for disintegration and dissolution would have reduced absorption owing to the rapid gastric emptying time that might accompany a fasting state. Delayed gastric emptying that might occur with a meal high in fat would facilitate drug absorption because the drug is given more time for maximal disintegration and dissolution. Clearly, a change in gastric emptying can affect drug absorption, but the impact of the change is related to the dosage form and dissolution characteristics of the drug. A change in the drug form or time of administration can potentially affect bioavailability. Questioning the food intake of a patient who has had a change in the effectiveness of a pharmacological therapy can be an important part of the clinical decision-making process.

In addition, the effect of food on the pH of the stomach can change bioavailability. The degree of ionization that occurs when a drug is taken into the stomach is a function of GI pH. If a drug is a weak acid with best absorption in the nonprotonated (nonionized) state, then the low pH of the stomach is essential to drug absorption to allow the acid to remain nonionized and absorbable.

Chemical and physical changes in the drug can also occur as a result of interaction with food. These changes affect the absorption of the drug. Every nurse is aware of the need to advise patients to take tetracycline on an empty stomach or with foods that are not high in calcium, aluminum, iron, and magnesium because of decreased absorption, as the drug chelates with these minerals. The binding of phenytoin with enteral nutrition products that results in fluctuation of phenytoin levels has provided the impetus for the development of protocols that stop enteral nutrition before, during, and after delivery of this medication when the patient is tube fed. The bisphosphonate alendronate (Fosamax) demonstrates a 40% decrease in bioavailability when taken with food and a 60% decrease in bioavailability when administered with coffee or orange juice.

Additional physiological factors that may change a drug's absorption from the GI tract include food-induced changes in splanchnic blood flow, resulting in variation of drug absorption. As pointed out earlier, use of the same cellular transport proteins could result in competition for transport systems. Levodopa absorption is thought to be reduced with high-protein diets because of competition for the same transport system.

The potential for change in drug absorption by food or nutrients in the GI system is quite high. Drugs that have decreased absorption with food may need to be administered on an empty stomach, unless that is the desired effect, as when griseofulvin is given with a high-fat meal. When food has no effect on drug bioavailability, then the drug may be administered without regard to food intake. Patient education regarding the coordination of medication administration and food intake should be integral to the prescribing process.

Drug Metabolism

The rate of drug metabolism in both the GI tract and the liver is affected by nutrient intake. A low-carbohydrate, high-protein diet may increase drug-metabolizing enzymes. Increasing intake of antioxidant cruciferous vegetables may increase the activity of these enzymes. Clinically, we see examples of the effect of foods on metabolism daily, as unexplained variability in drug response or therapeutic drug levels.

The cytochrome P450 (CYP450) system is the major enzyme group responsible for the metabolism of foreign chemicals that come into the body. Information is expanding about the clinically significant interactions between nutrients and drugs utilizing the CYP450 enzyme system. In addition, the CYP450 system has a significant amount of polymorphism associated with it; that is, there are between-individuals differences in the presence and/or function of a particular enzyme group. This difference reinforces the need to understand the nutrient effect on metabolizing enzymes. A more detailed discussion of the CYP450 system is provided in Chapter 8, including the genetic issues surrounding this system.

Grapefruit Juice and CYP3A4

Grapefruit juice influences the metabolism of many drugs because it contains components that inhibit CYP3A4, leading to alterations in the metabolism of drugs. Studies have determined that it is the furanocoumarins in the grapefruit juice that have been identified as CYP3A4 inhibitors, decreasing the first-pass metabolism of drugs (Gertz, Davis, Harrison, Houston, & Galetin, 2008; Mertens-Talcott, Zadezensky, De-Castro, Derendorf, & Butterweck, 2006; Paine et al, 2006). Ingestion of grapefruit juice leads to increased levels of calcium channel blockers, cyclosporine, tacrolimus, and the statins (Kuypers, 2009; Vaquero et al, 2010). The maximum inhibitory effect occurs if the grapefruit juice is ingested at the same time or within 4 hours of a drug (Gertz et al, 2008).

Foods and CYP1A2

Other foods or beverages that influence drug oxidation or conjugation reactions include indolic compounds in vegetables (cruciferous), methylxanthine-containing beverages (caffeine), and charcoal broiling. Cruciferous vegetables induce CYP1A2, an enzyme responsible for the metabolism of many drugs including theophylline. Patients who consume large amounts of cruciferous vegetables may have therapeutic failure if they are being treated with drugs that are metabolized by CYP1A2 (Peterson et al, 2009). Apiaceous vegetables (carrots, parsnips, celery or parsley family) inhibit CYP1A2 activity (Peterson, Lampe, Bammler, Gross-Steinmeyer, & Eaton, 2006). Tobacco smoking and charcoal-broiled meat induce CYP1A2 due to their high concentrations of olycyclic aromatic hydrocarbons (Larsen & Brosen, 2005). Patients will need to be educated regarding intake of foods that

induce CYP1A2 if they are on a medication with a narrow therapeutic index, such as theophylline.

Drug Excretion

Certain foods can change urinary pH, which then increases or decreases the amount of the ionized form of a drug or metabolite. The half-life of some medications may be changed by altering urine pH (Ishmail, 2009). For example, gentamicin as a basic drug would be more likely to be reabsorbed in the renal tubule when there is an alkaline pH. Foods that alkalinize the urine include milk, vegetables, and citrus fruits. Foods that acidify the urine include meat, fish, cheese, and eggs (Ishmail, 2009).

Drug-Induced Nutrient Depletion

Another mechanism of interaction between drugs and nutrients is the effect drugs can have on nutrient absorption, synthesis, transport, storage, metabolism, and excretion. The side-effect profile of a drug taken over a period of time can be related to the effect of that drug on nutrient depletion. The number of potential drug-induced nutrient deficiencies is large and growing, and research in this area continues.

The mechanisms of action for drug-induced nutrient deficiencies are varied. As discussed previously, the GI changes due to dietary factors that affect drug absorption can also be induced by drugs and thus affect nutrient absorption. The alterations in gastric emptying time, changes in pH, mucosal irritation (enteropathy), and formation of complexes that can result from drug therapy often have an impact on nutrient absorption. For example, changes in the pH from antacid therapy or potassium therapy can reduce absorption of folic acid, iron, and vitamin B_{12}. Drugs can induce or inhibit metabolic processes and, as a result, affect nutrient metabolism and bioavailability. For example, phenytoin reduces the level of folic acid by inhibition of intestinal enzymes needed for folic acid absorption. Many metabolic pathways rely on specific nutrient availability; therefore, a deficiency results in cellular dysfunction. For example, the synthesis of vitamins, coagulation factors, and neurotransmitters can be affected by reduction in nutrient substrates.

Just as the nutrient can affect excretion of drugs, drugs can affect urinary secretion, reabsorption, and elimination of nutrients. For example, the commonly seen depletion of sodium, calcium, and potassium with loop diuretic use is the result of interference with renal reabsorption. Thus, drug-induced nutrient malabsorption, maldigestion, and vitamin antagonism are potential adverse reactions to commonly prescribed drugs.

Outcomes of Nutrient–Drug Interactions

The physiological and cellular basis for nutrient–drug interactions is strong. However, it is the outcome of the interaction that takes the spotlight. Does the interaction cause a change in the expected outcome of drug therapy or a nutrient deficiency that enhances the potential for adverse reactions or disease progression? Clinically, practitioners often overlook this area. If the expected outcome of drug therapy is not occurring or the adverse reaction profile is enhanced, the practitioner must know the key questions to ask to determine what is happening. It should be clear that a piece of the data needed is related to food and nutrient intake. Could the patient who became pregnant on the low-estrogen birth control pill have a reduction in drug bioavailability owing to food intake? Is the antidepressant not working secondary to high caffeine intake? Is the digoxin (Lanoxin) serum level low because of an aggressive bowel care program with high-fiber intake? And even more important, did the change in dietary fiber intake contribute to the digoxin toxicity the patient is experiencing?

An example of a food–drug interaction is one that occurs between warfarin and vitamin K–containing foods. Patients who are taking warfarin should not ingest foods high in vitamin K, as the combination may lead to therapeutic failure. Patients taking warfarin need to be educated regarding the vitamin K content of foods (Table 9-1). Warfarin and vitamin K interactions are further discussed in Chapter 18.

A high intake of food containing tyramine can result in enhanced norepinephrine synthesis—which can be problematic if the same patient is taking drugs that increase norepinephrine availability at the neurological synapse. For example, the adverse effect of acute hypertension associated with the use of monoamine oxidase inhibitors (MAOIs) is enhanced by intake of foods high in tyramine. The inhibition of aldehyde dehydrogenase by metronidazole results in a disulfiram-like reaction—flushing, headache, nausea, and abdominal or chest pain—when it is taken with alcohol or alcohol-containing products because of alteration in the alcohol metabolism.

Food contains many highly interactive ingredients that can have an impact on drug therapy. For example, the use of caffeine with known central nervous system (CNS) effects is problematic for patients utilizing psychotropic medications. The ability to manage the mental health problem becomes a challenge when high or variable levels of caffeine are consumed. Sorbitol, a common ingredient in sugar-free foods, has a significant effect on GI transit time and thus can influence the absorption of both drugs and nutrients.

Alcohol consumption is also associated with significant drug interaction problems. Alcohol can either induce or inhibit the CYP450 system enzymes, depending on the ingestion pattern. Chronic low levels cause enzymatic induction, whereas high binge intake or high chronic use, resulting in hepatic failure, inhibits the metabolizing enzymes. Therefore, the provider needs to know the patient's specific level of alcohol consumption to better understand the potential for interaction with drugs.

Clinical Decision Making

What can providers do to improve their skill in recognizing nutrient–drug interactions? The provider should consider the following:

1. Use up-to-date resources to evaluate the potential for drug–food interactions.

Table 9–1 Vitamin K Content in Common Foods

Food	Serving Size	Daily Value (%)
Foods High in Vitamin K (more than or equal to 200% DV)	**Eat No More Than 1 Serving per Day**	
Kale, fresh, boiled	1/2 cup	660
Spinach, fresh, boiled	1/2 cup	560
Turnip greens, frozen, boiled	1/2 cup	530
Collards, fresh, boiled	1/2 cup	520
Swiss chard, fresh, boiled	1/2 cup	360
Parsley, raw	1/2 cup	300
Mustard greens, fresh, boiled	1/2 cup	260
Foods Moderately High in Vitamin K (60% to 199% DV)	**Eat No More Than 2 Servings per Day**	
Brussels sprouts, frozen, boiled	1/2 cup	190
Spinach, raw	1 cup	180
Turnip greens, raw, chopped	1 cup	170
Green leaf lettuce, chopped	1 cup	125
Broccoli, raw, chopped	1 cup	110
Endive lettuce, raw	1 cup	70
Romaine lettuce, raw	1 cup	70

Source: Warren Grant Magnuson Clinical Center, National Institutes of Health Drug-Nutrient Interaction Task Force, 2003.

2. Seek out educational materials that can provide accurate and appropriate drug information to patients.
3. Consult with other practitioners, pharmacists, and registered dietitians to identify drug–nutrient interactions.
4. Get a complete patient profile in terms of drug, herb, and nutrient intake. Knowing all of the medications taken—prescribed, over-the-counter, herbal, vitamin, alcoholic, nutrient supplementation—is key to the identification of interaction potential.

The nurse practitioner must understand how the medication is taken in relation to food and fluids. How stable is food intake in terms of the substances known to affect drug absorption, such as fiber, protein, and fat? Clearly communicate to the patient the best routine for medication administration. The nurse practitioner needs to ensure that he or she and the patient read warning labels for instructions about mixing with food, using with nutritional supplements, and taking with fluid.

NUTRITIONAL MANAGEMENT

Consumers have shown increased interest and awareness of the importance of nutrition and nutrients in staying healthy. An outcome of this knowledge is increased use of nutrient supplementation. Nutritional supplementation is the use of vitamins, minerals, or other food factors to support health and prevent or treat disease. There are approximately 50 essential nutrients that must be acquired in the diet to maximize health. Although all nutritionists will explain that the interplay of these nutrients is significant to their role in the body, many still will recommend supplementation of specific nutrients or combinations of nutrients for individuals at risk. It is vital that providers include recommendations about how to utilize diet as part of the plan of care, but it is not uncommon that the ability to accomplish the recommendation by diet alone is difficult for given individuals. In addition, recommended diet alterations might not be best when considering other health problems. Therefore, the provider must become skilled in accurately advising patients about the benefits of nutraceuticals in maintaining health, preventing disease, and treating disease. Those individuals who might be on drug therapy that can induce nutrient deficiencies need specific recommendations about diet and nutrient supplementation to avoid additional drug adverse reactions.

A complete or focused nutritional assessment should be part of the information gathered during the patient interaction. Data from the diet history, anthropometric measurement, physical examination, and laboratory findings are useful for pharmacological decision making. Such team members as a clinical pharmacist and a registered dietitian are especially important in the care of patients with complex medical problems or pharmacological treatment plans. Disease-specific nutritional therapy is beyond the scope of this chapter; the American Dietetic Association (ADA) has developed medical nutrition therapy protocols for a variety of diagnoses (http://www.eatright.org) and the American Society of Parenteral and Enteral Nutrition (ASPEN) has developed clinical guidelines to reflect current, evidence-based

approaches to the practice of nutrition support (http://www.nutritioncare.org).

Although much of the research surrounding use of supplements is not conclusive in terms of randomized clinical trials and is even sometimes contradictory, patients' use of nutritional supplementation is not waiting for conclusive outcomes. To partner with the patient who is interested in nutritional supplementation, nurse practitioners must have a clear understanding of the patient's philosophy surrounding nutritional supplementation and the recommendations of experts in the area. The ADA has developed a position statement about vitamin and mineral supplementation that provides a solid foundation for assisting patients with their nutrient supplementation decisions. The ADA supports obtaining nutrients through a wide variety of foods as the best way to promote health and reduce risk of disease (ADA, 2009).

However, the ADA also defines clearly in their position statement the circumstances in which supplementation is indicated. The following are populations that may warrant supplementation (ADA, 2009):

- Infants and children, including adolescents, need supplementation with 400 IU of vitamin D daily.
- Women of childbearing age who may become pregnant need 400 mcg/day of folic acid.
- Pregnant women need 600 mcg/day of folic acid, a multivitamin/mineral supplement, 27 mg/day of iron (60 mg/d if patient is anemic), and vitamin B$_{12}$ if the patient is vegan or lacto-ovo-vegetarian.
- Older adults over age 50 need vitamin B$_{12}$ 2.4 mcg/day and need to ensure adequate intake of vitamin D and calcium.
- Patients at risk for suboptimal vitamin D levels (older patients, patients with dark skin, patients who are not exposed to sufficient sunlight) should consume vitamin D–fortified foods and/or supplements.

The need to utilize nutritional supplementation is individualized and the nurse practitioner must guide patients to understand their need. Most important in this interaction between patient and practitioner is an open, honest discussion of the nutritional supplementation decision. Although vitamin supplementation is often inexpensive and unlikely to cause harm, the same cannot be said for many other nutrients for which there is no recommended daily allowance (RDA) and no established standard for supplementation. If you do recommend or prescribe a multiple vitamin and mineral supplement for an at-risk individual, it is important to frame the dosage needed around the RDA and recommended vitamin and mineral intake ranges.

NUTRACEUTICALS

As noted previously, nutraceuticals are foods that claim to have a medicinal effect on health. Nutraceuticals may also be referred to as functional foods, but the terms are not interchangeable; functional foods are foods that have health benefits, whereas neutraceuticals include dietary supplements (Crowe & Francis, 2013). There are five major categories of nutraceuticals used routinely in primary care: dietary fiber; vitamins and minerals; bioactive substances; fatty acids; and pre-, pro-, and symbiotics.

The list of nutraceuticals reviewed here is not exhaustive and is limited to those for which there are adequate safety and efficacy data to recommend their use. For a more expansive list of nutraceuticals with the current evidence, the reader is referred to the National Institutes of Health Office of Dietary Supplements (ODS) (http://ods.od.nih.gov). The ODS Web site contains extensive information for both providers and patients regarding nutraceuticals, including nutrient recommendations, a clinical trials database, and consumer safety information.

Fiber

Fiber is the term used to describe the substances in plants that the body cannot digest. According to the Institute of Medicine (2002), there are two types of fiber: dietary fiber and functional fiber. Dietary fiber is the nondigestible carbohydrates and lignin parts of the plant that are intrinsic and intact, whereas functional fiber is the nondigestible carbohydrates that have beneficial effects in human beings. Total fiber is the sum of the two types. The adequate intake for fiber recommendation is based on the fiber intake needed to decrease risk of coronary heart disease (ADA, 2008).

There are over 7.95 million visits per year to providers for constipation (Shah, Chitkara, Locke, Meek, & Talley, 2008). There have been controlled trials in chronically ill children (Daly, Johnson, & MacDonald, 2004), pregnant women (Jewell & Young, 2001), and women in the Nurses' Health Study (Dukas, Willett, & Giovanucci, 2003) that demonstrate a decrease in constipation with an increase in fiber in the diet. The American College of Gastroenterology recommends increased fiber intake to prevent constipation (Ward, 2010).

Dietary fiber intake may also lower cholesterol, improve cardiovascular health, and provide a feeling of fullness that may aid in weight loss. The National Health and Nutrition Examination Survey (NHANES) demonstrated a reduced lifetime risk of coronary heart disease and lower C-reactive protein level with increased fiber intake (Ning, Van Horn, Shay, & Lloyd-Jones, 2014). The American Heart Association (AHA) and the ADA both recommend increased fiber intake (at least 25 g/d) for cardiovascular health (ADA, 2008; AHA, 2014a).

Increased soluble fiber intake has been associated with a number of additional benefits, including better glucose control in diabetics and improved blood lipid levels (Aleixandre & Miguel, 2008; Vuksan, Rogovik, Jovanovski, & Jenkins, 2009), decreased risk of kidney stones in postmenopausal women (Sorensen et al, 2014), and improved bowel function and health-related quality of life in patients with Crohn's disease (Brotherton, Taylor, Bourguignon, & Anderson, 2014). Higher dietary fiber intake is associated with less periodontal disease and tooth loss in older male veterans (Schwartz, Kaye, Nunn, Spiro, & Garcia, 2012). Evidence that dietary fiber decreases cancer risk is inconsistent. Recommended fiber intake is found in Table 9-2.

Table 9–2   Recommended Fiber Intake

Gender/Age	Fiber (g/d)
1–3 yr	19
4–8 yr	25
Female 9–13 yr	26
Male 9–13 yr	31
Female 14–18 yr	29
Male 14–18 yr	38
Female 19–50 yr	25
Male 19–50 yr	38
Female 51 yr or older	21
Male 51 yr or older	30

Vitamins and Minerals

Vitamins and minerals are the most widely used supplements. When ingested as part of food sources, vitamins may be considered nutraceuticals. Evidence regarding recommended dosages and the preventive health properties of vitamins and minerals is constantly evolving. The most commonly recommended vitamins are discussed here and listed in Table 9-3. Iron is discussed in Chapters 18 and 27. More extensive information on vitamins and minerals may be found at the ODS Web site (http://ods .od.nih.gov).

Vitamin A

Vitamin A plays a critical role in vision, bone growth, reproduction, immune function, cell division and differentiation (ODS, 2013a). There are two types of vitamin A: preformed vitamin A, which is derived from animal sources, and provitamin A carotenoid, which is derived from plant sources. A

Table 9–3   Recommended Reference Intakes of Vitamins and Minerals

Nutrient	Age	RDA	Food Sources
Folate	Children: 1–3 yr 4–8 yr Adolescents aged 9–13 yr Adults Pregnancy	150 mcg/d 200 mcg/d 300 mcg/d 400 mcg/d 600 mcg/d	Enriched cereal grains, dark leafy vegetables, enriched and whole-grain breads and bread products, fortifie ready-to-eat cereals
Riboflavin (Vitamin $_{12}$)	Children: 1–3 yr 4–8 yr Adolescents aged 9–13 yr Adults Pregnancy	0.5 mg/d 0.6 mg/d 0.9 mg/d 1.3 mg/d 1.4 mg/d	Organ meats, milk, bread products, and fortified cereal
Thiamin (Vitamin $_1$)	Children: 1–3 yr 4–8 yr Adolescents aged 9–13 yr Adult males Adult females Pregnancy	0.5 mg/d 0.6 mg/d 0.9 mg/d 1.2 mg/d 1.1 mg/d 1.4 mg/d	Enriched, fortified, or whole-grain products; bread an bread products, mixed foods whose main ingredient is grain, and ready-to-eat cereals
Vitamin A	Children: 1–3 yr 4–8 yr Adolescents aged 9–13 yr Adult males Adult females Pregnancy	300 mcg/d 400 mcg/d 600 mcg/d 900 mcg/d 700 mcg/d 770 mg/d	Liver, dairy products, fish, darkly colored fruits and leaf vegetables
Vitamin B_6	Children: 1–3 yr 4–8 yr Adolescents aged 9–13 yr 14–18 yr male 14–18 yr female Adult males 19–50 yr Adult males >50 yr Adult females 19–50 yr Adult females >50 yr Pregnancy	0.5 mg/d 0.6 mg/d 1.0 mg/d 1.3 mg/d 1.2 mg/d 1.3 mg/d 1.7 mg/d 1.3 mg/d 1.9 mg/d	Fortified cereals, beans, meat, poultry, fish, and so fruits and vegetables (bananas, spinach, avocados)

Table 9–3   Recommended Reference Intakes of Vitamins and Minerals—cont'd

Nutrient	Age	RDA	Food Sources
Vitamin C	Children: 1–3 yr 4–8 yr Adolescents aged 9–13 yr 14–18 yr male 14–18 yr female Adult males Adult females Pregnancy	 15 mg/d 25 mg/d 45 mg/d 75 mg/d 65 mg/d 90 mg/d 75 mg/d 85 mg/d	Citrus fruits, tomatoes, tomato juice, potatoes, Brussels sprouts, cauliflower, broccoli, strawberries, cabbage and spinach
Vitamin D	Children: < 1 yr 1–3 yr 4–8 yr Adolescents aged 9–18 yr Adults to age 70 Adults > 70 years Pregnancy	 400 IU/d 600 IU/d 600 IU/d 600 IU/d 600 IU/d 800 IU/d 600 IU/day	Fish liver oils, flesh of fatty fish, liver and fat from sea and polar bears, eggs from hens that have been fed vitamin D, fortified milk products, and fortifie cereals
Calcium	0–6 mo 7–12 m 1–3 yr 4–8 yr 9–13 yr 14–18 yr 19–50 yr 50+ yr	210 mg 270 mg 500 mg 800 mg 1,300 mg 1,300 mg 1,000 mg 1,200 mg	Milk, yogurt, cheese and other dairy products. Nondairy sources: Chinese cabbage, kale, broccoli, sardines
Iron	0–6 mo 7–12 mo 1–3 yr 4–8 yr 9–13 yr 14–18 yr male 14–18 yr female 19–50 yr male 19–50 yr female 19 to 50 yr pregnant 50+ yr	0.27 mg/d 11 mg/d 7 mg/d 10 mg/d 8 mg/d 11 mg/d 15 mg/d 8 mg/d 18 mg/d 27 mg/d 8 mg/d	Chicken liver, oysters, beef, clams, turkey dark meat. Legumes, dark green vegetables. Fortified breads an cereals. Iron-fortified infant formula

healthy diet should contain a variety of carotenoid-rich fruits and vegetables.

Vitamin A deficiency is rare in the United States, but deficiencies may be found in developing countries. Vitamin A deficiency can lead to night blindness and decreased immune function. Vitamin A may reduce the severity and duration of diarrheal episodes in malnourished children in developing countries but not in well-nourished children (Imdad et al, 2011; ODS, 2013a). Vitamin A supplementation has also been found to decrease bronchopulmonary dysplasia in extremely low-birth-weight infants with no increase in mortality or neurodevelopmental disorder (Ambalavanan et al, 2005; Gadhia, Cutter, Abman, & Kinsella, 2014). Chronic alcoholism may lower vitamin A levels, and patients with chronic alcoholism may require supplementation. Patients with cystic fibrosis (CF) are predisposed to malabsorption and fat-soluble vitamin deficiency, with 10% to 40% of CF patients being vitamin deficient and requiring supplementation (Brei, Simon, Krawinkel, & Naehrlich, 2013).

Caution should be used to avoid excessive vitamin A supplementation, as toxicity may occur. Levels above recommended amounts may be teratogenic in pregnant women; vitamin A is labeled Pregnancy Category X if intake is greater than recommended amounts.

Vitamin B$_1$

Vitamin B$_1$ (thiamine) is a water-soluble vitamin critical for many body functions and is widely available in fortified breads and cereals. Deficiency of thiamine can lead to beriberi or Wernicke's encephalopathy. Alcoholic patients develop thiamine deficiency at 8 to 10 times the rate of the nonalcoholic population (Agabio, 2005). Wernicke's encephalopathy is a serious neurological illness in alcoholic patients and requires immediate high-dose levels of thiamine (500 mg IV TID for 2 days, then 500 mg/d IV or IM for 5 days). Patients should be given a daily 100 mg dose of oral thiamine until no longer considered at risk (Charness & So, 2009). Treatment for beriberi in children is IV thiamine 10 to 25 mg or 10 to 50 mg daily for 2 weeks, and

in adults 50 mg IM/IV for several days or 5 to 30 mg/day for a month.

Vitamin B_2

Vitamin B_2, also known as riboflavin, is a water-soluble vitamin. Riboflavin deficiency is rare but may be seen in alcoholics, anorexic patients, and those with lactose intolerance who cannot drink milk or consume other dairy products. Riboflavin has been found to decrease headaches and migraines in some patients (Taylor, 2009). MigreLief, an over-the-counter product that contains feverfew, riboflavin, magnesium, and other vitamins, is a commonly used preventive headache medication. Doses of 25 to 400 mg of riboflavin daily are used for migraine prevention.

Vitamin B_3

Vitamin B_3, or niacin, is a water-soluble vitamin and antilipidemic. Niacin deficiency or pellagra results from inadequate intake. Pellagra is treated with 50 to 100 mg niacin three times daily. Use of niacin in the treatment of hyperlipidemia is discussed in Chapter 39.

Vitamin B_6

Vitamin B_6, also known as pyridoxine, is a water-soluble vitamin needed for protein and red blood cell metabolism, as well as glucose regulation. Vitamin B deficiency may lead to microcytic anemia, dermatitis with mouth sores and cracked lips, and glossitis (ODS, 2011a). Vitamin B_6 deficiency may be drug-induced by use of isoniazid (INH), cycloserine, or hydrazine, or caused by a diet that is deficient in vitamin B_6–containing foods (fortified cereals, potatoes, bananas, meat). Pyridoxine (vitamin B_6) 25 mg/day should be added to the regimen for pregnant patients to decrease the incidence of peripheral neuropathy associated with INH (American Thoracic Society, 2003). Pyridoxine (adults 100 to 200 mg/d in divided doses) may also be given prophylactically to patients on isoniazid, cycloserine, or hydrazine to prevent drug-induced neuritis. Vitamin B_6 supplements may reduce the symptoms of premenstrual syndrome, and nausea and vomiting associated with pregnancy (10 to 25 mg TID) (ODS, 2011a).

Vitamin B_{12}

Vitamin B_{12} is a water-soluble vitamin that is essential for red blood cell formation and neurological function. Older adults and patients with reduced stomach acid levels, gastric bypass surgery, or intestinal disorders (celiac disease or Crohn's disease) may not absorb vitamin B_{12} well and are at risk for deficiency (ODS, 2011b). Also, women who follow strict vegetarian diets without supplementation place their breastfed infant at risk for vitamin B_{12} deficiency. Acid suppression medications (proton pump inhibitors or H2 receptor antagonists) and metformin reduce the absorption of vitamin B_{12}. vitamin B_{12} deficiency will lead to megaloblastic anemia, fatigue, loss of appetite, and neurological changes (numbness and tingling in hands and feet). A complete discussion of vitamin B_{12} replacement is found in Chapter 27 under the discussion of anemia.

Vitamin C

Vitamin C, also known as ascorbic acid, is a water-soluble vitamin that humans do not have the ability to synthesize so they must get adequate amounts of it in their diet. Patients with inadequate vitamin C intake may develop scurvy, with symptoms of fatigue, malaise, and gum inflammation or bleeding. Scurvy is rare in developed countries but may occur in cases of limited intake or limited food variety. Smokers and persons who are heavily exposed to secondary smoke have decreased vitamin C levels; therefore, it is recommended they take 35 mg more vitamin C per day than nonsmokers (ODS, 2013b). Other groups at risk of vitamin C deficiency are infants fed evaporated milk or boiled milk without additional supplementation of vitamin C, patients with malabsorption disorders, and patients with end-stage renal disease who are on hemodialysis (ODS, 2013b).

Vitamin C therapy has been studied for its effects on health because of its antioxidant and immune function action. It has been touted as prevention or treatment of the common cold since the 1970s, when Linus Pauling published his landmark study. A *Cochrane Review* in 2007 of 30 trials did not find that vitamin C decreases the incidence of colds in the general population (Douglas, Hemiliä, Chalker, & Treacy, 2007).

The role of antioxidants in reducing the risk of cardiovascular disease has been studied extensively with mixed results. The Nurses' Health Study found an inverse relationship between coronary heart disease and vitamin C intake (Osganian et al, 2003). In the Physicians' Health Study, vitamin C supplementation for a 5.5-year period did not decrease the risk for cardiovascular disease mortality (Muntwyler, Heenekens, Manson, Buring, & Gaziano, 2002). However, a large ($N = 20,649$ men and women) study in Great Britain found those who had the highest vitamin C concentrations at baseline had a 42% lower risk of stroke, when controlling for age, sex, lifestyle, and other risk factors (Myint et al, 2008). A meta-analysis of 16 studies examining vitamin C intake, circulating vitamin C levels, and risk of stroke suggests lower stroke risk with higher vitamin C intake and levels (Chen, Lu, Pang, & Liu, 2013).

Studies of vitamin C as an antioxidant to prevent cancers show mixed results. In a long-term (10-year), large ($N = 77,721$) study of the effect of vitamin C supplementation on the development of lung cancer, there was no decreased risk of cancer in the group taking vitamin C (Slatore, Littman, Au, Satia, & White, 2007). A large, multiethnic study of Hispanic and non-Hispanic white women did not find any protective effects against breast cancer in women who took dietary antioxidants including vitamin C (Wang et al, 2009). Decreased cervical cancer was found in a smaller study ($N = 144$) of women who had higher intakes of the antioxidant vitamins A, C, and E; the isolated effects of vitamin C are not known (Kim et al, 2010). Because of the mixed results, there is no strong recommendation for vitamin C supplementation,

beyond the recommended daily amounts, as prevention for cancer. Table 9-3 lists the recommended vitamin C intake levels for all ages.

Vitamin D

Vitamin D is a fat-soluble vitamin that is available in some foods, such as egg yolks and fatty fish (salmon and mackerel). The body synthesizes vitamin D when sunlight strikes the skin and triggers vitamin D synthesis. Vitamin D supplements, food sources, and the vitamin D synthesized from sunlight must be converted to an active form of drug in the liver and kidneys. The liver converts vitamin D into 25-hydroxyvitamin D, or calcidiol. The kidneys convert vitamin D into 1.25-dihydroxyvitamin D, or calcitriol. Vitamin D is critical to bone health as it is required for absorption of calcium from the intestinal tract and, when converted to calcitriol, regulates serum calcium and phosphate levels. It is a critical component in bone growth and remodeling. Vitamin D deficiency will lead to brittle bones that may become misshapen, a condition known as rickets in children and as osteomalacia in adults (ODS, 2011c).

Multiple studies link low vitamin D levels to increased asthma in adults and children. The use of oral corticosteroids places the patient at 20% to 40% higher risk of vitamin D deficiency (Korn et al., 2013). Vitamin D is an immunomodulator, which alters the development of immune cells, reduces airway remodeling and the inflammatory response, improves eosinophil function, and inhibits fibrotic mediators (Poon et al, 2013; Rance, 2013). Vitamin D supplementation may also improve asthma symptoms, particularly if the patient is deficient.

Serum levels of 25(OH)D can be drawn to determine whether the patient is vitamin D deficient. Table 9-4 lists ranges of 25(OH)D associated with deficiency and toxicity. Vitamin D is added to milk, most milk substitutes, infant formula, and dry cereal and is available in supplements as either vitamin D_2 or D_3. The use of vitamin D in the prevention and treatment of rickets, osteomalacia, and osteoporosis is discussed in depth in Chapter 38.

Vitamin K

Vitamin K, a critical component of blood clotting, is found in many foods and is synthesized by intestinal bacteria. Vitamin K deficiency is rare beyond the newborn period. Newborns are at risk for early vitamin K–deficiency bleeding, and the American Academy of Pediatrics recommends that all newborns receive vitamin K within the first 2 weeks of life (American Academy of Pediatrics [AAP] Committee on Fetus and Newborn, 2003), a recommendation it reaffirmed in 2009. The dose of vitamin K (phytonadione) recommended by the AAP is 0.5 mg to 1.0 mg IM, ideally given within the first hour of life (AAP Committee on Fetus and Newborn, 2003). Oral vitamin K is used by some countries and by some providers in the United States. The AAP notes that several countries have reported an increase in late-onset, vitamin K–deficiency bleeding in newborns who received oral vitamin K. The AAP recommends IM administration until further study of oral administration is conducted.

Warfarin interferes with the vitamin K–dependent clotting factors (II, VII, IX, and X), leading to decreased formation of clots. Vitamin K (phytonadione) is prescribed for patients who develop critically high INRs while on warfarin. Patients with an INR greater than 10 with no evidence of bleeding can be administered oral vitamin K (5–10 mg): if high INR with bleeding occurs, vitamin K (5–10 mg IV) is administered along with prothrombin complex (Guyatt et al, 2012).

Folate

Folate is a water-soluble vitamin that is critical to the production and maintenance of new cells. Folate is found in foods such as green leafy vegetables, citrus fruits, and dried legumes. Folic acid, the synthetic form of folate, is added to breads, flours, pastas, rice, and other grain products (ODS, 2012a). Folate deficiency occurs in times of increased demand, such as occurs in pregnancy and lactation, or when loss increases (malabsorption, alcohol abuse, dialysis, liver disease). Medications may interfere with folate utilization, leading to deficit (Box 9-1). Folic acid supplementation is recommended for all women of childbearing age (400 mcg/d),

Table 9–4 **Serum 25-Hydroxyvitamin D [25(OH)D] Concentrations and Health***

ng/mL**	nmol/L**	Health Status
<10–11	<25–37.5	Associated with vitamin D deficiency, leading to rickets in infants and childre and osteomalacia in adults
<10–15	<25–37.5	Generally considered inadequate for bone and overall health in healthy individuals
≥15	≥37.5	Generally considered adequate for bone and overall health in healthy individuals
Consistently >200	Consistently >500	Considered potentially toxic, leading to hypercalcemia and hyperphosphatemia, although human data are limited. In an animal model, concentrations ≤400 ng/mL (≤1,000 nmol/L) demonstrated no toxicity

* Serum concentrations of 25(OH)D are reported in both nanograms per milliliter (ng/mL) and nanomoles per liter (nmol/L).
** 1 ng/mL = 2.5 nmol/L
Source: Office of Dietary Supplements, 2010.

with extra given when a woman is pregnant (600 mcg/d) to prevent neural tube defects in the fetus (ODS, 2012a). Lactating women should take 500 mcg/day.

Folate is necessary for the normal maturation and functioning of red blood cells. Folate deficiency produces a macrocytic-normochromic anemia. Patients with folic acid–deficiency anemia commonly complain of glossitis, stomatitis, nausea and anorexia, and diarrhea, and a systolic ejection murmur may be heard. Oral folic acid is well absorbed, and doses of 1 to 2 mg/day result in correction of the deficiency in 4 to 5 weeks. Hemoglobin (Hgb) levels begin to rise within the first week, and anemia is completely corrected in 1 to 2 months.

Calcium

Calcium is a critical mineral in the function of the body, required for muscle contraction, blood vessel health, bone health, and normal nerve conduction. Maintaining calcium balance involves a complex relationship between adequate intake of calcium and vitamin D and endocrine system function. Populations at risk for calcium deficiency include postmenopausal women, amenorrheic women, women with female athlete triad, patients with lactose intolerance who cannot tolerate dairy products, and vegans. In the 2003–2006 NHANES study, the population groups with inadequate dietary calcium intake were females aged 9 to 13 years, 14 to 18 years, 51 to 70 years, and those over age 70 (Bailey et al, 2010). Calcium supplements were used by 43% of the NHANES 2003–2006 study population, leading to an adequate total calcium intake for all groups except for females in the 9- to 13-year-old and 14- to 18-year-old groups (Bailey et al, 2010). Recommended daily amounts of calcium are found in Table 9-3. The use of calcium for osteoporosis prevention is discussed in Chapter 38.

Iron

Iron is an essential mineral required for the regulation of cell growth and differentiation, as well as a component of oxygen transport. Patients with iron deficiency will develop microcytic-hypochromic anemia and have red blood cells that are small in size, pale, and low in hemoglobin. Iron-deficiency anemia (IDA) reduces the oxygen-carrying capacity of the blood, leading to fatigue and decreased immunity. Too much iron can lead to iron toxicity; therefore, patients should be advised to take only the recommended amount for their age and condition (Table 9-3). The use of iron for the treatment of IDA is discussed in depth in Chapter 27.

Fatty Acids

The fatty acids are also called *essential* fatty acids. Fatty acids need to be consumed in food or via supplements, as the body cannot make them. The polyunsaturated fatty acid alpha-linolenic acid (ALA) is ingested in the diet and is an omega-3 fatty acid; linoleic acid (LA), also ingested from the diet, is an omega-6 fatty acid. Omega-3 is converted to the fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in the body. Most Americans consume more omega-6 than omega-3 fatty acids, although it is recommended that more omega-3 than omega-6 should be consumed. Dietary sources of ALA are nuts, vegetable oils, and leafy green vegetables, whereas LA is found in vegetable oils and meat. Dietary sources of EPA and DHA are fish and organ meats (Vannice & Rasmussen, 2014).

The ODS conducted extensive evidence-based reviews to determine the best science regarding fatty acid supplementation. There is extensive evidence for the use of omega-3 fatty acids, either via the diet or supplementation, for its cardiovascular effects (Vannice & Rasmussen, 2014). Omega-3 fatty acid and its derivatives DHA and EPA have well-documented vascular protective effects, as well as anti-inflammatory effects.

Fish oil might have antiarrhythmic effects (ODS, 2004a) and consumption of omega-3 fatty acids, whether from fish or from supplements, reduces mortality and improves outcomes in patients with cardiovascular disease (Lee, O'Keefe, Lavie, Marchioli, & Harris, 2008; ODS, 2004b). In patients with diabetes, omega-3 fatty acids reduced triglyceride levels but have no significant effect on total cholesterol, high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol, fasting blood sugar, or glycosylated hemoglobin (ODS, 2004d).

Omega-3 fatty acids have received attention as a possible treatment for autism and attention deficit-hyperactivity disorder (ADHD). The theory is that either deficiency in omega-3 or an imbalance in the omega-3 to omega-6 fatty acid ratio is affecting neurocognitive development in children. It is clear that sufficient amounts of the essential fatty acids are crucial in central nervous development, with deficiency or imbalance found in multiple observational studies of children with neurocognitive issues (Schuchardt, Huss, Stauss-Grabo, & Hahn, 2009). This has led to the addition of DHA and ARA to commercial infant formulas (Enfamil LIPIL) to meet the need in the key developmental period of infancy.

In an extensive review of new and novel treatments for autism spectrum disorder, Rossignol (2009) rates omega-3 fatty acids with a C for supportive evidence (A to D scale; C indicates either one low-quality, randomized controlled trial or two case series reports). In another study by Meiri, Buchovsky, and Belmaker (2009), autistic children administered 1 g of omega-3 fatty acids daily demonstrated a 33% improvement on the Autism Treatment Evaluation Checklist.

Numerous studies of the use of omega-3 fatty acids in children with ADHD demonstrate improvement in ADHD scores (Schuchardt et al, 2009; Bloch & Qawasmi, 2011; Gillies, Sinn, Leach, & Ross, 2012). With these findings and the understanding of the need for essential fatty acids in neurological development, ensuring a diet that is rich in essential fatty acids throughout infancy and childhood is critical, with the trial of supplemental omega-3 fatty acids in children with autism or ADHD warranted.

Not all health claims for essential fatty acids are supported by evidence. For example, there is no supportive evidence for the use of omega-3 fatty acids in the care of asthma (ODS, 2004b), prevention of cancer or treatment after tumor removal (ODS, 2005a), or mental health disorders (including schizophrenia) (ODS, 2005b). Inconsistent findings in organ transplant patients warrant further study of omega-3 fatty acids in this population (ODS, 2005c). There was no reported improvement from the effects of omega-3 fatty acids in patients with rheumatoid arthritis in terms of patient report of pain, swollen joint count, erythrocyte sedimentation rate (ESR), and patient global assessment (ODS, 2004d). Research regarding the use of omega-3s in adult patients with cognitive decline is inconclusive (ODS, 2010e).

Recommended amounts of omega-3 fatty acids can be ingested in the diet by eating fatty fish or by taking fish oil capsules. The American Heart Association (2014b) recommends two servings a week of fatty fish such as salmon, mackerel, herring, lake trout, sardines, and albacore tuna for heart health. The recommended amount of omega-3 fatty acid from fish per day is 500 mg/day if there is no history of coronary heart disease (CHD), 1 g per day if there is a documented history of CHD, and 2 to 4 g/day to lower triglycerides (American Heart Association, 2014; Covington, 2004; Lee, O'Keefe, Lavie, Marchioli, & Harris, 2008). It may take 2 to 3 weeks for the effects of omega-3 to be seen. The National Heart Lung and Blood Institute (NHLBI) guidelines for reducing cardiovascular risk in children and adolescents recommend increasing dietary fish intake to increase omega-3 fatty acid intake (NHLBI, 2012). The studies of omega-3 for the treatment of ADHD and autism used 500 mg to 1 g/day.

Plant Sterols

Plant sterols are found in all plant-based foods as part of the structural components of the cell membrane (Ellegard, Andersson, Normen, & Andersson, 2007). Plant sterols are similar in structure to cholesterol but contain an extra methyl or ethyl group. When consumed in the diet, plant sterols compete with cholesterol in the intestine, reducing the amount of cholesterol that is absorbed (Devaraj & Jialal, 2006). Intake of 2 g/day of plant sterols has an associated 6% to 10% reduction in LDL cholesterol (Devaraj & Jialal, 2006; Ellegard et al, 2007). Combining plant sterols with cholesterol-lowering medications results in an additional 16% to 20% reduction in LDL (Berger, Jones, & Abumweis, 2004; Katan et al, 2003). The only adverse effect of plant sterols is reduced beta-carotene levels, which can be treated with an

increased intake of carotene-containing fruits and vegetables (Berger et al, 2004; Devaraj & Jialal, 2006).

Plant sterols are present in edible oils (corn oil and canola oil have the highest amount), seeds, and nuts (Ellegard et al, 2007). There are many commercial food products available with added plant sterols, including margarine (Promise Active 1 g/serving, Benecol spread 0.85 g/serving, Smart Balance HeartRight 1.7 g/serving), orange juice (Minute Maid Heart Wise 1 g/serving), and milk (Smart Balance HeartRight 400 mg/serving). The recommended amount of plant sterols for LDL reduction is up to 2 g/day (Devaraj & Jialal, 2006). The NHLBI guidelines for children and adolescents is that plant sterols up to 2 g/d can be used as a replacement for the usual fat sources after age 2 years in children with familial hypercholesterolemia (NHLBI, 2012). Plant sterols may be combined with a low saturated fat and cholesterol diet, dietary fiber, and/or lipid-lowering drugs for an additive effect on reducing LDL cholesterol (Devaraj & Jialal, 2006).

Pre-, Pro-, and Symbiotics

Probiotics are nonpathogenic bacteria normally found in the intestinal microflora, the most common of which are *Lactobacillus acidophilus* and the *Bifidobacterium* species. Prebiotics are nondigestible food ingredients that stimulate growth of probiotic organisms, and symbiotics are a mixture of probiotics and prebiotics. Probiotics are used to restore the normal balance of gut flora that is disturbed with antibiotics, immunosuppressive medications, and other conditions (Weichert et al, 2012; Williams, 2010).

Probiotics have been used for many years and have been studied extensively for their health benefits and their effects on diarrhea. A *Cochrane Review* of the use of probiotics in rotavirus-associated acute diarrhea in children found probiotics reduced diarrhea severity and duration by 1 to 3 days (Allen, Okoko, Martinez, Gregorio, & Dans, 2004). Probiotics also reduce antibiotic-associated diarrhea in adults (D'Souza, Rajkumar, Cooke, & Bulpitt, 2002; Safdar, Barigala, Said, & McKinley, 2008; Tong, Ran, Shen, Zhang, & Xiao, 2006) and in children (Johnston, Supina, Ospina, & Vohra, 2007). It is reasonable to prescribe probiotics for patients with infectious or antibiotic-associated diarrhea.

Probiotics may also improve inflammatory bowel disorders and necrotizing enterocolitis (NEC). Premature infants have sterile guts when they are born and are at risk for bowel problems, including NEC. Multiple studies and reviews have found probiotics beneficial in preventing NEC and death in preterm infants (AlFaleh & Bassler, 2008; Bosante, Iacobelli, & Gouyon, 2013; Deshpande, Rao, Patole, & Bulsara, 2010; Fernández-Carrocera et al, 2013; Lin et al, 2008). Probiotics improved colic symptoms in a multicenter, double-blind, placebo-controlled trial of infants started on probiotics soon after birth (Indrio et al, 2014). Use of probiotics improved Symptom Severity Scores in patients with irritable bowel syndrome (Williams et al, 2008). Probiotics have also been found to improve eradication rates in patients being treated for *Helicobacter pylori* (Tong et al, 2006).

HERBAL THERAPY AND NUTRITIONAL SUPPLEMENTS

Fujio McPherson

P hytomedicine, defined as "the practice of using plants or plant parts to achieve a therapeutic cure" (Fetrow & Avila, 1999), is the oldest known form of medicine. Originally, plants were considered only for their nutritional value. However, from experience in plant production and awareness of plant behavior, noting the influence of climate and environmental changes on planting outcomes and the effects of specific plants in creating or removing various symptoms in the body, humans began to use plants as medicine.

In many cultures, herbal traditions are a part of a history that began well before the scientific dissection of plant cellular components. It is impossible to determine precisely when humans first discovered the medicinal use of any given plant, but through time and observation every culture developed a pharmacopoeia of herbal remedies. The Egyptians were widely respected for their use and recording of herbal remedies, many of which are still used today, including opium, cannabis, myrrh, frankincense, and fennel. The Greek and Roman use of herbs was based on the principles of the four humors that derived from the Indian and Chinese cultures. One of the oldest forms of herbal medicine was their use in altering states of consciousness in the shamanic traditions of South American and many of the Native American cultures. The Greeks also used hallucinogenic herbs, such as opiates, to heighten the healing powers within the body while the patient lay in an altered state of consciousness in Asclepian healing temples.

Today, the use of herbal medicine in the United States has grown significantly since the early 1990s. As determined by the 2007 National Health Interview Survey, 55.1 million adults in the United States had used herbs or supplements in the past 12 months, up from 50.6 million in the 2002 survey (Wu, Wang, & Kennedy, 2011). And up to 2.9 million children aged 4 to 17 years had used herbs or dietary supplements in the previous 12 months (Wu, Wang, & Kennedy, 2013). As mainstream medicine diverged from a predominantly plant-based pharmacopoeia to a synthesized, chemically based pharmacopoeia that is accompanied by a myriad of harmful

side effects, a belief that herbal medicines are safer and have less harmful side effects has evolved to such a degree that many patients often abandon their use of synthetic medication for over-the-counter herbal substitutes. With limited regulation by the U.S. Food and Drug Administration (FDA), herbal formulas and products, which are classified as food sources, have become widely available.

Thus, allopathic providers are now faced with the challenge of drug and herbal interactions as well as by working with strong patient belief systems that can compromise management of the patient's condition. Providers need to consider the impact herbs may have on their medical and pharmaceutical management. In many cases, herbal therapy has proven to be very effective at either enhancing medical management of a disease and/or reducing the need for stronger pharmaceutical management, in some cases successfully replacing more harmful pharmaceutical drugs without the harmful side effects while achieving the same efficacy. For example, the root bark of *Hibiscus syriacus* has been used for many years in Asia as an antipyretic, antihelminthic, and antifungal agent. The results of a 2008 study indicated the herb had a significant and dose-dependent antiproliferative effect on lung cancer cells in vitro and in vivo (Cheng, Lee, Harn, Huang, & Chang, 2008).

Yet there are also many studies that identify potentially harmful effects of herbal therapy. Buettner, Mukamal, Gardiner, & Davis (2009) found lead levels to be 10% higher among women who used St. John's wort, Ayurvedic herbs, and some traditional Chinese herbs. Coenzyme Q10, a supplement commonly used to improve memory and cardiovascular function, was found to reduce the effectiveness of warfarin, and evidence is still inconclusive regarding its effect in reducing cardiovascular conditions like exercise-induced angina. When taken in doses higher than 3,000 mg per day for a prolonged period of time, CoQ10 can cause elevated liver enzymes.

Many studies support the argument that further research or regulation of herbal therapy is needed, but they also make clear that the safety and efficacious use of herbs in the treatment of specific disorders cannot be truly evaluated without considering the theories and principles of the traditional medicines of which they are a part. It is common knowledge that every pharmaceutical prescription has side effects that range from mild to life-threatening, so excluding the use of an herb solely due to its side effects is not only misguided but fails to consider the difference between herbal side effects and pharmaceutical side effects. For example, in Chinese medicine, an herb may be used for its cooling effect, and so the side effect that would indicate the herb is working properly would be the patient's display of symptoms of cold versus heat and a side effect of loose stools (which is an indication of cold) would actually be a positive sign rather than a negative side effect, as it would be considered by any Western research criteria. Most traditional herbal theories do not use scientific criteria in determining the use of an herb, and so allopathic medical practice does not recognize the theories and long traditions on which trained herbalists base their diagnoses and prescriptions of specific herbs and herbal formulas.

By definition, herbal therapy encompasses any plant source, which means that it also includes food. When the plant or a constituent of the plant is identified as a specific treatment for a disease or symptom, it is often referred to as an herb. And the designation of an herb as a medicine is based on how it is used. Herbs have long been considered one of the safest medicines to take and, like foods, can be classified by their effects on the body—mild, strong, or toxic. However, as mentioned, it is more important to understand the theory behind the herb before one can understand how it is used in the treatment of a disease. This includes understanding the various methods by which herbal preparations are prepared and manufactured. So it is imperative that nurse practitioners and other allopathic providers understand not only the name, ingredients, and source of a particular herb but also the various theories used in herbal medicine, or they should consult with clinicians who are trained in herbal medicine to better care for the patient who chooses to use herbal remedies.

This chapter serves as an introduction to phytomedicine. Because this is a relatively new area of study for Western health practitioners, the chapter includes definitions of terms and descriptions of the various principles involved in prescribing and using herbal medicines in North America. The purpose here is not to train readers to be herbalists but rather to introduce them to some of the major herbal theories used in the prescription of herbs, that is, the chapter is an introduction rather than a prescriptive resource.

OVERVIEW OF HERBAL MEDICINE

To understand the concept and theories of herbal medicine, it is important to examine the many herbal traditions practiced in the world today. For the purpose of this particular text, three traditions will be examined: Western herbal medicine, Ayurvedic herbal medicine, and traditional Chinese herbal medicine. Yet the reader is encouraged to explore other traditions of herbal medicine also, among them Unani medicine, homeopathic medicine, Native American traditional medicine, and shamanic herbal medicine.

DEFINITIONS

Medicinally an *herb* is any plant part or whole plant used for its therapeutic value. Yet many of the world's herbal traditions are not limited to plants only; mineral and animal substances are included as well. *Herbal medicine* is the art and science of using herbs for promoting health and preventing and treating illness. It has a written history that is more than 5,000 years old. Although the use of herbs in America has been overshadowed by dependence on modern medications in the last 100 years, 75% of the world's population relies primarily on traditional healing practices and the use of herbal medicine.

Pharmacognosy is the branch of pharmacology that uses the chemicals from plants, molds, fungi, insects, and marine animals for their medicinal value. Today, most pharmaceutical

drugs are single chemical entities from plant sources that have been highly refined, purified, and synthesized into a single active component of the plant. Many of the drugs used in allopathic medicine were derived from plants in this way, including digitalis from foxglove, ephedrine from *Ephedra*, and ergotamine from *Claviceps purpurea*. In 1987, about 85% of modern drugs were originally derived from plants. However, only about 15% of all drugs are derived from plants today owing to advancements in synthetic reproduction and purification of plant constituents. In contrast, herbal medicines are prepared only from living or dried plants and contain hundreds to thousands of interrelated compounds, creating a type of synergy between its many constituents that science is now considering as the reason for the safety, effectiveness, and lower incidence of side effects of herbs (American Herbal Guild [AHG], 2006).

Western Herbal Medicine

The beginning of science-based herbal medicine can be traced back to the European Renaissance, when political independence from the Church and advances in science contributed greatly to the study of medicine. William Turner (1510–1568), regarded as "the father of British botany," was the first to scientifically study plants. John Gerrard (1545–1612), a surgeon and the author or *Gerard's Herbal*, studied over 1,000 plants and recorded his observations of their behavior and uses. But one of the most interesting scientists of this era was Nicolas Culpepper (1616–1654), who studied the relationship of herbs to astrology. Although he was ostracized by his peers at the time for his theories, his understanding of herbs from an energetic perspective influenced by factors other than the physical components of nutrients was very similar to the Eastern interpretation of plant-based medicine. Yet he fared much better than his female counterparts outside of the scientific community who used herbal medicine to heal. These female healers, branded as witches, were hunted down during the Inquisition, which effectively suppressed and eliminated this form of medicine and succeeded in denigrating the efforts of lay healers. Another pioneer in herbal medicine was Johann Wolfgang Von Goethe (1749–1832), a German herbalist who stated that the chemical mixture of the plant was the "open secret" to its effectiveness. Despite these setbacks, many of these early discoveries have survived and continue to be practiced today.

In Western herbology, herbs are primarily classified according to their therapeutic properties and the constituents of the plant. For example, the categories of diuretics, diaphoretics, and tonics allow Western herbalists to group herbs with similar qualities and then use them accordingly. This system is primarily based on the chemical constituents of the plant and remains the basis of Western pharmacology as well some of the herbal therapies used by many naturopathic physicians and other herbalists who base their practice on scientific examination of the plant.

What makes this form of herbal therapy different from Western pharmacology is that it is based on constituents taken from the plant instead of the synthetic modification commonly found in prescription drugs. One example is bromelain, a sulfhydryl proteolytic enzyme that is found in pineapple juice and in the pineapple stem. Bromelain activates the proteolytic activity at sites of inflammation and is commercially used as a natural anti-inflammatory agent (Pizzorno & Murray, 2006). Therefore, an herbal option to reduce inflammation can be bromelain or pineapple. Another example is the rhizome ginger commonly used in cooking. Ginger is considered a tonic, and one identified constituent of ginger root (*Zingiber officinale*) is the sesquiterpenes, which have significant antirhinoviral activity that is used to combat colds (Mills & Bone, 2000). Products made from ginger (e.g., teas, candy, lozenges) are used in the treatment of cold symptoms.

It is common to see the same plant being used in several different herbal theories, and although the principle actions are the same, the differences lie in how the plant is used and which parts. One example is cinnamon. Cinnamon (*C. zeylanicum*) is often referred to as "true cinnamon" or Ceylon cinnamon. However, a commercially related species known as cassia (*C. aromaticum*), or Saigon cinnamon (*C. loureiroi*), and *C. burmannii* are also labeled as cinnamon. True cinnamon (Ceylon cinnamon) comes from the thin inner bark; is finer, less dense, and more crumbly in texture; and is considered to be less strong than cassia. Cassia is derived from the entire bark layer, so it is thicker and has a much stronger, harsher flavor than cinnamon. This distinction is important because of a moderately toxic component called coumarin, which can cause liver and kidney damage in the high concentration that is found in higher doses of cassia compared to Ceylon cinnamon, in which the levels of coumarin are negligible.

Often used for its oil, cinnamon contains primarily cinnamic aldehyde but also has ethyl cinnamate, eugenol (found in the leaves), beta-carvophyllene, linalool, and methyl chavicol; it is used to cure colds and treat diarrhea and problems of the digestive system. It has been reported to be effective in the treatment of type 2 diabetes mellitus (Khan et al, 2003). In traditional Chinese medicine, cinnamon (Gui Zhi) is used to treat colds but is defined by its ability to release excess wind-cold conditions, warm and open channels and collaterals, and warm yang and is identified as being contraindicated in patients with yin deficiency or those having blood disorders because it stimulates blood circulation (Chen & Chen, 2001).

Traditional Chinese Medicine

The origins of traditional Chinese herbal medicine (TCM) are difficult to date; however, one of the oldest surviving texts that form the basis of TCM is the *Huangdi Neijing*, "The Inner Canon of Huangdi or Yellow Emperor's Inner Canon," first referenced in the *Book of Han*, in 111 CE. The *Huangdi Neijing* is composed of two texts, each with 81 chapters or treatises, and is primarily a written record of questions and answers between the mythical Huangdi (Yellow Emperor) and six of his ministers. The first text, the *Suwen*, covers the theoretical foundation of Chinese medicine and its diagnostic

methods, and the second text, the *Spiritual Pivot*, discusses acupuncture therapy. The second important text in Chinese herbal medicine is the *Shang Hang Lun*, "Treatise on the Treatment of Acute Diseases Caused by Cold," written by Zhang Zhong-Jing (142–220 CE). The *Shang Hang Lun* describes the six stages of acute disease as an approach to the diagnosis and treatment of acute illness and is comprised of classical herbal formulas that can be used to treat them. Today, formulas contained in the *Shang Hang Lun,* such as Ge-Gen Tang, Shao Yao Gan Cao Tang, and Xiao Qing Long Tang, are still commonly used among TCM practitioners.

The *Huangdi Neijing* not only departed from the shamanic beliefs of the past but elaborated on the concepts of Daoist theory on which TCM is based. The Dao concept is that man is a microcosm of a larger macrocosm and to stay healthy or "in balance" there must be an intimate respect and understanding for the laws of nature and how those laws apply to man. Health or balance by definition results when there is a free flow of energy (qi). When qi is abundant and flowing freely, the body is able to heal itself and the patient will feel a balance of the mind, body, and spirit. Just as in nature, when there is enough water, nutrients, and sunlight, the plant will flourish and grow. Of course, knowing how to determine an imbalance (diagnosis before the presence of disease) or knowing the source of a disease resulting from an imbalance and how to prevent the progression of the imbalance, support self-healing, and treat the disease is the principle science of TCM.

There are a number of theories about how to interpret changes of balance in the human body, mind, and spirit. How TCM is practiced based on one or more of these theories often depends on the training of the practitioner and what the practitioner feels best suits the patient's condition. By understanding the basic principles of these TCM theories—yin and yang; the five elements; and the influence of environmental factors (wind, damp, hot and cold, dry, and wet)—along with the effects of diet, lifestyle, age, and emotions, a specific TCM diagnosis regarding the cause of imbalance can be determined and herbal therapy along with other treatment modalities like acupuncture, diet, counseling, movement, massage, and so on can be used to bring the body back into balance, promote self-healing, and treat diseases.

If there is one feature that distinguishes Western medicine from traditional Chinese medicine, it is the paradigm from which they view man and the role of plants. Instead of relying on science to identify the nature of disease and health, the Chinese look at nature from a Daoist perspective, paying attention to cycles of growth, the characteristics of the plant (according to taste and expression), the underlying condition of the individual consuming the herb, and most importantly the constitution of the individual.

In TCM, the herbs that represent energy (qi) are classified in a number of ways: by their amount of energy, quality, seasons in which they are at maximum strength, tastes, directions, and actions on the body (e.g., moving blood, reducing dampness or heat, breaking up stagnation, etc.). Traditionally, herbal formulas also include animal organs and minerals

for the same reasons. Using these principles, TCM practitioners use herbs to influence the imbalances unique to the patient. This symbiotic relationship is one of the most important aspects of TCM herbal medicine. Customizing the herbal formula and its properties to address the individual deficiencies or excesses assumes a more holistic approach to healing and the role of herbs in the treatment of diseases. For example, in TCM menopause is often considered a time of yin deficiency, so herbs that are yin in nature and that clear heat arising from deficient yin, such as mountain peony bark (*mu dan pi*) and phellodendron bark (*huang bai*), or formulas that contain each, are often recommended (Liu & Tseng, 2003). In doing so, TCM recognizes that if these herbs were applied inappropriately, for example, giving a yin herb to a yin excess patient, the herb could potentially make the condition worse even though the underlying condition is menopause. As mentioned, it is important to remember that TCM does not often restrict treatment to a single herbal therapy as does Western herbal medicine; it recognizes the principles of the Dao and concepts of change, so herbal therapy and formulas will often be changed within short intervals of time.

Although the focus of this chapter is herbal therapy, it is also important to remember that TCM places as much value on the power of food as it does on herbs in healing and never excludes food or herbs from the other aspects of TCM, which include the practice of acupuncture, energy movements (tai chi), massage (tui nai), and balance.

Ayurvedic Medicine

Ayurvedic medicine was developed in ancient India; it is defined as the study of life: *ayur* means "life" and *veda* means "to study." It is considered the oldest form of medicine in the world and is based on original texts derived from Vedic scriptures that date from 1500 BCE to 1200 BCE. Ayurvedic medicine eventually spread from India and influenced a number of cultures in the Far East, including TCM, Japanese acupuncture, Unani medicine, and the humoral medicine practiced by Hippocrates.

Although many of the teachings originate from knowledge that was handed down through generations of healers, many believe Ayurveda knowledge to be of divine origin received from the meditation of sages. Similar to TCM, Ayurvedic medicine encompasses a myriad of therapies based on the constitution of the individual and nature of the particular disease. But the use of herbal medicine is somewhat broader in that it is used in a number of different mediums and in delivery systems beyond the oral route. As well as being taken orally, herbs are used in body massage oils, in food preparation, and in aromatherapy, although the choice of therapy is still based on the individual and is linked to the patient's constitution and level of imbalance.

In Ayurvedic herbology, herbal therapy is interchangeable with food and spices, which are viewed as a sequence of herbal therapies that range from mild (food) to moderate (spices) to strong (herb). And their use depends on a person's constitution, classified according to a tridosha theory and the

nature of the disease. In the tridosha system, all entities of matter, including people and plants, contain three *doshas*: *vata* (air/ether), which corresponds to the nervous system and movement; *pitta* (fire/water), representing transformation, circulation, warmth, and digestion; and *kapha* (water/earth), representing nourishment, solidity, and the formative aspects of tissue, fluid, and bone (Tiwari, 1995a).

Although all three doshas exist together, often plants and people are classified by the one that is most dominant in them, referred to as the person's "Prakruti," and specific to them as an individual. Treatment is then based on balancing the specific constitutional type for a particular patient, since each dosha is aggravated or pacified by certain therapies, herbs, and foods. So in Ayurvedic medicine (similar to TCM) herbal therapy actually begins with the use of food and spices that are consumed on a daily basis to maintain the balance of a given doshic constitution.

An example of this theory would be treating a person with a vata constitution and a vata disorder. Vata, meaning "wind," conceptually is made up of the elements of ether and air. Ether (space) affects the ability of air to gain momentum; if unrestricted, air can gain momentum and become forceful, so when balanced, a vata-type person will have free movement and flow (e.g., breathing will be strong, movement of the muscle and bones easy and light, movement of blood smooth, movement of thought and emotions easy, movement of the colon unimpeded). If unbalanced in either an excess or deficient condition, the person will experience either an excessive movement (e.g., manic behavior, diarrhea, nervousness) or deficient movement (e.g., constipation, depression, asthma). Therefore, the goal of therapy would be to counter the excess or deficiency first with food and spice and then support it with specific herbal therapy.

One Ayurvedic principle similar to the one used in homeopathic medicine is that "like increases like." Consequently, substances of similar doshas will increase those qualities in the body. A person experiencing an excess vata imbalance tends to be intolerant of dry or bitter substances (which are considered vata in nature); therefore, treatment would consist of avoiding foods that are dry and bitter and incorporating food like honey and rose hips and herbs like calamus or marshmallow root in the diet (Tiwari, 1995b). Similar to TCM, Ayurvedic treatment of imbalances within the tridoshic theory is not limited to herbal therapy alone. It also includes the five purification therapies (*panchakarma*), diet, aromatherapy, massage (*abyanga*), meditation, daily routine (*dinacarya*), and the practice of yoga.

It is important to remember that in most traditional cultures throughout the world herbal therapy is applied according to the energetic effects on the body and not on the individual constituents found in the plant. This in part recognizes the synergistic effects of the plant as being more important than the individual components. The conceptual model upon which clinical decisions and herbal recommendations are made is remarkably different from that of Western allopathic medicine. In the West, herbal medicines are often viewed strictly in terms of their actions, disregarding

the energetic composition of the herb or the person consuming it. In the short term, this practice may result in a positive effect, but in the long and/or short term, it can often lead to poor or harmful effects. Therefore, it is important for Western clinicians who have an interest in herbal medicine or have patients who are taking herbal medicine to be aware of the different systems used to classify herbs and to recognize the importance of consulting with providers trained in a particular system. By doing so, practitioners can employ herbs efficiently and avoid the improper use of these therapies, which can either result in no effect or create an opposite and undesired effect.

HERBAL SAFETY

Today there are national standards and certification requirements for practitioners of TCM and naturopathic medicine (ND) for licensure to prescribe herbal therapy; however, state requirements may vary. In addition, herbal certification programs are now available, and guidelines for safe herbal practice have been established by the American Herbal Guild (AHG). The AHG is a nonprofit, educational organization founded in 1989 to represent the goals and voices of herbalists. It is the only peer-review organization in the United States for professional herbalists specializing in the medicinal use of plants. Herbalists from any tradition with sufficient education and clinical experience who demonstrate advanced knowledge in the medicinal use of plants and who pass the AHG credentialing process (a careful review by a multidisciplinary admissions board) receive professional status and the title Registered Herbalist, AHG. The AHG has also developed a code of ethics, continuing education programs, and specific standards for professional members as well as curriculum guidelines for herbal educational programs. The AHG Educational Guidelines recommend a curriculum with a minimum of 1,600 hours of total study, 400 of which should be in actual clinical work (AHG, 2006).

When considering herbal medicines it is important to understand that the development and preparation of medicines from plant and animal products can involve wide variations, based on the conditions of growth, harvesting, processing, storing, and shipping. Plants grown in the wild may be quite different from the same plants grown agriculturally. Methods of harvesting and weather variations in nature inevitably are different from those under controlled environments. In addition, variations in how plants are processed based on the drying and sterilizing techniques that are used have an effect on the potency of the herb. If products are not stored carefully, the inherent quality of the herb may be further compromised and it may be less effective.

In the United States, pharmaceuticals must meet a strict standard established by the FDA not only in the research and development stages but also in processing to maintain consistent standards of quality. Herbs, however, are regarded as food sources and do not come under the drug and pharmaceutical standards established by the FDA. However, many herbal manufacturers, particularly those

in the United States, have adopted the FDA Good Manufacturing Practice (GMP) criteria for manufacturing, packing, and handling human food in the preparation of herbal medicines.

The GMP establishes federal guidelines for plant management, disease control, harvesting, storage, and distribution of foods, and herb manufacturers that meet these standards are authorized to display the GMP label on their products. Herbal products also provide supplement facts, active ingredients, and serving recommendations. The Dietary Supplement Health and Education Act (DSHEA) also requires dietary supplements (among which herbs are included) to carry this statement on the label: "This product has not been evaluated by the FDA. This product is not intended to diagnose, treat, cure, or prevent any disease." These measures have been taken to ensure the safety of herbal products and should be reviewed with each patient and practitioner who recommends or reviews a patient's use of herbs.

Evidence Grading

In an effort to evaluate herbal therapy, several systems have been developed to provide clinicians with methods for understanding the mechanism, use, and potential harmful effects of herbal therapy using an evidence-based system.

Natural Standard

Natural Standard (www.naturalstandard.com) is a complementary medicine grading system founded by clinicians and researchers from more than 100 academic institutions. It is designed to provide clinicians with the latest scientific data and expert opinion on complementary therapies, including herbal therapies, and is based on the Jadad scoring system of study quality (Jadad et al, 1996). A Jadad score of 0 to 5 is assigned, with 5 being the highest-quality study. In addition, a "magnitude of benefit" score is given to evaluate how strongly a study is able to show the benefit of a therapy. Natural Standard determines magnitude of benefit by subtracting the mean of the treatment group from the mean of the placebo group.

Taking into account the Jadad score, the magnitude of benefit, and other factors, Natural Standard grades the treatment. Grades reflect "the level of available scientific evidence in support of the efficacy of a given therapy for the specific indication." Treatments are also graded based on "evidence of harm." The Natural Standard's evidence rating scale is graded on a scale from A to F. A grade of "A" indicates that there is strong scientific evidence of the benefit of the therapy, whereas an "F" suggests that there is strong negative scientific evidence.

Healthnotes

Healthnotes' *The Natural Pharmacy* (2006) was designed as a reference for both practitioners and consumers. It evaluates the current state of the evidence in regard to herbs and nutritional supplements. This text is a culmination of the research contained in 25,000 articles in more than 600 peer-reviewed journals. In addition, chapters are contributed by a team of medical doctors, pharmacists, naturopaths, and chiropractors—all of whom have been in clinical practice. New editions of this manual are updated continually with the latest evidence-based information and recommendations. *The Natural Pharmacy* (2006) is notable for providing evidence that is based almost solely on human studies, as well as on information that specifically addresses contraindications to any herb or supplement. In addition, each recommendation is based on evidence derived from clinical, double-blind, meta-analyses or traditional empirical studies.

Rakel Evidence Versus Harm Scale

The Rakel Evidence Versus Harm Scale (Rakel, 2007) utilizes the Strength of Recommendation Taxonomy (SORT) (Ebell, Siwek, & Weiss, 2004) to rate the scientific evidence of a variety of integrated medicine treatments. The scale evaluates the strength of the evidence along with the evidence of potential harm. The evidence of benefit is graded from A to C, with "A" indicating that the evidence is "based on consistent, good quality, patient-oriented evidence." On the other hand, the potential harm of a therapy is graded from 1 (little or no risk of harm) to 3 (potential to result in death or permanent disability). An A rating represents that evidence is culled from systematic reviews or meta-analyses. It also incorporates Cochrane reviews of high-quality, randomized controlled trials that resulted in clear recommendations.

Cochrane Database of Systematic Reviews

Cochrane Database of Systematic Reviews (Cochrane Collaboration, n.d.) was created to help health-care providers keep up with and evaluate relevant scientific evidence. The Cochrane Collaboration produces reviews of evidence and creates a database of health-care interventions. The quality of the studies included in a review is evaluated using specific, predefined criteria. Most Cochrane reviews are based on randomized controlled trials and are statistically summarized into meta-analyses, showing a more thorough validation of clinical effect. Cochrane is considered one of the best sources of reliable evidence for and against specific treatments for specific conditions.

German Commission E Monographs

The German Federal Institute for Drugs and Medical Devices Commission E is a federal organization formed in 1978 to determine the efficacy and safety of herbs and supplements sold in Germany (National Institutes of Health, National Cancer Institute, n.d.). The commission is a multidisciplinary team of scientists, physicians, pharmacists, and herbal medicine experts who together review and analyze available data and form clinical recommendations based on the current evidence. To date, more than 300 herbs have been included in the recommendations and have been approved for clinical use in Germany.

Recommendations are published as monographs for each herb. Monographs include all pertinent botanical data, an

explanation of mechanism (pharmacodynamic and pharmacokinetic action), and a complete therapeutic index (indications, contraindications, side effects, drug interactions, dosing, and duration). Additionally, the monographs include traditional uses, unapproved uses, and a summary of evidence. Commission E monographs are considered authoritative by experts in the field and have been reviewed for completeness and accuracy by the American Botanical Council (American Botanical Council [ABC], 2009).

The ABC is a nonprofit educational and research organization dedicated to the science of herbal medicine (American Botanical Council, 2009). It looks at evidence from both modern scientific and traditional perspectives. The ABC is comprised of an advisory council of experts and is affiliated with several natural medicine health science institutions and organizations. It maintains comprehensive databases; publishes a peer-reviewed journal (*Herbalgram*); and provides commentary, additions, and, in some cases, editor's notes for correction on all Commission E monographs. Although specific herbal indications by Commission E are not based on a true evidence-graded system, the ABC considers them as having strong supportive evidence for inclusion within the context of *Herbalgram*.

The two evaluation systems that may be the most valuable to the primary care provider are Natural Standards and Rakel, since they provide a broad approach to recommended interventions for a given condition. Healthnotes, however, provides the most comprehensive data on individual supplements and serves as an expert source for clinical investigation of an herbal product. The Cochrane Database contains high-quality data reviews but is clinically the least useful for complementary and alternative medicine (CAM) evaluation because of its specificity in regard to what is reviewed.

Matrix for Evidence Grading

The following is a simple chart for comparing the various evidence-grading criteria for the treatment of several disorders.

Hypertension

CAM Therapy	Natural Standard	Healthnotes	Rakel	WHO	Commission-E
Acupuncture	Grade C			Category 1 (Essential & Primary HTN)	
Diet/Exercise	Grade B (Qi gong/yoga)		A1		
Mind-Body	Grade B		B1		
CoQ10	Grade B	3 Star	B2		
Fish oil (mixed EPA/DHA)	Grade A	3 Star	A2		Approved component
Calcium	Grade B	2 Star			
Magnesium		2 Star			
Garlic	Grade C	2 Star			Approved
Hawthorn (*Crataegus* spp.)	Grade D	1 Star	B1		Approved

Cochrane Summary:
- Review of calcium demonstrated positive effects but reviewers concluded data was insufficient due to poor study design and lack of heterogeneity between trials, leading to bias.
- Garlic review for peripheral arterial occlusion was inconclusive. No statistical significance in walking distances was seen.

*Tables not inclusive.

Clinical Implications for Practice: Hypertension

Herb/Supplement	Indications	Contraindications	Dose	Rakel Harm Scale
CoQ10	HTN	None	90–150 mg/qd	2
Fish oil (mixed EPA/DHA)	HTN	Coagulation (bleeding) disorders	3 g/qd	2
Calcium	HTN	Hypercalcemia, constipation, kidney stones, prostate cancer	800–1,500 mg/qd	
Magnesium	HTN	Caution in renal insufficiency	250–350 mg/qd	
Garlic	Hyperlipidemia	Allergy Caution with warfarin (WHO)	1–3 g/qd	
Hawthorn (*Crataegus* spp.)	Cardiac insufficiency/ heart failure	Allergy	Varies with form: tincture 35% ETOH 406 mL/TID Tea: 5–10 g/TID	1

*Dosing recommendation compiled from Healthnotes, Natural Standards, ABC Clinical recommendations, and Bastyr University clinical monographs.

Hypertension Commentary

Evidence supports the inclusion of mixed fish oil, CoQ enzyme 10, and probably calcium in the treatment of both essential and primary hypertension. Clinical consideration should also be given to incorporation of both acupuncture and mind–body techniques in addition to diet modification and exercise. Due to the broad systemic effects and safety profile of these interventions, supplemental therapy should be used to help control hypertension, prevent progression to advanced stages, and potentially decrease poly-pharmacy use.

Hyperlipidemia

CAM Therapy	Natural Standard	Healthnotes	Rakel	WHO	Commission- E
Acupuncture				Category 2	
Diet/Exercise	Grade B (Yoga)		A1		
Mind-Body	Grade C				
Plant sterols	Grade A	3 Star	A2		
Psyllium	Grade A	2 Star	A2		Approved as fiber for constipation and diarrhea
Fish oil (mixed EPA/DHA)	Grade A	3 Star	A2		Approved component
B vitamins	Grade A	3 Star (Niacin, B^3)	A2		
Guggul (*Commifora mukul*)	Grade C	3 Star			Not approved
Fenugreek (*Trigonella foenum-graecum*)	Grade C	2 Star			Approved as appetite stimulator and digestive aid
Red yeast rice (*Monascus purpureus*)	Grade A	2 Star			
Garlic	Grade B	2 Star			Approved

Cochrane Summary:
- Omega-3 (fish oils) have strong evidence for lowering triglycerides and VLDL
- No conclusive data on dietary intervention for familial hyperlipidemia
- Plant sterol review currently pending
- Garlic protocol currently pending

*Tables not inclusive: Commission E approval is specific per condition unless otherwise noted.

Clinical Implications for Practice: Hyperlipidemia

Herb/Supplement	Indications	Contraindications	Dose	Rakel Harm Scale
Plant sterols	Hyperlipidemia	None (Caution in estrogen receptor + neoplasms)	2–3 g/qd	2
Psyllium	Hyperlipidemia	Caution in IBS	10–30 g/qd	
Fish oil (mixed EPA/DHA)	Hyperlipidemia HTN	Coagulation (bleeding) disorders	3 g/qd	2
Niacin (B^3)	Hyperlipidemia Depression	Active liver disease, active ulcer or arterial bleeding	1 g/tid	2
Guggul (*Commifora mukul*)	Hyperlipidemia	Allergy, coagulation (bleeding) disorders and pregnancy/lactation	25 mg/bid (standardized extract guggulsterone)	
Fenugreek (*Trigonella foenum-graecum*)	Poor digestion Hyperlipidemia Diabetes I & II	Early pregnancy, hyperchlorhydia/GERD, and active peptic ulcer	Tincture: 30% ETOH, 3–5mL/tid	
Red yeast rice (*Monascus purpureus*)	Hyperlipidemia	Pregnancy and lactation	1200 mg/bid	
Garlic	Hyperlipidemia	Allergy Caution with warfarin (WHO)	1–3 g/qd	

*Dosing recommendation compiled from Healthnotes, Natural Standards, ABC Clinical recommendations, and Bastyr University clinical monographs.

Hyperlipidemia Commentary

There is strong evidence for diet and lifestyle modifications, combined with appropriate supplementation, for treating high cholesterol. Psyllium husk as fiber and mixed EPA/DHA fish oil should be considered as standard treatment due to the impact on both cholesterol and blood pressure. Niacin (B ³) is available in prescription form. Red yeast rice, garlic, and guggul can be considered as adjuncts, as these herbs also impact blood glucose levels and hematological clotting parameters. The cholesterol-lowering properties of red yeast rice are largely due to fungal metabolites known as monacolins, one of which, monacolin K, is identical to lovastatin and has been found to be effective at lowering cholesterol with minimal side effects (Becker, Gordon, Halbert, & French, 2009). However, guggul has been associated with elevated liver function tests and acute hepatitis (Grieco, Miele, Pompili, & Biolato, 2009). Therefore, the practitioner should still screen patients for liver abnormalities prior to starting these herbs and monitor them during therapy. Although the risks are lower, product uniformity, purity, labeling, and safety cannot be guaranteed, and it is the responsibility of the provider to solicit information from a particular company regarding their production process to ensure patient safety.

Challenges to Using an Evidenced-Based Model

Although evidenced-based medicine (EBM) is currently considered the "gold standard" of care for practice, using blind randomized controlled trials (RCTs) that are based on a statistical analysis to validate and determine efficacy of a particular medication or medical procedure may not be the most effective way to evaluate a holistic approach to care, particularly when it is deemed the only acceptable basis for health care. The value and role of the doctor is undermined, the psychological and social aspects of medicine are neglected, and sole reliance on EBM presents the danger of creating a utilitarian orthodoxy (Williams & Garner, 2002).

There are three factors that become problematic when evaluating CAM therapies, particularly herbal therapy. The first is that the Western scientific method applied to drug-based or pharmaceutical research is designed to measure single chemical components in relation to outcome. This model is used in the evaluation of Western herbs, but it does not reflect the philosophy and treatment parameters used in Ayurvedic or traditional Chinese medicine, which use the whole plant and consider only its nature and effect at reducing or enhancing the body's balance. Second, definitions used in CAM pose a unique problem for EBM researchers. The scientific method cannot be used to measure things that have yet to be physically defined by Western science. The concepts of qi or prana, representing universal energy or life force, are one example, but other concepts, such as yin and yang, vatta, kapha, and pita, also illustrate the complexity of analyzing concepts that do not have equivocal biomedical definitions. And the third challenge is that outcomes in traditional Chinese medicine and Ayurvedic medicine are determined largely by empirical, rather than experimental, diagnostic measures. Changes in a person's tongue coat and pulse or a change in symptoms often are enough to satisfy clinical management and evaluate the efficacy of an herbal formula.

Diabetes mellitus type 2 can serve as an example of the fundamental differences between these systems in disease diagnostic and treatment criteria. In biomedicine, diabetes is seen as a specific set of characteristics and laboratory markers. A fasting blood glucose of less than 126 mg/dL on more than one occasion would validate a diagnosis of this disease (Joslin Diabetes Center, 2007). In Oriental medicine, diabetes is comprised of seven possible patterns, none of which would be called "diabetes" and each of which would have a different parameter for the selection of an herbal treatment (Flaws & Lake, 2005).

In traditional CAM modalities, herbs are prescribed based on the phenotypical manifestation of the disease and the constitutional expression of the patient. This is in direct opposition to the drug model of herbal prescription currently being used in biomedicine. This model is based solely on the pharmacological understanding that relies, "perhaps erroneously, on a preference for empirical evidence gained from controlled clinical trials regardless of the underlying theory of disease and healing" (Tonelli & Callahan, 2001). The drug-based model of herbal medicine is a reductionist view, and it purposely ignores thousands of years of observational and empirical evidence that has been validated within many traditional medical models.

In a review of 19 randomized controlled trials that utilized ginseng, the authors found no mention or consideration of the traditional patterns used in TCM to determine appropriateness of herb selection (Yan, Engle, He, Jiao, & Gu, 2009). Ginseng, specifically *Panax ginseng*, or Ren Shen, is an herb traditionally used to support specific symptom manifestations of "qi deficiency," which is characterized by symptoms like fatigue, gas or bloating and loose stools, weakness, cold, sweating, bleeding, and prolapsed organs (Kaptchuk, 2000). In addition, several of the 19 trials utilized a different species of ginseng, which traditionally have different properties and applications. Analyzing the results as if looking through the lens of Oriental medicine theory, the reviewer found that positive results of ginseng were seen only in the conditions that corresponded to the traditional Chinese concept of qi deficiency. This demonstrated that biomedical evidence-based research, directed by traditional theory, may have a totally different outcome. Research that can employ these concepts can both improve study design and help validate traditional theory within a biomedical context.

Another challenge in herbal therapy is the use of polyherbal formulations common to traditional medical systems. Using the same type of analysis as just mentioned for a single herb, the criteria for evaluating a polyherbal formula would have to take into account numerous factors based on the traditional medicine model. Thus, patients who just want to take an herbal formula for a particular problem without the assistance of a trained herbalist are faced with the ongoing dilemma of deciding what herbal remedy(ies) are best suited for them.

COMMON HERBS

Today it is possible to find a health section with a variety of herbal remedies in most grocery or supplement stores in communities throughout the United States. These remedies are available without prescription or any particular guidance except what the consumer may gather from the label or other sources that may or may not be reliable. Therefore, it is very important that nurse practitioners, nurses, and other health professionals be aware of herbal therapy and be able to distinguish how they are to be used. For the purposes of this chapter, herbal therapy for a particular disease state will be discussed in three primary categories: Western, traditional Chinese medicine (TCM), and Ayurvedic medicine, along with the criteria for dispensing.

There are several other medicinal practices that use herbs to heal, for example, homeopathic herbal therapy, Bach Flower remedies, and Unani medicine. However, the purpose here is not to teach any particular style of herbal medicine but rather to use examples from TCM and Ayurvedic medicine to illustrate the differences in how herbal therapy is used and to encourage practitioners interested in using or recommending these herbs to understand the differences in order to refer to or consult with an herbalist, naturopath, TCM, or Ayurvedic practitioner whenever herbal therapy is considered. This section is not meant as a recommendation for prescribing to clients but rather as a guideline and reference.

Western Herbs

Mental Health Symptoms

The most common symptoms for which people use herbs are anxiety, difficulty in sleeping, depression or dysphoria, and forgetfulness and confusion. Like pharmaceutical drugs, some herbs may be beneficial for multiple symptoms.

Anxiety

Kava (ava, awa, kava-kava, kawa, kew, tonga) comes from the dried root of *Piper methysticum*, a member of the black pepper family. This shrub is native to the Pacific Islands and is commonly used by Hawaiians as a celebratory drink, just as alcohol is used in the West. But unlike alcohol, kava does not stimulate aggression and is not associated with hangovers. It is prepared as a drink from the pulverized root but also comes in tablet, capsule, and extract forms. This herb has been studied in human subjects and appears to have more than one active component that produces its effects. One component acts as a local anesthetic when chewed and produces intense muscle relaxation. It appears to act on the limbic system to suppress emotional excitability and produce mild euphoria without affecting memory or cognition. In therapeutic drug trials, kava seems to act on the gamma-amino butyric acid (GABA) receptor, like the benzodiazepines, and like the benzodiazepines, kava can reduce seizure activity and be used for sedation. Dose varies, depending on the form and the amount of active components retained in the preparation; studies indicate that 70 to 240 mg daily is the adult dose. Pharmacokinetics data are

unavailable for kava, but users seem to prefer divided doses, usually 3 times a day. Unlike the benzodiazepines, it does not seem to produce dependence, but the studies are very limited.

When used short-term, kava seems to produce few adverse reactions, although these might include decreased motor reflexes, diminished judgment, and visual disturbances. Chronic use may decrease platelet count and cause dry, flaky skin; reddened eyes; shortness of breath; pulmonary hypertension; and weight loss. Because it seems to act like the benzodiazepines, it may potentiate alcohol, other sedatives, and GABA-nergic drugs such as phenobarbital and benzodiazepines. At higher doses, kava seems to block dopamine receptors and therefore to improve psychotic levels of anxiety as well as interact with antipsychotic drugs. It should not be used in pregnancy or when breastfeeding because its safety is uncertain during pregnancy (Volz, 1997). The FDA has issued a warning regarding the use of kava supplements leading to severe liver damage and the National Institute of Health National Center for Complementary and Alternative (NCCAM) suspended all NCCAM-funded studies of kava after the FDA warning (nccam.nih.gov/health/kava).

Mugwort (felon herb, wild wormwood, St. John's plant) comes from the root of the *Artemisia vulgaris* plant. It should not be confused with St. John's wort, which comes from a different plant. The name may have derived from the fact that it was commonly used to flavor beer before the use of hops. It is available as dried leaves and roots, fluid extract, tincture, or as a tea infusion, but only the root is used for its active constituents, which are believed to be from its volatile oil and acrid resin and tannins. It is a very versatile herb but its medicinal use lies more in its value as a nervine and emmenagogue (hastening menstrual flow when combined with pennyroyal and southernwood). When taken for anxiety and sedation, the usual dose is 5 mL of tincture 30 minutes before bedtime, although there are few studies that support this use. It does have an anticholinergic effect, observed in animal studies. In a recent study of mugwort, elements of alkaloids, coumarins, flavonoids, saponins, sterols, tannins, and terpenes were found with concentration-dependent (0.3 to 10 mg/mL) relaxation of spontaneous jejunum contractions, and a combination of anticholinergic and Ca(2+) antagonist mechanisms were found supporting its use in hyperactive gut and airway disorders, such as abdominal colic, diarrhea, and asthma (Khan & Gilani, 2009). This accounts for its use in the treatment of gastrointestinal problems and menstrual cramps.

One of the unique uses of mugwort comes from TCM, where it is applied topically and burned to treat pain and tonify deficient conditions. It is also used extensively in Japanese acupuncture as well as TCM, comes in several different forms, and is employed in a variety of ways (e.g., as a stick, directly on the skin, or by using a medium—holder, box, ginger—to hold it over acupuncture points or pain locations with or without needles). Adverse reactions to mugwort when taken internally include anaphylaxis and induction of premature birth or miscarriage or contact dermatitis if used topically. It should not be used during pregnancy or breastfeeding or by people who have clotting abnormalities or allergies to hazelnuts. Because

there are no controlled studies on mugwort, no therapeutic claims can be made.

Passionflower (*Passiflora*, passion vines) has been used by many cultures as an herbal remedy for the treatment of anxiety. However, there are over 500 species of this flowering plant, which makes clinical trials inconsistent because they use different species. Two of the most common species used today are *P. incamata* (maypop), commonly used in Native American cultures, and *P. edulis* (passion fruit), used extensively in Central and South America. Despite the different species, passionflower is generally considered safe but it can cause drowsiness, dizziness, and confusion in some patients. As a dried herb, passionflower is generally well tolerated at 2 g, 3 to 4 times a day, and as an infusion of 2 g in 150 cc water 3 to 4 times a day. The tincture ratio is 1:5 (g/mL).

Insomnia

In addition to mugwort, melatonin, valerian, passionflower, and chamomile are used for sedation. Melatonin and valerian are discussed here. Melatonin is not an herb but a hormone produced by the pineal gland. Because it is a hormone, exogenous consumption over extended periods of time may act as negative feedback and suppress normally secreted melatonin. Melatonin is produced when serotonin is broken down in the pineal gland with the help of two enzymes: arylakylamine- *N*-acetyl transferase (AA-NAT) and hydroxyindole- *O*-methyl transerase (HIOMT). It is the AA-NAT that seems to be the rhythm enzyme, because when it is elevated, melatonin is elevated. Unfortunately, AA-NAT is rapidly destroyed and the production of melatonin is reduced by light.

Under physiological conditions, melatonin is released during the fourth stage of sleep along with prolactin and growth hormone. It is used to induce sleep via the same GABA-nergic mechanism as benzodiazepine sedatives and is widely used to prevent and treat jet lag. A single study identified the utility of melatonin in elderly people to help induce and maintain sleep, probably because the elderly usually have some degree of melatonin deficiency under normal circumstances. Used long-term, it can increase prolactin secretion, which can decrease luteinizing hormone, progesterone, and estradiol levels. Long-term use can also reset the sleep-wake cycle and contribute to disturbed sleep cycling.

Melatonin is available in tablets, capsules, extended-release capsules, and liquid forms. For difficulty in getting to sleep, 1 to 5 mg taken at bedtime is the usual dosage, but it should not be used more than three nights a week. In the elderly, the dosage is usually 1 to 2 mg taken 2 hours before bedtime. To prevent jet lag melatonin (2 mg to 5 mg) is taken at the target destination bedtime (10 PM to midnight) for 3 days prior to departure and for three days' post-travel (Morgenthaller et al., 2007). Adverse reactions include altered sleep patterns, confusion, headache, tachycardia, and hypothermia. Melatonin potentiates benzodiazepines. It also potentiates succinylcholine, thereby increasing the blocking action, which can be dangerous. Its content of active drug may vary widely in commercial melatonin, making it difficult to determine correct dosages (Brzezinski, 1997; Fetrow & Avila, 1999).

Valerian (all-heal, amantilla, setewale capon's tail, herba benedicta) is derived from the roots of *Valeriana officinalis*. It seems to inhibit uptake and increase presynaptic release of GABA; however, it is not readily absorbed, is highly unstable, and readily decomposes. Therefore, availability of the active drug is minimal when it is taken orally. German Commission E suggests valerian root for anxiety, restlessness, and difficulty in getting to sleep. Because of the instability, dosages are difficult to determine, especially among different brands. Usually 400 to 900 mg of extract at bedtime or 1 teaspoon of dried herb in tea several times a day is useful in inducing sleep. Commercial valerian tea at bedtime acts more as a relaxant and permits the person to fall asleep spontaneously. Valerian has no adverse reactions when used at the recommended level; however, overdosage at 2.5 g or more can cause cardiac disturbance, excitability, headache, insomnia, and nausea. It can potentiate alcohol and other CNS depressants if taken in large amounts. Because clinical trial studies are limited, it should not be used by pregnant or breastfeeding women, children, or patients with impaired liver function.

Depression

The popular media have touted the benefits of St. John's wort for depression, contributing to its great popularity. Kava, mugwort, and DHEA have also been used to treat mild depression. Because kava and mugwort have already been discussed, St. John's wort and DHEA are covered here.

St. John's wort is obtained from the tops and flowers of the *Hypericum perforatum* plant, which is common all over Europe, Asia, and the United States. The exact mechanism of action is still unknown but assumed to be related to inhibition of serotonin presynaptic uptake. Early studies showed inhibition of monamine oxidase (MAO) type A and minimally type B; however, this was later attributed to contaminants. In studies to determine effective dosages, St. John's wort was effective at blocking serotonin reuptake at much higher doses than could be achieved. St. John's wort also seems to act on the benzodiazepine receptor of GABA, inhibit norepinephrine reuptake, and block acetylcholine, as well as inhibit stress-induced corticotropin-releasing hormone, adrenocorticotropic hormone (ACTH), and cortisol and increase nighttime release of melatonin. Some reports have also indicated antiviral activity, including retroviruses (Chavez, 1997). With such a wide range of receptor activity, it is not surprising that it is used to treat depression, enuresis, gastritis, hypothyroidism, insomnia, kidney disorders, scabies, hemorrhoids, wounds, HIV infection, and Kaposi's sarcoma.

Most commonly, St. John's wort is used to relieve mild to moderate depression, less than would meet the criteria for a major depressive episode, or dysthymia. Therefore, it seems most effective for those who have sadness and lesser degrees of depression. When used for clinically diagnosed depression, St. John's wort is relatively ineffective and may dishearten or demoralize the person who is trying to avoid using more potent antidepressants. For standardized, commercially prepared St. John's wort, the usual dosage is 300 mg taken 3 times daily; because of the delayed neuroreceptor response,

it may take 4 to 6 weeks to determine effectiveness. When St. John's wort is used as a tea, it requires 2 to 4 g of tea steeped in 1 to 2 cups of boiling water for 10 minutes and taken daily to be effective within 4 to 6 weeks.

There are a few adverse reactions, attributable to the anticholinergic blockade, including constipation, dry mouth, dizziness, gastrointestinal (GI) upset, restlessness, and insomnia. St. John's wort interacts with MAO inhibitors (MAOIs), tricyclic antidepressants, and serotonin reuptake inhibitors (SRIs) to cause serotonin syndrome. St. John's wort may decrease digoxin, phenytoin, and cyclosporine levels leading to therapeutic failure. Wafarin's effectiveness may be decreased. St. John's wort may lead to loss of virologic response and possible resistance to indinavir and other protease inhibitors. St. John's wort should be stopped 2 weeks prior to the beginning of treatment with the chemotherapy agent irinotecan and is contraindicated during therapy. St. John's wort reduces the effectiveness of oral contraceptives, increasing the risk of unintended pregnancy. Because there are inadequate studies available, St. John's wort should not be taken by children or pregnant or breastfeeding women. The primary care provider who determines that the patient meets the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (2013) criteria for depression might advise the client to consider taking another kind of antidepressant if there are minimal results in 3 to 4 weeks.

Dehydroepiandrosterone (DHEA) is a steroid precursor found in plants from the yam family and is secreted by primate adrenal glands. Physiologically, DHEA is converted into androgens and estrogens (depending on the person's gender) and may raise the blood level of a precursor of the human growth hormone. There are many benefits attributed to DHEA, including immune enhancement and prevention of osteoporosis as well as antineoplastic, antiaging, and antidepressant benefits. Because few studies on humans are available, exact pharmacokinetics and pharmacodynamics are not known, but it does not seem to be readily absorbed through the GI tract. Similarly, it is difficult to determine dosage for the particular effect that is desired. At present, 50 mg daily is commonly used for depression, but serum levels should be checked, with an expected level of 3,600 ng/mL for men and 3,000 ng/mL for women. When used for depression, DHEA may have a 4-week lag time before an effect on depression is seen (Wolkowitz, 1997).

Because DHEA is a hormone-like drug, it may give negative feedback to the adrenal glands, thereby reducing production of endogenous hormones. Adverse reactions to be expected with an androsteroid include aggressiveness, hirsutism, insomnia, and irritability. Patients with hormone-sensitive cancers should be discouraged from using DHEA, as should pregnant and breastfeeding women. DHEA is likely to interact with other hormone therapy, such as estrogen replacement therapy. DHEA may be used by athletes to increase muscle mass, but it is a banned substance in college athletes by the National Collegiate Athletic Association (NCAA).

Confusion and Forgetfulness

Confusion and forgetfulness, along with other cognitive impairments, are often seen in dementia, depending on the root cause of the dementia. Additionally, people who are concerned about benign forgetfulness take herbs both to improve their cognitive abilities and to prevent memory problems. Common herbs used include ginkgo, ginseng, chaparral, and galanthamine. Ginseng and ginkgo, which are often taken together or combined in a single preparation, are used here as exemplars.

Ginseng (American ginseng, Asian ginseng, Chinese ginseng, five-fingers, Japanese ginseng, Jintsam, Korean ginseng, ninjin, seng and sang, schinsent) is from the *Panax quinquefolius* plant, especially the root. Asian ginseng should not be confused with Siberian ginseng, which seems to bind with estrogen receptors. Asian ginseng is usually dried or cured and is highly valued; American ginseng undergoes less processing and is not as widely sought.

Several compounds are biologically active, producing different effects. The mechanisms of action are not understood, but ginseng is said to have differing effects depending on the active component involved: anticonvulsant, analgesic, and antipsychotic effects; CNS-stimulating, anti-fatigue, hypertensive, and stress ulcer exacerbation; improvement of cardiac function; depression of cardiac function; antiarrhythmic activity; reduction of cholesterol and triglycerides; decrease in platelet adhesiveness; impaired coagulation; and increased fibrinolysis. The presumed focus of action is in the adrenal gland, although there are claims in popular literature that ginseng decreases thymus gland activity. Consequently, it is used as a sedative, aphrodisiac, antidepressant, hypnotic, and diuretic. It is also used to improve stress resistance, stamina, work efficiency, concentration, mental performance, and general feelings of well-being. Some studies found it decreased fasting blood sugar and hemoglobin to such a degree that some diabetics no longer needed insulin.

Ginseng comes in capsules, tea bags, and extract, and in some places ginseng root can be bought in bulk, such as in Asian markets. In processed form, however, it is difficult to standardize. Used for illness, it is usually taken at 0.5 to 2 g a day of dry root or 200 to 600 mg of extract daily in divided doses. For dementia in frail elderly people, it is usually taken at 0.4 to 0.8 g of dry root daily. There seems to be a lag time in achieving maximum effectiveness—up to 90 days to see full results. It seems to have minimal and mild adverse reactions, including dizziness, drowsiness, headache, and insomnia, although chest pain, diarrhea, hypertension, impotence, nervousness, agitation, palpitations, nausea, and vomiting have also been reported. It may potentiate insulin and oral hypoglycemics, and it interacts with MAOIs to cause headaches, tremors, and mania. There are more studies of ginseng than of other herbs to identify its effectiveness, yet the pharmacodynamics are elusive. The German Commission E considers ginseng to be an effective drug (Sorensen & Sonne, 1996; Wesnes et al, 1997).

Ginkgo (*Ginkgo biloba)* is an extract from the leaves of the ginkgo tree, with the toxic ginkgolic acid removed. It is available in many forms, including tablets, capsules, sublingual sprays, and even in juices and foods. It is believed to stimulate prostaglandin synthesis and thereby cause vasodilatation, increasing tissue perfusion and cerebral blood flow. Ginkgo has

been used for centuries in Asian countries to improve mental alertness, and today is used in the treatment of cerebrovascular disease and peripheral vascular disease. Additionally, it is popularly taken to improve thinking ability, concentration, and memory.

Dosage for confusion and dementia symptoms is 120 to 240 mg daily in two or three divided doses. For vascular disease, 120 to 320 mg daily has been used, but there is a 4- to 6-week lag time before maximum effect is obtained. Adverse reactions include diarrhea, headache, nausea, vomiting, bruising, excessive bleeding, and seizures in overdose. Trying to use ginkgo leaves to make a home remedy is potentially dangerous because of the ginkgolic acid and the difficulty of determining the quantity of active ingredients. Because it reduces platelet-activating factor and erythrocyte aggregation, it should not be taken with anticoagulants or antiplatelet medications. The German Commission E approved ginkgo for the treatment of dementia and peripheral arterial occlusive disease (Fetrow & Avila, 1999).

Gastrointestinal Problems

Probably the most common use of home remedies is for GI upset, such as constipation, diarrhea, indigestion, and nausea. Because the underlying causes of these complaints are also common, the herbal medications used for them overlap. The herbs most often used for constipation are also incorporated into commercial OTC medications: cascara, castor bean, and senna.

Cascara sagrada is dried bark from the *Rhamnus purshiana* tree (found primarily in the Pacific Northwest and from Canada to California) that has been dried and aged for at least 1 year and up to 3 years. Cascara acts by increasing the smooth muscle tone of the large intestine and thus peristalsis. The FDA has approved cascara as a safe and effective laxative to be sold OTC. It is available in an extract or extract capsules. Although it is very safe, it may produce such adverse reactions as abdominal cramping, diarrhea, fluid and electrolyte imbalance, steatorrhea, vomiting, and vitamin and mineral deficiencies in long-term use. Cascara can be used in pregnancy but should not be used by breastfeeding women because it is excreted in milk and may cause serious diarrhea in the infant. Because a person can become dependent on cascara, it should be limited to short-term use.

Senna comes from the leaves and pods of the *Cassia* shrub. It is the active ingredient in OTC medications such as Senokot, Senokot-S, and Senolax and comes in capsules, tablets, and syrup. Dried senna leaves can also be made into a tea by adding 100 g of leaves to a liter of boiling water and steeping for 10 minutes. Sliced ginger or crushed coriander leaves make the tea more palatable. When senna enters the intestinal tract, bacteria convert it into a biologically active agent. Senna increases peristaltic action in the lower bowel. The usual adult dosage is about 340 mg taken at bedtime or 0.5 to 1 dram of syrup. Adverse reactions are similar to those of cascara: abdominal cramping, diarrhea, hypokalemia, and clubbing of the fingers with chronic use. Calcium channel blockers or indomethacin blocks the diarrheal effects. It is excreted in breast milk and should not

be taken by breastfeeding woman. A patient with irritable bowel, hemorrhoids, GI inflammatory conditions, or prolapsed rectum should not use senna. Like cascara, it can be overused and create a laxative dependency.

Indigestion and heartburn plague Americans, as evidenced by the large amounts of medications sold to treat dyspepsia. In addition to antacids, common household herbs can be used effectively and safely. Caraway oil distilled from dried seeds of the *Carum carvi* herb or caraway water made from soaking 1 oz of crushed caraway seeds in a pint of cold water for 6 hours can be used for indigestion, flatulence, constipation, and menstrual cramps. Because of its mild action, it can be given to infants for colic. The usual dosage for adults is 1 to 4 drops of oil in a teaspoon of sweetened water; and for infants 1 to 3 tsp of caraway water. The only adverse reactions reported are diarrhea and mucous membrane irritation.

Licorice root has also been used for gastric irritation and dyspepsia. Licorice comes from the dried root of the *Glycyrrhiza glabra* shrub and is available in capsules, tablets, liquid extracts, chewing gum, tea, and candy. Studies indicate that glycyrrhetic acid is the active element that potentiates endogenous steroids and stimulates gastric mucus synthesis. It is a soothing and mild expectorant, mild laxative, and antispasmodic. Additionally, licorice has antiarrhythmic effects, lowers cholesterol and triglyceride levels, and may cause immunosuppression. The usual dose is 200 to 600 mg tablets taken daily for 4 to 6 weeks or licorice tea simmered for 5 minutes and taken 3 times a day after eating. Reported adverse reactions include mineralocorticoid effects of headache, lethargy, sodium and water retention, hypokalemia, and hypertension, as well as, in overdose, muscle weakness, heart failure, and cardiac arrest.

Licorice interacts with many medications: antihypertensives, diuretics, corticosteroids, digoxin, loratadine, procainamide, quinidine, and spironolactone. A patient who is taking licorice regularly should be warned against excessive and chronic use, especially when it is combined with diuretics. Licorice candy does not actually contain the herb but rather licorice flavoring, usually from anise oil.

Papaya enzymes, available in tablets and chewable tablets, are frequently used to prevent or treat common heartburn, although it is not effective with gastroesophageal reflux. Papaya is a proteolytic enzyme in the leaves, seeds, pulp, and latex of the *Carica papaya* tree. The clinical trials with humans have mostly focused on treating inflammation from trauma and surgery. It also has been used effectively as a debriding agent and for intradisk injections in patients with herniated disks. The dosage for inflammation is 10 mg 4 times a day for 1 week. Dosage for dyspepsia is variable and not standardized, but usually 4 to 5 tablets are taken immediately after eating. Adverse reactions are uncommon and limited to dermatitis, hypersensitivity, decreased heart rate and CNS activity, and perforation of the esophagus with excessive ingestion. No drug interactions have been reported. There have been no studies with pregnant and breastfeeding women, so it is safest to avoid use during pregnancy and breastfeeding.

Pain

Joint pain, soft tissue pain, and headache are frequent problems that people often treat with herbal and home remedies. There is little overlap in medications to treat each of these kinds of pain. Two products currently in health food stores are glucosamine and chondroitin, both of which are not herbal.

Glucosamine has been widely used for its anti-inflammatory and cartilage repair ability and is supported by in-vitro studies in the management of osteoarthritis. Glucosamine is thought to stimulate cartilage production and enhance rebuilding of damaged cartilage and has been demonstrated to provide relief of pain and rapid restoration of mobility and range of motion. There are two forms of glucosamine currently being sold as an herbal supplement: glucosamine sulfate (GS) and glucosamine HCL (GH). Both contain similar or equal concentrations of glucosamine, but GS has more salt content and GH has slightly higher concentrations of glucosamine. Although the effects are similar, glucosamine sulfate has been used in the majority of clinical trials; glucosamine HCL is often combined with other materials like chondroitin or MSM.

Glucosamine is a naturally occurring component found in shellfish; however, most of what is sold in the United States is synthetically made. It is sold under such names as Arth-X Plus, Glucosamine Mega, Joint Factors, and Nutri-Joint, in capsules or tablets in a range of dosages, so the upper limit advised is 1.5 g per day and the source an organic natural product. It has very few side effects and there is only rare occurrence of symptoms like constipation, diarrhea, drowsiness, headache, heartburn, nausea, and rash. There have been no drug interactions reported. Frequently, glucosamine is combined with chondroitin for greater efficacy.

Chondroitin is extracted from the cartilage of animals, often cows and pigs. It seems to stimulate chondrocyte metabolism and synthesis of collagen, improving the formation of cartilage. Other studies identified stimulation of hyaluronic acid in synovial cells in patients with rheumatic disease, resulting in increased viscosity and amount of synovial fluid. When it was used for up to 4 months, patients used much less pain medication and were doing weight-bearing exercises comfortably. Often combined with glucosamine, the dosage depends on the patient's weight: for patients under 120 lb, the recommended dosage is 1,000 mg of glucosamine and 800 mg of chondroitin; for patients 120 to 200 lb, the dosage is 1,500 mg of glucosamine and 1,200 mg of chondroitin. Used alone, the usual dose is 800 to 1,200 mg daily, taken in either divided doses or a single dose. Adverse reactions include dyspepsia, headache, motor restlessness, euphoria, nausea, and risk of internal bleeding. Chondroitin may potentiate anticoagulants. Because there have been no studies with pregnant or breastfeeding women, chondroitin should not be used by this population.

Tumeric (curcumin) is a rhizome from the ginger family, commonly used as a spice in Indian curry. It has been used for 2,000 years to treat conditions of inflammation, particularly in the gastrointestinal system. However, today turmeric is being used extensively for the treatment of chronic pain. Tumeric in food is considered safe but may come in many forms, most commonly as a standardized powder in which the recommended doses range from 400 to 600 mg, 3 times a day. Tumeric is often combined with bromelain or piper longum (black pepper) to increase its absorption from the GI tract. However, caution is advised when tumeric is combined with these agents due to their potential secondary risk of gastritis and increased absorption of other medications.

Wintergreen oil and liniments have been deemed effective in relieving pain from muscle strains, inflamed muscles, ligaments, and joints. Usually the oil is a combination of oil extracted from the leaves and bark of *Gaultheria procumbens* and methyl salicylate. Although there have been no studies of the efficacy of wintergreen, it is assumed to act through counterirritation, which masks pain, or through the analgesic and anti-inflammatory effects of the salicylate. The 10% wintergreen oil is applied to the skin no more often than 3 to 4 times a day. Overgenerous application can result in salicylate poisoning from absorption into the bloodstream. People who are allergic to aspirin or who are taking oral anticoagulants should not use it.

Feverfew is an interesting herb used most often to treat headache and migraines. It has also been used for toothache, joint pain, asthma, stomachache, menstrual problems, and threatening miscarriage. Feverfew (bachelors' button, featherfoil, Santa Maria, midsummer daisy) is extracted from the leaves of the feverfew plant, *Chrysanthemum parthenium*. The assumed mechanism of action is the inhibition of serotonin release from platelets. It is available in capsules, liquid, tablets, and dried leaves for tea. The feverfew research showed a decrease in the number, duration, and severity of migraines in a double-blind crossover study (Murphy, Hepinstall, & Mitchell, 1988). The average daily dose for the treatment of migraines was 543 mcg of parthenolide (the active component of feverfew); for migraine prevention, the dose was 25 mg daily of freeze-dried leaf extract. The most common adverse reactions were mouth ulcerations, hypersensitivity, and a withdrawal syndrome characterized by moderate to severe pain and joint and muscle stiffness.

Traditional Chinese Herbs

It is important to remember that traditional Chinese medicine does not isolate herbal medicine as the single remedy for any disorder but rather includes it as a part of four distinct methods of treatment that include herbal therapy, acupuncture, manipulative therapies (tui na), food, and exercise (qi-gong and tai chi). The application of herbs specifically is based on the nature and capabilities of the herb and the energies, flavors, movement, and meridian the herb affects.

The Four Energies

The four energies in herbal medicine are cold, hot, warm, and cool. The concept was derived from years of empirical research and observation of the direct effect of taking the herb over time. If the herb is effective in the treatment of a heat condition per se, it is classified as having a cooling energy. In the most basic sense herbs can be divided into yin (cooling)

and yang (heating) energies. But since temperature can be a matter of interpretation, many TCM practitioners will refer to the herbal energy as extremely warm or slightly warm and extremely cold or slightly cold.

The Five Flavors

The five flavors refer to the effect the herb has on a person's sense of taste and are classified as pungent (or acrid), sweet, sour, bitter, and salty. Not only do the five flavors describe taste, they also exhibit properties that are medically useful. Pungent herbs can disperse and promote the flow of energy; sour herbs can constrict and obstruct; sweet herbs can slow down, tone up, and harmonize; bitter herbs can harden, dry up, and cause diarrhea; and salty herbs can soften up and promote downward movement. Often a question arises about things that are tasteless. Tasteless is still considered a flavor and tends to be classified with sweet; it can help disperse dampness and promote urination.

The Four Movements

The four movements of herbs are upward, downward, floating, and sinking. Pushing upward means that the herb has the capacity of lifting that which can no longer be supported, for example, prolapsed organs like the uterus or rectum. Pushing downward means the herb is capable of suppressing a rebellious symptom, for example, hiccups or a cough. Floating means the herb is capable of dispersing outward, as in inducing perspiration or a purging action. And sinking means the herb is capable of promoting diarrhea and directing excess energy down. Often the movement of an herb is a combination. Herbs that push upward and those that can float have the common function of moving upward and outward, by inducing perspiration and vomiting and elevating the yang energy. While the herbs that can push downward and those that can sink have the common function of moving downward and inward and relieving symptoms like vomiting or excess perspiration or diarrhea.

Meridian Routes

Meridian routes refer to the meridians the herb can enter and move through (or pathways of energy identified in TCM that correspond to the 12 organ systems). This is important to know because two herbs with the same energy and flavor can display two different actions because their meridian routes are different (e.g., two heating herbs may have different actions—one may be better for cold lung conditions while the other may work better for cold spleen conditions).

Actions

All Chinese herbs or herbal formulas have a number of common actions, but the actions are expressed differently than in Western medication. A Western medication will be classified as an antihistamine because it blocks the effects of histamine, but a Chinese herb will be classified by its action to clear heat, stop wind, or reduce fire. And a formula will have multiple actions that are designed specifically for the patient's condition; for example, one herb will clear lung heat, the other may

transform phlegm, and another cool blood. In this way, the formula can be changed as the patient's symptoms change. This is one argument against the prolific use of standardized formulas.

Herbal Formulas

In most cases, a syndrome will have more than one symptom and cannot be treated with a single herb. Thus, the primary method of herbal therapy used in TCM is the herbal formula. Although many practitioners will use their own formulas to treat patients, most will use established classic formulas with one or two modifications. The general format for herbal formulas is the use of three or more specific herbs. The primary herb that treats the major symptom is called the king herb; the second herb, called the subject herb, will reinforce the action of the king herb as well as treat the concurrent symptoms. Then there are herbs that are added to control undesirable effects of the first two, called the assistant herb; and the fourth herb, called the servant herb, may be one that can direct the formula to the affected region and harmonize the herbs in the formula.

How to Take Chinese Herbs

There are three common ways to taking TCM formulas. A decoction is considered the best method, although it is often not practical for many patients. Decoctions are made from raw herbs that are placed in a pot of water and cooked/boiled for an average of 20 minutes. The benefit of a decoction is that it is readily absorbed, takes effect more quickly, and can produce the best therapeutic effect. The second method of taking herbs is in the form of powders or granules, which can be dissolved in water. The quantity will depend on a patient's weight. The disadvantage of a powder is similar to that of most powdered drinks: they are difficult to dissolve completely and absorption is slower. The third and most common method of taking herbs is by tablet, normally prepared by a manufacturer. The advantage of tablets is the ease of taking the medication and convenience, but they have slow absorption rates, cannot be adjusted, and their quality depends on the manufacturing process.

Rules for Taking a Formula

In general, there are three rules for taking Chinese herbal formulas. The first is timing. To get the most effect from an herbal formula it is very important to know when and how to take the herb. Some herbs are better absorbed with food while others without. In addition, in accordance with TCM theory, there are certain times of the day when the energy of a certain organ system is higher. Depending on the action of the herb, and the organ condition, taking the herb during these times will improve the effect the herb has on the organ. The second rule is that temperature should be considered, depending on the condition being treated. If treating a cold condition, the temperature of the herbal formula should be hot; and if treating a heat condition, the herb may best be taken cold. The last rule is to refrain from taking herbal formulas with tea. Tea can obstruct the movement of the herb

and reduce its effect. Tea is also cold in nature and can interfere with warming herbs. And third, tea contains caffeine and can excite the nervous system, cancelling the effect of calming herbs.

Insomnia

Depending on the source, according to TCM insomnia can be caused by several conditions; heart–spleen deficiency, heart–kidney disconnect, heart–gallbladder deficiency, phlegm fire, or just indigestion from eating too late in the evening. To illustrate the rationale behind the selection of an herbal formula and how each ingredient can be modified (added or removed) depending on the patient's clinical presentation, one of these differential diagnoses (heart–spleen deficiency) is presented here.

Heart–Spleen Deficiency

In TCM, insomnia is often associated with the heart because it is considered to be the place where the mind (shen) resides. And disturbances of the shen often result in the symptom of insomnia. Symptoms of a heart–spleen deficiency include sleeplessness and waking often, abdominal swelling, watery thin stools, low appetite, fatigue, impotence, night sweats, and palpitations. The treatment principle is to tone the heart and spleen and calm the mind.

Herbal Formula for Insomnia

Gui-Pi-Tang (restore the spleen decoction) is used for spleen qi deficiency with heart blood and yin deficiency, to tonify qi and blood, and to nourish the heart and strengthen the spleen. Therefore, the indications for its use are similar to those for heart–spleen deficiency: fatigue, palpitations, insomnia, poor sleep or dream-disturbed sleep, night sweats, but also anxiety, phobias, poor appetite, sallow complexion, poor memory, withdrawal, and early periods with loss of excess blood, continuous spotting, blood in the stool, and metrorrhagia.

Gui Pi Tang Ingredients

- Bai Zhu (*Rhizoma atractylodis macrocephalae*): 5 to 10 g; properties: aromatic, slightly acrid, nontoxic, sweet and warm; supplements the spleen and qi; dries dampness; enters the spleen and stomach channels; used in the treatment of indigestion and stomach disorders.
- Dang gui (*Angelica sinensis*): 12 g; properties: warm, bitter, sweet, slightly pungent; supports the liver and spleen; used as a tonic for female deficiencies and to enrich blood, promote circulation, stimulate appetite, improve muscle tone, stimulate the immune system, and moisturize dryness.
- Fu-shen (*Poria cocos*, a mushroom): 12 g; properties: sweet taste; used to calm the liver and heart and quiet the spirit; enters the heart, spleen, and lung channel; used for palpitations, fearfulness, and bad memory due to a frightful experience; considered a superb yin tonic.
- Gan cao (*Radix glycyrrhizae* or licorice root): 6 g; properties: sweet, neutral; tonifies the spleen and strengthens the qi, improving symptoms like fatigue, lack of appetite, loose stools, and shortness of breath; enters all 12 primary channels but particularly the lung, heart, spleen, and stomach; used to lessen the harsh and toxic nature of other herbs and protect the middle jiao (the primary source of digestion) and enhance the overall effects of a formula; often used with honey to treat drug poisoning or Xing Ren (*Semen armeniacaae amarum*) for lead poisoning.
- Huang qi (*Radix astragali membranacei* or *astragalus*): 20 g; properties: sweet, slightly warm; enters the lung and spleen channels; tonifies qi and blood; used to treat symptoms of spleen deficiency, can raise yang, tonify the wei qi (protective qi), treat spontaneous sweating, promote urination, and expel pus.
- Long yan rou (*Arillus euphoriae longanae* or flesh of the longan fruit, translated as "dragon eye flesh"): 15 g; properties: sweet and warm; enters the heart and spleen channel; actions are primarily to tonify the blood.
- Suan zao ren *(Ziziphus jujuba,* commonly called sour jujube seed): 10 to 18 g or 1.5 to 3 g in powder at bedtime; properties: the temperature and taste are neutral, sweet, and sour; supports several channels (gallbladder, heart, liver, spleen) and nourishes heart yin and blood, calms the spirit, and inhibits sweating; used to treat insomnia, irritability, dream-disturbed sleep due to yin and blood deficiency, as well as wind-damp bi syndrome, and wind-heat skin rashes/and itching and also given as a nourishing sedative.
- Yuan Zhi (*Radix polygalae tenuifoliae* or Chinese senega root): 6 g; properties: bitter, spicy, slightly warm; enters the heart, lung, and liver channels; used to nourish the heart and calm the shen.

The following are some of the single herbs that can be added to the formula:

- Bai zi ren (*Biota orientalis,* commonly called arbor vitae seed): 10 to 18 g every day; properties: the temperature and taste are neutral and sweet; supports several channels (heart, kidney, large intestine, and spleen) and is therefore used to nourish the heart, calm the spirit, as well as moisten the intestine and unblock the bowels; indications for its use include the treatment of insomnia/irritability/palpitations/anxiety/ and forgetfulness due to heart blood deficiency; also used to treat constipation due to yin and blood deficiency and night sweats due to yin deficiency.

- Yin Tonic Herbs
  - Bai he (commonly called lily bulb): 10 to 30 g daily; properties: the temperature and taste are cold, bitter, and sweet; supports heart and lung channel; used to moisten the lung, clear heat, calm spirit, heart, and stop cough; often used to treat menopause and also to treat dry cough and sore throat, insomnia, restlessness, and irritability and also used to treat qi and yin deficiency after a febrile disease.
  - Bai mu er (common name is fruiting body of tremella): 3 to 10 g of herb, soaked for 1 to 2 hours in soup until it is soft; properties: the temperature is neutral, sweet, and bland; supports the lung and stomach channel; used to tonify the lung and stomach, nourish yin, and generate fluids and also used to treat dry cough from lung heat and night sweats.

The herbal therapy above is just one example of the several differential diagnoses for the causes of insomnia according to the theories of TCM. It demonstrates the complexity of TCM herbal medicine and the diversity of choices and considerations available to the TCM herbal practitioner when choosing an herb or herbal formula specifically suited for the patient and the disease. The complexity of diagnosis is one of the reasons there is a long-standing debate among practitioners of TCM regarding the value of the standardized TCM formulas that are commonly found on the market today and the use of granules and raw herbs. Yet consumer behavior may ultimately determine the outcome of this debate because, as mentioned, raw herbs are difficult to prepare and to take because of the taste and consumers are more apt to take a pill than a preparation.

Ayurvedic Herbs

Ayurvedic herbology is based on the tridoshic theory that there exist six basic tastes (sweet, sour, salty, pungent, astringent, and bitter). When used correctly, these tastes (which are associated with all plants, herbs, and food) can be used to balance or counter an excess or deficient condition. Therefore, the first and basic principle in Ayurvedic medicine is the use of food, spices, and herbs not only to maintain good health but also to prevent and treat diseases. In general, sweet, sour, and salty tastes reduce vata, and bitter, pungent, and astringent tastes enhance it. Astringent, bitter, and sweet tastes reduce pitta; sour, salty, and pungent tastes enhance it. Bitter, pungent, and astringent foods reduce kapha; sweet, salty, and sour tastes enhance it. Based on these concepts, food, spices, and herbs with these specific effects are used to balance disharmonies in vata, pitta, and kapha conditions according to an excess or deficient condition.

For example, Ayurvedic medicine considers women to possess a greater amount of vata-type characteristics (tendency to be cold, dry, and light), which increase with age (old age is considered to be vata-dominant). Therefore, foods, spices, and herbs emphasizing sweet, sour, and salty tastes are often prescribed. However, taking into consideration the uniqueness in all of us, Ayurveda also recognizes that, as different as our body types are, so too are our nutritional requirements. For example, if you are a thin-framed, always-cold person with dry skin, you are considered to have a vata constitution and should eat a vata-balanced diet as a lifetime program. However, if you start to retain water, feel sluggish, and have excess mucus, you are demonstrating kapha imbalance and should avoid a sweet, sour, and salty diet to achieve balance.

Additional Approach to Choosing

Although tridoshic theory is the primary method used by Ayurvedic practitioners to individualize herbal therapy, they commonly use herbs and herbal formulas that target specific disorders when recommending commercial Ayurvedic herbs and herbal formulas.

Digestive Disorders

In Ayurvedic theory, most digestive disorders are a result of poor digestive "Agni" fire, which is responsible for absorbing nutrients in food, destroying pathogens, and converting food to be acceptable to our digestive systems. If Agni fire is weak, the body will not be able to perform these functions and food can become a negative pathogen for the body, creating toxins and undermining the immune system.

Herbs that enhance Agni fire are generally pungent, sour, or salty (e.g., black pepper, cayenne, or ginger). However, recommendations should be based on the condition of the Agni fire: if it is too high, herbs like aloe, barberry, and gentian are more appropriate; and if variable, spices like ginger, cumin, or rock salt are recommended. Generally, sustaining digestive fire is done with mild herbs (e.g., cardamom, turmeric, coriander, and fennel).

Ayurvedic formulas include the following:

Triphala is a blend of herbs or three fruits: amla (*Emblica officinalis*), bibitaki (*Terminalia belerica)*, and haritaki (*Terminalia chebula*). The fruits are dried, powdered, and mixed together and given as a general tonic and detoxifier. Triphala is taken every day to help balance all three doshas: each herb balances one of the three doshas—amla controls pitta, bibitaki controls kapha, and harataki controls vata. Triphala has traditionally been used to treat gastrointestinal disorder and restore bowel health. Most research has been done in animal trials; however, a 2007 study to evaluate the inhibitory activities of triphala against common bacterial isolates from HIV-infected patients supported an antibacterial activity by triphala against the bacterial isolates (Srikumar et al, 2007).

Trikatu mean "three herbs": ginger (*Zingiber officinale*), black pepper (*Piper nigrum*), and Indian long pepper (*Piper longum*). Used for its bitter taste, it is intended to rejuvenate the digestive fire as well as the respiratory tract.

Rejuvenative Disorders

In Ayurvedic theory, disorders that include symptoms of low energy, fatigue, lack of sexual motivation, anxiety, and impotence are often caused by vata (air) conditions. Therefore, tonification therapy will include an anti-vata diet, including

foods like dairy products, ghee (clarified butter), nuts, okra, and meat. However, tonics like shatavari, chyavanprash, and aswagandha are commonly prescribed as well.

Shatavari root (*Asparagus racemosus,* "hundred husbands") is the main Ayurvedic tonic for women, with a role similar to that of the Chinese tonic dong quai. But it can also be used by men, having a similar role as ginseng, to treat impotence. Shatavari is a woody climber that has leaves that are like pine needles and white flowers with small spikes. It belongs to the *Liliaceae* family. By taste it is sweet, bitter, and cooling in nature; it is used as a nutritive and calming agent, to regulate menstrual flow, and to boost hormonal triggers, making it valuable in treating menopausal complaints such as vaginal atrophy and to increase female sexuality. Research on shatavari has found it to have multiple influences on the body, acting as an adaptogen, antitussive, antioxidant, antibacterial, immune-modulator, digestive, cyto-protective, galactogogue, anti-oxytocic (preventing the stimulation of involuntary muscles of the uterus), antispasmodic, antidiarrheal, and sexual tonic (Thomsen, 2002).

Amla fruit (*Emblica officinalis*, Indian gooseberry) is a small, very sour fruit that is the most widely used in

Ayurveda as a general rejuvenative herb. This fruit is particularly high in vitamin C, with 20 to 30 times the amount found in oranges. The vitamin C in amla is also heat stable, surviving the cooling and drying process, making it an extremely powerful antioxidant. Amla is the principle ingredient in a jelly called *Chyavanprash* that has been used for over a thousand years to help rejuvenate the body and fortify the mind.

Aswagandha (*Withania somnifera* or "Indian ginseng") has been used for hundreds of years for its ability to restore vitality and strength. In Sanskrit the word means "the smell of a horse" and the herb has traditionally been used as a male tonic. Classified as an adaptogen, ashwagandha contains steroidal lactones, alkaloids, choline, fatty acids, amino acids, and a variety of sugars.

Herbs for Common Disorders

Table 10-1 presents additional information on herbal medicines for common health problems. Although many other herbs may be used for these disorders, the ones listed have all been studied in human trials. Others that are not listed in the

Table 10–1 Selective Herbal Agents Used for Common Conditions

Condition	Treatment
Candida	Garlic Berberine-containing herbs: Oregon grape, goldenseal, scutellaria, gentian, grapefruit seed extract Ginseng, astragalus, red clover, dandelion root, burdock root, asafetida, cumin
Constipation	Psyllium seeds, fennel, fenugreek, olive oil, cannabis seeds For constipation due to heat: turmeric, gentian, dandelion, Oregon grape, yellow dock Ayurvedic herb: triphala or rhubarb
Diarrhea	Blackberry root, raspberry leaf, agrimony, bayberry bark, oak bark, yarrow Spleen qi tonics: ginseng, *Codonopsis*, white atractylodes, and *Dioscorea* Cinnamon, ginger, or cardamom
Pain Headaches	Chinese herbs: Ligusticum (chuan xiong) or Chinese lovage Feverfew, chamomile, willow bark Western herbs: angelica Bupleurum, *Artemisia annua* (Sweet Annie) Menstrual headaches:, black cohosh, dandelion, chrysanthemum, and feverfew or the formula of dang gui, cooked rehmannia, white peony, and Ligusticum
Arthritis	Borage, capsicum, chondroitin, evening primrose oil, ginger glucosamine, turmeric
Insomnia	Chamomile, skullcap, valerian, or kava kava, passionflower, hops, ashwagandha to calm the nervous system, St. John's wort, lemon balm, schisandra, jujube dates
Benign prostatic hypertrophy	Nettle, pumpkin seed, saw palmetto
Menorrhagia	Shepherd's purse tincture, 3 to 6 drops every 2 h or a combination of cattail pollen, agrimony, mugwort, yarrow, shepherd's purse, raspberry, and blackberry leaves Building blood with iron floradix or blackstrap molasses, along with Chinese herbs dang qui, lycii, cooked rehmannia, and white peony
Dysmenorrhea	Combination of equal parts of vitex, wild yam, block cohosh, dang qui, sassafras, and licorice with ½ part ginger
Urinary tract infections	Cornsilk tea, parsley, dandelion, horsetail, cranberry, and for extreme burning, use goldenseal, gentian, gardenia

table are in use but have been reported on only in case or anecdotal reports.

HERBAL PREPARATIONS

Although understanding the use of herbs is important, proper preparation ensures their maximum effect. The following is a summary of several of the most common preparations and their proper use.

Bolus refers to a suppository inserted into the rectum. Common herbs used in this way are astringents such as white oak bark, bayberry bark; demulcents such as comfrey root or slippery elm; and antibiotics such as garlic, echinacea, chaparral, and golden seal.

Compress/fomentation are two terms that refer to the same treatment of applying herbs externally to the body. Especially effective for herbs that are too strong to take internally but that can be absorbed slowly in small amounts, compresses are used to treat many superficial ailments like swelling and pain and to stimulate circulation of blood or lymph in the area where the compress is applied.

Liniments are warming herbal extracts rubbed into the skin and are commonly used to relieve sore or strained muscles and treat conditions like arthritis or itchy skin.

Oils are concentrated extracts used for massaging the body. There are two types of oil preparations: *soothing emollients* that use herbs like calendula flower, lavender, lemon balm; and *warming and stimulating oils* that use herbs like ginger, peppermint, and eucalyptus. Oils are usually infused with a particular herb chosen with consideration of the moistening capacity of the oil:*nondrying oils* include jojoba, cocoa butter, and avocado; *semidrying oils* include safflower and sunflower; *drying oils* include soybean and linseed (flax).

Capsules or pills are one of the most popular preparations used in herbal therapy today because they are convenient and mimic Western medicine. They are entirely made up of herbs; however, capsules are generally twice more concentrated than pills.

Poultices and plasters are a topical application of herbs that have been powdered, crushed, or mashed and are usually applied moist, either hot or warm, and left on an area of the body for 12 to 20 hours. Caution must be taken to avoid skin reactions and burns.

Smoking mixtures are used for smoking herbs, like datura leaf for the treatment of asthma. Smoking of herbs should be done only occasionally, and patients should be warned about the risk of lung disease, as with any smoking habit.

Teas are the most well-known method of taking herbs. Although tea is generally considered a beverage, it can have the strongest medicinal effect of any preparation, making it suitable for the most serious illnesses. To be effective, the proportion of herbs to water must be greater than usual.

Tinctures are an alcoholic or vinegar extract of herbs. Their advantage is that they have a long shelf-life when stored in a cool, dry place, whereas dried herbs begin to lose potency after the first year. Tinctures tend to make herbs energetically "hotter," which affects the circulatory system. Consideration must be given to other chemical constituents found in alcohol, such as glycosides and sugars.

CONSIDERATIONS FOR THE APRN PRESCRIBER

There are many reasons people use herbal remedies instead of conventional medicines. Sometimes these reasons may not be consistent with those of Western medicine or supported by evidence-based studies; however, we have to respect the consumers' right to choose and acknowledge that consumers are using herbs at an ever-growing rate. Therefore, APNs and other health-care providers should be prepared to educate the patient about the many different concepts and herbal traditions and help guide them to the appropriate resource. In addition, providers need to educate themselves about the herbs that are commonly used by their patients and be aware of the growing amount of research being conducted to evaluate interactions with herbal therapy and allopathic medicines.

Because a product is natural does not mean it is risk-free. In the late 1980s, a particular brand of L-tryptophan tablets resulted in several cases of fatal eosinophilia myalgia, and from 1993 to 1997, several hundred cases of serious adverse effects were documented from ephedra in diet and weight-loss supplements. Yet some herbal preparations have been accepted and found to be relatively safe when used in combination with Western medication, such as astragalus and dong quai for the treatment of infections and menopause.

When consumers and nonherbalists speak either positively or negatively about any given herb, what they seriously fail to acknowledge is the many different herbal traditions and those practitioners who are either certified

in herbal therapy or trained in a given medical discipline that has a history of using herbal therapy but that does not fall within the definitions of Western medicine. Often, it is a failure to evaluate a specific herbal theory or or to consult a practitioner of herbal medicine that leads to many of the adverse effects cited in clinical research and by consumers.

Health-care professionals need to keep an open mind to all the possible ways of treating health problems, and that ultimately may require the inclusion or consideration of medical systems that are not commonly practiced in Western culture. Primary care providers may need to explore the resources that are available to the public at large, critique the information, and assist the patient in finding practitioners of non-Western–based treatments that can meet their needs. However, professionals must also recognize their scope of practice and not venture into prescribing or recommending without adequate knowledge and training in other areas of therapy.

INFORMATION TECHNOLOGY AND PHARMACOTHERAPEUTICS

Jane M. Carrington

OVERVIEW

According to the essentials for Doctoral Education for Advanced Nursing Practice (DNP), established by the American Association of Colleges of Nursing (2006), graduates of these programs are trained to use information systems and patient-care technologies to improve and transform patient care. The federal government has also instituted the Healthcare Information Technology for Economic and Clinical Health (HITECH) provision of the American Recovery and Reinvestment Act (ARRA) of 2009, whereby providers, including advanced practice nurses (APN), are to be meaningful users of technology to increase patient safety and reduce health-care costs. Regardless of the practice setting, reimbursement is now connected to the provider's ability to use the electronic health record, computerized provider order entry, and clinical decision support. Furthermore, providers are also held to revised patient privacy standards, which will influence patient education and patient engagement.

This chapter will review the technologies that are involved in pharmacotherapeutics and that are essential to meaningful use. In addition, the chapter also discusses items that are essential to increased patient safety: medication reconciliation, sustaining all elements of patient privacy, supporting patients' use of the personal health record, patient education, and quality matters.

INTRODUCTION

The literature contains an abundance of evidence that the health-care system is inefficient and can ultimately be a threat to patient safety. The often cited report out of the Institute of Medicine (IOM), *To Err is Human: Building a Safer Health System*, brought to light the astonishing statistics that up to 98,000 lives are lost each year in our nation's hospitals due to medical errors (Kohn, Corrigan, & Donaldson, 1999). This report was the impetus for both legislative and regulatory initiatives that were designed to ultimately increase patient safety. One of these initiatives is ARRA. The goal of ARRA is to provide affordable health care by means of health information technology. The act states that reimbursement for care delivery will be attached to adoption and compliance with the electronic health record (EHR) beginning in 2015 and that health-care providers are to become meaningful users of EHR. Health-care providers are defined as meaningful users when they have effectively adopted EHR to improve patient safety and quality of care, engage patients in their care, improve care coordination, and protect patient health information (ARRA, 2009).

The EHR Incentive Program is a list of meaningful-use objectives to assist providers regardless of the type of practice (hospital, critical access hospital, primary care, and so forth) to become meaningful users. Of these 14 objectives, 9 directly involve the process of ordering or prescribing medications,

2 contribute to the process, and 2 are indirectly related. Table 11-1 is a list of the objectives and their relationship to pharmacotherapeutics. The objectives for professional meaningful use serve as organizers for this chapter (see Table 11-1), which will discuss the EHR, information storage and exchange, computerized provider order entry (CPOE), clinical decision support (CDS), patient privacy, and patient safety.

THE ELECTRONIC HEALTH RECORD

A number of definitions of EHR have been used in the literature, but for this chapter, the EHR is a computerized patient record in which all members of the health-care team enter patient information. This definition is all-encompassing, as it includes elements of an earlier definition of the electronic medical record (clinician based) and EHR that contained information generated by patients, family members, and other services (Garets & Davis, 2006). The broadest of definitions for EHR thus accounts for the diversity of practice settings and the inclusion of patients and family in their own care.

It can be argued that regardless the size of the practice, from a small private practice to larger organizations, the EHR can improve the quality of care patients receive, assist in measuring outcomes, and improve organizational efficiency (Chaudhry et al, 2006). Despite these advantages, the implementation of the EHR has been impeded by its cost. For example, hospitals have reportedly paid over $10 million in up-front costs to implement the EHR (Doyle, 2009). Doyle further suggests that health-care organizations should keep their EHR budget to within 1.5% of their annual operating expenses. Staying within this guideline may yield more offsetting costs, however. Budget estimates will soon include the money recouped through ARRA.

EHRs can be implemented within a practice or hospital or implemented across an entire health-care system that includes clinics, hospitals, and offices in one system. The larger implementation has the advantages of a single-vendor EHR, mechanisms for large data storage, and the exchange of patient information from provider to provider and across care settings. The smaller site implementations have internal communication advantages within the practice or hospital; however, they may lack the ability to exchange patient information with outside agencies due to incompatible interfaces between different vendors.

Information Storage and Exchange

Following adoption of the EHR, providers have access to vast amounts of patient data. Unlike data from the early electronic medical records, where the patient information is in the form of individual medical records akin to separate file documents, the EHR can provide data from a clinical warehouse and

Table 11–1   Core Elements for Meaningful Use for Providers

Core Element	Measures	Associated with Pharmacotherapeutics
Use of CPOE*	>30% medication orders created using CPOE	Yes
Drug-drug and drug-allergy interaction checks	Full functionality	Yes
Up-to-date problem list of diagnosis	>80% of patients	Contributing
Generate and transmit prescriptions electronically (eRx)	Exclusions for smaller practices and availability of a pharmacy	Yes
Active medication list	>80% patients	Yes
Active medication allergy list	>80% patients	Yes
Record demographics (language, gender, race, ethnicity, date of birth)	>50% patients	Contributing
Record changes in (height, weight, blood pressure, BMI, growth charts for pediatrics)	>50% patients	Yes
Smoking status for patient 13 years and older	>50% patients	Indirect
Report ambulatory clinical quality measures	Complete	Indirect
Implement one clinical decision support rule	One clinical decision support rule	Yes
Provide patients with electronic copy of health information	>50% of all patients who request, provided within 3 business days	Yes
Provide clinical summaries for patients	>50% patients within 3 business days	Yes
Protect electronic health information	Conduct a review to reflect success with this objective	Yes

CPOE = Computerized Provider Order Entry
Adapted from https://www.cms.gov/Regulations-and-Guidance/Legislation/EHRIncentivePrograms/downloads/EP-MU-TOC.pdf. Retrieved June 11, 2013.

recall the data in aggregate. The strength of this capability is evident in the scope for potential search questions. Using the EMR, a search question could be: "all admissions for diabetes for Jones, MR# (number)." Compare this to the EHR in a clinical warehouse: "all patients >65, diagnosis of congestive heart failure, with potassium levels of 2.9, with readmission <30 days." Both searches can provide the provider useful results; however, the relational clinical data warehouse has the potential for influencing broader care decisions, including establishing benchmark data and tracing the impact of quality improvement programs, which inform the root-cause analysis of suspected or known problems. Contents of the data warehouse can vary but may include: patient visits (in- and outpatient), surgeries, test results, and billing (Einbinder, Scully, Pates, Schubart, & Reynolds, Summer 2001).

These data in aggregate are useful at the local level, but what about regional or multiple health-care organizations? Can comparisons in care and outcomes be made available? Regional health information organizations (RHIOs) are designed to address these questions.

A RHIO unites patient-care stakeholders within a defined region for the purpose of improving care (HRSA, np). Critical issues must be resolved for the RHIO to survive. First, agreement on what patient data will be collected. For example, data could be collected on specific diagnoses and medications and then combined with data on ambulatory care, acute care facilities, and home-health care. Second, who should be members of the RHIO must also be agreed upon. For example, representatives from ambulatory, acute, home care, public health, and payers can be included. A strong RHIO would have stakeholder representation that would best appreciate the patient data so that its measures become more significant and potential changes in care could be developed. Third, the RHIO must be able to sustain itself through successful funding. In the United States, RHIOs use federal grant monies or fees from members (Adler-Milstein, McAfee, Bates, & Jha, 2007). Finally, standards for maintaining privacy when exchanging patient information must be established. RHIOs are not excluded from state and federal privacy standards (Solomon, 2007). Unfortunately, RHIOs face challenges to endure in our economy and our independent health-care systems. One possible solution is

building the RHIO according to business models designed to sustain themselves beyond the timeframe of government funding (Osterwalder, Pigneur, & Tucci, 2005).

The next level of organization is provided through the electronic Health Information Exchange (HIE), which is part of the HITECH Act of 2009. The HIE supports access by providers and patients to patient medical information in order to ultimately improve the quality and safety of patient care and reduce costs by connecting RHIOs (Adler-Milstein, Bates, & Jha, 2011; HealthIT, np; Overhage, Evans, & Marchibroda, 2005). The goal of this program is to increase the completeness of patient records, which would lead to reduced readmissions and medication errors, reduce duplicative tests, and lead to more timely diagnoses (HealthIT, np). HIE has the potential of connecting RHIOs across zip codes, city and county borders, and the states. It is a concerted effort to interconnect patient information in a highly mobile society (Vest & Gamm, 2010). It is not uncommon for patients to initiate care for a diagnosis in one state and then for a variety of reasons, continue care in another state. Consider the retirees who winter in one region of the United States and summer in another region. The HIE permits the exchange of health information in both locations.

Computerized Provider Order Entry

Computerized provider order entry (CPOE) is an application that supports orders entered in the EHR by providers. According to the The Leapfrog Group (2008), it is considered the piece of technology the most helpful for reducing medication errors. The reduction of errors has been attributed to increased legibility, decreased use of unapproved abbreviations, and fewer incidences of incomplete orders (Devine, et al, 2010). Unfortunately, a mere 10% of our nation's hospitals had implemented CPOE as of 2010 (HIMSS Analytics, 2010), which is especially concerning given that CPOE has been in existence in some form along with the EHRs for over 40 years (Goolsby, 2002). The current decade has seen an acceleration of adoption and use of EHRs and CPOE.

Table 11-2 contains a brief review of the literature demonstrating the established advantages and disadvantages of

Table 11–2 Advantages and Disadvantages of Computerized Provider Order Entry

Resource	Advantages	Resource	Advantages
Franklin, O'Grady, Donyai, Jacklin, & Barber (2007)	Positive impact on error reduction using electronic prescribing and administration systems	Campbell, Sittig, Ash, Guappone, & Dykstra (2006)	Additional work, difficult information gathering, difficult workflow
Shulman, Singer, Goldstone, & Bellingan (2005)	Reduction in medication errors compared to manual system	Koppel et al (2005)	Fosters errors
Raebel, Carrlo, Kelleher, Chester, Berga, & Magid (2007)	Reduced error for pregnant women; did not stop errors completely	Walsh et al (2006)	Found errors with system; duplicate medication orders, menu selection errors, incorrect abbreviations, order set errors
Vaidya, Sowan, Mills, Socken, Gaffoor, & Hilmas (2006)	Pediatric ICU, chemotherapy-error reduction		

CPOE. From this very brief review of the literature, research suggests that CPOE has the potential for reducing medication errors. Prior to implementation of CPOE, providers must take into account changes in workflow between a manual system and a computerized system. For example, the workflow or process of providing care in a health-care system using paper records is different from that of a system using electronic systems. Starting with obtaining patient information, the provider locates the chart, reads information, visits the patient, and writes updates, and then goes on to the next patient. Using an electronic system, signing on to a computer gives ready access to all the patient's information. Updates can be entered during the visit, reducing the risks of error due to forgetfulness.

Electronic health systems require extensive training and testing at each stage of design, construction, and implementation. Failure to do any of these well has the potential for catastrophic error and results in failure to adopt the system, ultimately resulting in failure to meet the requirements for meaningful use.

CLINICAL DECISION SUPPORT SYSTEMS

Clinical decision support systems (CDSS) are generally considered to be expert systems with defined decision aids that require two or more items of patient data to generate advice (Johnston, Langton, Haynes, & Mathieu, 1994). Clinical decision support systems can stand alone within the EHR, like CPOE, or can function with CPOE, and the two applications together increase patient safety by reducing adverse drug errors (ADE). Killbridge, Campbell, Cozart, & Mojarrad (2006) determined that these technologies, when combined, detected ADEs at a rate 3.6 times greater than a manual system. For example, CDSS function within the EHR to alert the health-care provider to patient allergies, drug-drug issues, and laboratory/medication inconsistencies. The extent to which the alerts are set is dependent upon the vendor system and agreement of the stakeholders (providers, pharmacists, laboratory personnel, etc.). Once an ADE has occurred, a root-cause analysis may shed light on the elements of the health-care system that led to the error and may result in a modification of an alert or the development of a new alert.

Depending on the number of patients seen by a provider and the medication list and tests entered into the system, alert fatigue may occur. Alert fatigue is the result of excessive alerts or clinical warnings resulting in providers potentially ignoring clinically useful alerts and thereby threatening patient safety (Avery et al, 2005). The challenge in resolving alert fatigue is finding the balance between the legal responsibilities of the vendor providing the alert mechanism and using principles of human–computer interaction to reduce alert fatigue.

Software developers who market their products in the United States are regarded by the Food and Drug Administration as providers of a medical device (Kesselheim, Cresswell, Phansalkar, Bates, & Sheikh, 2011). This presents legal risks to providers who ignore alerts that result in harm to the patient. To improve provider appreciation for alerts and reduce alert fatigue, researchers have suggested that alerts should be parsimonious (fewer words that still convey the message), while others have suggested a staged implementation, for example, first implementing alerts for drug allergy, then drug dosing, followed by drug-drug interaction, and finally formulary support followed by alerts for specific patient types, laboratory testing, and drug-disease alerts (Kesselheim et al, 2011; Kuperman et al, 2007).

The process for the provider of making therapeutic decisions connects each of these technologies and systems (EHR, CPOE, CDS, RHIOs, HIE). Regardless of the size of the practice (office, clinic, large health-care organization), the provider is responsible for the adoption of these technologies and for functioning as a meaningful user of them. From patient assessment to recording the information in the EHR, prescribing or ordering medications supported by CPOE, acknowledging alerts, and information storage for the RHIOs and HIE, what appears to be a linear task is a process and part of a larger information and health-care system.

PATIENT SAFETY

Patient safety is the ultimate goal of care for a provider. Complementary to this goal is the reduction of health-care costs. The health-care system in the United States is complex. Providers who are also patients have a frontline view of the complexities. From untangling payer documents to dissecting hospital bills, seeking care has become a quagmire for patients. By using technology and striving to meet standards for meaningful use, providers are poised to facilitate patient understanding. The following sections will present information on technology and patient safety for pharmacotherapeutics.

MEDICATION RECONCILIATION

According to the CMS and EHR Incentive Program (np) Meaningful Use Core Measure 14, medication reconciliation is the process of identifying and listing the most accurate list of medications that the patient is taking, including the name of the medication, current dose, frequency, and route. Furthermore, for this standard to be met, medication reconciliation must be done for each encounter after long gaps in care, changes in medications, or other reasons as determined by the provider. This standard also includes when patient care is transferred from one provider to another or when the care setting changes (in- or outpatient, home health, and so forth).

The patient may be taking several medications and only know them by color, size of the pill, number taken per day, and by some unofficial nickname "my water pill," for example. Storing medication records in the EHR reduces the challenge of medication reconciliation. As described previously, using an EHR that is connected across an entire health-care system supports this standard. In this case, the information entered at one location appears when another provider within the same care system signs on to the system. For stand-alone EHR systems (those that are not connected), the

provider is dependent on the exchange of patient information (using portable storage devices or paper) and on the patient as a historian. Once medications are accurately entered into the system, manually updating per encounter or patient transfer is then required to meet this standard.

In the case of controlled substances, it is possible to track individual prescriptions by date, substance, and provider using a state database. These databases are now accessible in almost every state but are not searchable across state lines. Providers individually enroll in the system to gain access, which in most states requires a prescriptive license and Drug Enforcement Agency (DEA) number. The database returns information that can provide a picture of "doctor shopping"—multiple providers dispensing controlled medication to the same patient—and evidence of urgent care or emergency room dispenses. This evidence can be used to track adherence to pain/controlled substance contracts and those who are under care for addiction issues.

PATIENT PRIVACY

In 1996, the Health Insurance Portability and Accountability Act (HIPAA) established the standard for patient privacy. The act encompasses a number of statutes that apply to insurance and the patient and includes the privacy rule. The privacy rule includes the Protected Health Information (PHI) statute and a number of others that apply to providers (Terry, 2009). This standard was updated in 2013 to take into account the vast changes in health care that have taken place in the past 17 years. Along with the expansion of aspects of privacy for patient information now covered and an increase in penalties for violations, HIPAA also includes an expansion of patient rights. According to the U.S. Department of Health and Human Services (2013), patients can now ask for a copy of their electronic health record and can expect to receive the copy in an electronic format. As stated by the department, this provision of the revised HIPAA standard implies that providers must now have the capability to provide patients with copies of their health record, which may include, for example, digital recording, e-mail, or electronic storage devices.

Despite efforts to fully implement and adopt the EHR, the portion that involves the personal health record (PHR) has received less national attention. This is curious because of our national experience with disasters that have revealed the fragility of health-care records. Thankfully, these losses appear to be infrequent; however, the damage can last for years.

The EHR and data storage systems provide solutions for health-care organizations and office practices; however, patients have often been in the care of a variety of providers in their lifetimes, especially those with complex health histories and chronic illnesses. Because it is specific to pharmacotherapeutics, the PHR may assist in maintaining the medication health records of patients. The PHR captures health data entered by patients and consumers of health care and, in some cases, the care provider (Tang, Ash, Bates, Overhage, & Sands, 2006). PHRs can be as sophisticated as those "tethered" to the EHR, be stand-alone systems purchased by the patient, or be as simple as a paper document or spreadsheet.

The tethered EHR is supported by a number of vendors and made available by health-care organizations. This type of PHR allows data from the EHR to populate the PHR, for example, laboratory results, radiology results, surgical pathology, and medication changes. These PHRs also support patients contacting their providers via e-mail and scheduling or rescheduling appointments, to name a few functions. In some cases, the PHR tethered to the EHR may also be connected to the neighborhood pharmacy. This feature has the potential of supporting interprofessional communication with the patient regarding their medications. Patients have expressed satisfaction with tethered systems and were generally positive about having electronic access to their EHR and messaging their providers (Hassol et al, 2004).

Stand-alone PHRs, or those not connected to the EHR, require patients to enter their own health and medication information. While this is better than not having a PHR, it lacks the features mentioned above. This type of PHR places additional responsibility on the patient for entering accurate health information. The positive outcome can be the improved self-care accountability that comes with being a partner in one's own health. These systems can often be downloaded on a portable drive for provider access during appointments and in- and outpatient events. At the simplest level, a "recording" glucometer or peak flow meter can be considered a technological aid for gathering information. Providers should acknowledge the individual effort patients extend in gathering this data and reinforce that they are major partners in creating the therapeutic plan.

PATIENT EDUCATION

Providers are responsible for patient education. Educating by providing patients with a copy of their health information might be considered one way to satisfy the meaningful use objective. Specific to pharmacotherapeutics, patients should receive education regarding their medications and changes in medication therapy during the visit or inpatient stay. The challenge is making time in a busy practice to meet this objective. One solution is to use a "patient instructions" feature within the documented plan of care. This section can be printed out as an after-visit summary provided at discharge while the data is simultaneously recorded in the clinical note.

Having an EHR that features medication education handouts in the practice or at the health-care organization is also useful. This information can be tailored to the specific needs of the patient and printed or e-mailed (or both) for the patient's handy reference. These applications require updating to remain current, which is usually done by the vendor or internal support personnel.

Another option is the use of computing tablets or smartphones to download applications designed for patient education. As of 2012, there existed nearly 30,000 applications, or "apps," related to health care designed for both the Apple and Android platforms (Bresnick, 2012).

Bresnick estimates that over half of the adults in the United States use smartphones that are capable of uploading these apps. The provider can use a computing pad or smartphone with an app and teach the patient about the medication, as well as other issues that emerged during the visit. Examples of long-established products are *Epocrates* and *MicroMedix*. These and many others supply both provider-level information and simpler patient handouts. In lieu of these formal pharmacology aids, a simple search on the Internet or using a smart device will reveal the apps available for use with pharmacotherapeutics and patient education.

The Internet as a source of information for patients is both wonderful and challenging. It contains a vast amount of information—some accurate, some less so. For a provider, patient education includes assisting patients to understand what Web sites contain accurate and useful information associated with health and pharmacotherapeutics. Table 11-3 lists those sites that suggest how to screen for accuracy, and each provides a list for users to scan and apply to health-related Web sites.

All sites listed in Table 11-3 are consistent with each other in terms of search criteria, and the table includes pointers from the Setting Priorities for Retirement Years (SPRY) Foundation, and information about whether the site includes the options "Contact us" and "Copyright" when scanning for accuracy of information. MedlinePlus has taken an additional step by including the provider in the screening. On its Web site, Medline Plus suggests that patients consult with their provider to validate the information on the site. Providers can also search the Internet to identify Web sites that meet the standard and provide patients with an appropriate list during a visit. This information can also be part of the assessment "what have you learned about your medications (or topic) on the Internet?" This creates an opportunity for discussion with the patient and for gathering added information to enhance care.

QUALITY IMPROVEMENT

As a nation, we are over a decade beyond the 1999 IOM report and yet a significant number of people continue to die each year due to medication errors (Landrigan et al, 2010). The original emphasis on quality improvement in EHR documentation was not initially linked with patient safety. The fortunate outcome is that both are inextricably interlocked. For this reason, the process of pharmacotherapeutics does not conclude when the patient walks out the door or is discharged from hospital care.

The first step in the process of pharmacotherapeutics may be assessing a patient, followed by entering the prescription or medication order in the EHR, educating the patient, and

Table 11–3 Suggestions for Screening Web Sites

Web Site/Source	Screening Suggestions
Medical Library Association (MLA) http://www.mlanet.org/resources/userguide.html (Included list of useful Web sites on their site; very helpful information)	1. Sponsor of site 2. Regularly updated 3. Factual, look for sources 4. Stated audience

Completeness of information 10. Written with clarity

reassessing for effectiveness. This process continues to include quality improvement, which involves using data to monitor patient outcomes and using improvement methods to design and test changes to continuously strive to improve the quality of patient care (Cronenwett et al, 2007).

APNs are clinical leaders and are responsible for assessing their practice for quality and patient safety. Those who hold the DNP degree have the education required to facilitate such assessments at all levels of the practice. The health-care organization or fellow practice providers will turn to these clinical leaders to explore troubling outcomes or questions regarding the best evidence-based practice. An in-depth discussion of the process of quality improvement, program evaluation, and creation of a program with logic models, however, is outside the scope of this chapter, which is focused on the use of technology to explore and challenge current practice.

Box 11-1 lists sample questions specific to pharmacotherapeutics that may initiate discussion within a practice and begin the process of quality improvement. The question may arise from observation: "I have seen this same reaction with five other patients," or "In my practice, our patients are not doing as well on this medication; are we using it correctly?" The first place to then turn may be the EHR database. Based on these examples, the search could be: "patients >65 years of age, male, diagnosis congestive heart failure with type 2 diabetes, currently prescribed XXX medication." This search may then provide the information necessary for establishing a pattern of patient responses to medications. From there, technology can assist with a comprehensive literature review specific to the practice question. If the technology is not available within the practice, hospital libraries most often will have computers with access to the Internet for searches and access to specific articles. When teaching patients about a specific medication, the APN may discover that an important point is being missed or not well understood. The APN provider can then design a quality improvement plan that will include education for both staff and providers, institute changes in practice policies and workflow, and create an evaluation plan for key quality outcomes.

CONCLUSION

This chapter has presented information regarding the intersection between technology and pharmacotherapeutics, including elements involved in the meaningful use of guidelines that are directly related to medications, in the hope of reducing medication errors, a leading cause of patient deaths in the United States. To be a meaningful user, the APN has the professional responsibility to appropriately use the EHR, CPOE, and CDS to increase patient safety and reduce health-care costs.

The professional responsibility of the ANP provider expands beyond the obvious process of pharmacotherapeutics to include patient safety. Patient safety includes medication reconciliation, sustaining all elements of patient privacy, supporting patients' use of the PHR, patient education, and quality improvement. Again, technology supports each of these elements of patient safety.

PHARMACOECONOMICS

Teri Moser Woo

Today more than ever, third-party payers, health-care providers, government regulators, and patients are demanding that new drug treatments be not only clinically more effective but also cost-effective. Angiography, stent placement, transplantation, and use of monoclonal antibodies for the treatment of oncological disorders have become relatively routine treatments. After transplantation, patients who were dialysis-dependent are restored to relatively normal lives and are able to contribute to society. These accomplishments do not come without cost to the patient or society.

Pharmacoeconomics provides a framework for evaluating drug treatments in terms of comparing one treatment against another and whether the treatment is providing "value for the money" spent (Hay, 2008). Pharmacoeconomic evaluations of medical and surgical procedures have very seldom taken into account factors other than the actual cost to the health-care system of pharmaceutical agents (Berger & Teutsch, 2005; Tunis, 2009). This approach underestimates the real cost of drug treatment, which depends on adherence, efficacy of therapeutic agents, hospitalizations and treatment for adverse drug reactions, and finally productive life years. Also, a disturbing trend in modern medicine is the achievement of excellent short-term benefits that have relatively little long-term impact on comorbid conditions, drug toxicities, or drug nonadherence. The introduction of "me-too drugs" (similar drugs developed by multiple drug companies) and the number of highly promoted drugs also distort the facts about the actual cost of drug therapy.

Prescription drug spending has increased significantly over the past few years, from $239.9 billion in 2004 to $320 billion in 2011 (IMS Health, 2012). Health-care organizations and pharmacy benefits managers have tried to control drug costs by using generic drugs and strict formularies. Generic-drug sales accounted for 71.2% of drug sales in 2010, up from 49.4% in 2005 (Pal, 2013). Although generic drugs have a place in health care, the decision to use them should be based on more than just cost-cutting reasons. However, with today's cost-consciousness in health-care delivery, quality of care may be compromised in exchange for lower cost. Health care has become more like a business with a bottom line, but medicine cannot be just a business. Now, more than at any time in history, we are responsible for distinguishing between excellent care and inappropriate cost cutting. Factors that influence pharmacoeconomics are found in Table 12-1.

PHARMACOECONOMIC STUDIES

Pharmacoeconomic studies were originally designed to study the cost to the health-care system of drug therapy. Clinical studies evaluate the safety and efficacy of a drug therapy,

Table 12–1 Factors Influencing Pharmacoeconomic Outcomes

Research Type
Clinical outcomes
Efficacy
Safety
Adverse drug reaction
Drug-drug reaction
Hospital admission, clinic visits
Humanistic outcomes
Patient satisfaction with care
Quality of life measured by validated instrument
Economic outcomes
Cost associated with immunosuppressive therapy
Cost to treat adverse drug reactions
Cost to treat drug-drug interactions
Cost to treat long-term toxicity (nephrotoxicity, hypertension)
Cost of laboratory work-ups

whereas pharmacoeconomic studies investigate the dollar value of patient care. Pharmacoeconomic studies are an increasing trend in all fields of health care; these studies should focus primarily on clinical and humanistic outcomes and secondarily on economic factors. Unfortunately, most pharmacoeconomic drug studies have focused solely on economic outcomes, with little attention paid to clinical efficacy, safety, and humanistic outcomes. All health-care providers must understand the limitations of these pharmacoeconomic studies.

The criteria routinely used in the study of pharmacoeconomics include cost-minimization, cost-benefit, and cost-effectiveness. The information obtained from a well-designed, on-site (local) pharmacoeconomic study should help health-care providers make important decisions regarding which protocol, treatment, services, and drugs should be used. A well-designed study should include several components (Table 12-2).

Components of Well-Designed Studies

Pharmacoeconomics is the analysis of the costs and consequences of any given health-care–related treatment or service. Pharmacoeconomic analysis may involve several different studies, each performed to answer different and specific types of questions. For any given analysis, knowing the *point of view*—whether a third-party payer, hospital, or government is determining the cost to society—is critical. Along with point of view, one should have a good understanding of the various *types of costs* and which are included in each type of analysis.

Direct costs are those that can be directly attributed to the treatment or disease state in question. They can include factors such as the acquisition price of medications, health-care provider time, or the cost of diagnostic tests. Direct, nonmedical costs must also be considered. This latter category includes transportation to the medical facility or child-care expenses incurred while receiving treatments. Direct costs can further be divided into fixed and variable costs, but because fixed costs are usually associated with overhead and are not influenced by the treatment or disease state, they are often excluded in a pharmacoeconomic analysis.

Besides direct costs, *indirect costs* associated with the therapy must be considered in an analysis. These costs derive from morbidity and mortality and include things such as loss or reduction of wages owing to illness or the costs associated with premature death.

Indirect costs can be calculated by two different methods, each having its own inherent flaws. The human capital method assumes losses based on an individual's capacity to earn money and is therefore skewed against the elderly, homeless, and unemployed. The second method is the willingness-to-pay method. In this method, the patient is asked how much money he or she would be willing to spend to reduce the likelihood of a particular illness. This method tends to have a wide range of answers and is often not realistic.

Intangible costs are very difficult to measure. They are related to nonfinancial outcomes and are hard to express monetarily. Included here are things such as inconvenience, pain and suffering, and grief. These costs are included in the willingness-to-pay calculation, but not the human capital calculation.

Table 12–2 Commonly Used Pharmacoeconomic Research Methodologies

Method	Outcome	Examples
Cost-minimization	Outcome must be clinically identical in similar patient population All social costs should be considered	Adalat CC vs. Procardia XL Generic azathioprine vs. brand-name azathioprine
Cost-effectiveness	Different clinical outcome Justify the incremental cost increase for the therapeutic benefit from extra costs associated with treatment	Antilymphocyte induction vs. no induction
Cost-benefit	Expressing clinical outcome purely in monetary units Assigns a dollar value to specific disease state Unethical and should be avoided	10 mm Hg reduction in blood pressure worth $100

Cost-of-Illness Analysis

Cost of illness identifies the costs of a specific disease in a given population. It is a good baseline number when looking at different treatment or prevention strategies. The total for the cost-of-illness evaluation includes the cost for the medical resources used to treat the specified illness, the cost of nonmedical resources, and the loss of productivity by the patient. Intangible costs, such as pain and suffering, are difficult to quantify and thus are not included in this calculation. For many disease states, including diabetes and certain cancers, the cost-of-illness number has already been calculated. According to the American Diabetes Association (2013), the cost of diabetes in the United States was estimated at $245 billion in 2012, up from $174 billion in 2007, a 41% increase in 5 years. (*Note*: This is strictly an estimate of economic burden and does not distinguish among treatment options.)

Cost-Minimization Analysis

Cost-minimization analysis is very straightforward. It looks at two or more treatment alternatives that are considered equal in efficacy and compares the cost of each alternative in dollars. It assumes that evidence supporting the efficacy of each alternative already exists and strictly looks at which would be the least costly to administer. An example of this is a comparison between two or more generic medications in the same therapeutic class for treatment of the same condition. (*Note*: The costs are not just related to acquisition of the product, but include costs for any preparation, administration, or monitoring needed.) A comparison of heparin and its counterpart, the low-molecular-weight enoxaprin, is a good example. Heparin is inexpensive, but patients receiving it have associated laboratory costs, technician time, and pharmacist dosage adjustments that must be figured into the cost. Although enoxaprin is more expensive to acquire, the lack of need for laboratory monitoring may help to bring the overall cost of enoxaprin down to be about equal to that of heparin. Therefore, cost-minimization analysis applied to pharmaceuticals reveals that generics are not necessarily always the least costly alternative.

Cost-Effectiveness Analysis

Unlike cost-minimization analysis, cost-effectiveness analysis compares two or more treatments or programs that are not necessarily therapeutically equivalent. This type of analysis compares various treatment costs with a specific therapeutic outcome. The outcome is usually a nondollar unit, such as a mm Hg drop in blood pressure or number of cases cured. One of the following three conditions must be met for a treatment to be considered cost-effective: the alternative treatment may be less expensive and at least as effective as its comparator; it may be more expensive but provide an additional benefit worth the cost; or it may be less expensive and less effective in a situation in which the extra benefit is not worth the extra cost.

This method aims to find and promote the most efficient therapy for the given problem and find the best health care for each dollar spent. An example of this type of analysis is a comparison of two different regimens for treating hypertension. Regimen A might consist of three medications and decrease systolic blood pressure by an average of 35 points. Regimen B, consisting of two medications that cost significantly less per month than regimen A, lowers systolic blood pressure by 20 points. To determine which is more cost-effective, the analysis team must decide if the extra drop in blood pressure is worth the added cost of regimen A.

For example, one cost-effectiveness model for long-acting risperidone examined the cost of the longer-acting formula versus increased compliance with a simpler dosing schedule, factoring in the economic implications of poorly managed schizophrenia (Haycox, 2005). Another example is a comparison of the costs of colchicine and NSAIDS for the treatment of gout, where the monthly cost of colchicine is much higher than NSAIDS (Wertheimer, Davis, & Lauterio, 2011). When the total cost of treatment, including treating gastrointestinal complications in a patient taking NSAIDS, is calculated, colchicine is more cost-effective (Wertheimer et al, 2011).

Cost-Benefit Analysis

In cost-benefit analysis (CBA), the costs of a specific treatment or intervention are calculated and then compared with the dollar value of the benefit received. One way to think about this analysis is whether or not a given benefit will exceed the cost needed to implement it. Many CBAs will look at two separate interventions or programs and determine which produces a greater benefit for the money. The two benefits may or may not be similar. The results of a CBA can be described in two different formats. The first is a ratio and the second is the dollar difference between the two. If a specific treatment is valued at $5,000 and the benefit is determined to be $50,000, one could determine that the cost-benefit ratio was 10:1 (benefit divided by cost) or the benefit of this specific treatment is $45,000 (benefit minus cost). The net benefit (or cost) is more commonly used than a ratio, because a 10:1 ratio could imply numbers with vastly different benefits (i.e., $1,000,000 to $100,000 versus $40 to $4).

One of the challenges of this type of analysis is that the benefits are often perceived; thus, it is difficult to quantify them. A common use of CBA is for budgeting purposes. A pharmacy can determine whether an existing anticoagulation program is worth keeping or whether that money would be better spent on a new hypertension clinic or diabetes education program.

Cost-Utility Analysis

In cost-utility analysis, the costs of the treatment choice are in dollars and the outcomes are expressed in terms of patient preference or quality-adjusted life years (QALY). A full year at full health is considered 1 QALY, whereas various diseases and their treatments produce a lower number (0.01–0.99).

These QALY values are quite subjective, and agreement on a scale to measure utility is lacking. The best use for this analysis is when quality of life is the most important factor to be considered; the analysis is commonly used in situations in which the treatment option can be life-extending but have significant side effects. Cancer treatment options are often reviewed with CBA. A chemotherapy treatment regimen, for example, may bring about a 6-month extension of life expectancy, but if the patient is too nauseated to get out of bed or eat, it may not be worth the extra 6 months.

IMPACT OF GENERIC DRUGS ON DRUG THERAPY

Drug pricing in today's health-care system is complex. The goal is to reduce drug acquisition costs to the lowest possible amount without affecting quality of care. Most pharmacies can control acquisition costs by purchasing generic drugs. However, in some situations, brand-name drugs are less expensive than generic-drug products owing to internal bidding, group purchasing, and negotiations with vendors. The cost of generic drugs and single-source, brand-name drugs to pharmacies and patients differs and is driven by market-force competition for the limited pool of dollars.

Although most drugs are sold for 15% to 20% less than the average wholesale price (AWP) and prices vary widely, AWP is routinely used for comparing different agents. A common method for determining reimbursement and controlling health-care system costs used by the Federal Health Care Financing Administration (HCFA) and private payers is the maximum allowable cost (MAC). Although drug pricing is complex, most pharmacy benefits groups are still businesses that seek profits. According to the MAC list prices, most pharmacy benefits groups select a drug with the lowest acquisition cost regardless of generic or brand-name status to reduce the cost of drug therapy. In most cases, pharmacy benefits groups pass this cost savings on to the patients by means of substantially lower co-payments for generic drugs.

Many benefit plans have a two- or three-tiered benefit, in which the patient pays a greater co-payment for brand-name drugs than for generic equivalent prescriptions. Most pharmacy benefits groups have maximum annual benefits for brand-name drugs ranging from $1,500 to $2,000 per year. The generic-drug benefit is unlimited and the purchase of generic drugs will not count against the $2,000 annual ceiling. For many generic drugs, the AWP is at least 50% that of the brand-name drug. Therefore, in general, co-payments are usually 50% of the wholesale price for single-source brand-name drugs. Patients may also take advantage of the numerous prescription programs offered by many large retail pharmacies where they can get a month's supply of a generic drug for $4 and not have to be concerned about their prescription coverage.

Generic medications are available to treat the most common diseases seen in primary care, including diabetes, hypertension, asthma, and common infections; therefore, patients benefit from the prescription of generic equivalents (IMS Health, 2012). Lipitor, the number-one-selling drug in 2011, with sales of $7,668,425,000, went off patent in November 2011, which has provided savings to consumers (Bartholow, 2012). The availability of less costly generic-drug products for expensive agents would ease financial burdens for most patients, enabling them to comply with their treatments. Increased compliance may decrease health-care utilization in these patients, allowing greater access to health care for other patients. In addition, most patients can easily be stabilized on a generic-drug product with a narrow therapeutic index as well as on an innovator brand.

Generic Substitution

As health-care system costs continue to escalate, accountability in health-care spending and patient outcomes as a measure of effectiveness of health-care delivery has become crucial. Decreasing the total cost of drug therapy while improving outcomes has become a challenging responsibility for health-care providers. Today, generic substitution for brand-name drugs is a common practice in most health-care organizations in order to decrease the total cost of pharmacotherapy. In 2011, 80% of all prescriptions in the United States were filled with generic drugs, yet generic drugs accounted for only 27% of dollars spent on prescriptions (IMS Institute for Healthcare Informatics, 2012).

The practice of generic-drug substitution has been an emotional issue for health-care providers, payers, and patients. Health-care providers are under pressure from both innovator companies and payers. Innovator companies that have supported the field of medicine over the past two decades through educational grants and clinical drug studies apply subtle pressure on health-care providers to continue to prescribe brand-name drugs only. The critical issue in using generic drugs involves justifying conversion from a brand-name drug to a generic agent in stable patients or using the drug de novo in terms of safety, efficacy, and economics. To help address this issue, the generic bioequivalence standards and different methods of studying pharmacoeconomics should be considered.

Generic Bioequivalence

The U.S. Food and Drug Administration (FDA) regulates the manufacturing of generic drugs by setting rigorous standards for bioequivalence and is responsible for protecting patients and assuring prescribers that generic-drug products truly are "equivalent" to those of the innovator pharmaceutical companies. To gain FDA approval (FDA, 2013), a generic drug must:

- Contain the same active ingredients as the innovator drug. Active ingredients make the drug effective against the disease or condition it is treating.
- Come in the same dosage form. If the brand name is a capsule, the generic should be a capsule too.
- Be administered in the same way. If the brand name is taken orally, the generic should be taken orally too.

- Be identical in strength.
- Have the same conditions of use.
- Be bioequivalent (an equal rate and extent of drug absorbed in the bloodstream).
- Meet the same standards for identity, strength, purity, and quality.
- Be manufactured under the same standards that the FDA requires for the manufacture of innovator products.

The FDA monitors complaints regarding generics. In the case of Budeprion XL 300 mg, a generic form of Wellbutrin XL, the FDA even conducted studies to determine Budeprion XL 300 was not bioequivalent to Wellbutrin XL 300 (FDA, 2013). These strict standards for generic medications ensure the availability of safe generic equivalents for the public.

Pharmaceutical Equivalents

Drug products are considered pharmaceutical equivalents when both agents contain identical amounts of active ingredients in the same salt or ester form, dosage form, and route of administration and possess identical disintegration times and dissolution rates.

Therapeutic Equivalents

Drug products are considered therapeutically equivalent when the generic drugs are pharmaceutical equivalents and show the same efficacy and safety profile as that product whose efficacy and safety has been established.

Bioequivalence

Bioequivalence is defined as pharmaceutical equivalents that display the same rate and extent of absorption. Biological equivalence means delivering the same amount of active drug moiety to the site of action when generic and innovator drugs are administered at the same molar dose under similar conditions. Only therapeutically equivalent drug products of those already FDA-approved are safe and should be considered for generic substitution in most patients.

APPLYING PHARMACOECONOMICS TO PRACTICE

Generic-drug versus brand-name drug prescribing is discussed in this section, using clinical examples of and rationales for generic substitution. An explanation of Medicare Part D will demonstrate why prescribers need to be familiar with their patients' prescription drug coverage, as it may affect compliance.

Prescribing Generic Versus Brand-Name Medications

Generic drugs that are considered therapeutic equivalents may be exchanged for brand-name drugs with confidence. Pharmacists may substitute a generic equivalent for a brand name unless the prescriber specifies "Dispense as Written"

on the prescription. Shrank and colleagues (2011) studied 5.6 million prescriptions written for 2 million patients and found there was a greater chance that the prescription was not filled if "Dispense as Written" was on the prescription or requested by the patient. It is critical to discuss pharmacy benefit coverage with the patient before prescribing a drug as "Dispense as Written."

Many retail stores offer prescription programs in which a select list of generic drugs are offered for $4 for a 30-day supply and $10 for a 90-day supply. This may be a substantial savings for patients, especially those without prescription drug coverage or with a high co-payment for their medications. For example, generic metformin 500 mg tablets are $4 for a 30-day supply, whereas the retail price for the brand-name Glucophage is $70 for the same 30-day supply. The caveat is that the patient must live near or have transportation to one of the retail pharmacies that have retail drug programs, such as Walmart, Target, Kroger, and Sam's Club stores.

Medicare Part D

In 2004, Congress added a prescription drug benefit to the Medicare program called Medicare Part D. Part D was enacted to assist seniors with the high cost of their medications, but the implementation has been confusing for many. When initially passed, Part D covered 75% of drug costs once the patient paid a deductible of $250 per year. Prescriptions that cost between $250 and $2,250 require the patient to pay 25% of the price of the medication. Once the patient's medication costs reach $2,250, the patient pays 100% of the costs of the medication until the total reaches $5,100. The coverage gap between $2,250 and $5,100 has been referred to as the "donut hole" point of coverage. After the patient reaches $5,100 in drug costs, Part D provides 95% coverage for drug costs for the remainder of the calendar year. The Affordable Care Act gradually narrows the gap and decreases the amount paid by Medicare recipients in the "donut hole." In 2013, the gap is $2,970 to $4,750, and Medicare enrollees get a 52.5% discount on brand-name drugs and 70% on generic-drug costs during the gap in the coverage period (Medicare.gov, 2013). Drug costs in the gap will be gradually reduced from 100% to 25% by 2020.

Part D has increased the use of essential drugs such as statins, warfarin, and clopidogrel among elders who did not have drug coverage before the prescription benefit plan was implemented (Schneeweiss et al, 2009). Schneeweiss and colleagues noted a 5% decline in the proportion of patients filling their clopidogrel prescription when patient drug costs reached the coverage gap. Similarly, a 4.8% decline in warfarin and a 6.3% decline in statin prescription refills were noted (Schneeweiss et al, 2009). Duru and colleagues (2010) examined cost-related noncompliance among diabetics covered by Part D and found noncompliance among beneficiaries using insulin increased when their benefits during the gap did not have generic-drug coverage. Providers must work with patients to determine if less expensive but equally effective prescriptions can be used to prevent patients with limited

means from reaching the point of having to pay the full amount for their prescriptions, because paying the full amount may decrease compliance, increasing the overall cost of care due to poor outcomes.

CONCLUSION

Pharmacoeconomics is the study of the appropriate application of drug utilization for the treatment of a specific disease. Pharmacoeconomic studies characterize the improved outcomes while justifying additional drug expenditures. Because the value and economics of many approved drugs are unknown at the time, the true impact of new drug substitution on the cost and care of most patients with complicated conditions is also unknown. In theory, if a therapeutically equivalent and less expensive product is available, it should be substituted; this may substantially affect the cost of drug therapy and overall health-care costs. Applying pharmacoeconomics to prescribing practice involves understanding the impact of drug costs on patients and making an educated prescribing decision to ensure the best outcome.

OVER-THE-COUNTER MEDICATIONS

Teri Moser Woo

Patients are now taking a more active and informed role in their own health care. Thousands of self-help books, articles, Web sites, television commercials, and social media demonstrate the rapidly growing trend in self-care. Surveys consistently show that consumers are increasingly self-medicating with nonprescription drugs.

OVER-THE-COUNTER MEDICATIONS

An over-the-counter (OTC) drug has the following characteristics: (1) it must be safe (the benefit must outweigh the risks), (2) it has low potential for misuse or abuse, (3) it can be labeled, (4) the patient must be able to self-diagnose the condition for which the drug is being taken, and (5) it must be for a condition that the patient can manage without supervision by a licensed health professional (U.S. Food and Drug Administration Center for Drug Evaluation and Research [FDA CDER], 2012). The FDA CDER is responsible for ensuring that OTC drugs are properly labeled and that their benefits outweigh their risks. New OTC drug ingredients must undergo the New Drug Application process, just as prescription drugs do (FDA CDER, 2012). There are more than 80 therapeutic categories of OTC drugs and over 100,000 OTC drug products (FDA CDER, 2012).

In addition, there has been a dramatic increase in the number of prescription medications that have moved to OTC status, for a variety of reasons. Cohen, Paquette, and Cairns (2005) propose three motives for this: "pharmaceutical firms' desire to extend the viability of brand names, attempts by healthcare funders to contain costs, and the self-care movement" (p 39). A blockbuster drug such as the proton pump inhibitor Prilosec or the antihistamine Zyrtec can continue to reap large profits by moving to OTC status. Insurers often drop drugs from coverage when they become OTC and so have pushed for drugs to become OTC, as in the case of WellPoint's petitioning the FDA to designate three antihistamines (loratadine, cetirizine, and fexofenadine) as OTC (Cohen et al, 2005; Sullivan, Nair, & Patel, 2005). Clearly, when drugs are close to reaching the end of their patent, pharmaceutical firms and insurers are motivated to move the drug to OTC status.

Because patients are likely to treat many symptoms and conditions first with nonprescription drugs, the practitioner should assume that some therapy has been started when patients present for care and therefore should ask about OTC medication use. Patients are more likely to self-treat themselves or their children when they feel their illnesses are not serious enough to require medical care. Table 13-1 presents conditions for which OTC drugs are marketed.

Table 13–1 Conditions for Which OTC Drugs Are Marketed

Most frequently treated conditions	Acne, athlete's foot, cold sores, colds, cough, cuts, dandruff, headache, heartburn, indigestion, insomnia, premenstrual, sinusitis, sprains
Other conditions	Abrasions, aches and pains, allergic rhinitis, anemia, arthralgia, asthma, bacterial infection (superficial), boils, burns, candidal vaginitis, canker sores, chapped skin, congestion, conjunctivitis, constipation, contact lens care, contraception, corns, dental care, dermatitis (contact), diaper rash, diarrhea, dysmenorrhea, dyspepsia, feminine hygiene, fever, gastritis, gingivitis, hair loss, halitosis, head lice, impetigo, insect bites, jet lag, motion sickness, nausea, obesity, otitis (external), periodontal disease, pharyngitis, pinworms, prickly heat, psoriasis, ringworm, seborrhea, smoking cessation, sty, sunburn, swimmer's ear, teething, toothache, vomiting, warts, xerostomia

OTC = over-the-counter.

Nonprescription drug therapy should not be undervalued or underestimated in the current health-care environment. OTC medications are powerful drugs that should be considered just like prescription drugs with respect to their pharmacology, toxicology, contraindications, precautions, adverse effects, and drug interactions. Because many former prescription drugs have recently been converted to nonprescription (OTC) status, the same care and thought needed to monitor prescription drug use are necessary for nonprescription drugs.

This chapter discusses in general terms OTC drugs that patients commonly use and OTC drug adverse effects. For more specific information on these drugs, see the appropriate chapters in this book.

OTC MEDICATION SALES

Sales of OTC medications reported by the Consumer Healthcare Products Association were $33.1 billion in 2013 (Consumer Healthcare Products Association [CHPA], 2014a). CHPA data can be used to determine the common physical complaints patients self-treat with OTC medications. Over $4 billion was spent on cough and cold medications in 2008, representing the highest sales category (CHPA, 2014b.) Internal analgesics represented $3.99 billion in 2013 sales, indicating acute and chronic pain were common self-treated conditions. Self-treatment of heartburn led to $2.28 billion in sales of heartburn remedies in 2013, doubling in 5 years as multiple proton pump inhibitors became OTC. Other conditions commonly treated by OTC medications include constipation ($1.3 billion), acne ($617 million), and diarrhea ($225 million). Nicotine replacement products used for tobacco cessation represented $855 million in sales in 2013 (CHPA). The CHPA proposes that every dollar spent on OTC medications by consumers saves the U.S. health-care system $6 to $7, based on cost savings in clinical visits and drugs (CHPA, 2012).

SELF-PRESCRIBING OTC MEDICATIONS

Self-prescribing or self-medication is defined by the World Self Medication Industry as "the treatment of common health problems with medicines especially designed and labeled for use without medical supervision and approved as safe and effective for such use" (World Self-Medication Industry, n.d.). In order to safely self-medicate, the patient will need to accurately self-diagnose the condition and then take the appropriate medication, at the appropriate dose, for the correct duration, without creating interactions with other medication. Caregivers of children or those who are cognitively impaired need to accurately diagnose the ailment in the child or impaired person before choosing an OTC remedy. There is room for misdiagnosis and error in the process of self-medication.

Multiple studies have been conducted to investigate the process of self-medication with OTC medications. Pineles and Parente (2012) used the theory of planned behavior to explore belief about medications and the individual pain experience to predict intent to self-medicate with OTC analgesics. The authors discovered that patients tend to self-medicate when the patient values pain relief over harm and that 49% of the study participants reported taking more than the recommended dose of OTC analgesics (Pineles & Parente, 2012). In a telephone survey study of OTC topical corticosteroid use ($N = 2,000$), 83% of respondents were using the product consistent with labeling instructions (Ellis et al, 2005). Use of topical corticosteroids was usually short-term (less than 7 days) in both adults (92% used for ≤ 7 days) and in children (94%), and applied appropriately 4 times a day or less (adults 98%; children 97%) (Ellis et al, 2005). Pharmacists may be available for consultation, but even so, patients may not follow the direction of the expert pharmacist as to when to appropriately seek medical care rather than self-treat (Mehuys et al, 2009).

The FDA mandated a redesign of OTC drug labeling to ensure uniformity of labeling, consistent presentation of information, and use of lay language (FDA, 2014a). McDonald and others (2007) studied the use of the new FDA label by 137 adults and found that 61.2% were likely to read the medication label before taking an OTC analgesic. But despite being provided a pamphlet and the label regarding the use of the OTC analgesic, 25.4% were likely to give ibuprofen to a family member who takes an antihypertensive, 21.2% said they were likely to take another dose before the recommended time, and 27.7% were not likely to read the label before taking the medication (McDonald et al, 2007). Even if the consumer reads the label, its readability level is well above the average reading ability in the United States. Trivedi, Trivedi, and Hannan (2014) examined the labels of 40 OTC products (NSAIDS, antacids, laxatives, antihistamines, H2 blockers, proton pump inhibitors, sleep aids, and cough and cold medications) to determine the reading level. The authors found that the average Flesch–Kincaid reading ease score was 38 (±12), the average Flesch–Kincaid grade level score was 16 (±5), and the average Gunning–Fog grade level score was 17 (±5)—all were above the eighth-grade

reading level of the average U.S. adult (Trivedi et al, 2014). There is clearly a need to revisit the OTC medication label to ensure the safe use of OTC medications.

HAZARDS OF OTC SELF-MEDICATION

Over-the-counter medications may be harmful if misused or may cause harmful interactions with prescription drugs. Acetaminophen has well-documented toxic effects on the liver if higher-than-recommended doses are taken. Patients may take higher doses due to the severity of symptoms or if they do not feel they are getting better with the recommended dose (Pineles & Parente, 2012). Patients may accidentally overdose on acetaminophen due to unknowingly taking two OTC medications that both contain acetaminophen or by taking OTC acetaminophen with prescription drugs that contain acetaminophen, such as Vicodin or Percocet. The FDA has been addressing acetaminophen toxicity by lowering the recommended daily dosage on OTC labels to 3 g per day and recommending providers only prescribe prescription acetaminophen combination drugs 325 mg per tablet or less (FDA, 2014b).

A concern with decongestant medications is their use in young children, specifically children under age 5. The safety and efficacy of these medications have been questioned after a number of reports of deaths of infants taking cold medications (U.S. Centers for Disease Control and Prevention, 2007). In October 2007, an FDA panel recommended that all pediatric cough and cold medications be relabeled as not indicated for use in children under age 4. In October 2007, manufacturers voluntarily removed all infant drop formulas of cough and cold medications from the market. In spite of the labeling change and withdrawal of infant formulations, one-third (33%) of parents surveyed by Hanoch, Gummermum, Miron-Shatz, & Himmelstein (2010) were not aware of the FDA recommendations, with 32.9% planning on continuing to administer OTC cough and cold medication to their young child. Use of decongestants in children is discussed in Chapters 17 and 50.

ADVERSE EFFECTS OF OTC SELF-MEDICATION

Self-medication with OTC products may lead to adverse effects, drug interactions, and potentially to abuse. Adverse effects and drug interactions are often listed on the label of the OTC medication, but as noted previously patients may not read or comprehend the label information.

Adverse Effects

All medications, whether prescription or OTC, have predictable and unpredictable adverse effects. When a prescriber is choosing a medication, this understanding of adverse effects is integral to the decision making and patient education regarding the medication. Likewise, when pharmacists fill a prescription, they will often discuss significant adverse effects with the patient. These safeguards are lost when a patient self-medicates with an OTC product.

Adverse effects of OTC medications may be mild, such as gastrointestinal upset, or severe, as in the case of gastrointestinal bleeding associated with NSAID or aspirin use. Exceeding treatment duration or taking the wrong dose increases the likelihood of adverse reactions (Schmeidl et al, 2014). The elderly are the most likely to be hospitalized due to adverse effects associated with OTC medication use (Villany, Fok, & Wong, 2011; Schmeidl et al, 2014).

Patients need to be educated regarding the adverse effects of OTC medications. Education includes reading the label carefully and asking questions of a pharmacist or the provider. Patients should be advised that some OTC medications may impair driving; most state laws do not differentiate between alcohol or prescription or OTC drugs in regard to impaired driving (American Automobile Association, 2011). Table 13-2 discusses OTC medications that may impair driving.

Table 13–2 Over-the-Counter Medications That May Impair Driving or Operating Machinery

Medication	OTC Products
Antihistamines: diphenhydramine, chlorpheniramine, brompheniramine, dexbropheniramine, clemastine, cyproheptadine, doxylamine, pyrilamine (maleate)	Allergy medications Cold medications Sleep aids Menstrual cramp medications Motion sickness medications
Antimotility agents (loperamide)	Antidiarrheals
Antitussives (dextromethorphan)	Cough and cold medications
H2 antagonists (ranitidine, famotidine, nazatidine)	H2 antagonist/heartburn medications
NSAIDS (naproxen, ibuprofen)	NSAID analgesics
Alcohol	Cough and cold medications Expectorants Multivitamins with or without iron (liquid) Antihistamines (liquid forms) Motion sickness medications (liquid)

Drug Interactions

When patients receive a prescription from a provider or fill a prescription in the pharmacy, a review of current medications occurs and potential drug interactions are identified. When a patient self-medicates with an OTC medication, often no professional knowledgeable about drug interactions is involved. Patients may not be aware that OTC medications may interact with prescription or other OTC medications or alcohol.

Antacids

Antacids consist of a metallic cation and basic ion (calcium carbonate, magnesium hydroxide, etc.), which neutralize acidity in the stomach by raising the pH. The basic property of these drugs causes them to interact with most medications, by either binding with the drug molecule or altering pH and thus the absorption of drugs that need an acidic environment for optimal absorption. Most interactions can be avoided by separating the dosing of antacids by at least 2 hours from the dosing of the other oral medications. Intraluminal interactions occur in the stomach when an antacid chelates another drug or adsorbs another drug onto its surface.

The best-known antacid interaction is with tetracycline. Aluminum hydroxide and magnesium hydroxide have a strong affinity for tetracycline and form an insoluble and inactive chelate. This interaction can reduce the bioavailability of tetracycline by 90% and result in clinical failures. This chelation occurs with all other forms of tetracycline, including doxycycline and minocycline. Patients should not take any antacid until at least 2 hours after tetracycline administration. A similar interaction exists with the quinolone antibiotics, such as ciprofloxacin and ofloxacin. Antacids are discussed in Chapter 20.

Anticholinergics

The primary adverse effects of diphenhydramine and dox - ylamine are anticholinergic, such as dry mouth, constipation, blurred vision, and tinnitus. Older male patients may have difficulty in urinating. These effects may be additive with the anticholinergic effects of other drugs that are being taken. Older patients may develop delirium from modest doses of diphenhydramine.

Central Nervous System Depressants

Patients may be aware that their prescription medication may cause sedation, but they may not be aware of the additive central nervous system (CNS) sedating effects of OTC medication taken with their prescribed medication. Over-the-counter medications that contain alcohol, antihistamines, antitussives, or antidiarrheals may all cause additive sedation when taken with CNS-sedating medications.

NSAIDS and Aspirin

The cyclooxygenase inhibitors, including aspirin and the NSAIDS ibuprofen and naproxen, have a well-documented risk of gastrointestinal bleeding. When combined with antiplatelet or anticoagulant medications, the risk is significantly increased and may be life-threatening. Patients who are taking antiplatelet or anticoagulant medications should be educated to not take any OTC medication without consulting with a pharmacist or their provider.

ABUSE OF OTC MEDICATIONS

Over-the-counter medications have the potential for abuse. Many liquid products, such as cough and cold medications, expectorants, and liquid multivitamins or iron, contain alcohol. Common products like Geritol liquid vitamins contain 12% alcohol. Cough and cold medications may contain up to 25% alcohol. Dextromethorphan is abused for its ability to produce hallucinations and a dissociative state, with the peak age for abuse at 15 to 19 years (Drug Enforcement Administration, 2014; Wilson, Ferguson, Mazer, & Litovitz, 2011). Abuse of combination cough and cold medications that contain dextromethorphan may lead to toxic levels of multiple substances, including acetaminophen and anticholinergics.

Concern over the use of OTC decongestant medications to manufacture methamphetamine has led to changes in how the drugs are sold in the United States. The Combat Methamphetamine Epidemic Act, which is part of the 2006 U.S. Patriot Act, restricts the sales of all cough and cold products (including combination products) that contain the methamphetamine precursor chemicals ephedrine, pseudoephedrine, or phenylpropanolamine. The law specifically includes a daily and 30-day limit on retail store and Internet purchases of known methamphetamine precursors. All potential precursors are to be stored behind the counter in retail stores and retailers are required to ask for identification and keep a log of who is purchasing the drugs. Some states have additional restrictions; for example, Oregon and Mississippi have listed pseudoephedrine as a Schedule III drug under state law. Multiple states are enacting similar legislation to control the sales of pseudoephedrine (Office for State, Tribal, Local and Territorial Support Centers for Disease Control and Prevention, 2013). Internationally, countries including Mexico, Australia, New Zealand, and the United Kingdom are limiting unrestricted OTC sales of pseudoephedrine.

PATIENT EDUCATION REGARDING OTC MEDICATIONS

Given the concerns over OTC self-medication, providers are required to educate their patients about safe OTC use. Reading the label and following the label instructions are critical, but if patients do not understand the label, they should ask for assistance from a pharmacist or the provider. In a study of OTC medication consultation by pharmacy students in a community pharmacy, McConaha, Finole, Heasley, and Lunney (2012) found that only 37.6% of consumer participants initiated a consultation with the pharmacist, and that consultation resulted in significant cost savings by switching to a generic product and nonsignificant but clinically relevant prevention of OTC medication-related adverse outcomes. Educating patients that even though a medication is available over-the-counter, it still

has the same concerns for adverse effect, drug interactions, and toxicity as prescription medication may increase safety when self-medicating (see Box 13-1).

SUMMARY

The provider must keep in mind that the prescription drug history, although very important, is usually not the only part of a patient's drug use. A careful history of both OTC medications and herbals is needed to avoid overlooking important aspects, such as adverse drug effects and drug interactions caused by these drugs and herbal products in tandem with any prescription drugs. Many people diagnose their own symptoms, select a nonprescription drug product, and monitor their own therapeutic response. This process is not often reliably reported when, during a routine health history, a patient is asked, "Do you take any medications?" Specific questions need to be asked.

Properly used, OTC medications are useful in self-care to relieve minor complaints and transient conditions. If used improperly or in combination with other medications, OTC medications can cause a multitude of problems, adverse drug events, and drug interactions.

BOX 13–1   PATIENT EDUCATION REGARDING OTC MEDICATIONS

- Read the label of the medication to determine dose, duration of treatment, adverse effects, and drug interactions.
- If you do not understand the label information, ask a pharmacist or your health-care provider to clarify.
- Inform your provider and the pharmacist of any OTC medications you are taking, even medications you only take occasionally.
- Do not drive or operate machinery if you take sedating OTC medications. You may be charged with driving under the influence.
- Inform your provider if you have any adverse effects from the OTC medication.

PHARMACOTHERAPEUTICS WITH SINGLE DRUGS

DRUGS AFFECTING THE AUTONOMIC NERVOUS SYSTEM

Tracy Scott

The resting activity of most organs is maintained by opposing influences from the parasympathetic nervous system (PNS) and its neurotransmitter, acetylcholine (ACh), and the sympathetic nervous system (SNS) and its neurotransmitters, epinephrine, norepinephrine, and dopamine. Changes in resting activity can occur by increasing the activity of either the PNS or the SNS or by decreasing the activity of the opposing system (Fig. 14-1).

It is important to evaluate the risk for adverse drug effects when using these or any drugs. The drug may have a therapeutic effect on the target organ and an adverse effect on ancillary organs. An example of this may be damage to the renal system or liver as medications are cleared from the body.

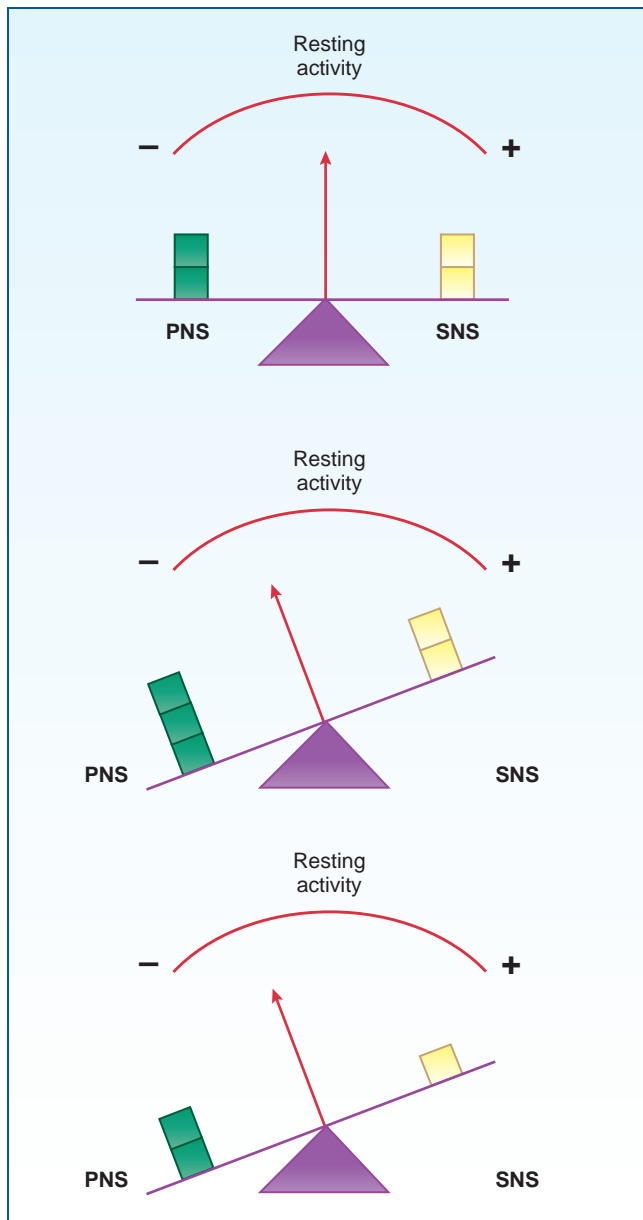
Drugs that affect the autonomic nervous system are used for a wide variety of diseases and in settings from intensive care to primary care. This chapter will focus on the drugs used in primary care to treat conditions typically managed by advanced practice nurses. Intravenous forms of the drugs are generally not used in primary care and are not discussed. Drugs such as peripherally acting alpha$_1$ agonists are used mainly as decongestants, and beta agonists are used mainly for their bronchodilating effects. These drugs are discussed in Chapter 17.


Figure 14–1. Resting activity and the autonomic nervous system.

ADRENERGIC AGONISTS

Through direct receptor binding to organs or tissues, promotion of norepinephrine release, or mimicking the action of norepinephrine or epinephrine, adrenergic agonists target the SNS by direct receptor binding to organs or tissues, promotion of norepinephrine release, or mimicking the action of norepinephrine or epinephrine. Four main receptor types are involved in this process: $alpha_1$, $alpha_2$, $beta_1$, and $beta_2$. $Alpha_1$ receptors are mostly associated with excitation or stimulation and are found mainly in the eye, salivary glands, arterioles, postcapillary venules, and gastrointestinal (GI) and genitourinary (GU) sphincters. $Alpha_2$ receptors are mostly associated with relaxation or with inhibition of norepinephrine release, and the majority are located in the presynaptic nerve terminals of smooth muscles, the islet

cells of the pancreas, salivary glands, skin, and mucosa. $Beta_1$ receptors, found mostly in the heart, brain, kidney, and lipocytes, are associated with stimulation of adenylyl cyclase via G_5-G-protein–coupled receptors to increase cAMP production. $Beta_2$ receptors are located in the smooth muscle of the eye, arterioles, venules, bronchioles, liver, pancreas, and GI and GU systems. They stimulate adenylyl cyclase, increase cAMP, and activate cardiac G_1 under certain conditions. Norepinephrine stimulates the alpha and $beta_1$ receptors, and epinephrine stimulates all four types of receptors (McCance & Huether, 2014). Centrally acting $alpha_2$ agonists are the relevant agonist drugs, and they are discussed here (Table 14-1).

ALPHA$_2$ AGONISTS: CENTRAL

Pharmacodynamics

Activation of central $alpha_2$ receptors results in inhibition of cardioacceleration and vasoconstriction centers in the brain. This action causes a decrease in peripheral outflow of norepinephrine, leading to decreases in peripheral resistance, renal vascular resistance, heart rate, and blood pressure. Because they lower blood pressure by reducing sympathetic function, they can produce compensatory effects on blood pressure, resulting in retention of sodium and expansion of blood volume through mechanisms that are not dependent on adrenergic nerves. For this reason, they may be given in combination with a diuretic. Centrally activating $alpha_2$ agonists are used largely as second-line or third-line drugs in the treatment of mild to moderate hypertension. Clonidine has several off-label uses, including treatment of withdrawal symptoms from opioid or alcohol based on its ability to lower the adrenergic stimulation that is associated with this withdrawal (WHO, 2009). It is also important to note that according to the BEERS criteria, drugs in this classification may be inappropriate for use in geriatric patients (AGS, 2012). The drugs in this class, commonly used to treat hypertension, are clonidine (Catapres), guanabenz (Wytensin), guanfacine (Tenex, Intuniv), and methyldopa.

Clonidine and other drugs in the class activate alpha$_2$ receptors in the medulla of the brain, reducing sympathetic tone and increasing parasympathetic tone, due to down regulation of $alpha_2$ receptors after chronic use. This results in a decrease in peripheral resistance, reduced heart rate, reduced blood pressure, and reduced renal vascular resistance. These medications should not be stopped abruptly because the relative "lack" of $alpha_2$ receptors impair the homeostatic balance that regulates SNS action. The prescriber should gradually taper the dose when discontinuing the medication over 4 days. Some of the common adverse reactions related to oral and transdermal doses of these medications include: bradycardia, AV block, palpitations, tachycardia, hallucinations, sleep disorders, contact dermatitis, dry mouth, orthostatic hypotension, constipation, nausea, urinary retention, decreased sexual activity, weight gain, leg cramps, and thrombocytopenia, with dry mouth being the most common adverse reaction (Food and Drug Administration [FDA], 2012).

Table 14–1 Actions of Autonomic Nervous System Based on Receptor

Organ or Tissue	Receptor	Adrenergic Effect	Receptor	Cholinergic Effect
Eye (radial muscle)	$Alpha_1$	Contraction (mydriasis)	M_3	None
Eye (ciliary muscle)	$Beta_2$	Relaxation for far vision	M_3	Contraction for near vision
Eye (sphincter muscle)	—	None	—	Contraction (miosis)
Lacrimal glands	—	None	—	Secretion
Nasopharyngeal glands	—	None	—	Secretion
Salivary glands	$Alpha_1$	Secretion of potassium and water	—	Secretion of potassium and water
Heart (SA node)	$Beta_1$	Increases heart rate	M_2	Decreases heart rate; vagus arrest
Heart (atria)	$Beta_1$	Increases contractility and conduction velocity	M_2	Decreases contractility; shortens action potential duration
Heart (AV junction)	$Beta_1$	Increases automaticity and propagation velocity	—	Decreases automaticity and propagation velocity
Heart (ventricles)	$Beta_1$	Increases contractility	—	None
Arterioles (coronary)	$Alpha_1$ $Beta_2$	Constriction Dilation	— —	Dilation
Arterioles (skin and mucosa)	$Alpha_1$ and $alpha_2$	Constriction	—	
Arterioles (skeletal muscle)	$Alpha_1$ $Beta_2$	Constriction Dilation	M_3 —	Dilation
Arterioles (cerebral)	$Alpha_1$	Constriction (slight)	—	None
Arterioles (pulmonary)	$Alpha_1$ $Beta_2$	Constriction Dilation	— —	None
Arterioles (renal)	$Alpha_1$ $Beta_1$ and $beta_2$	Constriction Dilation	— —	None
Veins (systemic)	$Alpha_1$ $Beta_2$	Constriction Dilation	— —	None
Platelets	$Alpha_2$	Aggregation	—	None
Lungs (bronchial muscle)	$Beta_2$	Relaxation	M_3	Contraction
Lungs (bronchial glands)	$Alpha_1$ $Beta_2$	Decreases secretion Increases secretion	— —	Stimulation
GI (motility)	$Alpha_1$ and $beta_2$	Decrease	M_1	Increase
GI (sphincters)	$Alpha_1$	Contraction	M_3	Relaxation
GI (secretion)	—	M_3	Stimulation and increased secretion	
Liver	$Alpha_1$, $alpha_2$, and $beta_2$	Glycogenolysis and gluconeogenesis	—	Glycogen synthesis
Pancreas (islet cells)	$Alpha_2$ $Beta_2$	Decreases secretion Increases secretion	— —	None
Adrenal medulla	—		N and M_3	Secretion of epinephrine and norepinephrine (nicotinic effect)

Continued

Table 14–1 Actions of Autonomic Nervous System Based on Receptor—cont'd

Organ or Tissue	Receptor	Adrenergic Effect	Receptor	Cholinergic Effect
Kidney	Alpha$_1$ Beta$_1$	Decreases renin secretion Increases renin secretion	— —	None
Ureter (motility and tone)	Alpha$_1$	Increases	—	Decreases
Urinary bladder (detrusor)	Beta$_2$	Relaxation	—	Contraction
Urinary bladder (detrusor)	Beta3	Relaxation	-	
Urinary bladder (trigone and sphincter)	Alpha$_1$	Contraction	M$_3$	Relaxes
Uterus	Beta$_2$	Promotes smooth muscle relaxation	—	None
Male sex organs	Alpha$_1$	Ejaculation	M	Erection
Fat cells	Alpha$_2$ Beta$_1$	Inhibition of lipolysis Stimulation of lipolysis	— —	
Endothelium	—		M$_3$	Releases EDRF

   M = muscarinic receptors.

Guanabenz and guanfacine are also used to treat hypertension. Extended release guanfacine with a trade name of Intuniv is approved for use in the treatment of ADHD as both an adjunct therapy or monotherapy. Guanfacine also reduces sympathetic outflow by activating alpha $_2$ receptors in the brain but does not directly stimulate peripheral receptors, so blood pressure is reduced in both the supine and standing positions without alterations in normal postural mechanisms. The most common adverse reaction in monotherapy trials were somnolence, fatigue, nausea, lethargy, and hypotension. In the monotherapy trials, 12% of patients experienced adverse reactions, which resulted in their being discontinued from the trial. These adverse reactions were sedation, fatigue, hypotension, headache, and dizziness. In trials of adjunctive therapy, the most common reactions were somnolence, fatigue, insomnia, dizziness, and abdominal pain. In the trials of adjunctive therapy, only 3% of patients experienced adverse reactions leading to discontinuation from the trials (FDA, 2013a).

Methyldopa is an analogue of L-dopa. Because the pathways for its metabolism directly parallel the synthesis of norepinephrine (NE), its metabolite alpha-methyl-norepinephrine is stored in adrenergic nerve vesicles where it replaces NE. Stimulation of central alpha$_2$ receptors by this active metabolite produces a decrease in sympathetic outflow to the heart, kidneys, and blood vessels. In addition to the adverse effects associated with other drugs in the classification, rare cases of hemolytic anemia have been reported after taking methyldopa. A positive Coombs test has occurred in between 10% and 20% of patients taking methyldopa within 6 to 12 months of the initiation of therapy (FDA, 2004). The end result from the use of methyldopa is a decrease in blood pressure, peripheral resistance, and heart rate with a slight decrease in cardiac output. It also produces a reduction in renal vascular resistance.

Pharmacokinetics

Absorption and Distribution

Absorption following oral administration varies among the drugs in this classification. Clonidine is easily absorbed from the GI tract and the skin and is lipid-soluble, allowing it to rapidly enter the brain from the circulation. Guanabenz and guanfacine are also well absorbed. All of the drugs are widely distributed in body tissues. Both clonidine and methyldopa cross the placenta and are found in breast milk (FDA, 2004, 2012c). Methyldopa is not completely absorbed in the gut and is absorbed via an aromatic amino acid transport system (Skerjanec, Campbell, & Robertson, 1995).

Metabolism and Excretion

The liver, in varying degrees, metabolizes each of these drugs. Guanfacine has a significant first-pass effect. The drug is metabolized by CYP3A4 with about 50% of the oral dose metabolized to inactive sulfate metabolites and 50% eliminated unchanged in the urine. Methyldopa is also extensively metabolized by the liver to inactive metabolites, with only approximately 20% of the active drug appearing in the plasma. The kidney is the organ of excretion for each of these drugs. Patients with renal failure will experience increased adverse effects as methyldopa and its metabolites accumulate, resulting in prolonged hypotensive action. Approximately 50% of the clonidine dose is hepatically metabolized to inactive metabolites, and the remaining 50% is excreted unchanged in the urine (FDA, 2004, 2012,

2012c, 2013a). Table 14-2 shows the pharmacokinetics of these drugs.

Pharmacotherapeutics

Precautions and Contraindications

Cautious use is recommended in the presence of severe coronary insufficiency, recent myocardial infarction (MI), and renal function impairment. Because they cross the blood–brain barrier, methyldopa and clonidine are used cautiously in the presence of cerebrovascular disease. Clonidine should be used with caution with patients who are at risk for mental depression, and it should be discontinued if depression occurs. Clonidine should be avoided in patients at risk or with a history of bradycardia. Because they affect cognitive function, centrally acting alpha$_2$ agonists should be avoided or used with extreme caution in populations such as older adults for whom this adverse response creates a significant problem (FDA, 2004, 2012, 2012c).

Both guanabenz and clonidine are Pregnancy Category C. No adequate human studies have been done on guanabenz, and skeletal anomalies were found in the offspring of mice that were given the drug. Clonidine crosses the placenta and no well-controlled studies have been done in pregnant women. Both guanfacine and methyldopa are listed as Pregnancy Category B in oral form, but methyldopa is listed as Pregnancy Category C in an injectable form (FDA, 2004, 2012, 2012c).

Methyldopa appears in breast milk and should be used with caution in nursing women. Long-term follow-up of 195 participants and children born to women treated with methyldopa while pregnant did not find any significant effect on the children (FDA, 2004). All of the other drugs discussed in this category are not recommended for nursing mothers. Methyldopa and clonidine are available in pediatric doses. Methyldopa can be safely used in children, and sources vary regarding the safe use of clonidine in this age group (FDA, 2004, 2012).

Adverse Drug Reactions

The major adverse reactions related to this category of drugs is the effect they have on organs other than the targeted organ. These reactions include drowsiness, dry mouth, constipation, urinary retention, and impotence. Nightmares and insomnia have been associated with clonidine. Cardiac symptoms include hypotension, chest pain, and bradycardia. GI symptoms are more commonly associated with guanabenz and additionally include abdominal pain, vomiting, anorexia, and altered taste. Gynecomastia has also been associated with guanabenz and clonidine. All drugs in this class have also been associated with life-threatening rebound hypertension mediated by increased SNS activity after sudden withdrawal of these drugs. Clonidine and methyldopa have especially been noted to have this adverse reaction, which is exacerbated if the patient is also taking beta-adrenergic blockers (Table 14-3). All patients given these drugs should be warned about this possibility. If the drug must be withdrawn, it should be done gradually. All of the drugs in this class may result in pruritic rashes. The transdermal form of clonidine has also been associated with a rash that is an allergic reaction to the adhesive on the patch (FDA, 2004, 2012, 2012c).

Table 14–2 ⬛ **Pharmacokinetics: Selected Centrally Acting Alpha$_2$ Agonists**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Clonidine	Oral: 30–60 min	Oral: 3–5 h	Oral: 8 h	20%–40%		12–16 h: up to 41 h in impaired renal function	40%–60% unchanged in urine; 50% metabolized in liver
	Transdermal: 2–3 days	Transdermal: unknown	Transdermal: 7 days (8 h of effect after patch is removed)				
Guanabenz	60 min (onset of anti-HTN action)	2–5 h	12 h	90%		6 h: prolonged in renal impairment	<1% unchanged in urine
Guanfacine	1 h	1–4 h	24 h	70%	80%	*Adults:* 17 h; *Younger adults:* 13–14 h; *Older adults* 17–18 h	50% unchanged in urine; 70% in urine unchanged or as metabolites
Methyldopa	2–3 h	2–6 h	12–24 h	>20%	50%	1.8 h: blood pressure reduction is pronounced and prolonged in renal failure	Extensively metabolized in liver; 70% in urine as metabolites

Table 14–3 ⚏ Drug Interactions: Centrally Acting Alpha₂ Agonists

Drug	Interacting Drug	Possible Effect	Implications
Clonidine	Alcohol, antihistamines, phenothiazines, barbiturates, benzodiazepines	Additive sedation	Avoid concurrent use
	Beta-adrenergic blockers	Attenuation or reversal of antihypertensive effect of clonidine; may result in life-threatening hypertension (HTN)	Avoid concurrent use; if patient is taking both drugs and withdrawal is required, withdraw beta-adrenergic blocker first to prevent excessive unopposed alpha stimulation that may lead to malignant HTN within 12 h
	Nitrates, other antihypertensives	Additive hypotensive effects	Avoid concurrent use
	Prazosin	Decreased antihypertensive effect of clonidine	Choose alternative drug
	TCAs	Block antihypertensive effects of clonidine and may result in life-threatening HTN	Choose alternative antidepressant
	Verapamil	Synergistic pharmacological and toxic effects; may result in atrioventricular block and severe hypotension	Choose alternative calcium channel blocker or antihypertensive
Guanabenz, guanfacine	Alcohol, antihistamines, phenothiazines, barbiturates, benzodiazepines	Additive sedative effects	Avoid concurrent use or choose alternative antihypertensive
	Alcohol, nitrates, other antihypertensives	Additive hypotension	Avoid concurrent use or monitor blood pressure closely
Methyldopa	Alcohol, antihistamines	Additive sedation	Avoid concurrent use
	Beta-adrenergic blockers	May result in life-threatening HTN	Less likely with beta₁ selective agents; see clonidine above for implications
	Haloperidol	Potentiate antipsychotic effects or may produce psychosis	Choose different antipsychotic
	Levodopa	Potentiate antihypertensive effects of methyldopa and central effects of levodopa in Parkinson's disease	Avoid concurrent use; choose alternative antihypertensive
	Lithium	Increased risk for lithium toxicity	Choose alternative antihypertensive
	Monoamine oxidase inhibitors (MAOIs)	Metabolites of methyldopa stimulate release of endogenous catecholamines that are usually metabolized by MAOIs; result is excessive SNS stimulation	Avoid concurrent use
	Nitrates, other antihypertensives	Additive hypotension	Avoid concurrent use
	Phenothiazines, sympathomimetics, barbiturates, amphetamines	May result in serious HTN	Avoid concurrent use
	Tolbutamide	Tolbutamide metabolism may be impaired, resulting in enhanced hypoglycemic effects	Choose alternative hypoglycemic
	TCAs	Attenuation or reversal of antihypertensive effect of methyldopa	Avoid concurrent use; choose alternative drugs for depression or HTN
	Herbals: licorice; yohimbe, ginseng	May affect electrolyte levels. May decrease efficacy of methyldopa	Monitor blood pressure and inform patient

Source: FDA, 2004, 2012, 2012c.

Methyldopa has been associated with the development of a positive Coombs' test. Rarely, this is associated with hemolytic anemia (Wendell & Stanley, 2013). Perform a baseline Coombs' test, hemoglobin and hematocrit levels, and repeat them at 6 and 12 months after initiation of therapy (FDA, 2004).

Drug Interactions

All centrally acting alpha$_2$ agonists have additive sedative effects with central nervous system (CNS) depressants and additive hypotensive effects with other drugs that also reduce blood pressure (see Table 14-3). Tricyclic antidepressant (TCA) agents decrease the antihypertensive effects of all centrally acting alpha$_2$ agonists. Several other drugs used to treat psychoses interact with centrally acting alpha$_2$ agonists, resulting in toxicity, psychoses, or excessive SNS stimulation. Careful selection of the drugs to treat each condition is required.

Beta-adrenergic blockers interact with clonidine and methyldopa to produce potentially life-threatening hypertension if either clonidine or methyldopa is abruptly discontinued. They should not normally be used concurrently, but there are occasions, such as when beta-adrenergic blockers are used for MI prophylaxis, when use of both drugs is necessary. If withdrawal of one or both of these drugs is required because of adverse effects, the beta-adrenergic blocker is always withdrawn first to prevent excessive unopposed stimulation of alpha$_2$ receptors that can result in a hypertensive crisis in as little as 12 hours (FDA, 2004, 2012, 2012c).

Clinical Use and Dosing

Hypertension

Centrally acting alpha$_2$ agonists are used to treat mild to moderate hypertension and are second-line drugs usually chosen when other drugs are not effective in achieving blood pressure control. The exception is methyldopa, which is first-line therapy for pregnant patients. These drugs are not well suited for monotherapy because they produce troublesome adverse reactions in almost all patients who take them. Methyldopa and clonidine can be used effectively when combined with a diuretic to address the problems with sodium and water retention. Clonidine is now available in a combination tablet with chlorthalidone, a thiazide diuretic (Clorpres) (FDA, 2004, 2012, 2012c, 2013a).

Doses vary with each drug, but adverse reactions occur at higher doses and with older adults. Beginning with the lowest dose recommended for each drug, the dose is increased at weekly intervals until blood pressure control or the maximum dose is reached. To minimize the sedation, which is more common with clonidine and methyldopa, the dose may be divided, with a higher dose in the evening than in the morning. Smaller doses are required in renal impairment. Use of the low end of the dose range of guanfacine produces the least problems for patients with renal insufficiency (FDA, 2004, 2012, 2012c, 2013a).

Chapter 40 provides detailed discussion of the management of hypertension.

Unlabeled Uses of Clonidine

Clonidine has been evaluated for many off-label uses. It lowers the adrenergic stimulation associated with alcohol,

heroin, and nicotine withdrawal and lessens the unpleasant symptoms of withdrawal. Attention deficit-hyperactivity disorder is associated with decreased stimulation of certain centers in the brain, and the stimulation of central alpha$_2$ receptors by clonidine has resulted in improved concentration and reduced behavioral symptoms in some children (Yoon, Cohn, Rocchini, Kershaw, & Clark, 2012).

Rational Drug Selection

Age

Only clonidine and methyldopa have pediatric doses and are approved for use with children. Clonidine works better in adults but should be used with caution in elderly patients. Dosage reductions may be required for methyldopa and clonidine when prescribed for older adults because of the risk for fluid retention and orthostatic hypotension (FDA, 2004, 2012).

Pregnancy

Traditionally, methyldopa was the drug of choice for pregnant women due to the longevity of experience by providers. Now other medications are also selected. Drugs used for the treatment of hypertension, including during pregnancy, are discussed in Chapter 40 and discussed in depth in the ACOG practice Bulletin No. 125 (ACOG, 2012).

Route of Administration

Patients who have difficulty taking pills, who have trouble remembering more frequent doses, or who for other reasons would have better adherence to the treatment regimen with a transdermal system can be given clonidine, the only antihypertensive currently available in a transdermal formulation (Table 14-4). Because the transdermal form of the medication results in lower serum levels (lack of a peak associated with oral administration), this dosage form may minimize many of the drug's bothersome adverse effects.

Monitoring

Clinical monitoring of blood pressure is appropriate for all drugs in this class as with any other antihypertensive drug. Baseline blood pressure should be taken before initiating therapy and with each change in dosage. Weight and other indicators of fluid status should also be monitored. (See Chapter 40 for further discussion of blood pressure monitoring.)

For patients who have or are at risk for renal impairment, dosage alterations are required. Assess serum creatinine prior to initiation of therapy and regularly thereafter for up to 1 year. Liver function studies should also be conducted prior to therapy and at 6 and 12 months. Methyldopa has been associated with hepatotoxicity (FDA, 2004, 2012, 2012c, 2013a).

Patient Education

Administration

The drug should be taken exactly as prescribed, at the same time each day, even if the patient is feeling well. Missed doses are taken as soon as they are remembered unless it is almost time for the next dose. Doses are not doubled These drugs must be withdrawn slowly over 2 to 3 days to prevent rebound hypertension, and missed doses increase the risk for

Table 14–4 ⊗ Schedule: Centrally Acting Alpha$_2$ Agonists

Drug	Indication	Form	Initial Dose	Maintenance Dose
Clonidine	Hypertension	**Tablets:** 0.1 mg (Catapres is scored) 0.2 mg (Catapres is scored) 0.3 mg (Catapres is scored) **Transdermal:** 0.1 mg patch 0.2 mg patch 0.3 mg patch **Transdermal:** Catapres-TTS 1: 0.1 mg/24 hr Catapres-TTS 2: 0.2 mg/24 hr Catapres-TTS 3: 0.3 mg/24 hr **Tablets:** (scored) Clonidine 0.1 mg Chlorthalidone 15 mg Clonidine 0.2 mg Chlorthalidone 15 mg Clonidine 0.3 mg Chlorthalidone 15 mg	*Adults:* 0.1 mg bid PO (older adults may need lower dose)	*Adults:* Increase in increments of 0.1 mg PO in weekly intervals; maintenance dose 0.1–0.3 mg bid; max dose: 1.2 mg bid
			Transdermal: Catapres-TTS 1 (0.1 mg)	After 1–2 wk, if desired blood pressure (BP) is not achieved, increase in increments of 0.1 mg/wk (Catapres-TTS comes in 2 [0.2 mg] and 3 [0.3 mg] patches)
			Children (12 yr and older): 0.1 mg bid	*Children:* Increase in 0.1 mg increments at weekly intervals; maintenance dose 0.1–0.3 mg bid; max dose: 2.4 mg/d
Clonidine HCl and Chlorthalidone (Clorpres) (B)	Hypertension		0.1 mg clonidine plus 15 mg chlorthalidone once or twice daily	Max dose 0.6 mg clonidine plus 30 mg chlorthalidone
Guanabenz	Hypertension	Tablets: 4 mg 8 mg (scored)	4 mg bid	Increase in increments of 4–8 mg/d every 1–2 wk until target BP achieved; max dose 32 mg bid
Guanfacine	Hypertension	**Guanfacine (G) (Tenex) (B)** **Tablets:** 1 mg 2 mg **(Intuiv)** **Tablets (extended-release):** 1 mg 2 mg 3 mg 4 mg	1 mg daily at bedtime	May increase to 2 mg qd after 3–4 wk if target BP not achieved; 2 mg dose may be given as 1 mg bid; max dose 3 mg qd
Methyldopa	Hypertension	Methyldopa **Tablets:** 250 mg 500 mg Methyldopa/ hydrochlorothiazide **Tablets:** 250 mg methyldopa/ 25 mg hydrochlorothiazide	*Adults:* 250 mg bid or tid for first 48 h	Increase in increments of 250 mg every 2 d until target BP is achieved: to minimize sedation, increase dose in evening; smaller doses should be used in renal impairment; maintenance dose 500–2,000 mg/d in 2–4 divided doses
			Children: 10 mg/kg/d in 2–4 divided doses	*Children:* max dose is 65 mg/kg or 3,000 mg, whichever is less

Source: FDA, 2004, 2012, 2012c, 2013a.

the occurrence of rebound hypertension. To prevent missing doses, patients should make certain they have enough medication available for weekends, holidays, and vacations (FDA, 2004, 2012, 2012c, 2013a).

Methyldopa has known interactions with several herbals; therefore, prescribers should ask patients about herbal use and be aware that drug interactions may occur. Drug–herbal interactions are listed in Table 14-3.

Instruct patients who are on the transdermal clonidine system in proper application of the patch. Apply the patch to a hairless area of intact skin on the upper arm or torso once every 7 days. Use a different site from the previous application. They should not cut or trim the patch. If the patch loosens, apply tape to secure it (FDA, 2011).

Adverse Reactions

Hypotension is the most common adverse reaction. Changing positions slowly, not exercising in hot weather, avoiding alcohol, and drinking an adequate amount of noncaffeinated fluid per day will decrease these reactions. For patients with heart failure, fluid intake should be discussed with the healthcare provider.

Drowsiness and dry mouth are also common. Patients should avoid activities requiring mental alertness until their individual response to the drug is known. Dry mouth can be minimized by practicing good oral hygiene, chewing sugarless gum, or sucking on hard candy (FDA, 2004, 2012, 2012c, 2013a). Concurrent use of alcohol or other CNS depressants should also be avoided. Centrally acting alpha $_2$ agonists can produce additive sedation with these drugs.

Fluid retention is indicated by weight gain and swelling in the feet and ankles. Patients should report any weight gain of more than 2 lb (1 kg) in 1 day to the health-care provider. Fluid retention may be treated by the addition of a diuretic to the treatment regimen and consideration of salt intake (FDA, 2004, 2012, 2012c, 2013a).

Methyldopa has some unique adverse reactions. Jaundice may indicate hepatotoxicity and should be reported to the health-care provider. Decreased energy levels may indicate anemia. In the absence of another explanation for decreased energy, this symptom should also be reported to the health-care provider (FDA, 2004, 2012, 2012c, 2013a).

Lifestyle Management

Drugs control hypertension, but they do not cure it. Encourage patients to adhere to other interventions for management of hypertension, such as weight loss, aerobic exercise, a low-sodium diet, smoking cessation, and stress management (see Chapter 40).

ADRENERGIC ANTAGONISTS

Adrenergic antagonists act directly by blockading adrenergic receptors or indirectly by decreasing norepinephrine release within SNS terminals. Most of the clinically useful actions of these drugs result from the blockade of alpha $_1$ receptors in blood vessels, beta $_1$ receptors in the heart, and alpha $_1$ receptors in the bladder neck and prostate gland. Adrenergic

antagonists are categorized on the basis of receptors that are blocked and include drugs that block only one receptor and those that block more than one receptor. The following section discusses antagonist drugs whose major effect is on alpha $_1$ and beta receptors outside the CNS (peripherally acting).

ALPHA$_1$ ANTAGONISTS

Alpha 1 antagonists include nonselective and selective types. Following are their differences and the drugs in each category.

Nonselective Alpha Antagonists

Nonselective alpha antagonists include phentolamine (Regitine) and phenoxybenzamine (Dibenzyline). These drugs have approximately equal affinities for both the postsynaptic alpha $_1$ receptors and the presynaptic alpha $_2$ receptors. Phenoxybenzamine blocks the receptors irreversibly, whereas the blockade by phentolamine is reversible. These drugs will result in lowered blood pressure as a result of the blockade of the postsynaptic alpha $_1$ receptors. In addition, blockade of the presynaptic alpha $_2$ receptors results in reflex cardiac stimulation because the negative feedback inhibition of neurotransmitter release is being blocked (FDA, 2009a). For this reason, these drugs are not used in the treatment of hypertension. They do have a role in the treatment of pheochromocytoma, in which they are used to prophylax against hypertensive crisis as a result of the release of norepinephrine from the tumor (Young, Kaplan, & Kebebew, 2013). Additionally, given by the intradermal route, they have a role in the treatment of extravasation of vasopressor drugs. Because these drugs are used almost exclusively by specialists, they are not discussed further here.

Selective Alpha$_1$ Antagonists

The alpha $_1$ antagonists reversibly block the effects of catecholamines at the postsynaptic alpha $_1$ receptors in vascular smooth muscle and in the smooth muscle of the bladder neck and prostate. These drugs are useful in lowering blood pressure as well as relieving outflow obstruction secondary to benign prostatic hypertrophy (BPH). Six drugs in this class are used clinically: doxazosin (Cardura), prazosin (Minipress), terazosin (Hytrin), tamsulosin (Flomax), alfuzosin (Uroxatral), and silodosin (Rapaflo). It should be noted that prazosin is not typically used to treat BPH due to the frequent dosing requirements and risk of cardiovascular side effects (McVary, Roehrborn, & Avins, 2011).Tamsulosin, alfuzosin, and silodosin have increased selectivity for the alpha $_1$ receptors in the prostate, and as a result these drugs have little effect on blood pressure while relieving symptoms associated with BPH (FDA, 2009c, 2010b, 2011a, 2012a).

Pharmacodynamics

Reversible alpha $_1$ antagonists block postsynaptic alpha $_1$ receptors in the vasculature, resulting in a decrease in both arterial and venous vasoconstriction. Because arteriole and venous tone are determined largely by the stimulation of

alpha$_1$ receptors in vascular smooth muscle, the result is a decrease in peripheral vascular resistance and lowered blood pressure. Both supine and standing blood pressures are lowered, with the most pronounced effect on diastolic blood pressure. Orthostatic hypotension may result from their action on receptors in venous smooth muscle. Reflex tachycardia may result from compensatory mechanisms but is minimal. Since the remaining alpha$_1$ antagonists are more specific for the receptors found in the prostate, they do not cause reflex tachycardia. Prazosin and terazosin rarely produce reflex tachycardia. Chronic use of alpha$_1$ antagonists may result in compensatory increases in blood volume but at a fairly low rate of incidence. Studies of the newer selective blockers do not mention edema. Tamsulosin, silodosin, and alfuzosin have not been approved for treatment of hypertension (FDA, 2010b, 2011a, 2012a).

It should be noted that the ALLHAT (2002) trial compared doxazosin to chlorthalidone and found an increased risk of heart failure with doxazosin, so an alpha blocker is not recommended for initial monotherapy in hypertension.

The reduction in symptoms and improved urine flow rates in patients with BPH is related to relaxation of smooth muscle produced by the blockade of the alpha$_1$ receptors, which are densely located in the bladder neck and prostate gland. Blockade of these receptors decreases urethral resistance and may relieve the obstruction and improve urine flow and BPH symptoms. Because there are few alpha$_1$ receptors in the body of the bladder, these drugs are able to reduce bladder outflow obstruction without affecting bladder contractility.

Three subtypes of the alpha$_1$ receptors have been pharmacologically identified and cloned: alpha$_{1a}$, $_{1b}$, and $_{1d}$. Approximately 70% of the alpha$_1$ receptors in the prostate are subtype 1a and are also localized to the prostatic stroma (McCance & Huether, 2015). Presumably, if the efficacy of the selective alpha$_1$ blockers is mediated by the relaxation of the prostate smooth muscle, then the development of a selective alpha$_{1a}$ receptor antagonist would be advantageous. This would also result in fewer adverse drug reactions, which are theoretically mediated by the alpha$_{1b}$ and $_{1d}$ receptor subtypes. However, there is evidence that the selective alpha$_{1a}$ receptor antagonists relieve the lower urinary tract symptoms (LUTS) by a mechanism that is unrelated to prostate smooth-muscle relaxation. Therefore, an alpha$_1$ antagonist that does not demonstrate

selectivity for subtypes may still be useful in the treatment of BPH. This premise is borne out when looking at the available alpha$_1$ antagonists with indications for BPH. Large numbers of alpha$_1$ receptors are found in the base of the bladder and the prostate. The three subtypes of alpha$_1$ receptors identified as 1a, 1b, and 1d are selective for doxazosin, terazosin, and alfuzosin, and silodosin demonstrates a 583-fold selectivity for the alpha$_{1a}$ receptor subtype and 56-fold selectivity for the alpha$_{1d}$ receptor subtype (FDA, 2010b, 2011a, 2012a).

Pharmacokinetics

Absorption and Distribution

Five of the drugs in this class are well absorbed after oral administration (Table 14-5); silodosin is the exception. Tamsulosin is the most slowly absorbed. The absorption of alfuzosin was reduced by 50% when taken in a fasting state, so it should be administered with food. Taking tamulosin in a fasting state increases bioavailability by 30% and increases C_{max} by 40% to 70%. Since there is a risk for adverse effects when given in a fasting state, the dose should be administered 30 minutes following the same meal each day.

The bioavailability for silodosin is about 32% and the package insert recommends administering the drug with a meal. All drugs in this class are widely distributed in the body and all are highly protein bound. Doxazosin accumulates in breast milk with a concentration 20 times that in maternal plasma. Prazosin is found in small amounts in breast milk, and it is not known if terazosin is excreted in breast milk. No information about breast milk concentration is provided for tamsulosin, alfuzosin, or sildosin, which would not be given to female patients (FDA, 2009c, 2010b, 2011a, 2012a).

Metabolism and Excretion

Extensively metabolized by the liver, reversible alpha$_1$ antagonists are excreted in both feces and urine. Doxazosin has significant first-pass metabolism, and enterohepatic recycling of this drug causes plasma elimination to be biphasic. After morning dosing, the area under the curve (AUC) was 12% less than after evening dosing. The time to peak concentration after evening dosing occurred significantly later than after morning dosing. Doxazosin is primarily eliminated in the feces (FDA, 2009c).

Table 14–5   Selected Alpha$_1$-Adrenergic Antagonists

Drug	Onset	Peak	Duration	Protein Binding (%)	Bioavailability (%)	Half-Life	Elimination
Alfuzosin	Unknown	8 h	Unknown	82–90	49 (with food)	10 h	69% in feces; 24% in urine
Doxazosin	60–120 min	2–3 h	24 h	98	65	22 h	63% in bile/feces; 9% in urine
Prazosin	120–130 min	1–3 h	6–12 h	92–97	48–68	2–3 h	90% in bile/feces; 10% in urine
Silodosin	Unknown	2.6 h	Unknown	97	32	13.8 h	35.5% in urine; 55% in feces
Tamsulosin	Unknown	5 days	Unknown	94–99	>90	9–15 h	<10% unchanged in urine
Terazosin	15 min	1–2 h	12–24 h	90–94	90	9–12 h	60% in bile/feces; 40% in urine

Source: FDA, 2009c, 2010b, 2011a, 2012a.

Prazosin undergoes demethylation and conjugation in the liver, where a majority of the dose is eliminated via biliary excretion in the feces. Prazosin has four active metabolites that have approximately 10% to 15% of the activity of the parent drug and may contribute to the pharmacological effect of the drug. In the presence of renal failure, elimination half-life of this drug may be prolonged, protein binding decreased, and peak plasma levels increased (FDA, 2009b).

Terazosin has minimal hepatic first-pass metabolism to one active and three inactive metabolites. Nearly all of the circulating dose is in the form of the parent drug. Tamsulosin is extensively metabolized by CYP 450 enzymes; less than 10% of the dose is eliminated unchanged, but the specific isoenzymes have not been identified. The resulting metabolites undergo conjugation with glucuronide or sulfate and then are eliminated in the urine (FDA, 2011a).

Alfuzosin is extensively metabolized to inactive metabolites via CYP 3A4, and only about 11% of the administered drug is eliminated unchanged in the urine. The metabolites are eliminated primarily in the feces (FDA, 2010b).

Silodosin is metabolized by hepatic CYP 3A4, along with glucuronidation and alcohol and aldehyde dehydrogenase. Silodosin has an active metabolite that has a half-life of approximately 24 hours (FDA, 2012a).

Pharmacotherapeutics

Precautions and Contraindications

All the "azosin" drugs are contraindicated in the presence of volume depletion. Peripheral vasodilation caused by these drugs decreases venous return to the heart and may precipitate significant heart failure (HF). Several of the drugs are associated with fluid retention that may exacerbate HF (FDA, 2009b, 2010b, 2011a, 2012a).

The dosing for prazosin, doxazosin, terazosin, and tamsulosin does not need to be adjusted in renal or hepatic impairment. However, since each of these drugs is extensively metabolized by the liver and has significant potential for hypotensive events, it is prudent to start with the lowest dose and adjust based on clinical response. This approach is especially true for doxazosin because of the enterohepatic recycling discussed previously.

With creatinine clearance (CrCl) of less than 30 mL/min, limited safety data are available for alfuzosin; therefore, the drug should be used cautiously (FDA, 2009b, 2009c, 2010b, 2011a, 2012a). Alfuzosin should not be given to patients with mild to moderate hepatic impairment (Childs-Pugh classes B and C). Silodosin requires no adjustment of dose in patients with mild to moderate hepatic impairment but is not recommended in those patients with severe hepatic impairment (Childs-Pugh score equal to or greater than 10). For patients with CrCl greater than or equal to 50 mL/min, no dose adjustment is required for silodosin; for patients with CrCl 30 to 49 mL/min, the dose should be halved, and when the CrCl falls below 30 mL/min, the use of silodosin is not recommended (FDA, 2009b, 2010b, 2011a, 2012a).

Doxazosin, prazosin, and terazosin are Pregnancy Category C. Teratogenicity and reduced fertility have been demonstrated in animal studies. There are no adequate and well-controlled studies in pregnant women. Because of its high concentration in breast milk, doxazosin should not be given to nursing mothers. Prazosin has also been found in breast milk. Exercise caution when administering prazosin or terazosin to nursing mothers, and do so only when benefits clearly outweigh risks to the baby. Tamsulosin, alfuzosin, and silodosin are not prescribed to female patients. Safety and efficacy for use with children have not been established (FDA, 2009b, 2009c, 2010b, 2011a, 2012a).

Adverse Drug Reactions

Each of these drugs carries a risk for significant first-dose orthostatic hypotension that may result in syncope that tends to occur within 30 to 90 minutes of drug administration. This adverse reaction is decreased with continued doses but returns if therapy is interrupted for even a few doses, if the dosage is increased, or if another antihypertensive is added to the treatment regimen. The first dose should be given in the clinic or taken at bedtime. The "first-dose" reaction may be minimized by starting with a 1 mg dose and slowly increasing the dosage at 2-week intervals (Table 14-6). Terazosin exhibits this reaction most often, prazosin is average, and it occurs least with doxazosin (FDA, 2009b, 2009c, 2010b, 2011a, 2012a).

Fluid retention that results in peripheral edema occurs with several of these drugs. Close monitoring of weight changes may be needed, especially early in therapy. The addition of a diuretic to the therapy regimen may be required. Other adverse reactions are associated with alpha $_1$-adrenergic blockade (nasal congestion, blurred vision, dry mouth, constipation, impotence, and urinary frequency). Hypotensive symptoms of dizziness, headache, fatigue, tachycardia, and nausea are also potential adverse effects (FDA, 2009b, 2010b, 2011a, 2012a).

Drug Interactions

The major drug interactions result in decreased antihypertensive effects with the interacting drug or in additive hypotension, with increased risk for postural hypotension and falls. All six drugs have increased risk for postural hypotension when administered with acute alcohol ingestion, other antihypertensives, or nitrates. Doxazosin has the fewest published drug interactions and prazosin has the most. Cimetidine interacts with tamsulosin to decrease tamsulosin's effects. Alfuzosin is predominately metabolized by the CYP 3A4 isoenzyme systems, and other drugs also metabolized by this subsystem present a risk of interaction (FDA, 2009b, 2009c, 2010b, 2011a, 2012a). Table 14-7 depicts the common drug interactions.

Clinical Use and Dosing

Hypertension (HTN)

Alpha$_1$-adrenergic antagonists (except alfuzosin, tamsulosin, and silodosin, which are not approved to treat HTN) are the drugs of choice for treating HTN in older men with

Table 14–6 ⊗ **Dosage Schedule: Selected Alpha₁-Adrenergic Antagonists**

Drug	Indication	Form	Initial Dose	Maintenance Dose
Doxazosin	Hypertension	Tablets: 1 mg, 2 mg, 4 mg, 8 mg	1 mg daily at bedtime	2–16 mg daily. Depending on standing blood pressure (BP), increase dose in 2 mg increments until target BP is achieved. Doses >4 mg increase risk of postural hypotension.
	BPH		1 mg daily at bedtime Extended-release form is 4 mg taken once daily at breakfast	1–8 mg daily. Depending on the urodynamics and BPH symptoms, the dose is increased to 2 mg and then to 4 mg and 8 mg/daily. The recommended maximum dose is 8 mg. The titration interval is 1–2 wk.
Prazosin	Hypertension	Generic capsules: 1 mg, 2 mg, 5 mg Minipress capsules: 1 mg, 2 mg, 5 mg	Adults: 1–2 mg bid or tid; take first dose at bedtime	Adults: 6–15 mg/daily in 2–3 divided doses. Depending on standing BP, increase dose in 1 mg increments, with the larger dose being given at bedtime until target BP is achieved. Doses >20 mg/d usually do not increase efficacy.
Silodosin	BPH	Capsules: 4 mg, 8 mg	8 mg once daily with a meal	No data are published about increasing dosage. Depending on standing BP, the starting dose may be 4 mg with increases to 8 mg as tolerated.
Tamsulosin	BPH	Capsules: 0.4 mg	0.1 mg daily 30 min prior to the same meal	May be increased after 2–4 wk to 0.8 mg daily
Terazosin	Hypertension	Generic tablets: 1 mg, 2 mg, 5 mg, 10 mg	1 mg daily at bedtime	1–5 mg daily. Depending on standing BP, increase dose in 1 mg increments until target BP is achieved. Doses >20 mg/daily do not increase efficacy.
	BPH		1 mg daily at bedtime	Increased in a stepwise fashion to 2, 5, and then 10 mg. Doses at 10 mg are usually required for clinical effect. Dose may be 10–20 mg daily. Four to 6 wk are required to assess for beneficial response, so this is the interval for dosage adjustment.
Alfuzosin	BPH	Tablet: 10 mg extended-release	10 mg daily after the same meal	10 mg daily after the same meal

Source: FDA, 2009c, 2010b, 2012a.

concomitant BPH. Their actions simultaneously improve both conditions. Doxazosin and terazosin also lower low-density lipoprotein levels. They also enhance insulin sensitivity, cause regression of left ventricular hypertrophy, and improve the activity of the fibrinolytic system, making them useful for patients with diabetes and heart failure. Because they do not aggravate bronchospastic disease, they are useful for patients with asthma. Alpha₁-adrenergic antagonists are usually not used for monotherapy because they cause troublesome adverse reactions in almost all patients who take them. They can be used effectively in combination with other drugs that address these adverse reactions (FDA, 2009b, 2009c, 2010b, 2011a, 2012a).

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack (ALLHAT) trial was recently reevaluated in the face of information from new clinical trials, meta-analyses, and recent subgroup and explanatory analyses from ALLHAT. The reevaluation included special focus on studies related to the consequences of cardiovascular disease. Findings in the initial study and supported in the reevaluation show alpha₁-adrenergic antagonists are surpassed by thiazide-type diuretics as initial therapy for

reduction of cardiovascular and renal risk associated with hypertension (Wright et al, 2009). In the initial ALLHAT study, the drug used was doxazosin; this part of the study was discontinued early because so many subjects dropped out because of adverse effects and because the blood pressure lowering effect was the least. Given these data, it seems appropriate that this class of drugs be used mainly when a primary goal is treatment of BPH symptoms rather than hypertension.

To reduce "first-dose" postural hypotension, the dose is begun at 1 mg 1 to 2 times daily, depending on the drug (see Table 14-6). The dose is then gradually increased until target blood pressure is achieved or the maximum dose is reached. When the dose is increased, the first, larger dose is always given at bedtime to reduce orthostatic hypotension effects. Doxazosin has once-daily dosing. Postural hypotension effects are most commonly seen 2 to 6 hours after taking a dose. Measure the blood pressure at this time interval for the first dose and when increasing the dose to determine if the target blood pressure is being reached. Prazosin has a 2 to 3 times daily dosing schedule. Measure blood pressure 2 to 3 hours after dosing to see when maximum and minimum benefits

Table 14–7 ⠿ **Drug Interactions: Selected Alpha$_1$-Adrenergic Antagonists**

Drug	Interacting Drug	Possible Effect	Implications
Alfuzosin	Ketoanazole, itraconazole, ritoniver	Decrease metabolism and increase effects of alfuzosin	Avoid concurrent use
	Cimetidine, atenolol, dilitiazem	Increase level of alfuzosin and may increase effects of atenolol and dilitiazem	Monitor blood pressure and heart rate
	Antihypertensives, calcium channel blockers, nitrates, and alcohol	Increased hypotension risk	Monitor blood pressure or avoid concurrent use
Prazosin	Beta-adrenergic blockers	May enhance acute postural hypotension following first dose of alpha$_1$-adrenergic blocker	Select different alpha$_1$-adrenergic blocker. No adverse reaction seen with doxazosin or terazosin.
	Clonidine	May decrease antihypertensive effect of clonidine	Avoid concurrent use
	Indomethacin	Antihypertensive action of prazosin may be decreased	Select different alpha$_1$-adrenergic blocker or different NSAID. No adverse reaction with doxazosin or other NSAIDs.
Silodosin	Calcium channel blockers and thiazides	Increased incidence of dizziness and orthostatic hypotension	Exercise caution and monitor for adverse effects
	Azole antifungals, clarithromycin, and other strong CYP3A4 inhibitors	Ketoconazole increased C$_{max}$ and AUC	Concomitant use with strong CYP3A4 inhibitors contraindicated
	Diltiazem, erythromycin, verapamil, and other moderate CYP3A4 inhibitors	May increase plasma levels	Exercise caution and monitor for adverse effects
	Phosphodiesterase type 5 inhibitors (e.g., sildenafil, tadalafil)	Increased incidence of orthostatic hypotension	Exercise caution and monitor for adverse effects
Tamsulosin	Cimetidine	May increase blood levels of tamsulosin, with increased risk for hypotension and toxicity	Select different histamine$_2$ blocker if one must be used
Terazosin	NSAIDs, sympathomimetics, estrogens	May decrease antihypertensive effects of terazosin	Avoid concurrent use or select doxazosin or another drug class for antihypertensive therapy
	Verapamil	Increases serum terazosin levels and may increase sensitivity to terazosin-induced postural hypotension	Avoid concurrent use
	Finasteride	Increase in peak plasma concentration and AUC of finasteride	Clinical significance unknown; monitor for adverse effects of finasteride
Doxazosin, prazosin, tamsulosin, terazosin, alfuzosin	Alcohol, antihypertensives, nitrates	Additive hypotension	Avoid concurrent use or administer first dose in the office and monitor blood pressure response closely

Source: FDA, 2009c, 2010b, 2011a, 2012a.

in blood pressure lowering result. If the response is substantially diminished at 24 hours on twice-daily dosing, consider increasing the dose or using a 3 times-a-day regimen. Measure blood pressure 2 to 3 hours after dosing for terazosin as well. Although terazosin usually has once-daily dosing, if the response is diminished, consider twice-daily dosing. When a diuretic is added to the treatment regimen of any of these drugs, the dose of the alpha$_1$-adrenergic antagonist is reduced for 2 to 3 days and then re-titrated to control the blood pressure (FDA, 2009b, 2009c, 2010b, 2011a, 2012a).

Benign Prostatic Hyperplasia

Tamulosin, alfuzosin, and silodosin have all been approved for treatment of symptoms of benign prostatic hyperplasia. The recommended dose of tamulosin is 0.4 mg once daily administered approximately 30 minutes following the same meal each day. If the patient fails to respond to this dose after 2 to 4 weeks, the dose is increased to 0.8 mg once daily. Alfuzosin is recommended at 10 mg of the extended-release tablet daily to be taken immediately after the same meal each day. The silodosin starting dose is 8 mg given once daily with a meal (FDA, 2009b, 2009c, 2010b, 2011a, 2012a).

Ureteral Stones

Doxazosin, tamsulosin, and terazosin have off-label use as adjunct treatment to promote ureteral stone expulsion. These drugs do so by reducing ureteral pressure, peristaltic frequency, and ureteral contractions. American Urological Association and European Association of Urology guidelines for the management of ureteral calculi indicate that the administration of these drugs can effectively accelerate the spontaneous passage of these stones (FDA, 2009b, 2009c, 2010b, 2011a, 2012a).

Rational Drug Selection

Doxazosin is less likely than the other two drugs to produce postural hypotension and fluid retention and may be used as monotherapy (FDA, 2009b, 2009c, 2010b, 2011a, 2012a). The overall cost of the treatment regimen is reduced if an additional drug is unnecessary.

Convenient Dosing and Tolerability

Terazosin and doxazosin are both longer-acting $alpha_1$-receptor antagonists, but both need to be titrated to the target dose because of hypotension issues. Tamsulosin is also a longer-acting $alpha_1$-receptor antagonist, but it produces a response without dose titration. Tamsulosin's disadvantage is an increased incidence of ejaculatory dysfunction. Alfuzosin is marketed as a slow-release formulation and thus has relatively low adverse drug reactions. It also does not require dose titration and has the advantage of not causing ejaculatory dysfunction. Silodosin does not require dose titration but has an increased incidence of ejaculatory dysfunction when compared with tamsulosin (FDA, 2009b, 2009c, 2010b, 2011a, 2012a).

Both doxazosin and terazosin offer once-daily dosing (see Table 14-6) and doxazosin is now available in an extended-release formulation for treating BPH. Prazosin requires dosing 2 to 3 times daily. Doxazosin is scored to allow the tablet to be broken in half, allowing dosages to be easily increased without a change in tablet size.

Tachycardia

Although all drugs in this class may exhibit reflex tachycardia due to their antihypertensive effects, prazosin is an exception to this. The antihypertensive effect is not usually accompanied by reflex tachycardia. Prazosin can also be mixed with concomitant administration of a diuretic or beta-adrenergic agent (FDA, 2009b, 2010b, 2011a, 2012a).

Indications

Doxazosin, prazosin, and terazosin are all approved to treat hypertension. Treatment of BPH symptoms is approved by the FDA only for doxazosin, tamsulosin, alfuzosin, silodosin, and terazosin, although dosage data for this indication are published for prazosin (FDA, 2009b, 2010b, 2011a, 2012a).

Monitoring

Clinical monitoring of symptoms according to guidelines for HTN (see Chapter 40) and for BPH is the main monitoring parameter. Fluid retention is monitored by weekly weighing and patient education about signs and symptoms of fluid overload to report (e.g., peripheral edema, weight gain of more than 1 kg in a 24-hour period). Reduced white blood cell (WBC) counts of 1% to 2.4% have been noted, although no patients became symptomatic with these lower counts. A baseline WBC is drawn prior to initiation of therapy and as part of regular physical examinations. This class of drugs is heavily metabolized by the liver, so baseline liver function tests are also recommended (FDA, 2009b, 2010b, 2011a, 2012a).

Cancer of the prostate gland and BPH often coexist and have the same symptoms. Patients who are to begin on $alpha_1$-adrenergic antagonist therapy for BPH should first have digital rectal examinations and the provider should consider obtaining prostate-specific antigen (PSA) levels, if indicated, to rule out prostate cancer. Research has indicated that doxazosin and terazosin do not affect PSA levels in patients treated for less than 3 years (FDA, 2009b, 2009c, 2010b, 2011a, 2012a).

Patient Education

Administration

The drug should be taken exactly as prescribed, at the same time each day, even if the patient is feeling well. The first dose at initiation of therapy and the first dose each time the dosage is increased should be taken at bedtime to minimize the first-dose effect (potential hypotension and syncope). Missed doses are taken as soon as they are remembered unless it is almost time for the next dose. Doses are not doubled. Drugs in this class that may be taken without regard to food intake are doxazosin, prazosin, and terazosin. Alfuzosin should be taken with food or after food intake and tamsulosin should be taken 30 minutes after food intake. Silodosin should be administered with a meal (FDA, 2009b, 2010b, 2011a, 2012a).

NSAIDs decrease the antihypertensive effects of most drugs in this class. Over-the-counter (OTC) medications that contain NSAIDs should be avoided. Advise the patient to consult the health-care provider before taking any OTC drug, especially cough, cold, and allergy remedies (FDA, 2009b, 2010b, 2011a, 2012a).

If the drug is given for BPH, teach the patient the signs and symptoms of BPH to monitor (urinary frequency, a feeling of incomplete bladder emptying, interruption of urinary stream, decreased size and force of stream, terminal urinary

dribbling, and straining to start the flow of urine). Improvement in these symptoms may take 4 to 6 weeks (FDA, 2009b, 2010b, 2011a, 2012a).

Adverse Drug Reactions

Hypotensive reactions are the most common. In addition to taking the first dose at bedtime, teach patients to rise slowly from a supine position and to dangle their feet over the side of the bed before arising. Not exercising in hot weather and limiting alcohol intake can also decrease these reactions (FDA, 2009b, 2010b, 2011a, 2012a).

Nasal congestion and/or rhinitis may occur. It should not be treated with OTC antihistamines or other cold remedies without first consulting with the health-care provider. Drowsiness and dry mouth are also common. The patient should avoid activities requiring mental alertness until the patient's individual response to the drug is known. Drowsiness frequently subsides after 7 to 10 days of continuous therapy (FDA, 2009b, 2010b, 2011a, 2012a). Dry mouth can be minimized by practicing good oral hygiene, chewing sugarless gum, or sucking on hard candy.

The leading cause of nonadherence to a treatment regimen with $alpha_1$-adrenergic antagonists is inhibition of ejaculation and impotence. These reactions should be reported to the health-care provider, who may choose a different drug to treat the disorder or change the dosage.

Lifestyle Management

If the drug is being given for HTN, encourage the patient to adhere to additional interventions for reduction of blood pressure, such as weight loss, low-sodium diet, smoking cessation, regular exercise, and stress management. Further discussion of patient education related to HTN is found in Chapter 40. BPH is discussed in the "Men as Patients" chapter (Chapter 49).

BETA-ADRENERGIC ANTAGONISTS (BLOCKERS)

Beta-adrenergic antagonists (blockers) are used in the treatment of cardiac disorders such as heart failure and asymptomatic   left ventricular dysfunction and after an acute myocardial infarction. They are also useful in a variety of other   disorders, including essential tremor, migraine headache prophylaxis, and hyperthyroidism (Mann, 2013). They act by occupying beta-receptor sites and competitively preventing occupancy of these sites by catecholamines and other beta agonists. A major difference among these drugs is their selectivity for $beta_1$- and $beta_2$-receptor sites, and this difference has important clinical implications.

These drugs blockade beta-adrenergic receptors, and they are usually referred to in health-care literature as beta blockers. Because this term is easily recognized, *beta blocker* is used throughout this text to denote beta-adrenergic antagonists.

Pharmacodynamics

The highest concentration of B_1 adrenergic receptors are located in the heart, and when bound with noreinephrne and epinephrine they influence heart rate and myocardial contraction. The receptors are also found in the respirator system and eyes (McCance & Huether, 2014). Blockade of beta-adrenergic receptors produces clinically significant action on the cardiovascular, renal, and respiratory systems and on the eye. This blockade also results in metabolic and endocrine effects.

Cardiovascular Effects

For the most part, the heart receptors are mainly $beta_1$ receptors. Blockade of these receptors acts at the sinoatrial (SA) node to decrease heart rate (negative chronotropism), in the atria and ventricles to decrease contractility (negative inotropism) and conduction velocity (negative dromotropism), and at the atrioventricular (AV) junction to slow conduction (McCance & Huether, 2014). Taken together, these effects decrease the incidence of angina, decrease cardiac rhythm disturbances associated with rapid rhythms, decrease both supine and standing blood pressure, and reduce reflex orthostatic tachycardia. In patients whose severely damaged hearts require sympathetic stimulation for adequate ventricular function, beta blockade may worsen the condition.

In the vascular system, beta blockade opposes $beta_2$-mediated vasodilation and may initially result in a rise in peripheral vascular resistance, but chronic drug administration leads to a fall in peripheral resistance through a possible central effect that causes reduced sympathetic outflow to the periphery. Up regulation of $beta_1$ receptors occurs with chronic use. These effects are key to the use of these drugs in the treatment of hypertension.

Renal Effects

Blockade of the $beta_1$ receptors in the juxtaglomerular apparatus of the kidney reduces the release of renin. This effect on the rennin-angiotensin-aldosterone system (RAAS) leads to less angiotensin II–mediated vasoconstriction and aldosterone-mediated volume expansion, resulting in decreases in blood pressure (McCance & Huether, 2014).

Respiratory Effects

$Beta_2$ receptors are located throughout the body. In the lungs, blockade of these receptors interferes with endogenous adrenergic bronchodilator activity, which results in passive bronchial constriction. This increase in airway resistance is particularly problematic for patients with reactive airway diseases such as asthma (Hall, 2013).

Ocular Effects

Opthalmic beta blockers decrease intraocular pressure as a result of decreased aqueous humor manufacture or outflow. The exact mechanism by which these drugs reduce intraocular pressure is not established, but is thought to be achieved by reduction in the production of aqueous humor (FDA, 2009d). Topical use of beta blockers is discussed in Chapter 27.

Metabolic and Endocrine Effects

$Beta_2$-blockade effects on the liver lead to inhibition of lipolysis, resulting in increased triglycerides and cholesterol and

decreased high-density lipoproteins. For patients with hyperlipidemia, beta$_2$ blockade may worsen the condition (Podrid, 2013).

Effects on the liver also lead to inhibition of gluconeogenesis. The action of epinephrine on the beta-adrenergic receptors impacts glucose metabolism by increasing glucose production through glycogenolysis and glyconeogenesis. The delivery of gluconeogenic substrates from peripheral stores restricts glucose uptake and inhibits insulin secretion (Podrid, 2013).

Effects on Other Systems

The effect of beta blockade on other body systems is the source of the adverse drug reactions that may cause nonadherence to the drug regimen. Data analysis indicates a small risk of sexual dysfunction in 5 out of every 1,000 patients. Fatigue was reported in 18 per 1,000 patients. Depression is frequently cited as an adverse effect of beta blockade but recent data does not support this reaction. Due to this recent data, fatigue, depression, and sexual dysfunction are not reasons to withhold beta blockers (Podrid, 2013).

Pharmacokinetics

Absorption and Distribution

All beta blockers are well absorbed when given orally and are widely distributed in body tissues (Table 14-8). All cross the placenta and enter breast milk. CNS penetration varies, based on lipid solubility, with minimal penetration for acebutolol, atenolol, nadolol, and pindolol and moderate penetration for timolol and metoprolol, with propranolol having the highest CNS penetration. Nebivolol is highly lipophilic and has CNS penetration, but the exact degree of penetration is not clear. Several factors may account for the antihypertensive response of nebivolol, including lower heart rate, a decrease in myocardial contractility, impact on sympathetic outflow to the periphery, suppression of renin activity, and decreased peripheral vascular resistance (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011, 2013).

Metabolism and Excretion

Most beta blockers are metabolized extensively by the liver and eliminated via the bile and feces. Dosages of most of these agents may need to be decreased in patients with hepatic impairment. Nebivolol, a new third-generation beta blocker, has several routes of metabolism and a metabolic fate that is heavily genetically based. Most of the population are extensive metabolizers (EM) of the drug and small percentages are poor metabolizers (PM). The half-life of the active isomer, d-nebivolol, is about 12 hours in the EM population and 19 hours in the PM population. Metabolism includes glucuronidation and hydroxylation by CYP2D6 and to a lesser extent dealkylation and oxidation via this same isoenzyme system. It has two active sterospecific isomers. The d-isomer is the most active and

Table 14–8 **Pharmacokinetics: Selected Beta Blockers**

Drug	Onset	Peak	Duration	Protein Binding (%)	Bioavailability (%)	Half-Life	Elimination
Acebutolol*	60 min	4–6 h	24–30 h	26	<50	3–4 h; (18–13 h for diacetolol, the active metabolite)	30%–40% in urine; 50%–60% in feces/bile
Atenolol	60 min	2–4 h	24 h	6–16	50–60	6–9 h	50% unchanged in urine; rest in feces
Metoprolol	15 min	90 min	13–19 h	12	50–77	3–7 h	<5% unchanged in urine
Nadolol	5 days†	3–4 h	17–24 h	30	30–50	20–40 h	Unchanged in urine
Nebivolol	15 min	1.5–4 h	UK	98	UK	12–19 h based on genetic differences	38%–67% in urine; 13%–44% in feces
Pindolol*	7 days†	1 h	24 h	40	100	3–4 h	60%–65% metabolites and 35%–40% unchanged drug in urine
Propranolol	30 min	60–90	6–12 h	90	30	3–5 h	<1% unchanged min in urine
Propranolol	UK	6 h	24 h	90	9–18	8–11 h	<1% unchanged ER in urine
Timolol	UK	1–3 h	12–24 h	10	75	4 h	Metabolites and unchanged drug in urine

UK = unknown.

*Intrinsic sympathomimetic activity. Pindolol more than acebutolol.

†Onset of cardiovascular effects.

PMs attain a 5-fold higher maximal drug concentration (C_{max}) and a 10-fold higher AUC of this isomer than EMs (FDA, 2011d).

Several beta blockers (acebutolol, atenolol, nadolol, and nebivolol) require dosage adjustment in patients with renal impairment. The dose of acebutolol should be decreased by 50% when CrCl is less than 50 mL/min and by 75% if CrCl is less than 25 mL/min. Because approximately 40% of atenolol is excreted unchanged in the urine, the dose of this drug will need to be adjusted if creatinine clearance falls below 35 mL/min. Because nadolol is excreted unchanged in the urine, dosing must be adjusted in renal impairment. The recommendation for dosing nadolol in this situation involves extending the dosing interval. Last, with CrCl less than 30 mL/min, nebivolol dosing should be started at 2.5 mg daily and titrated (FDA, 2007a, 2007b, 2007c, 2011, 2011b, 2011c, 2012b, 2013).

Pharmacotherapeutics

Precautions and Contraindications

Beta blockers are contraindicated for patients with respiratory conditions that include a bronchospastic component. Although there are beta$_1$-selective drugs that have less effect on the beta$_2$ receptors in the lungs, to date no beta blocker is sufficiently selective to beta$_1$ to completely reduce the risk of beta$_2$ blockade. Even beta$_1$-selective drugs show beta$_2$ effects at higher doses. Because of their relative beta$_1$ selectivity, low doses of acebutolol, atenolol, betaxolol, bisprolol, and metoprolol should be used cautiously for patients with bronchospastic disease who do not respond to any other hypertensive treatment. Nebivolol is also beta$_1$-selective, but no recommendation about its use in pulmonary disease has yet been made (FDA, 2007a, 2007b, 2007c, 2011, 2011b, 2011c, 2012b, 2013).

These drugs are also contraindicated for patients with AV block, because their actions to decrease heart rate and myocardial contractility result in increased reduction in cardiac output and worsened failure. Decreased cardiac output and the initial vasoconstrictive action of these drugs may also worsen peripheral vascular diseases. Recognition that beta-adrenergic stimulation is a factor in heart failure has resulted in the use of nonselective beta blockers in heart failure, where the class was formerly contraindicated, but should be used with caution (FDA, 2007a, 2007b, 2007c, 2011, 2011c, 2011d, 2012b, 2013). Chapter 36 discusses their use for this indication in more detail.

Older adults often have limited cardiac and renal reserves. Beta blockers are used to treat conditions common to older adults, but care must be taken with dosing. Closer monitoring of cardiac and renal status is required. Based on meta-analyses of previous studies, beta blockers are less efficacious than other first-line therapies for cardiovascular disorders in patients who are 60 years or older, especially for stroke prevention (Institute for Clinical Systems Improvement [ICSI], 2008). Use of these drugs as initial therapy for older adults should be restricted to situations in which there is another indication for their use.

Beta blockers may precipitate or exacerbate type 2 diabetes. Because of their effects on carbohydrate metabolism and their ability to mask the common symptoms of hypoglycemia, beta blockers must be used cautiously in patients with diabetes (Podrid, 2013). Beta blockers have been proven effective in the management of the ischemic and congestive cardiac disorders that are more common in patients with diabetes, so they do have a role. According to Colucci (2013), the use of beta blockers in patients with diabetes was found to improve survival in a meta-analysis that included 1,883 people with diabetes.

In cases of hyperthyroidism, there is an increase in beta-adrenergic activity. Beta blockers have been successful in relieving symptoms such as palpitations, tachycardia, tremors, anxiety, and heat intolerance in patients with hyperthyroidism. Beta blockers are recommended for most hyperthyroid patients who have no contraindications to beta blocker use (Ross, 2013).

The Pregnancy category of beta blockers varies. Atenolol is Pregnancy Category D; betaxolol, acebutolol, metoprolol, nadolol, nebivolol, timolol, and propranolol are Pregnancy Category C. All cross the placenta and can cause fetal or neonatal bradycardia, hypotension, hypoglycemia, or respiratory depression (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2012b, 2013). The use of beta blockers during pregnancy is controversial because there have been individual reports of early labor, bradycardia, and restricted fetal growth. It should be mentioned that myometrial relaxation during pregnancy is mediated by beta$_2$ receptor processes (August, 2013). Sotalol and pindolol are listed as Pregnancy Category B. Note, however, that neonates of mothers who received these latter drugs had reduced birthweight and decreased blood pressure and heart rate at birth (FDA, 2007b, 2011f).

Propranolol and metoprolol are excreted in breast milk and the manufacturer recommends using caution when administering to nursing mothers. All other beta blockers are excreted in larger amounts. Nursing mothers should be given these drugs only when benefits clearly outweigh risks (FDA, 2011c, 2013).

Beta blockers were an early drug of choice in the treatment of hypertension in children. Propranolol was the subject of original studies in this population, but more selective drugs such as atenolol and metoprolol are found to be better tolerated. Extended-release metoprolol was evaluated in a population of 140 children with hypertension and found to be effective (Mattoo, 2013).

Adverse Drug Reactions

Beta blockade affects target organs and nontarget organs and tissues alike. This wide range of effects results in many adverse reactions to these drugs, although most adverse reactions have been mild and transient and have rarely required withdrawal of therapy. The discussion here focuses on the adverse reactions on each organ system.

Cardiovascular Reactions

Bradycardia, CHF with concomitant pulmonary edema, and hypotension are the most common cardiovascular adverse

reactions. They have been discussed here in the Precautions and Contraindications section.

Central Nervous System and Psychiatric Reactions

Fatigue, weakness, and dizziness are associated with reduced oxygen transport to the brain secondary to excessive hypotension. Anxiety, depression, drowsiness, insomnia, nightmares, and mental status changes are more common in those drugs that have higher CNS penetration and in older adults (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2012b, 2013).

Endocrine Reactions

Alterations in carbohydrate metabolism resulting in hyperglycemia, hypoglycemia, or unstable diabetes have been discussed in the Precautions and Contraindications section.

> **CLINICAL PEARL**
>
> For patients with diabetes who must take a **beta blocker**, the diaphoresis associated with hypoglycemia is not masked by these drugs. Patients should be taught to recognize this indication of possible hypoglycemia and test their blood glucose levels whenever unexplained diaphoresis occurs.

Gastrointestinal Reactions

Dry mouth is uncommon but may occur. It may be reduced by practicing good oral hygiene, chewing sugarless gum, or sucking on hard candy. Changes in GI motility may result in anorexia, nausea, vomiting, flatulence, and constipation or diarrhea (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2012b, 2013.

Genitourinary Reactions

One of the most likely reasons for nonadherence to a treatment regimen that includes beta blockers is the risk for impotence and decreased libido. This side effect may resolve with continued use of the medication (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2012b, 2013).

Respiratory Reactions

Bronchospasm and dyspnea have been discussed in the Precautions and Contraindications section. Nasal stuffiness may also occur.

Other Reactions

Less common adverse reactions include muscle and joint pain, pruritic rashes, and facial swelling (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2012b, 2013). These are not directly related to the actions of these drugs.

Drug, Food, and Laboratory Test Interactions

Drug Interactions

Many drug interactions occur with beta blockers. Before they are prescribed, Table 14-9 should be consulted. Common problems include additive hypotension with other antihypertensives, acute ingestion of alcohol or nitrates, bradycardia with digitalis, and altered effectiveness of hypoglycemic drugs. Concurrent use of several drugs found in OTC cold remedies (ephedrine, phenylephrine, pseudoephedrine) may result in unopposed alpha-adrenergic stimulation, causing excessive hypertension and tachycardia. Metoprolol, nebivolol, and propranolol have drug interactions in addition to those found with other beta blockers. The drug in this category with the fewest interactions is atenolol (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2012b, 2013).

Table 14–9 ⊞ Drug Interactions: Selected Beta Blockers

Drug	Interacting Drug	Possible Effect	Implications
All beta blockers	Aluminum salts, barbiturates, calcium salts, cholestyramine, colestipol, NSAIDs, ampicillin, rifampin, salicylates	Decrease bioavailability and plasma levels of beta-adrenergic antagonists, possibly resulting in decreased pharmacological effect	Avoid concurrent use. Separate administration of cholestyramine or colestipol from administration of beta-adrenergic antagonist by 4 h.
	Calcium channel blockers	Potentiate effects of beta-adrenergic antagonists	Do not administer within 24 h of each other. If must give both, monitor for heart failure and decreased peripheral perfusion.
	Ciprofloxacin and other quinolones, cimetidine	Bioavailability of beta-adrenergic antagonists metabolized by CYP450 may be increased	Select different antibiotic or different beta-adrenergic antagonist
	Digoxin	Additive bradycardia	Avoid concurrent administration. If must give both, monitor closely for digitalis toxicity. May need to adjust doses of one or both.
	Antihypertensives, alcohol, nitrates	Additive hypotension	Avoid acute ingestion of alcohol. Monitor blood pressure (BP) closely.

Table 14–9 ▦ **Drug Interactions: Selected Beta Blockers—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
	Amphetamines, cocaine, ephedrine, epinephrine, norepinephrine, phenylephrine, pseudoephedrine	Concurrent use may result in unopposed alpha-adrenergic stimulation, resulting in excessive hypertension and bradycardia	Avoid concurrent use. Warn patients because many of these are included in OTC cold remedies
	Prazosin	Concurrent administration may potentiate postural hypotension	Avoid concurrent administration
	Sulfonylureas	Hypoglycemic effects of sulfonylureas may be attenuated	Select different hypoglycemic or antihypertensive. If they must be given together, monitor blood glucose closely.
	Clonidine	Life-threatening and fatal increases in BP have resulted after discontinuance of clonidine in patients also receiving beta-adrenergic antagonist or after simultaneous withdrawal	
Metoprolol, propranolol	Ranitidine	May increase bioavailability of metoprolol; other beta-adrenergic antagonists not affected	Select different histamine$_2$ blocker, but avoid cimetidine (see above)
	Hydralazine	Additive pharmacological effect	Avoid concurrent use or closely monitor effects
	MAOIs	Bradycardia may develop	Avoid concurrent use or use within 14 days of MAOI
	Propafenone	Plasma levels of metoprolol increased	Avoid concurrent use
	Benzodiazepines (BDZ)	Effects of BDZ increased by lipophilic beta-adrenergic antagonist	Change to atenolol. It does not interact.
	Seratonin reputake inhibitors (SRIs)	Certain SRIs may inhibit metabolism (CYP2D6) of these beta blockers leading to exessive beta blockades	Avoid concurrent use. Select different beta blocker.
	Thyroid hormone	Decrease actives of these beta blockers when patient is converted to euthyroid state	Monitor for decreased effects. Increase beta-blocker dose if needed.
Propranolol only	Acetaminophen	Decreased acetaminophen clearance	Avoid concurrent use or reduce dose
	Gabapentin	Increased gabapentin adverse responses	Avoid concurrent use
	Haloperidol	Hypotensive episodes	Select different antipsychotic
	Loop diuretics	Propranolol plasma levels and cardiovascular effects enhanced	Atenolol not affected. Use atenolol instead.
	Phenothiazines	Propranolol bioavailability and phenothiazine plasma levels increased, with potential toxicity	Selected different beta-adrenergic antagonist
	Warfarin	Increased anticoagulant effect	Select different beta-adrenergic antagonist
Nebivolol only	CYP2D6 inhibitors (e.g., fluoxetine, paroxetine, propafenone, quinidine)	Increased inhibition of CYP2D6 leading to increased plasma levels of nebivolol	Dose of nebivolol may need to be reduced
	Histamine 2 blockers (e.g., cimetidine)	Increased plasma levels of nebivolol metabolite by 23%	Avoid concurrent use
	Disopyramide	Clearance of disopyramide decreased leading to hypotension and sinus bradycardia	Avoid concurrent use or use caution and monitor closely if must coadminister
	Sildenafil	Decreased AUC and C_{max} of sildenafil by 21% and 23%, respectively	May require dosage adjustment

Source: FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2013.

Life-threatening and fatal increases in blood pressure have been observed in patients taking clonidine and a beta blocker concurrently when the clonidine was withdrawn or when both the clonidine and the beta blocker were withdrawn. It is best to avoid using these drugs together, but if they are both given and withdrawal of one or both becomes necessary, taper the beta blocker first to avoid unopposed alpha stimulation and significant hypertension (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2012b, 2013).

Food Interactions

The beta blockers may be taken with or without food (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2012b, 2013).

Laboratory Test Interactions

Beta blockers may cause increased blood urea nitrogen (BUN), serum lipoprotein, potassium, triglyceride, and uric acid levels. They may also increase antinuclear antibody (ANA) titers and blood glucose levels (Podrid, 2013).

Clinical Use and Dosing

Regardless of the indication for which a beta blocker is given, there is no simple correlation between dose or plasma level and therapeutic effect. The dose-sensitivity range in clinical practice is wide because sympathetic tone and first-pass metabolism varies widely among individuals. Proper dosing requires titration (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2012b, 2013).

Angina

Atenolol, metoprolol, nadolol, and propranolol are indicated for long-term management of angina (Gibbons et al, 2003). Beta blockers lower blood pressure; reduce symptoms of angina; improve mortality; and reduce cardiac output, heart rate, and AV conduction. Both beta$_1$-selective and nonselective drugs affect the myocardial oxygen supply-demand equation on the demand side by decreasing the force of myocardial contractility, heart rate, and conduction velocity (National High Blood Pressure Education Program [NHBPEP], 2003). Nonselective agents, by a mechanism that is not clearly understood, decrease systemic vascular resistance and blood pressure, reducing afterload. Because they reduce myocardial oxygen demand, beta blockers are the drugs of choice for exertional angina. They are especially useful for patients with exertional angina whose lifestyle involves frequent vigorous activity, for patients with resting tachycardia, and for patients who have concomitant disease that might benefit from beta blockade (e.g., hypertension, post-MI migraine headaches). They do not improve myocardial oxygen supply, and propranolol has been reported to increase the risk for coronary artery vasospasm in some patients. Additional discussion of their use in patients with angina is found in Chapter 28.

To reduce the risk for adverse drug reactions, doses are started low and increased slowly, usually at no shorter than weekly intervals, based on resolution of symptoms. Dosage adjustment based on hepatic impairment and renal function is discussed in the metabolism and excretion section.

Hypertension

Initial drug therapy for hypertension is with a diuretic or a beta blocker in combination with a diuretic because they have been shown to reduce morbidity and mortality in numerous randomized controlled trials (RCT) (NHBPEP, 2003). Propranolol is now available in a combination form that includes hydrochlorothiazide. Beta blockers are also chosen because of reduced cost. They may be used in combination with other antihypertensives, largely to mitigate adverse effects. Atenolol, metoprolol, nadolol, and propranolol are the drugs most commonly chosen. Because of their relatively long half-lives, these drugs can be administered once daily, improving adherence. Pindolol and acebutolol have fewer myocardial depressant effects and do not increase cholesterol and triglyceride levels. Consideration of renal function is again important for dosing of some beta blockers (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2012b, 2013). Additional discussion of the use of beta blockers in hypertension management is found in Chapter 40.

Postmyocardial Infarction (MI) Prophylaxis

Use of beta blockers in post-MI prophylaxis has been shown to decrease mortality by 30% to 40%. They are most effective for patients who have had severe anterior MIs. The mechanism of action in MI prophylaxis appears to be related to limitation of infarct size, prevention of primary arrhythmic events, and protection from subsequent ischemia, and prevention of recurrent coronary occlusion. A clinical study of 1,395 patients in a double-blind, placebo-controlled trial found metoprolol to reduce 3-month mortality by 36% in patients with suspected or definite myocardial infarction. Atenolol, metoprolol, propranolol, and timolol have been shown to be effective for this indication. In a study of 1,456 patients, sotalol did not produce an increase in mortality rates at doses up to 320 mg/day in patients with a history of a recent MI and no ventricular arrhythmias. A second smaller study in a post-MI population did find suggestions of an increase in early sudden deaths (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013).

Migraine Headache Prophylaxis

Propranolol in doses of 20 to 80 mg 3 or 4 times daily has proved effective in reducing the incidence of migraine headache in some patients. The mechanism of action is related to prevention of beta receptor–induced vasodilation and promotion of increased extracellular levels of serotonin. For propranolol, if a satisfactory response to the maximum dose is not obtained in 4 to 6 weeks, the drug should be gradually withdrawn because a longer trial is not associated with any better outcome (FDA, 2011c).

Glaucoma

Topical application of beta blockers in the treatment of glaucoma is discussed in Chapter 26.

Withdrawal of Beta Blockers

For all beta blockers, abrupt withdrawal can be life-threatening. It can result in severe angina, MI, ventricular arrhythmias,

and death. The up-regulation of beta receptors with chronic use makes the system very sensitive to any SNS tone change. To withdraw any of these drugs, taper the dose by one-half every 4 days. Patients at high risk for serious consequences to rapid withdrawal include those with angina, coronary artery disease, and migraines (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013).

Rational Drug Selection

Beta Selectivity

In selecting the most appropriate beta blocker, first consideration is usually given to beta $_1$ selectivity, sometimes referred to as "cardio selective." Atenolol, acebutolol, and metoprolol are beta$_1$-selective drugs. Nadolol, pindolol, propranolol, and timolol are nonselective drugs. Nebivolol, a third-generation beta blocker, is beta$_1$ selective in extensive metabolizers (EMs) and nonselective in poor metabolizers (PMs) (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013).

The clinical significance of selectivity relates to the relative lack of action of beta$_1$-selective drugs on the beta$_2$ receptors. This relative lack of action makes beta $_1$-selective blockers more appropriate than nonselective agents for patients with chronic obstructive pulmonary diseases, asthma, peripheral vascular diseases such as Raynaud's syndrome, or diabetes mellitus. Among the beta $_1$-selective blockers, atenolol has greater selectivity than does metoprolol, which has greater selectivity than acebutolol (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013).

Pharmacokinetics

The best choice of drug based on pharmacokinetics would be one with a long enough half-life to permit once-daily dosing, consistent bioavailability and limited interpatient variability in dosing, limited CNS penetration to reduce adverse reactions, and an excretion mechanism that does not require dosage adjustments so that extensive laboratory testing prior to initiation of therapy is not required. No one drug meets all these requirements, but several come close.

Atenolol, metoprolol, nadolol, and nebivolol have longer half-lives that permit once-daily dosing regimens, although metoprolol frequently has its best effects with twice-daily dosing. All other beta blockers have half-lives that require at least twice-daily dosing, with propranolol requiring 2 to 3 times daily dosing. Propranolol has a plasma half-life of 3 to 6 hours while the half-life of atenolol is 7 hours. It should be noted that this half-life is longer in elderly patients (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013).

Atenolol and nadolol do not have significant hepatic first-pass effects. Acebutolol, metoprolol, and propranolol have significant first-pass effects and increased interpatient variability in the amount of drug that enters the patient's bloodstream. They also have short half-lives and require more frequent dosing. Timolol has some first-pass effects but the drug is about 75% bioavailable, so the first-pass effect is less significant. Pindolol does not have a significant first-pass effect (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013).

Beta blockers that are excreted primarily by the kidney have increased half-lives in renal failure. Dosage adjustments are necessary. Atenolol, nebivolol, and nadolol fall into this category (Table 14-10). Although acebutolol has some excretion through the GI tract, its active metabolite is excreted through the kidneys, and the daily dose must be reduced in renal failure. Poor renal function has only minor effects on pindolol clearance, and the half-life of metoprolol is essentially unchanged (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013).

Indications for Specific Drugs

Specific agents have been demonstrated to work with specific disorders. Other drugs in the class may not work as well. For example, propranolol is the only one proven useful in managing exertional or other stress-induced angina associated with idiopathic hypertrophic subaortic stenosis. A double-blind, placebo-controlled study of the effectiveness of propranolol in managing exercise-induced angina found it to be more effective than placebo (FDA, 2011c). The drug chosen should be backed by research that supports its use and an FDA approval for the intended use.

Monitoring

Monitoring parameters for beta blockers are essentially those used to monitor the disease process they are being used to treat (e.g., number of anginal attacks, lowering of blood pressure). For the drugs requiring dosage adjustments based on renal function, serum creatinine and/or creatinine clearance testing should be done prior to initiation of therapy. For drugs with significant first-pass effects, it may be appropriate to assess liver function before beginning therapy (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013).

Patient Education

Administration

The patient should take the drug exactly as prescribed, even if feeling well. They should not skip or double doses. If a dose of atenolol, metoprolol, or nadolol is missed, it can be taken up to 8 hours before the next dose is due. Pindolol, propranolol, and timolol may be taken up to 4 hours before the next dose. Abrupt withdrawal may precipitate life-threatening arrhythmias, hypertension, and myocardial ischemia (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013). The patient should make certain there is enough drug on hand to cover weekends or traveling and should carry identification describing the disease process and the medication regimen at all times.

Food may enhance the bioavailability of propranolol and metoprolol. They should be taken consistently either with food or on an empty stomach. Propranolol can be crushed and mixed with food, including oral solutions and semisolids, if it is consistently given with food. Food intake does not affect other beta blockers (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013).

Patients should consult with the health-care provider before taking any OTC drugs, especially cold remedies. Several

Table 14–10 ⊗ Dosage Schedule: Selected Beta Blockers

Drug	Indication	Form	Initial Dose	Maintenance Dose
Acebutolol (Sectral)	Hypertension	Capsules: 200 mg Capsules: 400 mg	*Adults:* 400 mg/d in single or 2 divided doses *Older adults:* 200 mg/d in single or 2 divided doses	If target blood pressure (BP) not achieved in 1–2 wk, increase to 800 mg daily. Max dose is 1,200 mg. Reduce dosage by 50% if creatinine clearance (CCr) <50 mL/min; by 75% if CCr <25 mL/min.
	Ventricular arrhythmias		200 mg bid	Increase to 600–1,200 mg/d as needed to control arrhythmia
	Angina		300 mg tid	May increase to 400 mg tid if needed
Atenolol (Tenormin) (Canadian drug name: Apo-atenolol)	Hypertension	Tablets: 25 mg, 50 mg, 100 mg Atenolol/ Chlorthalidone (G)(Tenoretic) (B) Tablets: 50 mg atenolol/ 25 mg chlorthalidone, 100 mg atenolol/ 25 mg chlorthalidone	*Adults:* 25–50 mg daily *Children:* 0.8 mg/kg/d	If target BP not achieved in 1–2 wk, increase to 100 mg daily for adults and 1.5 mg/kg/d for children. Max dose for children is 2 mg/kg/d. Higher doses not likely to help in adults. Reduce dosage to 50 mg if creatinine clearance (CCr) 15–35 mL/min; 50 mg qod if CCr <15 mL/min.
	Angina		50 mg daily	If symptoms continue, increase to 100 mg daily. Some patients may need 200 mg. Reduce dosage to 50 mg if CCr 15–35 mL/min; 50 mg qod CCr <15 mL/min.
	MI (prophylaxis)		50 mg daily	50–100 mg daily (see note above re CCr)
Metoprolol (Lopressor) (Canadian drug names: Apo-Metoprolol, Betaloc)	Hypertension	Tablets: 25 mg, (G) 50 mg, 100 mg Tablets, extended-release: 25 mg, 50 mg, 100 mg, and 200 mg	*Adults*: 50–100 mg/d in single or divided doses (extended-release tablets: 50–100 mg daily) *Older adults:* 25 mg/d in single or divided doses	If target BP not achieved, increase at weekly intervals. Maintenance dose usually 100–450 mg/d. Does better in divided doses (extended-release tablets: 100–400 mg daily).
	Angina		100 mg/d in two divided doses (extended-release tablets: 100 mg daily)	If symptoms continue, increase in weekly intervals up to 400 mg/d in two divided doses (extended-release: up to 400 mg daily)
	MI (prophylaxis)		100 mg/d in two divided doses	100 mg/d in two divided doses
Nadolol (Corgard)	Hypertension	Tablets: 20 mg 40 mg (G) 80 mg (G) 120 mg 160 mg	40 mg daily	Increase in doses of 40–80 mg/d until target BP achieved. Maintenance dose usually 40–80 mg/d. Max dose 320 mg/d in divided doses. Increase dosage interval in renal impairment: CCr >50 = q 24 h; CCr 31–50 = q 24–36 h; CCr 10–30 = q 24–48 h; CCr <10 = q 40–60 h.
	Angina		40 mg daily	If symptoms continue, increase in 3–7 d intervals to 80–160 mg/d. Max dose is 240 mg/d. Increase dosage interval in renal impairment: CCr >50 = q 24 h: CCr 31–50 = q 24–36 h; CCr 10–30 = q 24–48 h; CCr <10 = q 40–60 h.

Table 14–10 ⊗ **Dosage Schedule: Selected Beta Blockers—cont'd**

Drug	Indication	Form	Initial Dose	Maintenance Dose
Nebivolol (Bystolic)	Hypertension	Tablets: 2.5, 5, 10, 20 mg	5 mg daily CCr <30 or moderate hepatic impairment = reduce dose to 2.5 mg daily	May increase dose at 2-wk intervals up to max dose of 40 mg/d. CCr <30 or moderate hepatic impairment = cautious upward titration.
Propranolol (Inderal) (Inderal LA) (InnoPran XL) (Canadian drug name: Apo-pranolol and Novopranolol)	Hypertension	Tablets (G): 10 mg, 20 mg, 40 mg, 80 mg Tablets (G): 60 mg, 90 mg Solution: 20 mg/ 5 mL <u>Propranolol CR Extended Release</u> Capsules: 60 mg, 80 mg, 120 mg, 160 mg <u>(InnoPran XL)(B)</u> Capsules: 80 mg, 120 mg <u>Propranolol/ Hydrochloro- thiazide (G) (Inderide) (B)</u> Tablets: 40 mg, 25 mg 80 mg/25 mg	*Adults:* 40 mg bid (SR = 80 mg daily) *Children:* 0.5 mg/kg/d in two divided doses	*Adults:* Usual maintenance dose is 120–240 mg bid or tid (SR = 120–160 mg daily); max dose = 640 mg/d *Children:* Max dose 16 mg/kg/d
	Angina		80–320 mg in two, three, or four divided doses (SR = 80 mg daily)	If symptoms continue; give 160 mg SR tablet; max dose, 320 mg SR
	MI (prophylaxis)		180–240 mg/d in 2–3 divided doses	
	Migraine prophylaxis		80 mg/d (SR)	160–240 mg/d in divided doses
Timolol (Blocadren)	MI (prophylaxis)	Tablets: 5 mg, 10 mg (G only), 20 mg		10 mg bid
	Migraine prophylaxis		10 mg bid	Maintenance dose 10–30 mg. May take up to 8 wk of maximum daily dose

Source: FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2013.
   SR = sustained release

drugs common in these preparations have drug interactions that result in hypertension and excessive bradycardia.

If these drugs are being taken for angina, beta blockers cannot relieve acute anginal attacks. If acute chest pain occurs, the patient should call 911 and go to the nearest hospital.

Adverse Reactions

Hypotensive reactions and bradycardia are the most common adverse reactions. Arising slowly from a supine position and dangling the feet over the side of the bed before standing will reduce postural hypotension. No exercise in hot weather and adequate hydration with noncaffeinated fluids will also reduce these problems (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013). Assessment of blood pressure and pulse is necessary on a biweekly basis for those taking these drugs. Teach the patient home blood pressure and pulse monitoring and advise contacting the health-care provider if the pulse is less than 50 bpm or if the blood pressure changes suddenly.

Beta blockers may exacerbate diseases with a bronchospastic component. Teach patients to report wheezing or difficulty in breathing to the health-care provider immediately. Dizziness and drowsiness may occur with the drugs. Patients should avoid driving or other activities that require mental alertness until response to the drug is known. Insomnia can

be reduced by not taking the last dose of the day late in the evening (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013). Dry mouth responds to practicing good oral hygiene, chewing sugarless gum, or sucking on hard candy.

Depression and confusion have been associated with the beta blockers that have significant CNS penetration. The patient should report such problems, and a different beta blocker or a different class of drugs may be tried.

For diabetics, these drugs may mask the signs and symptoms of hypoglycemia and impair recovery from a hypoglycemic episode. Beta$_1$-selective drugs are less likely to cause this problem. The one indication of hypoglycemia that is not masked is diaphoresis. In the event of unexplained diaphoresis, the patient should check the blood glucose level immediately.

Beta blockers are contraindicated in the first trimester of pregnancy and must be withdrawn before delivery. Women of childbearing age should be given this warning. Other pregnancy considerations relate to the specific pregnancy category of the beta blocker being considered (FDA, 2007a, 2007b, 2007c, 2011b, 2011c, 2011d, 2011f, 2012b, 2013).

Nonadherence to a treatment regimen with a beta blocker is often caused by inhibition of ejaculation and impotence. If these occur, the patient should report them to the health-care provider, who may choose a different drug to treat the disorder or change the dosage.

Lifestyle Management

If the drug is being given for hypertension, encourage the patient to adhere to additional interventions for reduction of blood pressure, such as weight loss, a low-sodium diet, smoking cessation, regular exercise, and stress management. Further discussion of patient education is found in Chapter 40. Further discussion of patient education about angina is found in Chapter 28 and discussion of heart failure is found in Chapter 36.

COMBINED ALPHA- AND BETA-ADRENERGIC ANTAGONISTS

Drugs that exhibit blockade at both alpha and beta receptors have effects that would be expected from a combination of an alpha and a beta blocker. Because the alpha blockade predominates, however, they are less likely to produce significant reductions in heart rate or cardiac output. Alpha blockade also balances the tendency of beta blockers to produce reflex vasoconstriction.

Two drugs in this class are: carvedilol (Coreg) and labetalol (Normodyne). Both are used to treat hypertension, and carvedilol is also used to reduce progression of heart failure and to treat left ventricular dysfunction following an MI (FDA, 2010, 2011g). This section focuses on aspects of these drugs that are different from alpha-adrenergic antagonists and beta blockers. Aspects of these drugs that are similar to those of the other two classes are discussed only briefly.

Epinephrine also binds to both alpha and beta receptors and is used in the treatment of allergic reactions including anaphylaxis. The dose is delivered by subcutaneous injection. Auvi-Q is a brand which was approved in 2012 for this use and is available in auto-injectors for ease of use (FDA, 2012f).

Pharmacodynamics

These drugs combine selective alpha$_1$-adrenergic and nonselective beta blockade. The alpha and beta blockades decrease blood pressure; standing blood pressure is more affected than supine. They also decrease peripheral resistance by peripheral vasodilation (carvedilol more than labetalol). These combined effects decrease myocardial oxygen demand and lower cardiac workload. Single doses of labetalol have no significant effect on sinus rate, intraventricular conduction, or QRS duration. AV conduction time is only modestly prolonged. No significant change in cardiac output occurs. Labetalol has been associated with rare orthostatic hypotension. Carvedilol reduces orthostatic hypotension and exercise-induced reflex tachycardia. In hypertensive patients with normal renal function, it also decreases renal vascular resistance. Neither of these drugs demonstrates a significant effect on serum lipoproteins (FDA, 2010, 2011g).

Although beta blockade is useful in angina and hypertension, sympathetic stimulation is vital in some situations. For example, in patients with severely damaged hearts, adequate ventricular function may depend on sympathetic drive (FDA, 2010, 2011g).

Epinephrine (Auvi-Q) also decreases the vasodilation and vascular permeability, which are present during anaphylaxis. It causes bronchial smooth muscles to relax and relieves bronchospasm, wheezing, and dyspnea. Epinephrine decreases pruritis, angioedema, urticarial, and some of the genitourinary symptoms present with anaphylaxis.

Pharmacokinetics
Absorption and Distribution

Both carvedilol and labetalol are rapidly absorbed (Table 14-11). Carvedilol is more protein bound than labetalol. Both drugs are widely distributed in body tissues (FDA, 2010, 2011g). Epinephrine is given by injection and the onset is rapid and the duration short (FDA, 2012f).

Metabolism and Excretion

Carvedilol and labetalol undergo rapid hepatic first-pass metabolism resulting in bioavailabilities between 25% and 35%. Carvedilol is metabolized by CYP2D6 and 2C9 and labetolol undergoes glucoronidation and sulfation, which are not CYP meditated. Carvedilol undergoes more excretion in bile and feces than does labetalol (FDA, 2010, 2011g).

Pharmacotherapeutics
Precautions and Contraindications

Epinephrine is used in emergency situations in people who are at risk for anaphylaxis. There are no contraindications

Table 14–11 ⚙ **Pharmacokinetics: Combined Alpha-Beta Blockers**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Carvedilol	1 h	1–2 h	12 h	>98%	25%–35%	7–10 h	Primarily in bile and feces: <2% unchanged in urine
Labetalol	20 min	1–4 h	8–12 h	50%	25% (increased by food and in older adults)	3–8 h	In bile and feces; 50%–60% as conjugates in urine

Source: FDA, 2010, 2011g.

listed by the FDA for use, but it should be used with caution in patients with cardiac arrhythmias, heart disease, hypertension, diabetes, or hyperthyroidism. Populations identified for cautious use are the elderly and pregnant women. People with Parkinson's disease may have a temporary worsening of symptoms following administration of epinephrine (FDA, 2012f).

For the oral drugs in the category, because they include nonselective beta blockade, alpha-beta blockers are contraindicated for patients with respiratory conditions that include a bronchospastic component. They are also contraindicated in overt, New York Heart Association (NYHA) class IV heart failure, greater than first-degree AV block, and severe bradycardia due to their negative inotropic effects. However, carvedilol has been shown to be effective in the management of NYHA class II and III heart failure because of its limited effects on heart rate and myocardial contractility while improving hemodynamics and cardiac performance (FDA, 2010, 2011g).

Cautions related to diabetes and thyroid disease and problems with withdrawal are similar to those of beta blockers. Although alpha-beta blockers produce less reflex vasoconstriction, caution is still required when these drugs are administered to patients with peripheral vascular disease (FDA, 2010, 2011g).

Like many beta blockers, these drugs are heavily metabolized by the liver, and use in patients with clinically manifested liver disease is not recommended. Hepatic injury has occurred rarely with both drugs, and onset of jaundice or hepatic dysfunction indicated by symptoms or elevations of liver function tests necessitates withdrawal of the drug (FDA, 2010, 2011g).

These drugs are Pregnancy Category C for the same reasons as beta blockers. Epinephrine should only be used in pregnancy if the benefit outweighs the risk. Small amounts of labetalol (0.004%) are excreted in breast milk, and the amount of carvedilol excreted in breast milk is unknown. Caution should be exercised in giving labetalol to nursing mothers, with careful consideration of benefits versus risk. Carvedilol should not be given to nursing mothers (FDA, 2010, 2011g, 2012f).

According to the American College of Obstetricians and Gynecologists (ACOG, 2012), labetalol may increase the risk of small for gestational age (SGA) infants if used to treat hypertension during pregnancy. A meta-analysis of studies evaluating the use of labetalol included atenolol and this may have contributed to the finding of SGA. Consequently, ACOG finds the use of labetalol during pregnancy to treat chronic hypertension safe. It is reasonable to decrease the dosage or suspend treatment during pregnancy in those with mild hypertension defined as less than 150/100 mm Hg in the absence of comorbidities (ACOG, 2012).

Plasma levels of carvedilol average 50% higher in older adults than in young adults. Although there was no notable difference in adverse reactions in study subjects, it is advisable to monitor older patients more closely for adverse reactions such as dizziness, which places them at risk for falls (FDA, 2011g).

Safety and efficacy in children younger than 18 years of age have not been established for either drug. In a double-blind study discussed by the FDA on its pediatric exclusivity site, children ages 2 months to 17 years with chronic heart failure showed no significant effect of treatment with carvedilol on clinical outcomes after 8 months of follow-up (FDA, 2010, 2011g).

Adverse Drug Reactions

Adverse drug reactions are essentially the same as those seen with beta blockers, with the exception of fewer cardiac-related reactions (e.g., bradycardia, decreased contractility) and a lower incidence of CNS-related reactions. The risk for orthostatic hypotension is higher than with beta blockers and is related to the alpha$_1$-adrenergic blockade (FDA, 2010, 2011g). Adverse reactions to epinephrine include apprehensiveness, restlessness, tremor, anxiety, palpitations, dizziness, headache, and respiratory difficulties (FDA, 2012f).

Drug, Food, and Laboratory Test Interactions

Drug Interactions

Drug interactions are similar to those for beta blockers, with a few additions (Table 14-12). As with some of the other beta blockers, drugs that inhibit the CYP450 2D6 system increase plasma levels of carvedilol (FDA, 2010, 2011g).

Food Interactions

When carvedilol is taken with food, its rate of absorption is slowed, but the bioavailability is not affected. Taking it with food minimizes the risk for postural hypotension. Food slows the rate of absorption of labetalol but increases the absolute bioavailability. As a result, labetalol should be taken consistently with regard to food (FDA, 2010, 2011g).

Table 14–12 ▦ Drug Interactions: Combined Alpha-Beta Blockers

Drug	Interacting Drug*	Possible Effect	Implications
Carvedilol	Inhibitors of CYP450 2D6 (e.g., cimetidine, ciprofloxacin and other quinolones, quinidine, fluoxetine, paroxetine, propafenone)	Increased blood level of carvedilol	Avoid concurrent use
	Rifampin	Plasma concentration of carvedilol reduced by 70%	Avoid concurrent use
	Diphenhydramine	Inhibits metabolism of carvedilol leading to increased plasma concentrations and effects	Avoid concurrent use Warn patients related to OTC antihistamine
Labetalol	Beta agonists, theophylline	Labetalol can blunt the bronchodilator effect	A greater-than-normal dose of beta agonist may be required
	Cimetidine	Increases bioavailability of labetalol	Avoid concurrent use
Epinephrine	Cardiac glycosides or diuretics		Observe for development of cardiac arrhythmias
	Tricyclic antidepressants, monoamine oxidase inhibitors, levothyroxine, antihistamines	Effects of epinephrine potentiated	Avoid concurrent use
	Beta-adrenergic blocking drugs		Avoid concurrent use
	Alpha-adrenergic blocking agents	Vasocontriction and hypertensive effects antagonized	Avoid concurrent use
	Ergot alkaloids	Reverses the pressor effects of epinephrine	Avoid concurrent use

Source: FDA, 2010, 2011g.

Laboratory Test Interactions

The presence of a labetalol metabolite in the urine may falsely increase urinary catecholamine levels measured by a nonspecific trihydroxyindole reaction. There have also been reversible increases in serum transaminases (4% of patients) and, rarely, reversible increases in BUN. Labetalol has also produced a false-positive test for amphetamine in a patient whose urine was screened for the presence of drugs (FDA, 2010, 2011g).

Clinical Use and Dosing

Hypertension

Both carvedilol and labetalol are used to treat essential hypertension either alone or in combination with other antihypertensive agents, especially thiazide-type diuretics. Both drugs are begun at a low dose, and dosage is increased until target blood pressure is achieved (Table 14-13). Carvedilol begins at 6.25 mg twice daily. Adjustments are made at 7- to 14-day intervals, based on standing systolic blood pressure. Labetalol is initiated at 100 mg twice daily and increased in 100 mg increments every 2 to 3 days until target blood pressure is achieved (FDA, 2010, 2011g).

Congestive Heart Failure

Carvedilol has an indication for treatment of heart failure in a narrow group of patients: mild to moderate (NYHA class II or III) heart failure of ischemic or cardiomyopathic origin, in conjunction with diuretics and (ACE) inhibitors, to reduce the progression of disease and increase survival (Packer et al, 2001). Treatment is begun at one-half the hypertension dosage (3.125 mg 2 times a day), with increases at 2-week intervals. The maximum dose is based on patient weight.

Withdrawal of the Alpha-Beta Blockers

As with beta blockers, abrupt withdrawal can be life-threatening. Angina has not been observed, but withdrawal can result in MI, ventricular arrhythmias, and death. To withdraw either of these drugs, taper the dose by one-half every 4 days over a period of 1 to 2 weeks. Patients at high risk for serious consequences due to rapid withdrawal include those with angina, coronary artery disease, and migraines (FDA, 2010, 2011g).

Age

Because of the risk for orthostatic hypotension, carvedilol and labetalol drugs should be used with caution in older adults (FDA, 2010, 2011g).

Concomitant Diseases

Carvedilol may be chosen when the patient has concomitant mild to moderate heart failure. Labetalol may be chosen when the patient cannot tolerate changes in heart rate but needs beta blockade (e.g., post-MI prophylaxis) (FDA, 2010, 2011g).

Table 14–13 ⚕ **Dosage Schedule: Combined Alpha-Beta Blockers**

Drug	Indication	Form	Initial Dose	Maintenance Dose
Carvedilol	Hypertension	Tablets: 3.125 mg, 6.25 mg, 12.5 mg, 25 mg Capsules: (extended-release) 10 mg, 20 mg, 40 mg, 80 mg	6.25 mg bid; if dose is tolerated using standing systolic blood pressure (BP) measured 1 h after the dose, maintain this dose for 7–14 d	After initial dose, increase to 12.5 mg bid if needed, based on trough BP using same standing systolic BP. Maintain this dose for 7–14 d before increasing to 25 mg if needed. When increasing dose, give first larger dose at bedtime or give with food to slow or to avoid orthostatic hypotension. Full antihypertensive effect seen in 7–14 d. Maximum dose is 50 mg.
	CHF		3.125 mg bid for 2 wk	Individualize dose and closely monitor during up-titration. If initial dose is tolerated, increase to 6.25 mg bid. Dose can then be doubled every 2 wk to the highest level tolerated by the patient. Maximum dose is 25 mg bid for <85 kg; 50 mg bid for > 85 mg. Transient worsening of CHF may be treated by increasing diuretic or reducing carvedilol dose.
	LV dysfunction following MI		6.25 mg bid	Increased after 3–10 d, based on tolerability, to 12.5 mg bid, then again to target dose of 25 mg bid
	Idiopathic cardiomyopathy (Children <62.5 kg)		6.25 mg daily	Increased as needed/tolerated. Max dose 75 mg/d. Continue for at least 6–8 mo.
	Idiopathic cardiomyopathy (Adults)		0.05 mg/kg bid	Increase dose twice at 2 wk intervals to 0.1 and 0.2 mg/kg bid. Max dose: 0.4 mg/kg.
	(Children > 62.5 kg)		3.125 mg bid	Increase twice at 2 wk intervals to 6.25 mg bid and 12.5 mg bid. Max dose 25 mg bid.
Labetalol	Hypertension	Tablets: 100 mg, 200 mg, 300 mg	*Adults:* 100 mg bid alone or added to a diuretic	If target BP is not achieved in 2–3 d, increase in increments of 100 mg bid every 2–3 d. Maintenance dose is usually 200–400 mg bid. Full antihypertensive effect seen within first 1–3 h of initial dose. Maximum dose 2,400 mg/d.
			Older adults: 100 mg bid	Maintenance dose is usually 100–200 mg bid.
Epinephrine (AUVI-Q)	Emergency treatment of allergic reactions (Type I) including anaphylaxis.	Injection: 0.3mg/ 0.3 mL prefilled auto-injector Injection: 0.15mg/0.15mL prefilled auto-injector	Patients greater than or equal to 30 kg (66 lb): Auvi-Q 0.3 mg Patients 15 to 30 kg (33– 66 lb): Auvi-Q 0.15 mg Inject Auvi-Q intramuscularly or subcutaneously into the anterolateral aspect of the thigh, through clothing if necessary. Each device is a single-use injection.	More than two sequential doses of epinephrine should only be administered under direct medical supervision.

Source: FDA, 2010, 2011g.

Monitoring

Liver function tests should be performed before initiating therapy, when adjusting dosage, and at the first indication of liver dysfunction (pruritus, dark urine, persistent anorexia, jaundice, upper-right quadrant tenderness, or unexplained flu-like syndrome). If the patient has laboratory evidence of liver injury, stop the drug and do not restart it (FDA, 2010, 2011g).

Renal function tests should be performed prior to initiating therapy and at regular intervals for any patients with a concomitant disease process that may impair renal function (FDA, 2010, 2011g).

Clinical monitoring of the disease process for which the drug was prescribed is also indicated. Discussion of such monitoring for hypertension is discussed in Chapter 40.

Patient Education

Administration

The patient should take the drug exactly as prescribed, at the same time each day, even if feeling well. Doses should not be skipped or doubled. If a dose of labetalol is missed, it should be taken up to 8 hours before the next dose is due. For carvedilol, the missed dose should be taken up to 4 hours before the next dose. Abrupt withdrawal may precipitate life-threatening arrhythmias, hypertension, and myocardial ischemia (FDA, 2010, 2011g). The patient should make certain there is enough drug on hand to cover vacations and holiday periods and should wear identification describing the disease process and the medication regimen at all times.

Carvedilol should be taken with food. This slows absorption and reduces the chance of orthostatic hypotension (FDA, 2010, 2011g). It is important to caution patients not to inject epinephrine into their hands, feet, or digits due to its strong vasoconstrictive properties. Epinephrine should not be injected into a vein and injection into the buttocks may not provide relief from an anaphylactic reaction (FDA, 2012f).

While taking an alpha-beta blocker, the patient should consult with the health-care provider before taking any OTC drugs, especially cold remedies. Several ingredients common in these preparations cause drug interactions that result in hypertension and excessive bradycardia.

Adverse Reactions

Hypotensive reactions and bradycardia are the most common adverse reactions. Alpha-beta blockers may exacerbate diseases with a bronchospastic component. Teach patients to report wheezing or difficulty in breathing to the health-care provider immediately.

Dizziness and drowsiness may occur with these drugs. Patients should avoid driving or other activities that require mental alertness until their response to the drug is known (FDA, 2010, 2011g).

For diabetics, these drugs may mask the signs and symptoms of hypoglycemia and impair recovery from a hypoglycemic episode. However, they are less likely to cause this problem because neither of these drugs is beta$_1$ selective.

Because alpha-beta blockers have beta-blocking activity, they are contraindicated in the first trimester of pregnancy and must be withdrawn before delivery (FDA, 2010, 2011g). Women of childbearing age should be counseled regarding these drugs. A leading cause of nonadherence to a treatment regimen with an alpha-beta blocker is inhibition of ejaculation and impotence. If these occur, they should be reported to the health-care provider, who may change the dosage or choose a different drug to treat the disorder.

Adverse reactions associated with epinephrine include apprehensiveness, tremor, anxiety, weakness, headache, difficulty breathing, and palpitations. Fatal arrhythmias may occur as well as rapid rises in blood pressure leading to cerebral hemorrhage, especially in elderly patients (FDA, 2012f).

Lifestyle Management

Lifestyle management is the same as for beta blockers. For patients with a history of severe allergic reactions it is important to avoid the allergen and keep an epinephrine injector with them at all time.

CHOLINERGIC AGONISTS

Cholinergic agonists, also known as parasympathomimetics or muscarinic agonists, promote or mimic the action of acetylcholine (ACh). These effects may be achieved either by direct agonist effect or indirectly by preventing the breakdown of ACh by acetylcholinesterase (AChE). As with adrenergic agonists, these drugs are not organ specific; when one organ is targeted for therapeutic reasons, the drug simultaneously produces effects in other organs. The targeted organ effects become the desired drug action, and the other organ effects become the adverse drug effects.

There are three categories of drugs in this class: muscarinic agonists, cholinesterase inhibitors, and ganglionic stimulants. Each category is discussed separately. The prototypic drug among ganglionic stimulants is nicotine, which is the only drug discussed in this category.

MUSCARINIC AGONISTS

Pharmacodynamics

Muscarinic receptors are located in the eye, heart, blood vessels, lung, GI tract, urinary bladder, and sweat glands. The results of stimulation of these receptors are depicted in Table 14-1. Their activation by muscarinic agonists modifies organ function by release of ACh from PNS nerves: (1) to activate muscarinic receptors on target organs to alter organ function and (2) to activate muscarinic receptors on nerve terminals to inhibit the release of their neurotransmitters (McCance & Huether, 2014).

There are five drugs in this group, each with a different susceptibility to breakdown by cholinesterase and different degrees of action at muscarinic and nicotinic receptors. ACh (Miochol) is highly susceptible to cholinesterase and very active at both types of receptors. Carbachol (Isopto Carbachol), pilocarpine (Isopto Carpine), and bethanechol (Urecholine)

have negligible susceptibility to cholinesterase, and all three act at muscarinic receptors. Carbachol also acts at nicotinic receptors. Methacholine (Provocholine) has little susceptibility to cholinesterase and is very active at muscarinic receptors only (FDA, 2006, 2006b, 2008a, 2010a).

Muscarinic agonists are used clinically to treat glaucoma and to improve GI and urinary bladder tone. ACh lacks selectivity to target tissues and is so rapidly destroyed by cholinesterase that its half-life is too short for most clinical applications. Its use is restricted to dilation of the pupil for ophthalmic surgery. Methacholine is used only for diagnosis of bronchial airway hyper-reactivity by specialists familiar with its use for this purpose (FDA, 2008a). Neither of these drugs is discussed here.

Carbachol and pilocarpine are used to treat glaucoma and are discussed in Chapter 26. Pilocarpine comes in an oral form that can be used to increase salivary gland secretion for the management of xerostomia in patients who have undergone radiation therapy of the neck (FDA, 2006b, 2010a). This use is too restricted for discussion in this text. The only remaining drug in this category is bethanechol, and the remainder of this section discusses that drug.

Bethanechol increases the tone of the detrusor urinae muscle, and produces contractions strong enough to initiate micturation and empty the bladder. It stimulates gastric motility as well, increasing gastric tone and often restoring rhythmic peristalsis. Doses that stimulate micturation and increase peristalsis do not usually stimulate ganglia or voluntary muscles (NIH, 2012).

Pharmacokinetics

Absorption and Distribution

Bethanechol can be given orally or subcutaneously (SC). Effects appear in 30 to 90 minutes after oral administration and 5 to 15 minutes after SC administration. The effects peak in 60 minutes for the oral dose and 15 to 30 minutes for the SC dose. Duration of action is approximately 1 to 6 hours for the oral dose and 2 hours for the SC dose. The dose required to produce a therapeutic effect is significantly different by these two routes because bethanechol is a quaternary ammonium compound carrying a positive charge, which greatly impedes absorption from the GI tract. Because bethanechol is not destroyed by cholinesterase, its effects are more prolonged than those of ACh. Because of its selective nature, nicotinic symptoms of cholinergic stimulation are usually absent or minimal while the muscarinic effects are prominent (NIH, 2012).

Metabolism and Excretion

The metabolic fate and mode of excretion of bethanechol have not been elucidated. The drug does not cross the blood–brain barrier (NIH, 2012).

Pharmacotherapeutics

Precautions and Contraindications

Bethanechol is contraindicated in the presence of many diseases. It is contraindicated in peptic ulcer disease because at the usual therapeutic doses it can cause excessive secretion of gastric acid that could intensify gastric erosion and precipitate gastric bleeding and possible perforation. It is contraindicated in patients with intestinal obstruction because of its ability to increase GI peristalsis. Because of its ability to contract the bladder and increase pressure within the urinary tract, it is also contraindicated in the presence of urinary tract obstruction or weakness of the bladder wall. Stimulation of the muscarinic receptors in the lungs may result in bronchoconstriction, and therefore it is contraindicated in patients with latent or active bronchospastic disorders. Bethanechol can rarely cause hypotension and bradycardia especially when given subcutaneously. However, more typically, therapeutic doses have very little effect on heart rate, blood pressure, or peripheral circulation. It is contraindicated for patients with preexisting hypotension, bradycardia, or cardiovascular disease (NIH, 2012).

Bethanechol is also contraindicated in patients with hyperthyroidism. When initially given bethanechol, patients with hyperthyroidism react similarly to other patients by experiencing hypotension and bradycardia. However, the body reacts to the hypotension with the release of increased amounts of norepinephrine from sympathetic nerves, resulting in increased heart rate. Because the heart tissue of patients with hyperthyroidism is highly sensitive to norepinephrine levels, even small increases in the amount of norepinephrine can produce cardiac arrhythmias (NIH, 2012).

It is not known whether bethanechol can cause fetal harm when given to pregnant women or if it can affect reproductive capacity. It is Pregnancy Category C and should be used only when the benefits clearly outweigh the potential risk to the fetus. Whether bethanechol is excreted in breast milk is also unknown (NIH, 2012).

Adverse Drug Reactions

Adverse reactions are rare following oral administration, but more common after SC administration. GI, respiratory, and cardiac reactions were discussed in the Precautions and Contraindications section. Additional GI symptoms include abdominal pain, nausea, belching, and diarrhea. Other adverse reactions include increased tearing and miosis of the pupils and flushing that produces a feeling of warmth and a sensation of heat about the face (NIH, 2012).

Toxicity

Muscarinic poisoning can occur from overdosage and from ingestion of certain poisonous mushrooms. Early symptoms of poisoning are abdominal cramps, salivation, flushing, nausea, and vomiting. Atropine is the specific antidote. The preferred route of administration is SC to provide a rapid response. The recommended dose for adults is 0.6 mg repeated every 2 hours, based on clinical response. The recommended dose for children under the age of 12 is 0.01 mg/kg repeated every 2 hours, based on clinical response. The maximal single dose in children should not exceed 0.4 mg (NIH, 2012).

Drug Interactions

Additive drug interactions may occur with cholinesterase inhibitors. A critical fall in blood pressure may occur with

ganglionic blockers. Quinidine, procainamide, and older phenothiazines such as chlorpromazine and thioridazine and histamine$_1$ blockers such as diphenhydramine and promethazine all have antimuscarinic activity. As a result, these drugs may antagonize the effects of bethanechol. Avoid concurrent administration of these drugs (NIH, 2012).

Clinical Use and Dosing

Urinary Retention

Bethanechol is used in primary care for neurogenic atony of the urinary bladder with retention. Oral dosing begins at 10 to 50 mg 3 or 4 times a day. The minimum effective dose is determined by giving 5 to 10 mg initially and repeating the dose every hour until a satisfactory response occurs or 50 mg is reached. SC dosing begins with 2.5 mg. The minimum effective dose is determined by injecting 2.5 mg initially and repeating every 15 to 30 minutes until satisfactory response is obtained or adverse reactions appear, but the maximum number of doses is four. The minimum effective dose is then given 3 or 4 times a day as needed (NIH, 2012).

Patient Education

Administration

To avoid nausea and vomiting, the patient should take the drug 1 hour before or 2 hours after a meal. The SC form is intended for subcutaneous use only and should never be given intramuscularly (IM) or IV because the resultant high drug levels can cause severe toxicity, evidenced by bloody diarrhea, bradycardia, profound hypotension, and cardiovascular collapse (NIH, 2012).

Adverse Reactions

This drug may cause abdominal discomfort, salivation, sweating, or flushing. Teach the patient to notify the health-care provider if these occur. The dose may be reduced or the drug discontinued (NIH, 2012).

Dizziness or lightheadedness may occur when the patient arises from a lying or sitting position. The probable cause is hypotension. Arising slowly from a supine position and dangling the feet over the side of the bed before standing will reduce postural hypotension. No exercise in hot weather and adequate intake of noncaffeinated liquids will also reduce these problems.

Bethanechol is contraindicated in patients with asthma and other diseases with a bronchospastic component. Teach the patient to report wheezing or breathing difficulties to the health-care provider immediately (NIH, 2012).

CHOLINESTERASE INHIBITORS

This class of drugs prevents the degradation of ACh by AChE, thereby enhancing the activity of ACh at cholinergic receptors. These inhibitors act as indirect cholinergic agonists, can intensify ACh activity at all cholinergic junctions (muscarinic, ganglionic, and nicotinic), and so have a wide range of responses and adverse reactions.

There are two basic categories of cholinergic inhibitors. (1) Reversible inhibitors produce effects of moderate duration. They include ambenonium (Myletase), demecarium (Humorsol), donepezil (Aricept), galantamine (Reminyl), pyridostigmine (Mestinon), physostigmine (Antilirium), rivastigmine (Exelon), and tacrine (Cognex). (Drugs in this group that are used for clinical diagnosis or for treatment of glaucoma are not discussed in this chapter.) (2) Irreversible inhibitors are highly toxic and, although they can be split from AChE, the split takes place extremely slowly and effects exist until new cholinesterase can be generated. They contain a phosphate atom and are referred to as organophosphate cholinesterase inhibitors. Because they are highly lipid-soluble, they can be absorbed even through the skin (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008a, 2011).

Although it is not a cholinesterase inhibitor, memantine (Namenda) is used to treat Alzheimer's disease (AD). Because several of the reversible AChE inhibitors mentioned above are also used to treat Alzheimer's disease, memantine will also be discussed in this section (FDA, 2003b).

Pharmacodynamics

The reversible AChE inhibitors act as poor substrates for AChE. The process by which AChE breaks down ACh into choline and acetic acid takes place in two steps: (1) binding ACh to the active center of AChE and (2) splitting of the ACh, which regenerates free AChE. This reaction is rapid so that one molecule of AChE can break down a large amount of ACh in a relatively short time. The reversible AChE inhibitors follow this same process, except that it takes place slowly; the drug is bound to the active center of AChE for a relatively long time, preventing the regeneration of free AChE and preventing AChE from catalyzing the breakdown of more ACh. The slowing down of the inactivation of ACh results in an increased intrasynaptic concentration of ACh and intensified neural transmission at virtually all junctions where ACh is the neurotransmitter. In doses higher than the usual therapeutic doses, neostigmine and pyridostigmine can produce skeletal muscle stimulation and activation of muscarinic, ganglionic, and nicotinic receptors in the CNS. In therapeutic doses, they usually affect only muscarinic and nicotinic receptors at the myoneural junction without altering CNS function (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008, 2011).

Tacrine, donepezil, rivastigmine, and galantamine, which are used to treat AD, are designed to alter CNS function. AD is associated with profound cholinergic depletion. All of these agents increase the availability of ACh in the brain by competitively inhibiting AChE but all are structurally dissimilar (FDA, 2006a, 2008b; NIH, 2008a, 2012b).

Tacrine is an acridine AChE inhibitor. Inhibition of AChE by tacrine is short-lived. In addition, the drug has more cholinergic activity in the periphery than do the other agents and, therefore, may have more peripheral cholinergic adverse drug reactions (ADR) associated with it. It may also act as a partial agonist at muscarinic receptors by blocking reuptake of dopamine, serotonin, and norepinephrine (NIH, 2008a).

Donepezil is a piperidine-type AchE inhibitor with increased affinity for the CNS and, thus, a decreased number of peripheral ADRs. It has a longer duration of inhibitory action than tacrine (NIH, 2012b). Rivastigmine is a potent, selective inhibitor of AChE in the cortex and hippocampus. The selectivity of this drug, like donepezil, for the brain accounts for the decreased number of peripheral cholinergic ADRs. Because of its carbamate structure, after binding to the esteratic site, the drug dissociates much more slowly from AChE than does ACh. Thus, it is considered to be a pseudo-irreversible inhibitor of the enzyme. This action also helps explain why that enzyme is inhibited for a much longer time frame than the plasma half-life would suggest (FDA, 2006a).

Galantamine is a natural tertiary alkaloid that reversibly inhibits AChE. Some evidence suggests that along with the AChE inhibition, the drug may enhance the effect of ACh on nicotinic receptors by binding at an allosteric site. Whether this effect results in increased clinical efficacy has not been demonstrated. Because these agents work to increase levels of ACh released from cholinergic neurons, as AD progresses and the patient has fewer functional cholinergic neurons, these drugs may have less effect (FDA, 2008b).

Persistent stimulation of the N-methyl-D-aspartate (NMDA) receptors by the excitatory amino acid glutamate may contribute to the symptomatology of AD. Memantine is a low to moderate, noncompetitive antagonist at NMDA receptors. It binds preferentially to the receptor-operated cation channels. The drug has low to negligible affinity for gamma-aminobutyric acid (GABA), benzodiazpine, dopamine, adrenergic, histamine, and glycine receptors. It does show antagonistic effects at the 5-HT3 (serotonin) receptor and blocks nicotinic ACh receptors, but with less potency. It does not effect the inhibition of AChE by donepezil, galantamine, or tacrine (FDA, 2003b).

Pharmacokinetics

Absorption and Distribution

Each of the AChE inhibitors differs in its pharmacokinetics (Table 14-14). Neostigmine and pyridostigmine carry a positive charge. This charge results in poor absorption from the GI tract. Oral doses must be much greater than SC doses to produce a therapeutic effect. Once absorbed, these drugs distribute to sites of action in the myoneural junction and at peripheral muscarinic receptors; they have limited ability to

Table 14–14 ▐ Pharmacokinetics: Selected Acetylcholinesterase Inhibitors

Drug	Onset	Peak	Duration	Protein Binding (%)	Bioavailability	Half-Life	Elimination
Donepezil	Within 6 wk*	4 h	24 h	94–96	100%	60–100 h	57% in urine; 15% in feces
Galantamine	Within 6 wk*	1 h; delayed 90 min by food	UK	18	90%	7 h	95% in urine; 5% in feces
Memantine	Within 6 wk*	3–7 h	UK	45	UK	60–80 h	82% unchanged in urine. Urine pH increase decreases elimination.
Memantine XR	Within 6 wk	9–12 h (even if capsule is opened to sprinkle on food)	UK	45	UK	60-80h	48% unchanged in urine; remainder in 3 plasma metabolites.
Neostigmine	45–75 min	UK	2–4 h	15–25	1%–2%	40–60 min	By enzymatic degradation
Pyrido-stigmine PO	30–35 min	UK	3–6 h	UK	11%–17%	3.7 h	By enzymatic degradation
Pyrido-stigmine SR	30–60 min	UK	6–12 h	UK	UK	3.7 h	By enzymatic degradation
Rivastigmine	Within 6 wk*	1 h; delayed 90 min by food	UK	40	36%	1.5 h	97% in urine as metabolites
Tacrine	Within 6 wk*	1–2 h	4–8 h	55	5%–30%; food reduces BA by 30%–40%	2–4 h	1% as unchanged drug in urine

Source: FDA, 1982, 2001, 2008b, 2011e; NIH, 2008a, 2011.

UK = unknown.

*Observable reduction in clinical symptoms.

cross the blood–brain barrier (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008, 2011).

Tacrine is rapidly absorbed following oral administration but then undergoes extensive first-pass metabolism, resulting in an absolute bioavailibility of 5% to 30%. Absorption is significantly reduced when the drug is taken with food, and a 30% to 40% decrease in bioavailability results; therefore, it should be given on an empty stomach. Because it is lipid-soluble, it crosses the blood–brain barrier. Its drug concentration is highest in the brain. Women tend to have concentrations that are 50% higher than those of men, even when they take the same dose (NIH, 2008a).

Food has no effect on the absorption of donepezil; the disintegrating tablets and the solution are bioequivalent to its regular tablets. Total galantamine absorption is also not affected by food, but C_{max} is decreased by 25% and T_{max} is delayed 90 minutes when the drug is taken with food. Both donepezil and galantamine are well absorbed following oral administration, with a bioavailability of greater than or equal to 90%. Unlike tacrine, donepezil is concentrated in the CNS, with very little peripheral activity. Both drugs exhibit linear pharmacokinetics (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008a, 2011).

Rivastigmine is completely absorbed following oral administration; however, its bioavailability is only 36%, indicating a significant first-pass effect. When taken with food, the absorption of rivastigmine is delayed and C_{max} is decreased by 30%. However, the AUC increases by about 30%. Thus this drug should be taken with food to maximize bioavailability. It also has nonlinear pharmacokinetics; doubling the dose from 3 to 6 mg twice daily results in a 3-fold increase in AUC (FDA, 2006a).

Memantine is highly absorbed following oral administration. Food has no effect on absorption. It has linear pharmacokinetics over the dosage range of the original formulation (FDA, 2003b).

Metabolism and Excretion

Neostigmine and pyridostigmine are degraded by AChE and metabolized by hepatic microsomal enzymes to inactive products, but only to a small extent. Both drugs are eliminated largely as unchanged drug in the urine: for neostigmine 50% to 70% of the dose is unchanged; pyridostigmine is mainly eliminated unchanged. Both drugs will potentially require dosing adjustment in renal impairment (NIH, 2011; FDA, 2001).

Tacrine is extensively metabolized by CYP 1A2 isoenzymes in the liver. The higher concentrations of drug in women may be related to decreased CYP 1A2 isoenzyme activity in women. Cigarette smoking also reduces this isoenzyme; smokers have higher drug concentrations than nonsmokers. The relatively high first-pass effect in the metabolism of tacrine is dependent on the dose administered. The CYP 1A1 system can be saturated at low doses. Once in the plasma, elimination is not dose-dependent. Although studies in patients with liver disease have not been done, it is reasonable to expect that hepatic dysfunction reduces

clearance of this drug. Dosing of this drug does not require adjustment in elderly patients or in patients with renal impairment (NIH, 2008a).

Donepezil is extensively metabolized by CYP 2D6 and 3A4 isoenzyme systems in the liver to two active and two less active metabolites. Approximately 57% of it is excreted in the urine and 15% in feces. Hepatic impairment has been shown to decrease clearance by 20%. Dosing of this drug does not require adjustment in elderly patients or in patients with renal impairment (NIH, 2012b).

Galantamine is extensively metabolized by CYP 2D6 and 3A4 isoenzymes. Approximately 20% of the dose is excreted as unchanged drug in the urine. Total renal elimination is 95%, with 5% eliminated in feces. Approximately 7% of the population has a genetic variation that leads to reduced levels of activity of CYP 2D6. However, there are no AUC changes seen in these individuals and no dosage adjustments are required. Galantamine clearance is decreased by about 25% in patients with moderate hepatic impairment, and these patients, as well as those with moderate renal impairment, probably should not have a dosage exceeding 16 mg/d (FDA, 2008b).

Rivastigmine is rapidly and extensively metabolized primarily by cholinesterase-mediated hydrolysis to one active metabolite. Evidence suggests that there is minimal involvement of the CYP450 system. Most of the drug is excreted as its metabolite in the urine. Moderate renal impairment reduces clearance by 64%, and moderate hepatic impairment reduces it by 60%. Dosage adjustment is not required in either scenario because the drug is usually titrated to tolerability. Nicotine use increases the clearance of this drug (FDA, 2006a).

Memantine undergoes little metabolism with the majority (57% to 82%) of an administered dose excreted unchanged in the urine. The remainder is converted primarily to three polar metabolites that possess minimal *N*-methyl-D-aspartate (NMDA) receptor antagonism. The CYP450 enzymes system does not play a significant role in its metabolism. Renal clearance involves active tubular secretion moderated by a pH-dependent tubular reabsorption. Although data on the effect of renal impairment are limited, based on its renal excretion, it is very likely that patients with moderate to severe renal impairment will have higher levels of the drug (FDA, 2003b).

Pharmacotherapeutics
Precautions and Contraindications

The only absolute contraindications for neostigmine and pyridostigmine are mechanical intestinal and urinary obstruction. The reasons are the same as those given for bethanechol. A relative contraindication is a history of reaction to bromides. Neostigmine and pyridostigmine are Pregnancy Category C because they may cause uterine irritability, and neonates may display muscular weakness. Use these drugs only when clearly needed and the benefits clearly outweigh the risks to the fetus. Neostigmine is ionized at physiological pH and is not expected to be excreted in breast milk. Pyridostigmine is excreted in breast milk and should not be used by breastfeeding

women. Safety and efficacy have not been established for children (FDA, 2001; NIH, 2011).

Tacrine has been associated with hepatotoxicity. It is contraindicated for patients who have previously been treated with the drug and developed jaundice and for patients with abnormal transaminase levels or clinical jaundice with a serum bilirubin above 3 mg/dL. Patients who are unwilling or unable to avoid drinking alcohol should also not have this drug prescribed because concurrent use may have additive toxic effects on the liver. Unlike tacrine, donepezil, galantamine, and rivastigmine are not associated with hepatotoxicity. Memantine has been temporally associated with hepatic failure, but data are insufficient to document causality (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008a, 2011).

Both tacrine and donepezil are Pregnancy Category C. There are no data to support findings that either of these drugs causes harm to the fetus. Safety has not been established in pregnancy. For rivastigmine, animal studies did not demonstrate teratogenicity with doses 2 to 4 times the maximal dose used in humans. Animal studies also showed that at doses 3 to 6 times the amount used for treatment, galantamine caused a slight delay in fetal development and some skeletal variations. Both rivastigmine and galantamine are Pregnancy Category B. Memantine is Pregnancy Category B because no adequate and well-controlled studies in pregnant women have been conducted (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008a, 2011).

Drug clearance of rivastigmine and galantamine decreases in the presence of hepatic impairment and renal impairment. However, recommendations for both these drugs are to titrate to response and tolerability rather than specific dose recommendations. Administration of galantamine to patients with severe hepatic impairment or CrCl less than 9 mL/min is not recommended. In patients with renal impairment, no dosage adjustments are recommended for donepezil or tacrine. However, in patients with hepatic impairment donepezil should be titrated to response and tolerability, and tacrine should be discontinued when the transaminase levels are greater than 5 times the upper limit of normal (ULN) (FDA, 2006a, 2008b).

Because memantine undergoes little metabolism, no dosing adjustment is required in patients with hepatic impairment. No dosing adjustment is required in mild to moderate renal impairment, but with CrCl between 5 and 29 mL/min, the dosage should not exceed 14 mg. There are no specific recommendations for CrCl less than 5 mL/min (FDA, 2003b).

Cholinergic agonists are thought to have some potential to cause generalized seizures. Tacrine is also contraindicated for patients with a history of stroke, subdural hematoma, hydrocephalus, or CNS tumor because they are at increased risk for this adverse reaction (NIH, 2008a).

Cholinergic agonists and cholinesterase inhibitors tend to increase gastric acid secretion because of increased cholinergic activity. Monitor patients closely for indications of active or occult GI bleeding, especially patients at increased risk for developing ulcers (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008, 2011).

All of these drugs should be used with caution for patients with a history of bronchospastic disorders, peptic ulcer disease, cardiovascular diseases that may worsen in the presence of hypotension or bradycardia, and hyperthyroidism. The reasons are the same as for muscarinic agonists and are based on the increased activity of ACh (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008, 2011).

Adverse Drug Reactions

Each of these drugs differs in adverse reactions; however, all except memantine are associated with the adverse reactions common to all cholinergic agonists. (See precautions above.) In addition, muscle weakness, fasciculations, cramps, and spasms have been noted. Memantine has been associated with syncope, bradycardia, and hypotension; vertigo and ataxia; dyspnea and bronchospasm; and emotional lability and paranoid reactions in a small percentage of patients (FDA, 1982, 2001, 2003b, 2008b, 2011e; NIH, 2008, 2011).

Donepezil, galantamine, and rivastigmine are well tolerated, with few adverse reactions. The most common are headache, nausea, diarrhea, and insomnia. Patients with a history of frequent GI complaints may be prone to recurrence of these problems while taking these drugs. Because of their effects on the SA and AV nodes of the heart, bradycardia has been observed. As with tacrine, cholinergic-associated adverse reactions are usually dose-dependent and can be treated by temporarily reducing the dose or by taking the drug with meals, although the latter reduces bioavailability (FDA, 2006a, 2008b; NIH, 2012b).

Toxicity

The warning signs of overdose are very similar to common adverse reactions, and there is a narrow margin between the first appearance of adverse reactions and serious toxic effects. Adverse reactions such as excessive GI stimulation, excessive salivation, miosis, and fasciculations of voluntary muscles should be reported to the health-care provider immediately, and the drug will be temporarily discontinued. Atropine 0.5 to 1 mg IV may be required (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008, 2011).

Hepatotoxicity

Tacrine has been associated with hepatotoxicity and it has been demonstrated that metabolites of tacrine are cytotoxic. A significant number of patients develop elevated serum transaminases (aspartate transaminase [AST] and alanine aminotransferase [ALT]). If the drug is promptly withdrawn, clinical evidence of liver injury is rare. To prevent liver injury in patients on this drug, monitor their liver function frequently. This topic is discussed in the Monitoring section (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008a, 2011).

Drug Interactions

Synergistic effects occur between these drugs and other cholinergic agonists. Antagonistic effects occur with anticholinergic drugs. Neostigmine and pyridostigmine have increased risks for neuromuscular blockade with aminoglycoside antibiotics and succinylcholine. With the latter drug, respiratory support

may be needed. These combinations should be avoided. Atropine and belladonna derivatives suppress many of the early warning symptoms of neostigmine and pyridostigmine overdose and toxicity. Given the narrow margin between therapeutic dose and overdose, this increased risk is unacceptable, and these drugs should not be given together. Corticosteroids and magnesium also interact with these drugs (FDA, 1982, 2001, 2008b, 2011e; NIH, 2008, 2011). Their interactions are presented in Table 14-15.

Many drug interactions for donepezil, galantamine, and tacrine occur because they undergo significant metabolism by the CYP enzyme systems of the liver. Any drug metabolized by the CYP 1A2 isoenzymes has interactions with tacrine, and those metabolized by 2D6 and 3A4 have interactions with donepezil and galantamine. The number of drugs metabolized by the 1A2 isoenzymes is relatively small, but the number metabolized by 2D6 and 3A4 is large. To date, these drug interactions have largely been in vitro and

Table 14–15 ▦ Drug Interactions: Selected Acetylcholinesterase Inhibitors

Drug	Interacting Drug	Possible Effect	Implications
Donepezil	Anticholinergics	Donepezil antagonizes activity of anticholinergics	Avoid concurrent administration
	Bethanechol, succinylcholine	Synergistic cholinergic activity	Reduce bethanechol dose if they must be given concurrently
	NSAIDs	Donepezil increases gastric acid secretion	Monitor for active or occult bleeding
	Furosemide, digoxin, warfarin	At concentrations of 0.3–10 mg/mL did not affect binding of these drugs	
	Ketoconazole, quinidine, other drugs metabolized by CYP450 2D6 and 3A4 isoenzymes	Potentially inhibit donepezil metabolism	Choose alternative "azole" or antiarrhythmic
	CYP2D6 and 3A4 inducers: carbamazepine, dexamethasone, phenobarbital, phenytoin, rifampin	Potentially increase rate of elimination	Avoid concurrent administration
Galantamine	Succinylcholine, bethanechol	Synergistic effect when combined	Memantine does not have this effect
	Cimetidine	Increased bioavailability of galantamine by 16%	Ranitidine does not have this effect
	Ketoconazole	Increased galantamine AUC by 30%	Select different antifungal
	Paroxetine	Increased bioavailability of galantamine by 40%	Avoid concurrent use
	Erythromycin	Increased galantamine AUC by 10%	Select different antibiotic
	Other inhibitors of CYP3A4: amitriptyline, fluoxetine, fluvoxamine, quinidine	Clearance of galantamine decreased by 25%–33%	Select different antidepressant or antiarrhythmic
	NSAIDs	Galantamine increases gastric acid secretion	Monitor for active or occult bleeding
Memantine	Amantidine, ketamine, dextromethorphan	Interaction not evaluated, but also NMDA antagonists	Use with caution
	Hydrochlorothiazide, cimetidine, ranitidine, quinidine, nicotine, triamterene	Potential altered plasma levels of both drugs since both use same renal cationic system for elimination	Avoid concurrent use or monitor for increased drug effects
	Drugs, diet, and clinical states that make urine alkaline	Clearance of memantine reduced by 80% under alkaline urine concentrations at pH 8. Can lead to accumulation of drug with increased adverse effects.	Use memantine with caution under these conditions
Neostigmine, pyridostigmine	Succinylcholine	Increase neuromuscular blocking; prolonged respiratory depression with extended periods of apnea	Provide respiratory support as needed or avoid concurrent use

Table 14–15 ▦ **Drug Interactions: Selected Acetylcholinesterase Inhibitors—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
	Aminoglycoside antibiotics	Aminoglycosides have mild but definite nondepolarizing blocking action that may accentuate neuromuscular block	Choose different antibiotic or monitor closely for increased blockade
	Local and general anesthetics, antiarrhythmics	Decreased effects of neostigmine	Increase dose of neostigmine while patient is taking these drugs
	Atropine, belladonna derivatives	Suppress muscarinic symptoms of excessive GI stimulation, leaving only more serious symptoms of fasciculation and paralysis of voluntary muscles as signs of overdose	Avoid concurrent use. Margin of safety is already quite narrow, and this makes it narrower.
Corticosteroids	Decrease anti-AChE effects of neostigmine or pyridostigmine. Anti-AChE effects may increase after stopping steroids.	Avoid concurrent use or provide respiratory support as needed. Monitor respiratory status closely after stopping steroid.	
	Magnesium	Has direct depressant effect on skeletal muscle; may antagonize beneficial effects of neostigmine or pyridostigmine	Avoid concurrent use
	Methocarbamol	A single case report indicates this drug may impair effect of pyridostigmine	Only one case report. Monitor for possible effect.
Rivastigmine	No drug interactions based on no CYP450 activity		
	Anticholinergics	Rivastigmine may interfere with their activity	Avoid concurrent use. (See note below related to tacrine.)
	Cholinomimetics and other cholinesterase inhibitors	Synergistic effects	Avoid concurrent use
Tacrine	All drugs metabolized by CYP450 1A2 isoenzymes	May inhibit metabolism of tacrine	Avoid concurrent use, or monitor effects and adjust doses as needed
	Anticholinergics	Tacrine interferes with anticholinergic activity	Monitor for anticholinergic activity if they must be given together. *Note*: Many drugs have anticholinergic-like effects even if not anticholinergic drugs. These should also be watched.
	Cimetidine	Increases the peak plasma level of tacrine by 54% and the AUC by 64%	Choose different histamine$_2$ blocker
	Bethanechol, succinylcholine	Synergistic effects. Can cause bladder outlet obstruction	Avoid concurrent use
	Theophylline	Coadministration doubles theophylline elimination half-life and average plasma level	Monitor plasma theophylline levels and reduce theophylline dose if they must be given together
	NSAIDs	Increased risk for GI bleed	Monitor for occult bleeding with serial stool guaiac tests and hemoglobin determinations. May need to take antacids while on tacrine therapy.

Source: FDA, 1982, 2001, 2008b, 2011e; NIH, 2008, 2011.

AUC = area under curve.

theoretical, but as these drugs are prescribed for larger numbers of patients, the interactions are likely to occur. Donepezil does not interact with furosemide, digoxin, and warfarin, drugs often prescribed for older adults who are also likely candidates for donepezil. The bioavailability of galantamine increases when given with erythromycin due to inhibition of CYP 3A4 by erythromycin. Because of its inhibition of both CYP 3A4 and 2D6, paroxetine increases the AUC of galantamine. Cimetidine increases the bioavailability of galantamine, but ranitidine does not (FDA, 2008b; NIH, 2008a, 2012b).

Memantine interacts with other NMDA receptor antagonists such as amantadine, ketamine, and dextromethorphan. Drugs that make urine alkaline reduce renal clearance of this drug and many drugs that use the same renal cation exchange system also interact with this drug to decrease its renal clearance (FDA, 2003b).

Clinical Use and Dosing

Myasthenia Gravis

Neostigmine and pyridostigmine are used to treat myasthenia gravis. In this disorder, an autoimmune process occurs in which the patient's immune system produces antibodies directed against nicotinic receptors on skeletal muscle, reducing the number of receptors by 70% to 90%, resulting in muscle weakness. Reversible cholinesterase inhibitors are the mainstay of treatment, preventing ACh inactivation and intensifying the effects of ACh on motor neurons. These drugs do not cure the disorder, but manage its symptoms; treatment is lifelong (FDA, 2001; NIH, 2011).

Establishing an optimal dose for treatment can be a challenge because these drugs produce widespread effects, not just at selected target organs. A small initial dose is administered, followed by other small doses until an optimal dose is reached. Signs of improvement that indicate optimal dosage include improved ability to swallow and to raise the eyelids (FDA, 2001; NIH, 2011).

The initial adult dose of neostigmine is usually 15 mg/day, and for children it is 2 mg/kg daily in divided doses given every 3 to 4 hours. The interval between dose increases is highly individualized. The average adult dose is 150 mg/day, but the maximum dose may approach 375 mg/day. Larger portions of the daily dose may be given 30 to 60 minutes prior to activities that produce greater fatigue, such as eating or shopping. For pyridostigmine, the initial adult dose is 60 mg/day, and for children it is 7 mg/kg divided into five or six doses daily (Armstrong & Schumann, 2003). Sustained-release tablets are available that require once- or twice-daily dosing. Regular tablets or syrup may be administered with extended-release tablets for optimal control of symptoms. Both of these drugs can be given parenterally if the patient has difficulty swallowing, but it is important to remember that, because of their first-pass effects, oral doses are 30 to 40 times greater than parenteral doses (FDA, 2001; NIH, 2011).

Reversal of Nonpolarizing Neuromuscular Blockade

By producing increased ACh at the myoneural junction, neostigmine and pyridostigmine can reverse the effects of nondepolarizing blocking agents. They cannot be used to counter the effects of succinylcholine because it is a depolarizing neuromuscular blocker. The most common application of this role is immediately post-operative and is determined by the anesthesiologist. Because it would probably not be used in primary care or by a nurse practitioner, this use is not discussed further.

Alzheimer's Disease (AD)

This disease is associated with a significant deficiency in brain levels of choline acetyltransferase, the enzyme responsible for the synthesis of ACh. In addition, cholinergic neurons in the brain's basal ganglia degenerate, resulting in a loss of cholinergic input to the muscarinic receptors in the frontal and temporal lobes of the cerebral cortex (Lai et al, 2001; Minger et al, 2000). Enhancing cholinergic activity with drugs is designed to counteract the decreased stimulation of the remaining cholinergic neurons. Donepezil, galantamine, rivastigmine, and tacrine are all used to treat AD by preventing the degradation of ACh by AChE. Another mechanism thought to contribute to AD symptoms is persistent stimulation of NMDA receptors by glutamate. Memantine relieves symptoms by blocking this stimulation (FDA, 2003b, 2006a, 2008b; NIH, 2008a, 2012b).

Tacrine is a centrally active, noncompetitive, reversible AChE inhibitor. Approximately 30% to 40% of AD patients who were able to complete their drug trials demonstrated modest improvement in cognitive and functional measures. Unfortunately, these improvements were not noted to last longer than 30 weeks, and many patients did not complete the trials because of the adverse reactions associated with this drug. The response was dose-related, and adverse reactions increase as the dose increases (NIH, 2008a).

Dosing of tacrine usually begins with 10 mg given 4 times daily between meals. Taking the drug with meals makes it more tolerable, but the bioavailability is decreased by 30% to 40%, requiring higher doses for the same effect. Doses are increased at 6-week intervals, based on liver function studies, to a maximum of 160 mg/day. The monitoring requirements are discussed later. An adequate response is defined as the lack of apparent disease progression for 6 months. It requires at least 8 weeks at doses greater than 120 mg/day. The highest-tolerated dose is the most efficacious (NIH, 2008a).

Tacrine was the first drug to show some success in treating AD. Because it has many adverse reactions and requires extensive monitoring because of its hepatotoxicity, tacrine is currently the least used of the drugs to treat AD (NIH, 2008a).

Donepezil is a piperidine-based derivative dissimilar from other AChE inhibitors in its pharmacokinetics and tolerability. It is also a centrally active, noncompetitive, reversible AChE inhibitor, but its duration of inhibitory action is longer than tacrine's. This longer duration of action permits once-daily dosing, which is a major advantage for this drug. Another advantage is its better adverse reactions profile. The most problematic adverse reaction is digestive complaints. This may require dosage reduction (NIH, 2012b).

Clinical trials (Pratt, 2002; Salloway, Pratt, & Perdomo, 2003; Winblad et al, 2001) showed improvement in cognitive function for as long as 2 years, but after this period there were indications that the drug did not prevent further long-term disease progression. The improvement was dose-related, and adverse reactions also increased with the increased dose. Many patients do not have real improvement. Of concern, many others have serious side effects (Howard et al, 2012).

The mean age of patients in clinical trials was 73 years; 80% of the patients were between 65 and 84 years of age and 49% were 75 years or older. Although there was no clinically significant difference in response compared to other age groups, the most adverse reactions were reported by patients 65 to 75 years of age and younger than 65 years of age (NIH, 2012b).

The recommended starting dose of donepezil is 5 mg daily at bedtime. Doses are increased at 4- to 6-week intervals to reduce adverse reactions. The maximum dose is 10 mg daily. The higher dose should be used if tolerated because it is more efficacious, especially for severe disease. Unlike tacrine, donepezil is not likely to cause hepatotoxicity and does not require assessment of liver function in order to increase the dose or frequent monitoring of liver function throughout therapy. Patients are monitored for indications of active or occult bleeding because of the potential for anticholinesterase inhibitors to increase gastric acid secretion (NIH, 2012b).

Galantamine is administered twice daily, preferably with morning and evening meals. The initial dose is 4 mg 2 times a day. After a minimum of 4 weeks of treatment, if the drug is well tolerated, the dose may be increased to 8 mg 2 times a day. A further increase to 12 mg 2 times a day should be attempted only after a minimum of 4 weeks at the previous dose. If therapy is interrupted for several days or longer, the dose must be reinitiated at 4 mg 2 times a day and increased based on the same titration as above. The usual maintenance dose is 8 to 12 mg 2 times a day. Based on the reduced clearance seen in patients with moderate hepatic or renal impairment, the dose for these patients generally should not exceed 16 mg/d (FDA, 2008b).

Razadyne, the brand-name form of galantamine, is also available in an extended-release formulation allowing for once-daily dosing. The initial dose for this formulation is 8 mg. The dosage is increased at 4-week intervals, as with the regular formulation. The usual maintenance dose is 16 to 24 mg daily. This formulation also carries a dosage restriction for hepatic and renal impairment (FDA, 2008b).

Rivastigmine is also administered twice daily, in the morning and evening with food. The starting dose is 1.5 mg 2 times a day. If the dose is well tolerated, it may be increased to 3 mg 2 times a day after 2 weeks of treatment. Subsequent increases to 4.5 and 6 mg 2 times a day also require a 2-week interval. Treatment interrupted for several doses is reinstituted at the 1.5 mg 2 times a day dose and titrated as above. The most effective dose in clinical trials was 3 to 6 mg 2 times a day (FDA, 2006a).

For patients who have difficulty swallowing, Exelon, the brand-name formulation of rivastigmine, is available in an oral solution and in a transdermal patch (FDA, 2006a). Dosing regimens for these two forms are shown in Table 14-16.

Memantine is started at 5 mg once daily with a target dose of 20 mg daily in the original formulation. Forest Laboratory has ceased production and only has a newer XR form available at press. The starting XR dose of 7 mg is increased in 7 mg increments weekly if the prior dose is tolerated, up to a max of 28 mg/d. Dosages may need to be reduced in patients with moderate renal impairment. The drug is not recommended for patients with severe renal impairment (FDA, 2003b). When a generic form becomes available the old method of increasing 5 mg per week in divided doses up to a max of 20 mg/d would be used.

Table 14-17 shows the clinical use and dosing schedules for all of these drugs. Only uses associated with primary care are presented. Only currently available memantine XR is listed.

Rational Drug Selection

Formulation

For neostigmine and pyridostigmine, formulation is a consideration (see Table 14-16). Difficulty in swallowing is a common problem for patients with myasthenia gravis. Pyridostigmine is available in a syrup form that can be used by many patients with this problem without having to resort to an injectable form. In addition, the syrup can be used for children to administer their individualized doses based on body weight (FDA, 2001; NIH, 2011).

For patients with Alzheimer's disease, rivastigmine has an oral-solution dosing formulation that permits it to be taken directly from the syringe or mixed with juice or water for those who have difficulty in swallowing tablets. Once mixed, the drug is stable for 4 or fewer hours. Rivastigmine is also available in a transdermal patch. Donepezil is available in an oral solution and in orally disintegrating tablets. Galantamine and memantine are also available in an oral solution (FDA, 2003b, 2006a, 2008b; NIH, 2008, 2012b).

Dosing Schedule

The dosing schedules of neostigmine and pyridostigmine are similar. Those of the drugs used to treat Alzheimer's disease are quite different. Donepezil has a once-daily dosing regimen. Galantamine, rivastigmine, and memantine are all 2 times a day doses, but galantamine is available in extended-release capsules that are dosed once daily. Rivastigmine can also be dosed once daily in the transdermal patch form. Tacrine requires four daily doses and is most effective on an empty stomach, which results in the doses being adjusted for meals. For patients who are older adults and who have a disease process that includes memory problems, or for patients whose caregivers are also older adults, this complex regimen may present adherence problems (FDA, 2003b, 2006a, 2008b; NIH, 2008a, 2012b). If there is no evidence of positive effect in six months, or when the patient

Table 14–16 ⊗ Dosage Schedule: Acetylcholinesterase Inhibitors

Drug	Indication	Form	Initial Dose	Maintenance Dose
Donepezil	AD	Tablets: 5 mg, 10 mg Orally disintegrating tablets: 5 mg, 10 mg Oral solution: 1 mg/mL	5 mg daily at bedtime for 4–6 wk	May increase to 10 mg daily after 4–6 wk. The higher dose should be used if tolerated because it is more efficacious, especially for severe AD.
Galantamine (G) (Razadyne) (B)	AD	Tablets: 4 mg, 8 mg, 12 mg Capsules (extended-release): 8 mg, 16 mg, 24 mg	4 mg twice daily with morning and evening meals	Increase dose to 8 mg twice daily after 4 wk of therapy if drug well tolerated. Titration to 12 mg twice daily only after another 4-wk interval. Maintenance dose 8–12 mg bid. If therapy interrupted for several days or longer, reinitiate at 4 mg and follow same titration. Dose should not exceed 16 mg/d for patients with moderate renal or hepatic impairment.
(Razadyne) ER (B)		Oral solution: 4 mg/mL	8 mg once daily in the morning	Increase to 16 mg daily after minimum of 4 wk. May increase to 24 mg daily after another 4-wk interval. Maintenance dose 16–24 mg daily. See above for renal and hepatic impairment.
Memantine	AD	Tablets: 5 and 10 mg	5 mg once daily	Target dose is 20 mg daily. Titrate up in 5 mg increments/d if prior dose tolerated. Use one week dose increases rate in divided doses
Memantine (NamendaXR only available at press)	AD	Tablets: 7, 14, 21 and 28mg, Oral solution: 2 mg/mL	7 mg once daily	Target dose is 28 mg daily. Titrate up in 7 mg increments/d if prior dose tolerated. Minimal interval for titration is 1 wk. Dosages may need to be reduced if moderate renal impairment. Not recommended for severe renal impairment.
Non-FDA	Postherpetic neuralgia (adults 20–78 yr)		21 mg daily in divided doses	Max dose 55 mg/d in divided doses for up to 9 wk
Non-FDA	Prevention of migraine headaches (adults 15–78 yr)		7 mg daily	May increase to 28 mg daily. Use for at least 2 mo.
Neostigmine	Myasthenia gravis	Tablets: 15 mg	*Adults:* Oral: 15 mg/d divided and given every 3–4 h. Increase dose in 15 mg increments at daily intervals until optimal response is achieved.	Usual dose is 150 mg/d divided and given every 3–4 h. Maximum dose is 375 mg/d
			SC/IM: 0.5 mg every 2–3 h	Usually needed short-term, and dose is 5 mg every 2–3 h
			Children: Oral: 2 mg/kg/d in 6–8 divided doses	Same maintenance dose
			SC/IM: 0.01–0.04 mg/kg every 2–3 h	Usually needed short-term. Same dose.

Table 14–16 � **Dosage Schedule: Acetylcholinesterase Inhibitors—cont'd**

Drug	Indication	Form	Initial Dose	Maintenance Dose
Pyridostigmine (G) (Mestinon) (B)	Myasthenia gravis	Tablets: 60 mg Syrup: 60 mg/5 mL	*Adults:* Oral: 60 mg/d divided and given every 3–4 h. Increase dose in 60 mg increments at daily intervals until optimal dose is achieved.	Usual dose is 600 mg/d divided and given every 3–4 h. Maximum dose is 1,500 mg/d.
			IM: one-third the oral dose	
			Children: Oral: 7 mg/kg/d divided into 5–6 doses	Same maintenance dose
			IM: 0.05–0.15 mg/kg/dose every 2–3 h	Usually needed short-term. Same dose.
Mestinon ER (B)		SR tablets: 180 mg	180 mg daily	Usual dose 180–540 mg daily or bid with dosing interval of at least 6 hr
Rivastigmine (G) (Exelon) (B) Exelon oral solution (B)	AD and dementia associated with Parkinson's disease	Capsules: 1.5 mg, 3 mg, 4.5 mg, 6 mg Oral solution: 2 mg/mL Transdermal patch: 4.6 mg/24 h 9.5 mg/24 h	1.5 mg twice daily in the morning and evening with food	Increase dose to 3 mg twice daily after 2 wk, if well tolerated. Titration to 4.5 mg and 6 mg twice daily also requires 2-wk interval. If several doses missed, reinitiate at 1.5 mg and follow same titration. Most effective dose for AD is 3–6 mg twice daily; for PD is 1.5–6 mg bid.
Exelon transdermal patch		Transdermal patch: 4.6 mg/24 h 9.5 mg/24 h	Initiate with the 4.6 mg/24 h patch applied once daily	After a minimum of 4 wk, and, if well tolerated, increase to 9.5 mg/24 h patch applied once daily. If adverse reactions cause intolerance, therapy should be discontinued for several days and restarted at the next lower dose. If treatment is interrupted for longer than several days, reinitiate with the lowest daily dose.
Tacrine (Cognex)	AD	Tablets: 10 mg, 20 mg, 30 mg, 40 mg	10 mg qid between meals for 4 wk; may be given with food, but bioavailability is decreased 30%–40%	If ALT remains unchanged, increase by 40 mg/d every 4 wk up to a maximum of 40 mg qid. Usual maintenance dose is 120 mg/d. Elevated ALT requires detailed dosing adjustments.

Source: FDA, 1982, 2001, 2008b, 2011e; NIH, 2008, 2011.

ALT = alanine amino-transferase.

becomes noncommunicative, the drug should be tapered off over 4 weeks (Howard et al, 2012).

Adverse Reactions Profile

Neostigmine and pyridostigmine have similar adverse reaction profiles. Among the drugs used to treat Alzheimer's disease, tacrine and rivastigmine have the worst adverse reaction profiles and donepezil has the best (FDA, 2001, 2006a; NIH, 2008a, 2011).

Time to Recurrence of Disease Progression

Tacrine has been associated with loss of beneficial effects after about 30 weeks. Donepezil, galantamine, memantine, and rivastigmine have shown positive effects for at least 2 years

(FDA, 2001, 2006a; NIH, 2008a, 2011). There is no data to support using more than one medication together to increase effect (Howard et al., 2012).

Monitoring

Monitoring parameters for tacrine are complex and, at a minimum, continue for 9 months. Baseline liver function tests (total bilirubin, AST, and ALT) should be done prior to initiation of therapy. ALT levels, the ones most likely to indicate hepatotoxicity, should be monitored every other week for the first 16 weeks of therapy, then monthly for 2 months, and then every 3 months. If the ALT level remains less than double the upper limit of normal, then the dose may be left

Table 14–17 Pharmacokinetics: Selected Cholinergic Blockers

Drug	Onset	Peak	Duration	Half-Life	Elimination
Atropine PO	30 min	30–60 min	4–6 h	3 h	77%–94% in urine
Benztropine PO	1–2 h	Several days	6–10 h	Unknown	Unknown
Dicyclomine PO	1–2 h	60–90 min		9–10 h	80% in urine; 10% in feces
Darifenacin PO (extended-release tablets)	Unknown	7 h	Unknown	12–13 h for EM; 19 h for PM	60% in urine and 40% in feces
Fesoterodine PO (extended-release tablets)	Unknown	5 h	Unknown	7 h	70% in urine as active metabolite and 7% in feces
Propantheline	30–60 min	2–6 h	6 h	3–4 h	Inactivated in upper small intestine
Oxybutynin (tablets and syrup)	30–60 min	3–6 h	6–10 h	2–3 h	Unknown
Oxybutyin transdermal and gel	Within 24 h	36 h	3–4 d	7–8 h	<0.1% unchanged drug in urine
Oxybutynin XL	30–60 min	2–6 h	24 h	Unknown	<0.1% unchanged drug in urine
Scopolamine PO	30 min	1 h	4–6 h	8 h	Mostly metabolized by liver
Scopolamine transdermal	4 h	Unknown	72 h	9.5 h	Mostly metabolized by liver
Solifenacin PO	Unknown	3–8 h	Unknown	45–68 h	69% in urine; 23% in feces
Tolterodine	Unknown	1–2 h	12 h	1.9–3.7 h	77% in urine; 17% in feces
Tolterodine (LA)	Unknown	2–6 h	24 h	2.9–3.1 h	77% in urine; 17% in feces
Trihexyphenidyl	1 h	2–3 h	6–12 h	5.6–10.2 h	In urine
Trospium PO	Unknown	5–6 h	Unknown	20 h	85% in feces; 5.8% in urine. Active tubular secretion is a major factor in renal excretion.

Source: FDA, 2001a; NIH, 2006, 2008b, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g.

   EM = extensive metabolizers and PM = poor metabolizers.

unchanged or titrated upward as needed. If the ALT level is more than double the upper limit of normal, weekly monitoring of liver function is required. If the ALT level is 3 to 5 times the upper limit of normal, then weekly monitoring of liver function is required and the dose must be decreased by 40 mg/day. If the ALT level returns to the normal range with the reduced dose, then monitoring of ALT levels every other week is sufficient. Treatment is discontinued if the ALT concentration is more than 5 times the upper limit of normal (FDA, 2001, 2006a; NIH, 2008a, 2011).

Donepezil requires routine monitoring of blood chemistries and hematology. Baseline liver function studies seem advisable for galantamine and rivastigmine, but they are not required. Assessment of renal function is advisable for galantamine and memantine; dosage adjustments are based on renal function. Neostigmine and pyridostigmine do not have monitoring parameters beyond those of the disease process they are used to treat (FDA, 2001, 2006a; NIH, 2008, 2011).

Patient Education

Administration

Administration education differs for the two groups of drugs. All of the drugs should be taken exactly as prescribed. Doses should not be skipped or doubled up.

For neostigmine and pyridostigmine, patients may need to set a backup alarm to remind them to take a dose when the doses are every 3 to 4 hours. Taking the dose late may cause myasthenic crisis, and taking it early may result in cholinergic crisis. Because drug therapy is lifelong, it is important to establish a regimen that the patient can follow over time (FDA, 2011; NIH, 2011).

For donepezil, missed doses should be skipped and the schedule resumed the next day. Missed doses of galantamine, rivastigmine, and memantine should be skipped and the next dose taken as scheduled. Patients taking tacrine should deal with missed doses by taking them as soon as possible unless it is within 2 hours of the next dose. For all of these drugs,

increasing the dose may not improve the symptoms, but it does increase the risk for adverse reactions. Abruptly discontinuing the drug may cause a decline in cognitive function (FDA, 2001, 2006a; NIH, 2008a, 2011).

Donepezil is available as a liquid preparation and as orally disintegrating tablets. Donepezil orally disintegrating tablets should be allowed to dissolve on the tongue and then followed with water (NIH, 2012b).

Rivastigmine oral solution comes with a dosing syringe kept in a protective case. Push down and twist the child-resistant closure to open the drug bottle. Insert the tip of the syringe into the opening in the white stopper. Invert the bottle and, while holding the syringe, pull the plunger out to the appropriate markings on the side of the syringe that indicates the dose. Teach the patient how to remove any large bubble from the syringe to avoid an inaccurate dose. The drug may be taken directly from the syringe or mixed in a small glass of water, cold fruit juice, or soda. Do not mix it with other liquids. The syringe should be stored in its protective case (FDA, 2006a).

Memantine and galantamine are also available in oral solutions. Both of these also have oral dosing devices (FDA, 2003b, 2008b).

The rivastigmine transdermal patch is applied once daily (24 hours apart) to a clean, dry area of skin that does not have hair. Although no recommendation is made by the drug manufacturer, it is probably advisable to rotate the site used (FDA, 2006a).

Adverse Reactions

All of these drugs have in common the adverse reactions associated with an increased amount of ACh: dizziness, miosis, lacrimation, excessive secretions in the respiratory and GI tracts, bronchospasm, bradycardia, abdominal cramps, nausea, vomiting, diarrhea, and excessive salivation. Because they have fewer peripheral effects, drugs used to treat Alzheimer's disease have fewer of the peripheral adverse reactions and more of those associated with the CNS. Patients and their caregivers should observe safety precautions related to the dizziness (FDA, 2001, 2006a; NIH, 2008, 2011).

Administration of neostigmine or pyridostigmine with food or milk helps to minimize adverse GI reactions. Patients with myasthenia gravis often have difficulty with swallowing. Sustained-release tablets must be swallowed whole. Immediate-release tablets may be crushed, and syrup forms of pyridostigmine are available to facilitate administration in this situation. The mottled appearance of the sustained-release form of pyridostigmine does not affect its potency (FDA, 2001; NIH, 2011).

Administration with food may reduce GI complaints for donepezil and does not affect its bioavailability. Although tacrine can also be administered with food, this decreases its bioavailability by 30% to 40% and may necessitate increased dosage. However, higher doses are associated with increased risk for adverse reactions. For patients with difficulty in swallowing, tacrine capsules can be dissolved in any aqueous solution. Orange juice masks the bitter taste best. Memantine and

galantamine can be administered without regard to food. Rivastigmine should be given with food (FDA, 2001; NIH, 2011).

Tacrine has adverse reactions associated with hepatotoxicity. Patients who experience jaundice, rash, or fever should contact the health-care provider immediately. The drug will be discontinued (NIH, 2008a).

Lifestyle Management

No specific lifestyle modifications are directly related to these drugs. Patients with myasthenia gravis should at all times wear identification describing the disease and the medication regimen.

CHOLINERGIC BLOCKERS

Cholinergic blockers are also referred to as parasympatholytics, muscarinic antagonists, and anticholinergics. The term *anticholinergic* can be deceiving because it implies blockade of all cholinergic receptors. In reality, cholinergic blockers produce selective muscarinic blockade against the actions of ACh. Because muscarinic receptors are found in many organs of the body (the eye, heart, blood vessels, lung, GI tract, urinary bladder, and sweat glands), and these drugs cannot be targeted at a single organ, they have many adverse reactions. Throughout this section, *cholinergic blocker* will be synonymous with *muscarinic blockade* unless otherwise stated.

There are several subtypes of cholinergic blockers based on the organs they are likely to target. Atropine is the prototype drug in this class and affects most muscarinic receptors. Its main use orally is as an adjunct to treatment of GI disorders. Other uses are more related to hospital-based care. Its oral use is discussed in this section. Scopolamine has actions similar to atropine except for increased CNS depression and ability to suppress motion sickness and emesis. The antispasmodic group of drugs is indicated for reduction of GI motility and urinary tract smooth muscle spasm. Ipratropium bromide (Atrovent) is used to treat acute exacerbations of asthma and other respiratory diseases such as chronic obstructive pulmonary disease (COPD). It is discussed in Chapter 17 with respiratory drugs and in Chapter 30 where the management of asthma and COPD are discussed. Mydriatic cycloplegics are used for ophthalmic procedures. This use is covered in Chapter 26. Centrally acting cholinergic blockers are used to treat Parkinson's disease and to counteract the extrapyramidal adverse reactions associated with some psychotropic drugs. They are briefly discussed here, but their uses for this indication are covered in Chapter 15.

Pharmacodynamics

Cholinergic blockers competitively block the actions of ACh at muscarinic receptors. They have no direct effect on the receptor. Their actions are based on preventing interaction of endogenous neurotransmitters from activating the receptor and thereby blocking the action associated with stimulation of these receptors. The results of the stimulation of these receptors are depicted in Table 14-1. Blockade produces

clinically significant action on the cardiovascular, respiratory, urinary, GI, and central nervous systems; on exocrine glands; and on the eye. Different drugs in the class affect these systems to differing degrees.

Cardiovascular Effects

The sinoatrial (SA) node is very sensitive to muscarinic stimulation. Because stimulation of muscarinic receptors decreases heart rate, blockade increases heart rate. In the presence of high vagal tone, muscarinic blockade can significantly reduce the PR interval of the electrocardiogram (ECG) by blocking receptors in the atrioventricular (AV) node, increasing AV node conduction and decreasing the refractory period of the AV node. The effect on contractility and automaticity is minimal because control of these is primarily via the sympathetic nervous system. Blood vessels have no direct innervation from the parasympathetic nervous system (PNS); however, PNS stimulation does dilate coronary arteries.

Respiratory Effects

Both smooth muscle and secretory glands of the respiratory tract have vagal innervation and contain muscarinic receptors. Blockade of muscarinic receptors relaxes bronchial muscle resulting in bronchodilation, whereas blockade of receptors in the bronchial glands decreases bronchial secretions (Kaufman, 2013).

Exocrine Gland Effects

Muscarinic blockade is very effective in the salivary glands, resulting in dry mouth. It is used for this purpose preoperatively, but it is an unwanted effect in patients taking these drugs for such conditions as Parkinson's disease or urinary incontinence. Gastric acid secretions are less effectively blocked. The volume and amount of acid, pepsin, and mucin are reduced. Basal secretion is more affected than stimulated secretion. Sympathetic cholinergic fibers innervate eccrine sweat glands and many of these have muscarinic receptors. Cholinergic (muscarinic) blockers suppress thermoregulatory sweating (NIH, 2012c).

Urinary and Gastrointestinal Effects

Blockade of muscarinic receptors has extensive effects on smooth muscle in the gut and the urinary system. Gastrointestinal smooth muscle is affected from the stomach to the colon. In muscarinic blockade, the visceral walls are relaxed and both tone and peristalsis are diminished. This prolongs gastric emptying time and intestinal transit time. Smooth muscle of the ureters and bladder wall is relaxed with muscarinic blockade. This action is useful in treatment of urinary tract spasms, but it can precipitate urinary retention, especially in older adult males with benign prostatic hyperplasia (NIH, 2012c).

Central Nervous System Effects

At therapeutic doses, muscarinic blockade produces mild CNS excitation. At higher doses, scopolamine, and to a lesser extent atropine, can produce agitation, hallucinations, and delirium. The relative excess of cholinergic activity in parkinsonian tremor and extrapyramidal symptoms associated with antipsychotic drugs can be partially corrected by muscarinic blockade, especially if combined with a dopamine precursor (NIH, 2012c).

Optic Effects

The papillary constrictor depends on muscarinic receptor stimulation. Blockade of muscarinic receptors results in unopposed sympathetic dilator activity, producing mydriasis. Blockade of receptors on the ciliary muscle produces cycloplegia, which results in loss of the ability to accommodate for near vision (FDA, 2012c). Both effects allow complete retinal assessments during a fundoscopic exam.

Pharmacokinetics

Absorption and Distribution

Cholinergic blockers in the belladonna alkaloid group (atropine, scopolamine) are well absorbed from the gut and cross the conjunctival membrane (Table 14-17). When applied in a suitable vehicle, scopolamine is absorbed from the skin. In contrast, only about 10% to 30% of a dose of the drugs in the quaternary group (propantheline [Probanthine]) is absorbed after oral administration because these drugs have a positive charge, which decreases their ability to move across membranes. Benztropine (Cogentin), darifenacin (Enablex), fesoterodine (Toviaz), oxybutynin (Ditropan), solifenacin (Vesicare), tolterodine (Detrol), and trihexyphenidyl (Trihexy) are all well absorbed following oral administration and oxybutynin is also well absorbed from the skin. Less than 10% of trospium (Sanctura) is absorbed following oral administration (FDA, 2001a; NIH, 2006, 2008b, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

The belladonna alkaloid group is widely distributed, with significant levels reaching the CNS within 30 to 60 minutes after administration. The quaternary group is widely distributed except to the CNS, where it is poorly taken up. The distribution of benztropine and trihexyphenidyl is not clearly known. Darifenacin (Enablex), fesoterodine (Toviaz), oxybutynin, solifenacin (VESIcare), and tolterodine are highly bound to plasma proteins and have large volumes of distribution. Trospium (Sancture, Sanctura XR) has lower protein binding (50% to 85%) (FDA, 2001a; NIH, 2006, 2008b, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Metabolism and Excretion

Both the belladonna alkaloids and the quaternary groups are metabolized mostly by the liver and excreted in urine. Oxybutynin and solifenacin are metabolized by the CYP 3A4 isoenzyme system and tolterodine is metabolized by the CYP 2D6 isoenzyme system. Darifenacin and fesoterodine are metabolized by both the 3A4 and 2D6 systems. The metabolism of trospium is not clearly known but early studies suggest that the CYP isoenzyme systems are not inhibited in clinically relevant concentrations (FDA, 2001a; NIH, 2006, 2008b, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Pharmacotherapeutics

Precautions and Contraindications

Absolute contraindications to these drugs are few and based on their effects on various body systems. Cholinergic blockers are contraindicated in glaucoma, particularly angle-closure glaucoma, because of their ability to produce mydriasis and cycloplegia, thereby impeding the flow of aqueous humor. Cautious use is necessary in obstructive disorders of the GI and urinary tracts, including bladder outlet obstruction and BPH, based on the ability of these drugs to decrease tone and motility in these systems. Patients with hypertension and tachycardia or other cardiac arrhythmias require cautious use, based on the potential for these drugs to increase heart rate (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Older adults are particularly susceptible to the CNS effects of cholinergic blockers, with an increased risk for cognitive impairment and falls. Other drugs should be chosen when possible, or cholinergic blockers should be used with caution (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

All drugs in this class except dicyclomine and oxybutynin are Pregnancy Category C. There are no well-controlled studies in pregnant women, and these drugs should be used only when potential benefits clearly outweigh the risk to the fetus. Dicyclomine and oxybutynin are Pregnancy Category B. No risk to the fetus has been shown in animal or human studies (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

The quaternary group of drugs is not widely distributed in the body and is the least problematic for lactating women. All other cholinergic blockers either have wide distribution including breast milk or their distribution is not known. They should be avoided in nursing mothers unless clearly needed (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Safety and efficacy of many of these drugs have not been established in children. Atropine has safe dosing schedules down to infants weighing 7 pounds. Oxybutynin has safe dosing schedules for children older than 6 years of age with detrusor overactivity associated with a neurological condition. Tolterodine has been shown in studies to increase aggressive, abnormal, and hyperactive behavior and attention disorders in children and should not be used in children (FDA, 2001a; NIH, 2006, 2008b, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Adverse Drug Reactions

Adverse reactions to cholinergic blockers are based on their actions on tissues other than the target tissue or organ. The discussion here focuses on the adverse reactions on each organ system.

Cardiovascular

Cholinergic blockade eliminates the parasympathetic influence on the heart, resulting in tachycardia. This action can be used therapeutically to treat patients with bradycardia below 50 bpm. The belladonna alkaloids have the highest incidence of this adverse reaction (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Respiratory

Cholinergic blockers are sometimes used to produce relaxation of bronchial smooth muscle for patients with an acute exacerbation of asthma and with COPD, but their tendency to thicken and dry bronchial secretions can result in ineffective airway clearance and make patients more at risk for respiratory infection (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Exocrine Glands

Blockade of muscarinic receptors on sweat glands can produce anhidrosis. Because sweating is necessary for cooling the body, patients are at risk for hyperthermia. The effect on salivary glands produces xerostomia (dry mouth). This can be irritating and can impair swallowing. Practicing good oral hygiene, chewing sugarless gum, and using other methods to reduce this problem should be taught to patients (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Gastrointestinal and Urinary

Decreased tone and motility in the GI tract can lead to constipation, especially when the secretory function of the intestine is also reduced. Patients are taught to increase their intake of fluids and dietary fiber. Blockade of muscarinic receptors in the urinary tract reduces contractile force and pressure in the urinary bladder and increases tone in the urinary sphincter. These combined effects produce urinary hesitancy and urinary retention and increase the risk for urinary tract infection. Impotence has also been reported (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Eye

Mydriatic and cycloplegic action of cholinergic blockers results in increased intraocular pressure, blurred vision, and photophobia (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Central Nervous System

Cholinergic blockers that cross the blood–brain barrier produce varied adverse reactions, from mild excitation to dizziness and confusion and, in the case of scopolamine, CNS depression. These adverse reactions are more common in older adults (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Drug Interactions

Many drugs that are not cholinergic blockers can produce significant muscarinic blockade. These drugs include antihistamines, disopyramide, quinidine, phenothiazine antipsychotics, and TCAs. Additive or synergistic antimuscarinic effects occur when these drugs are given with cholinergic blockers. Additive CNS depression can occur with alcohol, antidepressants, opioids, and sedative-hypnotics (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Because cholinergic blockers alter transit time through the GI tract, they may alter the absorption of any orally administered drug. For drugs with a narrow therapeutic range or drugs that can reach toxic levels if retained too long in the GI tract, concurrent administration is not recommended.

Antacids and adsorbent antidiarrheals decrease the absorption of cholinergic blockers (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Drug interactions specific to each drug are presented in Table 14-18.

Table 14–18 ▦ **Drug Interactions: Selected Cholinergic Blockers**

Drug	Interacting Drug	Possible Effect	Implications
Atropine, dicyclomine, propantheline, scopolamine	Other drugs with cholinergic blocking effects: antihistamines, disopyramide, quinidine, phenothiazines, TCAs, MAOIs	Additive cholinergic blocking adverse effects; antipsychotic effects of phenothiazines decreased	Avoid concurrent use or select drug in each category with the fewest cholinergic blocking properties. Adjust phenothiazine dose.
	Orally administered drugs	Atropine may alter absorption by slowing GI motility	Separate administration or select drugs that do not have narrow therapeutic ranges for which altered absorption would create a problem.
	Antacids	Decrease the absorption of the cholinergic blocker	Separate administration. Give cholinergic blocker first and then antacid at least 30 min later.
	Amantadine	Coadministration may result in increased cholinergic blocking adverse effects	Consider decreasing the dose of the cholinergic blocker
	Atenolol	Pharmacological effects of atenolol may be increased	Metoprolol and propranolol not affected. Substitute one of these if possible.
	Oral potassium	May increase GI mucosal lesions	Take with food and at least 8 oz water.
Benztropine, trihexyphenidyl	Other drugs with cholinergic blocking effects: antihistamines, disopyramide, quinidine, phenothiazines, TCAs	Additive cholinergic blocking adverse effects; antipsychotic effects of phenothiazines decreased	Additive cholinergic blocking adverse effects. Antipsychotic effects of phenothiazines decreased. Adjust phenothiazine dose.
	Bethanechol	Counteracts the cholinergic effects of bethanechol	Avoid concurrent use
	Antacids and antidiarrheals	May decrease absorption	Separate administration. Give cholinergic blocker first and then antacid or antidiarrheal at least 30 min later.
	Haloperidol	Worsens schizophrenic symptoms, increases risk for tardive dyskinesia, decreases blood levels of haloperidol	Avoid concurrent use for schizophrenic patients. Increase dose of haloperidol for others.*
	Levodopa	Decreased GI motility, increased deactivation of levodopa, and reduced intestinal absorption	Effectiveness of levodopa is reduced. May need to alter dose of levodopa if both must be given.
Darifenacin	Strong inhibitors of CYP3A4 (e.g., clarithromycin, azole antifungals, nefazone, and protease inhibitors) Moderate CYP3A4 inhibitors (e.g., diltiazem, erythromycin, fluconazole, verapamil) CYP2D6 substrates (e.g., felcainide, thioridazine, despiramine, imipramine) Digoxin	Darifenacin levels may be increased Mean C_{max} and AUC of interacting drug may increase Increased in digoxin levels (16%)	Dose of darifenacin should not exceed 7.5 mg when coadministered with these drugs No dosage adjustments recommended Use caution when darifenacin is given with drugs metabolized by CYP2D6 and that have a narrow therapeutic window If must coadminister, monitor digoxin levels closely

Table 14–18 ⊞ **Drug Interactions: Selected Cholinergic Blockers—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
Fesoterodine, solifenacin	CYP3A4 inhibitors (e.g., clarithromycin, erythromycin, itraconazole, ketoconazole) CYP3A4 inducers (e.g., rifampin)	Increases the active metabolite of fesoterodine Coadministration decreases C_{max} and AUC of fesoterodine by 70% and 75%, respectively	For fesoterodine doses >4 mg/d and for solifenacin doses >5 mg/d are not recommended in patients taking these inhibitors No dosing adjustments recommended at this time
Oxybutynin	CNS depressants: alcohol, antihistamines, antidepressants, opioids, sedative-hypnotics	Additive CNS depression	Avoid concurrent administration or monitor closely for CNS effects. May need to alter dosage.
	Other drugs with cholinergic blocking effects: antihistamines, disopyramide, quinidine, phenothiazines, TCAs, MAOIs	Additive cholinergic blocking adverse effects; antipsychotic effects of phenothiazines decreased	Additive cholinergic blocking adverse effects. Antipsychotic effects of phenothiazines decreased. Adjust phenothiazine dose.
	Haloperidol	Worsens schizophrenic symptoms, increases risk for tardive dyskinesia, decreases blood levels of haloperidol	Avoid concurrent use for schizophrenic patients. Increase dose of haloperidol for others.*
	Atenolol	Bioavailability of atenolol increased; increased effects	Metoprolol and propranolol not affected. Substitute one of these if possible.
	Nitrofurantoin	Increased blood levels and bioavailability of nitrofurantoin	Choose different antibiotic to treat urinary tract infection if patient already on oxybutynin
Scopolamine	Alcohol, meperidine	Additive CNS depression	Unless desired therapeutic effect, may need to alter dose of one or both
Tolterodine	Erythromycin, ketoconazole, itraconazole, miconazole	May inhibit metabolism and increase effects of tolterodine	Avoid concurrent use
Trospium	Drugs that are eliminated by active renal tubular secretion (e.g., digoxin, procainamide, morphine, vancomycin, metformin, tenofovir)	May increase the serum concentration of trospium and/or the competing drug	If must coadminister, carefully monitor for adverse effects. For digoxin, monitor drug levels carefully.

*Administration of these drugs may be a therapeutic choice with phenothiazines to reduce extrapyramidal adverse reactions associated with phenothiazines.

Clinical Use and Dosing

Parkinson's Disease

First-line management of Parkinson's disease is accomplished with dopaminergics and dopamine agonists. Cholinergic blockers are useful adjuncts early in the course of the disease to control tremor by relaxing smooth muscle and oral secretion control. They are also useful for middle-aged patients who have tremor but little rigidity or bradykinesia and for control of salivation and drooling (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Trihexyphenidyl is one cholinergic blocker currently used as an adjunct to therapy with carbidopa/levodopa. The initial dose is 1 to 2 mg the first day, increased by 2 mg increments at 3- to 5-day intervals until a total of 6 to 10 mg are given daily (Table 14-19). Many patients receive maximum benefits at this dose, but postencephalitic patients often require doses of 12 to 15 mg/day. The drug is best tolerated when the daily dose is divided into three doses and taken at mealtimes. High doses may be divided into four doses and taken at mealtimes and bedtime. Because of the relatively high dosage of sustained-release capsules, they are not used for initial therapy. Once patients have been stabilized on regular formulations, they may be switched to sustained release. Sustained-release capsules are administered in a once-daily dose after breakfast or in doses 12 hours apart (NIH, 2006).

When given concurrently with levodopa, the usual dose may need to be reduced. Conversely, trihexyphenidyl decreases the total bioavailability of levodopa. Careful adjustment of the doses of the two drugs is required, depending on adverse reactions and degree of symptom control (NIH, 2006).

Benztropine is also used for this indication. The dose is 1 to 2 mg/day with a range of 0.5 to 6 mg/day. Therapy is

Table 14–19 ⊗ Dosage Schedule: Selected Cholinergic Blockers

Drug	Indication	Form	Initial Dose	Maintenance and Maximum Dose
Atropine	Irritable bowel syndrome, peptic ulcer disease	Tablets: 400 mcg	*Adults:* 400 mg q 4–6 h	May increase to 600 mcg if needed
	(In children also used for frequent urination and bed-wetting)		*Children:* 7–16 lb = 0.1 mg; 17–24 lb = 0.15 mg 24–40 lb = 0.2 mg 40–65 lb = 0.3 mg 65–90 lb = 0.4 mg >90 lb = 0.4 mg q 4–6 h	Not to exceed 400 mcg. Use lowest effective dose.
Benztropine	Parkinson's disease	Tablets: 0.5 mg, 1 mg, 2 mg (Cogentin in 0.5 mg tablets only) Injection: 1 mg/mL	1–2 mg/d For postencephalitic patients: 2 mg/d	Increase in increments of 0.5 mg/d gradually at 5- or 6-d intervals until symptom relief. Use smallest dose that achieves effect. Maximum dose is 6 mg/d. Older adults and thin patients may not tolerate higher doses. Giving dose at bedtime is preferred.
	Drug-induced EPS		1–2 mg daily or bid PO or IM	1–2 mg PO provides relief in 1–2 d and prevents recurrence. If inadequate relief in that time, may increase to 2 mg tid. 1–2 mg IM provides rapid relief. Maximum dose by either route is 6 mg/d.
Darifenacin	For overactive bladder with symptoms of incontinence, urgency, and frequency	Tablets, extended-release:7.5 mg 15 mg	7.5 mg once daily	May increase to 15 mg once daily as early as 2 wk after starting therapy. In moderate hepatic impairment or when coadministered with strong CYP3A4 inhibitor, daily dose should not exceed 7.5 mg. Maximum dose: 15 mg/d.
Fesoterodine	For overactive bladder with symptoms of incontinence, urgency, and frequency	Tablets, extended-release: 4 mg 8 mg	4 mg once daily	May increase to 8 mg once daily based on individual response and tolerability. In severe renal insufficiency or when coadministered with strong CYP3A4 inhibitor, dose should not exceed 4 mg/d. This drug should not be given to patients with severe hepatic impairment.
Dicyclomine	Irritable bowel syndrome	Tablets: 10 mg Tablets: 20 mg Capsules: 10 mg and 20 mg Syrup: 10 mg/ 5 mL	80 mg/d in 4 equally divided doses	Increase to 160 mg/d in 4 divided doses
Oxybutynin	Antispasmodic for bladder instability and overactive bladder	Tablets: 5 mg (G) Syrup: 5 mg/5 mL XL tablets: 5 mg, 10 mg, 15 mg	*Adults:* 5 mg bid or tid immediate-release The XL formulation is recommended for overactive bladder and is given once daily. Transdermal formulation is used only in adults. Dose is 3.9 mg system applied twice weekly (every 3–4 d). *Frail elderly:* 2.5 mg bid or tid *Children >5 years of age:* 5 mg bid	*Adults:* 5 mg qid or 10 mg bid of the XL formulation *Children >5 years of age:* Maximum doses of 5 mg tid of immediate release and 20 mg/d of extended release

Table 14–19 ⊗ **Dosage Schedule: Selected Cholinergic Blockers—cont'd**

Drug	Indication	Form	Initial Dose	Maintenance and Maximum Dose
	Detrusor overactivity associated with a neurological condition		*Children 6 years of age and older:* 5 mg once daily of extended-release tablets *Children >5 years of age:* 5 mg bid of immediate-release tablets or syrup	*Children 6 years of age or older:* Dosage adjustments in 5 mg increments to achieve a balance of efficacy and tolerability up to a maximum of 20 mg/d *Children >5 years of age:* Dosage adjustments in 5 mg increments to achieve a balance of efficacy and tolerability up to a maximum of 5 mg tid
Propantheline	Peptic ulcer	Tablets: 7.5 mg (B)	15 mg 30 min before meals and 30 mg at bedtime	Same as initial dose
Scopolamine	Prevention of nausea and vomiting associated with motion sickness	Transderm-Scop: 1.5 mg disk	One transdermal disk applied to postauricular skin 4 h before antiemetic effect is desired	One disk delivers 0.5 mg/d for 3 days. If effect needed for >3 d, remove and replace with new disk.
Solifenacin	For overactive bladder with symptoms of incontinence, urgency, and frequency	Tablets: 5 mg 10 mg	5 mg once daily	May increase to 10 mg once daily based on patient response and tolerability. In severe renal impairment, moderate hepatic impairment or when coadministered with strong CYP3A4 inhibitor, daily dose should not exceed 5 mg. This drug should not be given to patients with severe hepatic impairment.
Mirabegron	For overactive bladder	25 mg or 50 mg oval coated tablet	25 mg once daily	May increase to 50 mg once daily in patients with no renal or hepatic impairment
Tolterodine (Detrol)	Antispasmodic for bladder instability	Tablets: 1 mg, 2 mg	1 mg bid	Usual dose 2 mg daily. Adult with impaired hepatic or renal function or on concurrent enzyme inhibitors may require dose reduction to 1 mg bid.
Detrol LA		Capsules (extended-release): 2 mg, 4 mg	2–4 mg daily	Usual dose 4 mg daily. Adult with impaired hepatic or renal function or on concurrent enzyme inhibitors may require dose reduction to 2 mg bid.
Trihexyphenidyl	Parkinson's disease Drug-induced EPS	Tablets: 2 mg, 5 mg Sequels (sustained-release) (Artane brand only): 5 mg Elixir: 2 mg/5 mL	1–2 mg/d tablets or elixir. Initial therapy usually not begun with sustained release.	Increase in increments of 2 mg at 3- to 5-d intervals until 6–10 mg/d. Postencephalitic patients may require 12–15 mg/d. All doses tolerated better when given in 3 divided doses with meals. Higher doses given in 4 divided doses with meals and at bedtime. After dosage is stabilized, sustained-release forms may be used. Total daily dose is same as other forms but can be given daily at breakfast or in 2 divided doses 12 h apart.
Trospium (Sanctura)	For overactive bladder with symptoms of incontinence, urgency, and frequency	Tablets: 20 mg	20 mg bid Take at least 1 h before meals or on an empty stomach.	May increase to a total daily dose of 60 mg. In severe renal impairment (CrCl <30 mL/min) dose is 20 mg once daily at bedtime.
Sanctura XR		Capsules, extended-release: 60 mg	60 mg daily in the morning. Take at least 1 h before morning meal or on an empty stomach.	Not recommended for patient with severe renal impairment (CrCl <30 mL/min)

Source: FDA, 2001a; NIH, 2006, 2008b, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g.

EPS = extrapyramidal symptoms.

initiated with a 0.5 to 1 mg dose and increased in 0.5 mg increments until optimal benefits are achieved. Postencephalitic patients begin with 2 mg/day in one or more doses, which are increased by 0.5 mg/day until optimal benefits are reached (NIH, 2012d).

The long duration of action of benztropine makes it especially suitable for a bedtime medication, and some patients experience greatest relief by taking the entire dose at bedtime. Others do better with divided doses, from 2 to 4 times a day (NIH, 2012d).

Management of Extrapyramidal Symptoms (EPS) Secondary to Drug Therapy

Cholinergic blockers are the drugs of choice for treating akathisia arising from antipsychotic drugs. Both benztropine and trihexyphenidyl are used for this indication. Size and frequency of dosing are determined empirically within usual dosing recommendations (NIH, 2006, 2012d).

The initial dose of trihexyphenidyl for EPS is 1 mg in a single dose. If symptoms are not controlled within a few hours, the dose is gradually increased until control is achieved. Daily dosages range from 5 to 15 mg, although symptoms have been controlled on as little as 1 mg/day. An elixir form is available for patients who have difficulty with swallowing tablets. Control can be more rapidly achieved by temporarily reducing the dose of the antipsychotic drug when trihexyphenidyl therapy is initiated and then adjusting both drugs until the desired effects are achieved without EPS reactions (NIH, 2006).

Benztropine therapy is initiated with 1 to 2 mg daily or 2 times a day. Dosage titration is in 0.5 mg increments at 5- or 6-day intervals so that the smallest amount required for symptom relief is used. A dose of 1 to 2 mg 2 or 3 times a day usually provides symptom relief within 1 to 2 days. The maximum dose is 6 mg/day. Older adults and thin patients often cannot tolerate the higher doses. Benztropine also comes in an injectable form that can be used for patients with severe dystonic reactions or for those who cannot swallow a pill. The intramuscular dose is 1 to 2 mg, and relief of symptoms is rapid (NIH, 2012d).

For both of these drugs, after several weeks of therapy, the drug may be withdrawn to see if symptoms return and to determine the need for continued therapy. Some patients' symptoms will not return, and some drug-induced EPS reactions do not respond to these two drugs (NIH, 2006, 2012d).

Antispasmodic for Bladder Instability and Overactivity

Overactive bladder and urinary incontinence prevalence ranges from 10% to 50% in the general population (Parazzini, Lavezzari, & Artibani, 2002). Darifenacin, fesoterodine, oxybutynin, solifenacin, tolterodine, and trospium treat these disorders by exerting direct antispasmodic effects and inhibiting the muscarinic action of ACh on smooth muscle. Oxybutynin exhibits only one-fifth the cholinergic blocking activity of atropine, but has 4 to 10 times the antispasmodic activity.

No cholinergic blocking effects occur at the myoneural junction for any of these drugs. This combination of effects makes them especially useful to treat bladder spasms. Patients with conditions characterized by involuntary bladder contractions experience increased bladder capacity, diminished frequency of urination, and reduced urgency related to voiding. These effects are strongest for patients with uninhibited neurogenic bladder, including children with detrusor overactivity associated with a neurological condition. They are also extremely effective for patients who experience incontinence and are well tolerated in long-term administration (more than 2 years). Because oxybutynin increases blood levels and bioavailability of nitrofurantoin, a different antibiotic should be chosen to treat any concurrent urinary tract infection that may be associated with urinary retention. Assessment for bladder outlet obstruction should be done prior to prescribing because obstruction contraindicates the use of this drug (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

For adults, the initial dose of oxybutynin is 5 mg 2 or 3 times a day of the regular formulation or the syrup and 5 to 10 mg daily for the extended-release (XL) formulation (Table 14-19). For frail elderly, the initial dose is 2.5 mg given 2 or 3 times a day because of a prolongation of the elimination half-life from 2 or 3 hours to 5 hours. Symptom response usually occurs with the first dose but may require up to a week for the full effect. If the desired effects have not occurred in 1 week, the dose is increased. Both the regular and extended-release formulations are similarly effective and tolerable (Diokno et al, 2003). The maximum dose is 20 mg/day for immediate release and 30 mg/day for extended release. For children, the initial dose is 5 mg 2 times a day for immediate-release tablets or syrup (for children more than 5 years of age) and 5 mg once daily for extended-release tablets (for children more than 6 years of age), with a maximum dose of 15 mg/day of immediate release and 20 mg/day of extended release. Adverse reactions are more likely with higher doses, and lifestyle modifications should be made concurrently to keep the dose as low as possible. For children and adults who have difficulty swallowing pills, the drug is available in syrup form. There is also a transdermal formulation that is used only in adults. This 3.9 mg system is applied twice weekly (NIH, 2012f).

The remaining drugs are used only in adults and have no dosages for children. Darifenacin, fesoterodine, and solifenacin are extended-release formulations and are taken once daily. The initial dose of darifenacin is 7.5 mg. If the desired effects do not occur in 2 weeks, the dose can be increased to 15 mg once daily. Fesoterodine is started at 4 mg once daily. It may be increased to 8 mg once daily based on patient response and tolerability. Solifenacin is initiated at 5 mg once daily with an increase to 10 mg once daily if symptoms require. The initial dose of trospium depends on its formulation. The immediate-release formulation dose is 20 mg 2 times a day. The extended-release formulation is initiated at 60 mg daily in the morning. Administration with a high-fat meal resulted in reduced absorption, with AUC and C_{max} values 70% and 80% lower than those obtained while fasting. All doses should be taken at least 1 hour before meals or on an empty stomach (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

The newest drug approved for the treatment of overactive bladder in the adult population is mirabegron. Approved by the FDA in 2012, this drug works as an agonist of beta-3 adrenergic receptors and relaxes the detrusor smooth muscles of the urinary bladder to increase bladder capacity. The recommended dosage is 25 mg once daily and may be increased to 50 mg daily in patients who do not have renal or hepatic impairment. The medication may take up to 8 weeks to reach full effectiveness. This medication may cause increases in blood pressure and so should be used with caution in patients with poorly controlled hypertension. Mirabegron was evaluated for safety in a study of 2,736 individuals and another trial of 1,632 patients. The most common adverse effects were nausea, hypertension, constipation, dizziness, tachycardia, and headache. A small number of participants experienced atrial fibrillation (0.2%) and prostate cancer (0.1%) at a rate greater than placebo (FDA, 2012e).

Renal function is a factor in dosing most of these drugs. The dose should not exceed the initial dose in the case of severe renal impairment (CrCl less than 30 mL/min) for fesoterodine and solifenacine. No dosage adjustments are recommended in moderate renal impairment. Only the immediate-release formulation of trospium can be used in patients with severe renal impairment, but the dose must not exceed the initial dose (20 mg) (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Hepatic function is a dosing factor in all of these drugs. Doses should not exceed the initial dose for darifenacin and solifenacin in patients with moderate hepatic impairment. Cautious use in moderate hepatic impairment is recommended for fesoterodine. The metabolic pathway for trospium has not been fully defined and there is no information regarding the effect of severe hepatic impairment on exposure to this drug. Although caution should be used when administering trospium in circumstances of moderate or severe hepatic impairment, the drug is not contraindicated in this situation. All of these drugs except trospium are contraindicated in the presence of severe hepatic impairment. The initial dose of tolterodine is 1 mg 2 times a day with a usual dose of 2 mg daily for maintenance. Doses of 2 to 4 mg once daily of the extended-release capsules are used with a usual maintenance dose of 4 mg daily. Adults with impaired hepatic or renal function often require the lower dose both initially and for maintenance. Symptom relief is similar to oxybutynin (FDA, 2001a; NIH, 2006, 2008b, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

Prevention of Nausea and Vomiting Associated With Motion Sickness

Scopolamine in a transdermal form is used for this indication. One disk is applied to the clean, dry, postauricular skin at least 4 hours before the antiemetic effect is desired. Over a space of 3 days, 0.5 mg is delivered. If therapy is required for more than 3 days, the original disk is removed and replaced with a new one. Only one disk is worn at a time. After application of the disk, the hands are washed with soap and water to prevent any traces of the drug from coming into direct contact with the eyes (FDA, 2001a).

Adjunct Therapy in Management of Irritable Bowel Syndrome and Peptic Ulcer Disease

Atropine is used for both indications. Dicyclomine is used for the management of irritable bowel syndrome in patients who do not respond to the usual interventions with sedation and diet (NIH, 2007). Propantheline is indicated for its antisecretory activity in the management of peptic ulcer disease (NIH, 2009).

The initial adult dose of atropine for both indications is 400 mcg every 4 to 6 hours. Doses may be increased, if necessary, to 600 mcg. For children, the dose is 10 mcg/kg every 4 to 6 hours. The dose is not to exceed 400 mcg. Children are especially sensitive to the adverse reactions associated with atropine, and every effort should be made to keep the dose as low as possible (NIH, 2012c).

Symptoms of poisoning in infants and children differ from adult symptoms. They include burning sensations in the mouth; difficulty in swallowing; rash; blurred vision; tachycardia; tachypnea; fever up to 109.8°F; muscle incoordination; and eventually seizure, respiratory paralysis, and death. The antidote for atropine poisoning is physostigmine (NIH, 2012c).

The only oral dose of dicyclomine shown to be effective is 160 mg/day in four equally divided doses. However, because of adverse effects, the initial dose is 80 mg/day in four equally divided doses. The dose is then increased if tolerated. For patients who have difficulty with swallowing, a syrup form is available with the same dosage range. A formulation for IM administration is also available. The dose is 80 mg/day in four equally divided doses (NIH, 2007).

The oral dose of propantheline for adults is 15 mg 30 minutes before meals and 30 mg at bedtime. For patients with mild manifestations, older adults, and patients of small stature, the dose is 7.5 mg 3 times a day. The safety and efficacy of this drug for treating peptic ulcer in children have not been established. There is a dosage schedule published for antisecretory and antispasmodic use in children, but it is an unlabeled use. The dose for children is 1.5 mg/kg a day in three or four divided doses for antisecretory indications and 2 to 3 mg/kg a day in four to six divided doses given every 4 to 6 hours for antispasmodic indications (NIH, 2009).

Rational Drug Selection

Aside from clinical indications, there are few parameters that assist in deciding which is the best drug to choose. Some are associated with slightly fewer adverse reactions, but all have several reactions that cause patients not to adhere to treatment regimens.

Formulation

In addition to the cost data, formulation can be an issue when speed is a major concern (e.g., severe dystonic symptoms in a patient who is taking an antipsychotic) or when the patient has difficulty in swallowing for any of a variety of reasons, including the progression of a disease process itself. Several drugs come in injectable or syrup forms. Oxybutynin has a transdermal formulation that may also address this issue.

Extended-release formulations may improve adherence by simplifying the treatment regimen (NIH, 2012f).

Monitoring

No specific monitoring parameters are required for cholinergic blockers beyond monitoring for adverse reactions and the monitoring parameters that are appropriate for the disease being treated.

Patient Education

Administration

Instruct the patient to take the drugs exactly as prescribed. If a dose is missed, take it as soon as remembered unless it is almost time for the next dose. Doses should not be doubled. Benztropine is administered with food or immediately after meals to minimize gastric irritation. The tablet may be crushed and administered with food if the patient has difficulty in swallowing. Atropine, dicyclomine, and propantheline are administered 30 to 60 minutes before a meal; oxybutynin is administered on an empty stomach (may be given with food to minimize GI irritation); and trihexyphenidyl is administered after a meal (may be given before a meal for patients with dry mouth or with the meal if GI distress occurs). Extended-release formulations must be swallowed whole and not crushed or chewed. Calibrated measuring instruments such as medicine cups or syringes should be used with liquid formulations to make certain the dose is accurate (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g).

The scopolamine disk has specific instructions for its application. The disk is applied to clean, dry skin behind the ear at least 4 hours before the antiemetic effect is desired. It is left in place for up to 3 days. Only one disk at a time is worn. If longer effects are required, the disk is removed and replaced. Hands are washed with soap and water after application to make sure no trace of the drug comes in contact with the eyes. The same procedure is followed when removing the disk (FDA, 2001a).

Adverse Reactions

The following information is drawn from FDA and NIH sources (FDA, 2001a; NIH, 2006, 2008a, 2009, 2010a, 2011a, 2012d, 2012e, 2012f, 2012g):

- Cholinergic blockers have many adverse reactions because their actions are not organ-specific. Cardiovascular reactions include tachycardia. Teach patients to take their own pulses and report heart rates above 100 bpm. Dosage adjustments may be required. This adverse effect is especially problematic for patients who concurrently have coronary artery disease and for older adults.
- Cholinergic blockers tend to thicken and dry respiratory secretion. Advise the patients to drink at least 2 quarts of noncaffeinated fluid daily to maintain adequate hydration.
- Fluid and fiber intake are also important because these drugs may cause constipation and difficulty in voiding. Dry mouth can be relieved by practicing good oral hygiene, consuming cold drinks, sucking on hard candy, or chewing sugarless gum.
- The therapeutic goal for many of these drugs is to reduce gastric secretion. Substances that increase gastric acid secretion, such as alcohol, tobacco, caffeine, and aspirin, should be avoided.
- Activities that require visual acuity, mental alertness, and vigorous activity in warm weather can create problems. Cholinergic blockers may result in blurred vision, photophobia, and dizziness, and they reduce the sweating necessary to cool the body during exercise.

Lifestyle Management

Several of the disease processes for which these drugs are prescribed require lifestyle modifications. Incontinence can also be treated with a variety of therapies besides drugs. Bladder retraining, Kegel exercises, biofeedback, and other nonpharmacological therapies should also be used in treating many of these disorders.

DRUGS AFFECTING THE CENTRAL NERVOUS SYSTEM

Teri Moser Woo

This chapter addresses drugs that affect the central nervous system (CNS) in two broad ways: to treat psychiatric conditions and to treat other neurological conditions. Traditionally, drugs to treat psychiatric conditions were developed serendipitously and were identified with the psychiatric diagnosis associated with the responsiveness.

As the neurophysiology of psychiatric symptoms has been researched more deliberately, it has become clear that drugs affect specific neuroreceptors and neurotransmitters in different parts of the brain to bring about a response. The response is not limited to a psychiatric diagnosis because the diagnoses are based not on neurophysiology but on behavioral

presentations. Therefore, this chapter will try to make links between the traditional reference to drugs based on diagnoses (e.g., antidepressants) and their pharmacological mechanism of action (e.g., serotonin reuptake inhibitors).

Similarly, because some drugs that originally were used to treat a nonpsychiatric neurological condition have since been found to be useful in treating psychiatric conditions with similar neuropathological mechanisms (e.g., anticonvulsants used to treat mood lability), these drugs may be discussed in more than one section. This is because the brain functions in a very complex fashion but also has neurological redundancy, permitting efficiency in responsiveness.

This chapter focuses on drugs that affect the CNS. In addition, Chapter 29 focuses on drugs to treat anxiety and depressive disorders and Chapter 52 discusses pain management in greater depth. Some redundancy is necessary.

ANOREXIANTS

Anorexiants are short-term adjuncts to calorie-limiting, cognitive-behavioral, weight-loss programs for severely obese individuals. The anorexiants commonly in use today are non-amphetamine appetite suppressants that are chemically and pharmacologically related to amphetamines. In 2011, approximately 2.7 million patients received a prescription for an anti-obesity medication (Borders-Hemphill, U.S. Food and Drug Administration Division of Epidemiology, 2012). These drugs include phentermine (Adipex-P, Ionamin, Suprenza, Obenix, Oby-Cap, Phentercot, and Phentride), benzphetamine (Didrex), diethylpropion HCL (Tenuate), phendimetrazine tartrate (Bontril, Prelu-2, Plegine,), and lorcaserin (Belviq). A unique combination of phentermine and topiramate (Qsymia) is available for chronic weight management. Two formerly used drugs, fenfluramine (Pondimin) and dexfenfluramine (Redux), were removed from the market by the U.S. Food and Drug Administration (FDA) in 1997 because of potentially fatal cardiac and pulmonary adverse reactions. In October 2010, the FDA asked that the manufacturer voluntarily withdraw sibutramine (Meridia) from the U.S. market due to cardiovascular side effects.

Pharmacodynamics

Anorexiants are sympathomimetic amines and are thought to exert their action by stimulation of satiety centers in the hypothalamus and limbic region. They act through noradrenergic, dopaminergic, or serotonergic pathways. Lorcaserin promotes satiety by selectively activating 5-HT $_{2C}$ receptors in the hypothalamus. The exact mechanism of action of topiramate in the combination of phentermine and topiramate is not known, although topiramate is known to cause appetite suppression and satiety.

Pharmacokinetics
Absorption and Distribution

After oral administration, anorexiants are absorbed in the stomach and small intestine, depending on whether they are in regular or extended-release form. They are lipid-soluble, widely distributed, and cross the blood–brain barrier. Diethylpropion and its metabolites cross the placental barrier and are Pregnancy Category C.

Metabolism and Excretion

Anorexiants are metabolized in the liver and excreted through the kidneys. Duration of action is 4 to 6 hours in the regular form and longer in extended-release forms. Half-lives vary from 8 to 20 hours.

Table 15-1 presents the pharmacokinetics of anorexiants.

Pharmacotherapeutics
Precautions and Contraindications

Anorexiants carry a high risk of tolerance and dependence, both physical and psychological, and they should be used cautiously with patients who have known histories of alcohol or drug dependence because of the high risk of cross-tolerance. Actively drinking alcoholics taking anorexiants have experienced depression, paranoia, and psychosis. Use of anorexiants should be limited to a maximum period of 6 months and discontinued at any sign of tolerance. Anorexiant use is contraindicated in patients who abuse substances such as cocaine, phencyclidine, and methamphetamine because of the potential for excessive adrenergic stimulation. Patients with diabetes may experience altered insulin or oral hypoglycemic dosage requirements.

Lorcaserin is a serotonergic drug, and patients may develop serotonin syndrome or Neuroleptic Malignant Syndrome-like reactions if coadministered with serotonergic

Table 15–1 Pharmacokinetics: Anorexiants

Drug	Onset	Peak	Duration	Half-Life	Excretion
Phendimetrazine tartrate	—	—	4–6 h	1.9–9.8 h	Urine
Benzphetamine	—	—	4–6 h	—	Urine
Diethylpropion HCI	—	—	4–6 h	—	Urine
Phentermine	—	—	4–6 h	—	Urine
Lorcaserin		1.5–2 h		11h	Urine

drugs. Lorcaserin is Pregnancy Category X and is not approved in children under 18 years of age.

Adverse Drug Reactions

Adverse reactions to anorexiants include CNS overstimulation and agitation, confusion, insomnia, dizziness, hypertension, headache, palpitations, arrhythmias, dry mouth, mydriasis, dysuria, constipation, vomiting, diarrhea, and impotence. Patients taking high doses of anorexiants over a long period may experience dizziness, fatigue, and depression if the drug is suddenly withdrawn.

The most common adverse reactions to lorcaserin are headache, dizziness, fatigue, nausea, dry mouth, and constipation. Development of valvular heart disease has been reported with a slightly greater incidence (2.4% versus 2.0%) of valvular regurgitation noted over patients taking a placebo (Arena Pharmaceuticals GmbH, 2012). Cognitive impairment has been reported in 1.95% of patients in clinical trials (versus 0.5% for placebo). Potential adverse effects of lorcaserin include psychiatric disorders (euphoria, hallucination, and dissociation), potential risk of hypoglycemia in patients with type 2 diabetes mellitus on antidiabetic therapy, priapism, prolactin elevation, and hematological changes (leukopenia, lymphopenia, neutropenia, and decreased white blood cell count).

Drug Interactions

The potential exists for hypertensive crisis with coadministration of anorexiants and MAO inhibitors. Anorexiants may elevate serotonin levels and should not be prescribed to patients on other serotonergic agents because of the increased risk of serotonin syndrome (hyperthermia, agitation, restlessness, confusion, ataxia, myoclonus, tremor, rigidity, tachycardia, hypotension or hypertension, diaphoresis). The actions of adrenergic blockers, insulin, sulfonylureas, and phenothiazines may be antagonized during concomitant administration of anorexiants. Table 15-2 presents drug interactions.

Based on its pharmacologic mechanism of action on the serotonin 2C receptor, locaserin should be used with extreme caution with other drugs that work on serotonin, including triptans, MAOIs, including linezolid, an antibiotic which is a reversible nonselective MAOI; SSRIs; SNRIs; dextromethorphan; tricyclic antidepressants (TCAs), bupropion, lithium, tramadol, tryptophan, and St. John's wort (Arena Pharmaceuticals GmbH, 2012). Locaserin should also be used cautiously with drugs that are CYP 2D6 substrates because locaserin may increase exposure to the interacting drug.

Clinical Use and Dosing

Anorexiants are indicated for the treatment of morbid exogenous obesity in conjunction with a calorie-restrictive diet. The course of treatment should last no longer than 6 months. An alternative method of dosing is to use the drug for a few weeks followed by no drug for a period, suggested to be half the length of time with the drug, followed by reinstitution of the drug for a few more weeks. Evening dosing should be avoided because of the likelihood of insomnia. Lorcaserin may be administered in the evening as it is not a stimulant and should not affect sleep. Table 15-3 presents the dosage schedule and available dosage forms for anorexiants.

Rational Drug Selection

Significant increases in blood pressure, palpitations, and arrhythmias can occur with phentermine; thus, use is not advisable in hypertensive clients or those with cardiovascular disease. Diethylpropion causes less insomnia than does phentermine. Diethylpropion is considered one of the safest noradrenergic appetite suppressants and may be used in patients with mild to moderate hypertension or angina pectoris.

ANTICONVULSANTS

Seizures are the result of the abnormal discharge of neurons. Anything that disrupts the stability of the neuron may

Table 15–2 Drug Interactions: Anorexiants

Drug	Interacting Drug	Possible Effect	Implications
All anorexiants	MAOIs	Hypertensive crisis	Do not prescribe during or within 14 d of use of MAOI
	Alcohol	CNS depression	Abstain from alcohol use
	Phenothiazines	Psychosis	Monitor for increased psychotic symptoms
	Insulin, sulfonylureas	Altered requirements	Monitor blood glucose
	Guanethidine	Antagonization of effect	Monitor for increased blood pressure
	Furazolidone	Serotonin syndrome	Monitor for symptoms of syndrome
Lorcaserin	Drugs that affect serotonin (triptans, MAOIs, linezolid, SSRIs, SNRIs, dextromethorphan, TCAs, bupropion, lithium, tramadol, tryptophan, and St. John's wort	Increased potential for serotonin syndrome	Use with extreme caution

Table 15–3 ⊗ **Dosage Schedule: Anorexiants**

Drug	Indications	Dosage	Available Dosage Forms
Benzphetamine (Didrex)	Short-term adjunctive treatment of exogenous obesity	25–50 mg daily; max 50 mg tid Not approved for children	Tablets: 50 mg, scored tablets
Diethylpropion (Tenuate, Tenuate Dospan)	Short-term adjunctive treatment of exogenous obesity	25 mg tid ac* or prn if needed; sustained-release: 75 mg q a.m.	Tablets: 25 mg Sustained-release: 75 mg
Phendimetrazine tartrate (Bontril PDM, Prelu-2)	Short-term adjunctive treatment of exogenous obesity	35 mg bid or tid 1 h ac; sustained-release: 105 mg daily 30–60 min before breakfast *Not for children*	Tablets: 35 mg Capsules: 35 mg Sustained-release: 105 mg
Phentermine (Zantryl, Adipex-P, Ionamin)	Short-term adjunctive treatment of exogenous obesity	*Adults*: 8 mg tid, 30 minutes ac or 15–37.5 mg daily before breakfast or 10–14 h before bedtime	Tablets: 8 mg, 30 mg, 37.5 mg Capsules: 15 mg, 30 mg, 37.5 mg
Lorcaserin (Belviq)	Adjunct to a reduced-calorie diet and increased physical activity for chronic weight management in adult patients	10 mg bid	10 mg tablets

*ac = *ante cibum* (before meals).

trigger abnormal activity and seizures. Many factors can precipitate seizures, including hyperventilation, sleep deprivation, sensory stimuli, emotional stress, and hormonal changes. Some drugs with anticonvulsant properties are increasingly being used in the treatment of mood disorders and will be discussed in that section of this chapter (e.g., valproates, gabapentin, lamotrigine). Phenobarbital, used to treat seizure disorders, will be discussed with sedative-hypnotics later in this chapter. Benzodiazepines, also used to treat seizures, will be discussed with anxiolytic drugs. Three major classes of antiepileptic drugs (AEDs), the hydantoins, iminostilbenes, and succinimides, are discussed here.

HYDANTOINS

The hydantoins—phenytoin (Dilantin), ethotoin (Peganone), and fosphenytoin (Cerebyx)—are the first-line treatment of choice for tonic-clonic and partial complex seizures and the least sedating drugs used to treat seizure disorders of any type. Phenytoin is the most commonly used.

Pharmacodynamics

Hydantoins inhibit and stabilize electrical discharges in the motor cortex of the brain by affecting the influx of sodium ions into the neuron during depolarization and repolarization, slowing the propagation and spread of abnormal discharges. They also affect the brainstem's contribution to grand mal seizures and have antiarrhymic properties.

Pharmacokinetics
Absorption and Distribution

The usual route of administration is oral. Absorption occurs in the small intestine and is slow, although the rate varies with the form of the drug. Hydantoins enter the brain quickly, and are then redistributed to other body tissues, saliva, and breast milk. The rate and degree of absorption from intramuscular (IM) administration is erratic, generally resulting in lower plasma levels than the oral route. Hydantoins are 87% to 93% protein bound. The therapeutic plasma level range is 10 to 20 mcg/mL and correlates well with treatment effect.

Metabolism and Excretion

Metabolism of hydantoins takes place in the liver; excretion, via the kidneys. Plasma half-lives range from 6 to 24 hours.
Table 15-4 presents the pharmacokinetics of hydantoins.

Pharmacotherapeutics
Precautions and Contraindications

Hydantoins are contraindicated under conditions of hypersensitivity. Phenytoin-induced hepatitis is a common hypersensitivity reaction. Other hypersensitivity reactions include fever, rash, arthralgias, and lymphadenopathy. Phenytoin may cause severe cardiovascular events and death has resulted from too-rapid IV administration. Phenytoin has a Black-Box Warning that IV administration should not exceed 50 mg/minute in adults and 1 to 3 mg/kg/minute in pediatric patients owing to risk of cardiovascular reactions associated with a too rapid rate of administration. Phenytoin is contraindicated in sinus bradycardia, sinoatrial block, second- and

Table 15–4 Pharmacokinetics: Antiepileptic Drugs

Drug	Onset	Peak	Duration	Half-Life	Excretion
Hydantoins					
Ethotoin (Peganone)	Rapidly absorbed	—	4–6 h	3–9 h	Urine
Fosphenytoin (Cerebyx)	—	—	—	12–29 h	Urine
Phenytoin (Dilantin)	Slow	4–12 h (extended) 1.5–3 h (rapid)	5 h	22 h	Urine
Iminostilbenes					
Carbamazepine		4–8 h Chronic use: 1.5 h		25–65 h Multiple dosing *Children:* 8–14 h *Adults:* 12–17h	Urine
Oxcarbazepine		4.5 h		2 h Metabolite 9 h	Urine
Succinimides					
Ethosuximide		2–4 h		Children 30 h *Adults:* 50–60h	Urine Small amounts in feces
Methsuximide	Rapid	1–4h		2.6–4h	Urine
Drugs That Affect GABA					
Gabapentin	—	2–2.5 h		*Adults:* 2.5–3.5 h Children 9 mo–12 y: 2.4 h Neonates: 2.4 h	80% to 90% excreted unchanged in urine
Tiagabine	Rapid Food slows absorption	45 min		7–9 h Patients on enzyme-inducing AEDs: 2–5 h	Urine 25% Feces 63%
Topiramate	Rapid	2 h		Urine	
Lamotrigine		1.7–2.2		25.4–35.8h	Renal

third-degree atrioventricular block, and Stokes–Adams syndrome. It should be used cautiously in patients with hepatic or renal disease. Ethotoin is contraindicated in the presence of hepatic or hematological disorders.

Although fetal defects have been associated with use of hydantoins during pregnancy and it is classified as Pregnancy Category D, the overall risk of malformations in children exposed to phenytoin during pregnancy is 10%. Pregnant women who take phenytoin can decrease the risks to the fetus by taking 400 international units (IU) of folic acid per day. Some women with epilepsy have fewer seizures during pregnancy; in others, the risks to the woman who goes without the drug may outweigh any risks to the fetus. Hydantoins are present in breast milk; their safety during lactation has not been established.

Newborns who have been exposed to phenytoin in utero may experience decreased levels of vitamin K-dependent clotting factors, and it is critical that the mother receive vitamin K before delivery and that the newborn receives vitamin K at birth.

Rebound status epilepticus may result from abrupt discontinuation of these drugs. Phenytoin has a narrow therapeutic range and older adults or those with impaired liver function may manifest signs of toxicity at lower-than-usual doses. Use cautiously in patients with myocardial insufficiency and hypotension.

Adverse Drug Reactions

Possible adverse effects are multiple and may include CNS effects such as agitation, ataxia, confusion, dizziness, drowsiness, headache, and nystagmus; cardiovascular effects such as hypotension, tachycardia, atrial and ventricular conduction depression, and ventricular fibrillation; gastrointestinal (GI) effects such as nausea, vomiting, anorexia, altered taste, constipation, dry mouth, and gingival hyperplasia; and genitourinary effects such as urinary retention and reddish-brown discoloration of the urine. Serious dermatologic reactions, including Stevens–Johnson syndrome and toxic epidermal necrolysis may

occur. Other possible adverse effects include skin rashes (scarlatiniform or morbilliform), hyperglycemia, tinnitus, gynecomastia, coarsening of facial features and enlargement of the lips, hematopoietic changes, photophobia, and polyarthropathy.

Drug Interactions

Drug interactions consist of those that either increase or decrease the effect of the hydantoin and those that decrease the effect of the other drug. Interactions that increase hydantoin's effect because of increased metabolism, competition for binding sites, or for unknown reasons occur with benzodiazepines, cimetidine, disulfiram, tricyclic antidepressants, salicylates, and valproic acid. Conversely, interactions that decrease hydantoin's effect include barbiturates, rifampin, theophylline, influenza vaccine, pyridoxine, and antacids. Acute acohol intake may increase phenytoin serum levels, whereas chronic alcohol use may decrease levels. IV phenytoin should only be mixed with normal saline and should not be mixed with dextrose-containing IV solutions because a precipitate may form.

Concurrent administration causes the decreased effect of carbamazepine, estrogens, corticosteroids, haloperidol, methadone, levodopa, sulfonylureas, oral contraceptives, and cardiac glycosides.

Table 15-5 presents drug interactions.

Table 15–5 ⁛ **Drug Interactions: Hydantoins (Anticonvulsants**

Drug	Interacting Drug	Possible Effect	Implications
All hydantoins	Allopurinol, cimetidine, diazepam, disulfiram, alcohol (acute intake) phenacemide, succinimides, valproic acid	Increased plasma level of hydantoins	May need to decrease hydantoin dose; monitor plasma level
	Barbiturates, carbamazepine, alcohol (chronic use), theophylline, antacids, calcium	Decreased plasma level of hydantoins	May need to increase hydantoin dose; monitor plasma level
	Corticosteroids, dicumarol, digitoxin, doxycycline, haloperidol, methadone, oral contraceptives, dopamine, furosemide, levodopa	Decreased effect of interacting drug	Monitor plasma levels where possible; monitor signs and symptoms
Iminostilbenes			
Carbamazepine	CYP 3A4 inhibitors: cimetidine, danazol, diltiazem, macrolides, erythromycin, troleandomycin, clarithromycin, fluoxetine, fluvoxamine, nefazodone, trazodone, loxapine, olanzapine, quetiapine, loratadine, terfenadine, omeprazole, oxybutynin, dantrolene, isoniazid, niacinamide, nicotinamide, ibuprofen, azoles (e.g., ketoconazole, itraconazole, fluconazole, voriconazole), acetazolamide, verapamil, ticlopidine, grapefruit juice, protease inhibitors, valproate	CYP 3A4 inhibitors inhibit carbamazepine metabolism and can thus increase plasma carbamazepine levels	
	CYP 3A4 inducers: cisplatin, doxorubicin HCl, felbamate, fosphenytoin, rifampin, phenobarbital, phenytoin, primidone, methsuximide, theophylline, aminophylline	CYP 3A4 inducers can increase the rate of carbamazepine metabolism leading to decreased plasma carbamazepine levels	
Oxcarbazepine	Carbamazepine, phenobarbital, phenytoin, valproic acid	Decreased oxcarbazepine levels	
Succinimides			
Ethosuximide	Phenytoin Valproic acid	Elevated phenytoin levels Increased or decreased ethosuximide levels	
Methsuximide	Carbamazepine, hydantoins (e.g., phenytoin) Lamotrigine	Methsuximide plasma concentrations may be reduced	

Table 15–5 ⠿ **Drug Interactions: Hydantoins (Anticonvulsants)—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
	Phenobarbital, primidone	Plasma concentrations of the active metabolite of primidone, phenobarbital, may be elevated by methsuximide	
Drugs That Affect GABA			
Gabapentin	No significant drug interaction		
Tagabine	Bupropion, gemfibrozil	Tiagabine plasma concentrations may be increased	
	Enzyme-inducing antiepileptic drugs (e.g., carbamazepine, phenobarbital, phenytoin, primidone)	Tiagabine clearance may be increased	
Topiramate	Phenytoin Ethinyl estradiol	Decreased plasma concentrations of Topiramate	
	Carbamazepine	Decreased ethinyl estradiol levels	
	Carbonic anhydrase inhibitors (e.g., zonisamide, acetazolamide, or dichlorphenamide)	May increase the severity of metabolic acidosis and may also increase the risk of kidney stone formation	If topiramate is given concomitantly with another carbonic anhydrase inhibitor, the patient should be monitored for the appearance or worsening of metabolic acidosis
Levetiracetam	No significant drug interactions		
Lamotrigine	Estrogen-containing oral contraceptive preparations containing 30 mcg ethinylestradiol and 150 mcg levonorgestrel Carbamazepine, Phenobarbital/ Primidone, Phenytoin, Rifampin	Decreased lamotragine levels Decreased levonorgesterel levels Decreased lamotrigine levels	Decreased lamotrigine levels approximately 50% Decrease in levonorgestrel component by 19%
	Valproate	Increased lamotragine levels	Decreased lamotrigine concentration approximately 40% Increased lamotrigine concentrations slightly more than 2-fold

Clinical Use and Dosing

Table 15-6 presents the indications and dosage schedules of hydantoins.

Rational Drug Selection

Hydantoins are used for the treatment of grand mal and psychomotor seizures. Phenytoin, however, may worsen absence seizures. Hydantoins are not the first-line treatment of status epilepticus, but IV phenytoin can be used for the control of grand mal types of seizures. Fosphenytoin is used for short-term (less than 5 days) management of seizures when oral use is not feasible. Ethotoin is dosed in 4 to 6 doses a day with food, spaced as evenly as possible, which may be a complex regimen for some patients.

Monitoring

Patients should be assessed for phenytoin hypersensitivity syndrome (fever, skin rash, lymphadenopathy), which usually occurs at 3 to 8 weeks. Baseline complete blood count, urinalysis, and liver function tests should be assessed prior to onset of treatment, with frequent reassessment during the first few months of treatment.

Plasma levels should be monitored, especially when drugs that increase plasma hydantoin, such as ibuprofen, are used. As well, other drugs that are negatively affected by concurrent administration with hydantoins may also require monitoring of the plasma level. Phenytoin may alter thyroid hormone demand, which may require monitoring.

Patients started on hydantoins or any AED should be monitored for suicidality (suicidal thoughts, depression, behavior changes).

Patient Education

The patient should be instructed to take the medication exactly as directed and to avoid missing doses. Abrupt withdrawal may lead to status epilepticus. Advise the patient to

Table 15–6 ⊗ Dosage Schedule: Selected Anticonvulsants

Drug	Indications	Dosage	Available Dosage Forms
Ethotoin (Peganone)	Generalized tonic-clonic or psychomotor seizures	*Adults:* Initially 1 g/d or less in 4–6 divided doses, spaced as evenly as possible, taken after food; increase gradually to usual maintenance dose of 2–3 g/d *Children:* Initial maximum dose of 750 mg/d in divided doses as with adult; usual maintenance dose of 500–1,000 mg/d	*Tablets:* 250 mg
Fosphenytoin (Cerebyx)	Status epilepticus	IV loading dose: 15–20 mg PE/kg diluted in 5% dextrose or 0.9% saline solution at rate of 100–150 mg PE/min (PE: phenytoin sodium equivalent units) Other measures such as IV diazepam will be needed Nonemergent loading dose and maintenance: loading dose 10–20 mg PE/kg IV or IM; maintenance 4–6 mg PE/kg/d at rate of 150 mg PE/min or less *Children:* usual range 100–400 mg/d	Solution for injection: 100 mg/2 mL, 500 mg/10 mL
Phenytoin (Dilantin)	Generalized tonic-clonic, psychomotor, and simple partial seizures; status epilepticus	*Adults:* Initial PO dose 1 g in 3 divided doses, then after 24 h, 300 mg/d in 1 dose (extended-release); IV loading dose of 10–15 mg/kg at rate of 50 mg/min; maintenance dose of 100 mg PO or IV every 6–8 h *Children:* 4–8 mg/kg/d PO in divided doses; 15–20 mg/kg IV at rate of 50 mg/min	*Chewable tablets:* 50 mg *Suspension:* *Extended-Release Capsules:* 30 mg, 100 mg, 200 mg, 300 mg *Injection:* 50 mg/mL
Drugs That Affect GABA			
Gabapentin (Neurontin) (Gralise) Gabapentin enaccarbil (Horizant)	Epilepsy	*Adults and children >12 yr:* The starting dose is 300 mg tid. The dose may be increased using 300 or 400 mg capsules, or 600 or 800 mg tablets tid up to 1,800 mg/day. Dosages up to 2,400 mg/ day have been well tolerated in long-term clinical studies. The maximum time between doses in the tid schedule should not exceed 12 h. *Children 3–12 yr:* The starting dose should range from 10–15 mg/kg/d in 3 divided doses, and the effective dose reached by upward titration over a period of approximately 3 d. The effective dose of gabapentin in patients 5 yr of age and older is 25–35 mg/kg/d and given in divided doses (tid). The effective dose in pediatric patients ages 3 and 4 yr is 40 mg/kg/d and given in divided doses (tid). Dosages up to 50 mg/kg/d have been well tolerated in a long-term clinical study. The maximum time interval between doses should not exceed 12 hr.	*Capsules:* 100 mg, 300 mg, 400 mg *Oral solution:* 50 mg/mL *Tablets:* 300 mg, 600 mg *Extended-release tablet:* 300 mg, 600 mg
	Postherpetic neuralgia	*Adults:* Therapy is initiated as a single 300 mg dose on day 1, 600 mg/d on day 2 (divided bid), and 900 mg/d on day 3 (divided tid). The dose can subsequently be titrated up as needed for pain relief to a daily dose of 1,800 mg (divided tid).	
Tiagabine (Gabitril)	Adjunctive therapy in adults and children 12 yr and older in the treatment of partial seizures	*Enzyme-induced adults and adolescents >12 yr:* Week 1: 4 mg q day Week 2: Increase dose by 4 mg/d, to 8 mg/d divided bid Week 3: Increase dose by 4 mg/d, to 12 mg/d divided tid Week 4: Increase dose by 4–16 mg/day divided bid or qid Week 5: Increase dose by 4–8 mg/day, to 20–24 mg/day divided bid or qid Week 6: Increase dose 4 mg/d, to 24–32 mg/d divided bid or qid Usual adult maintenance dose in induced patients: 32–56 mg/day divided bid or qid	*Tablets:* 2 mg, 4 mg, 12 mg, 16 mg
Topiramate (Topamax)	Monotherapy for epilepsy	*Adults and children ≥10 yr:* Week 1: 25 mg bid Week 2: 50 mg bid	*Tablets:* 25 mg, 50 mg, 100 mg, 200 mg *Sprinkle capsules:* 15 mg, 25 mg

Table 15–6 ⊗ **Dosage Schedule: Selected Anticonvulsants—cont'd**

Drug	Indications	Dosage	Available Dosage Forms
		Week 3: 75 mg bid Week 4: 100 mg bid Week 5: 150 mg bid Week 6: 200 mg bid	
	Adjunctive therapy for epilepsy, partial seizures, Lennox–Gastaut syndrome	*Adults age ≥17 yr:* Initial dose: 25–50 mg/d, titrate dose in 25–50 mg/d increments in weekly intervals to a dose of 200–400 mg/d *Pediatric patients (age 1 to 16 yr):* Initial dose of 1–3 mg/kg/d (max 25 mg) for a week. Dosage is increased by 1–3 mg/kg/d in 1–2 wk intervals. The dose is divided in bid dosing. The total recommended daily dose is 5–9 mg/kg/d. Dose titration is guided by clinical response.	
	Migraine prophylaxis	Week 1: 25 mg in p.m. Week 2 25 mg bid Week 3: 25 mg in a.m., 50 mg in p.m. Week 4: 50 mg bid The recommended dosage for migraine prophylaxis is 100 mg/d.	
Levetiracetam (Keppra) (Keppra XR)	Partial onset seizures	*Adults and adolescents ≥16 yr:* Initial dose 500 mg bid. Increase dose in increments of 1,000 mg/d every 2 wk until a maximum of 3,000 mg/d divided bid. *Children 4 yr to < 16 yr:* Initial dose 20 mg/kg in 2 divided doses (10 mg/kg bid). Increase dose every 2 wk by 20 mg/kg to the recommended daily dose of 60 mg/kg/d.	*Tablets:* 250 mg, 500 mg, 750 mg, 1,000 mg *Liquid:* 100 mg/mL *Extended-release tablet:* 500 mg, 750 mg
	Myoclonic seizures in patients ≥12 yr with juvenile myoclonic epilepsy	Initial dose of 1,000 mg/d (500 mg bid). Increase dose by 1,000 mg/d every 2 wk to the recommended dose of 3,000 mg/d.	
	Primary generalized tonic-clonic seizures	*Adults >16 yr:* Initial dose 1,000 mg/d divided bid (500 mg bid). Increase dose 1,000 mg/d every 2 wk to the recommended dose of 3,000 mg/d. *Pediatric patients age 6 yr to < 16 yr:* Initial dose 20 mg/kg/d divided bid (10 mg/kg bid). Increase dose 20 mg/kg/d every 2 wk to the recommended daily dose of 60 mg/kg/d divided bid.	
Lamotrigine (Lamictal) (Lamictal XR)	Epilepsy therapy in patients not taking enzyme-inducing AEDs	*Adults and children ≥12 yr:* Weeks 1 and 2: 25 mg/d Weeks 3 and 4: 50 mg/d Week 5: 100 mg/d Increase dose by 50 mg per day every 1–2 wk until the usual maintenance dose of 225–375 mg per day in 2 divided doses. *Children 2 yr to 12 yr:* Weeks 1 and 2: 0.3 mg/kg/d in 1 or 2 divided doses. The dosage should be rounded down to the nearest whole tablet and tablets should not be cut. Weeks 3 and 4: 0.6 mg/kg/d in 2 divided doses rounded down to the nearest whole tablet. Starting in week 5 the dose is increased every 1–2 wk by calculating 0.6 mg/kg/d; round this amount down to the nearest whole tablet and add this amount to the previously administered daily dose. The dose is titrated to effect, with an average daily dose of 4.5–7.5 mg/kg/d. Maintenance dose may need to be increased by as much as 50% in children who weigh less than 30 kg.	*Tablets:* 25 mg, 100 mg, 150 mg, 200 mg *Chewable tablets:* 2 mg, 5 mg, 25 mg *Orally disintegrating tablets (ODT):* 25 mg, 50 mg, 100 mg, 200 mg *Extended-release tablets:* 25 mg, 50 mg, 200 mg, 300 mg
	Patients taking enzyme-inducing AEDs (not valproate)	*Adults and children ≥12 yr:* Weeks 1 and 2: 50 mg/d Weeks 3 and 4: 100 mg/d in 2 divided doses	

Continued

Table 15–6 ✖ Dosage Schedule: Selected Anticonvulsants—cont'd

Drug	Indications	Dosage	Available Dosage Forms
		Beginning in week 5 the dose is increased by 100 mg/d every 1–2 wk to the usual maintenance dose of 300–500 mg/d in 2 divided doses. *Pediatric patients 2 yr to 12 yr:* Weeks 1 and 2: 0.6 mg/kg/d in 2 divided doses, rounded down to the nearest whole tablet Weeks 3 and 4: 1.2 mg/kg/d in 2 divided doses, rounded down to the nearest whole tablet Beginning in week 5 the dose is increased by 1.2 mg/kg/d, rounded down to the nearest whole tablet and added to the previously administered daily dose. The usual daily maintenance dose is 5–15 mg/kg/d, with a maximum of 400 mg per day in 2 divided doses. The maintenance dose of lamotrigine may need to be increased by as much as 50% in children who weigh less than 30 kg.	
	Patients taking valproate	*Adults and children >12 yr:* Weeks 1 to 4: 25 mg per day Beginning in week 5 the dosage is increased 25–50 mg/d every 1–2 wk. The usual maintenance dose of lamotrigine in patients taking valproate alone is 100–200 mg/d. If patients are taking valproate and other drugs that induce glucuronidation, the usual maintenance dose is 100–400 mg/d. *Children age 2 yr to 12 yr:* Weeks 1 and 2: 0.15 mg/kg/d in 1 or 2 divided doses, rounded down to the nearest whole tablet. Children that weigh more than 6.7 kg and less than 14 kg 2 mg: every other day. Weeks 3 and 4: 0.3 mg/kg/d in 1 or 2 divided doses, rounded down to the nearest whole tablet. Week 5: Calculate 0.3 mg/kg/d and round this amount down to the nearest whole tablet and add this amount to the previously administered daily dose. The usual maintenance dose in children taking valproate is 1–5 mg/d with a maximum of 200 mg/d. The maintanence dose of lamotrigine may need to be increased by as much as 50% in children who weigh less than 30 kg.	
	Bipolar disease	*Adult patients with bipolar disorder not taking enzyme-inducing AEDs or valproate:* Weeks 1 and 2: 25 mg/d Weeks 3 and 4: 50 mg/d Week 5: 100 mg/d Week 6: 200 mg/d, which is the maintenance dose of lamotrigine *Adults taking enzyme-inducing AEDs (carbamazepine, phenytoin, phenobarbital or primidone) and not taking valproate:* Weeks 1 and 2: 50 mg/d Weeks 3 and 4: 100 mg/d in divided doses Week 5: 200 mg/d Week 6: 300 mg/d divided bid Week 7: 400 mg/d in divided doses *Adults with bipolar disease valproate:* Week 1 and 2: 25 mg every other day Weeks 3 and 4: 25 mg/d Week 5: 50 mg/d Week 6: Increase to the maintenance dose of 100 mg/d	
	Women taking oral contraceptives	Oral estrogen-containing contraceptives decrease lamotrigine levels by approximately 50%. If the patient is already taking lamotrigine and an oral contraceptive is started, the lamotrigine dose is increased 50 mg/d weekly. The lamotrigine dose may need to be twice the normal dose.	

wear a medical identification bracelet, to avoid hazardous situations if drowsiness occurs, and to report adverse effects to the clinician. Patients should avoid alcohol use while taking a hydantoin. Advise the patient to maintain good oral hygiene to prevent tenderness, bleeding, and gingival hyperplasia. Inform the patient that phenytoin may color the urine pink, red, or reddish brown but that this color change is not a cause for alarm. Advise diabetic patients to monitor blood glucose levels and report significant changes to the clinician.

IMINOSTILBENES

Carbamazepine (Tegretol) and oxcarbazepine (Trileptal, Oxtellar XR) are iminostilbene derivatives structurally related to TCAs. They are used to treat epilepsy, bipolar affective disorder, aggressive and assaultive behavior, and some neuralgias.

Pharmacodynamics

The exact mechanism of action of carbamazepine and oxcarbazepine is not known, but they are thought to affect the sodium channels, slowing influx of sodium in the cortical neurons and slowing the spread of abnormal activity. Carbamazepine exerts its effect by depressing transmission in the nucleus ventralis anterior of the thalamus. This area is associated with the spread of seizure discharge. Other actions not explained by effects on sodium channels include anticholinergic, antidiuretic, antidysrhythmic, and antidepressant activity.

Absorption and Distribution

Carbamazepine is absorbed through the stomach, the suspension being absorbed more quickly than the tablet form. Absorption from immediate-release tablets is slow and erratic because of its low water solubility. The drug is highly lipophilic, resulting in high body tissue binding. Oxcarbazepine is well absorbed after oral administration and is 67% protein bound, with its active metabolite 40% bound.

Metabolism and Excretion

Carbamazepine is metabolized in the liver and has the unique ability to induce its own metabolism (autoinduction). Due to autoinduction, initial concentrations within a therapeutic range may later fall despite good compliance. It also induces the metabolism of many CYP450 enzymes and other substrates. Excretion is through urine and feces.

Oxcarbazepine is metabolized into an active metabolite 10-monohydroxy metabolite, which is responsible for the pharmacologic effect of the drug. The metabolites of oxcarbazepine are excreted 95% in the urine, 4% in the feces, and 1% as unmetabolized oxcarbazepine. Oxcarbazepine does not autoinduce metabolism.

Onset, Peak, and Duration

Average peak blood levels of carbamazepine occur approximately 6 hours after administration. Half-life can be as long as 65 hours with initial dosing, but is typically 12 to 17 hours as administration continues. It is noteworthy that the half-life after a single dose is much longer than the half-life after long-term use. Steady state is attained in 2 to 4 days.

Oxcarbazepine peaks 3 to 13 hours (median 4.5 hours) after ingesting tablets and 6 hours after administration in suspension. Food has no effect on rate of absorption or time to peak. The half-life of oxcarbazepine is 2 hours, but its active metabolite has a half-life of 9 hours. Half-life is prolonged to 19 hours in patients with renal impairment.

Pharmacotherapeutics

Precautions and Contraindications

Contraindications include hypersensitivity to carbamazepine or TCAs, history of bone marrow suppression, and concurrent administration with MAOIs. Carbamazepine is Pregnancy Category D; teratogenic defects have occurred, including spina bifida. It is excreted in human milk but is not contraindicated during lactation.

Oxcarbazepine is Pregnancy Category C; it crosses the placenta and adverse effects have been noted in animal studies, but no well-designed human studies have been done. It is recommended that pregnant patients taking oxcarbazepine (Trileptal) be enrolled in the NAAED Pregnancy Registry (1-888-233-2334 or http://www.aedpregnancyregistry.org).

Carbamazepine has a Black-Box Warning regarding serious dermatological reactions, particularly among patients of Asian ethnicity. (Stevens–Johnson syndrome and toxic epidermal necrolysis) and the risk of developing aplastic anemia and agranulocytosis. Patients of Asian ethnicity should be screened for the presence of the HLA-B*1502 genetic variant prior to starting carbamazepine. Use with caution in patients with increased intraocular pressure because of its mild anticholinergic effects. Caution is also advised in patients with a history of previous adverse hematological reactions to any drugs and in those with cardiac, renal, or hepatic impairment.

The only contraindication to oxcarbazepine is hypersensitivity to oxcarbazepine.

Adverse Drug Reactions

Carbamazepine has a Black Box warning regarding the development of Stevens-Johnson Syndrome (SJS) and toxic epidermal necrolysis (TEN) in patients of Chinese ethnicity (1 to 6 per 1000) versus patients of caucasian ethnicity (1 to 6 per 10,000). There is a strong association with the HLA-B*1502 allele variant and the development of SJS/TEN. Patients from Asian countries are more likely to have the HLA-B*1502 variant and should be screened for the presence of HLA-B*1502 prior to beginning carbamazepine.

Carbamazepine has a Black-Box Warning due to its potential to cause blood dyscrasias, some potentially lethal. Although a transient decrease of the white blood cell count can occur and is manageable, carbamazepine can depress the bone marrow and lead to leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia. For that reason, a baseline blood screen that includes a complete blood count (CBC), chemistry, liver function tests, and thyroid-stimulating hormone (TSH) test should be obtained, followed by periodic monitoring. Follow-up studies should be more frequent initially, decreasing to every 3 to 4 months if the results remain normal or the CBC and differential are only minimally lowered.

Other adverse reactions to carbamazepine include hepatic damage and impaired thyroid function. Less serious early adverse events may include drowsiness, dizziness, blurred vision, ataxia, nausea, vomiting, dry mouth, diplopia, and headache.

The most common adverse effects (5% or greater incidence) observed in patients taking oxcarbazepine were dizziness, diplopia, somnolence, fatigue, nausea, vomiting, ataxia, abdominal pain, tremor, and dyspepsia. Hyponatremia (serum sodium less than 125 mEq/L) may occur, particularly in the first 3 months of therapy. Pediatric patients experienced effects similar to those of adults.

Drug Interactions

The interactions of most significance are those that increase the plasma level of carbamazepine to potentially toxic levels, such as the concurrent administration of propoxyphene, hydantoins, cimetidine, some antibiotics (erythromycin, clarithromycin), isoniazid, and verapamil. Interactions that can result in hepatic damage occur with coadministration of some anesthetics and with isoniazid. Interactions that decrease plasma levels of the other drug occur with beta blockers, succinimides, valproic acid, warfarin, haloperidol, doxycycline, and nondepolarizing muscle relaxants. Grapefruit juice increases serum levels and effects of carbamazepine.

Oxcarbazepine can inhibit CYP2C19 and induce CYP3A4/5, leading to increased levels of drugs metabolized by CYP2C19. Oxcarbazeine may decrease the effectiveness of hormonal contraceptives containing ethinylestradiol and levonorgestrel.

Table 15-7 presents drug interactions.

Clinical Use and Dosing

Table 15-8 presents the indications, dosage schedules, and available dosage forms of carbamazepine.

Rational Drug Selection

Carbamazepine is indicated in the treatment of partial complex seizures. It is also useful for generalized tonic-clonic seizures. Its relative lack of side effects compared to phenytoin and phenobarbital has resulted in increased use for a variety of seizure disorders. The drug is also used as a third-line mood stabilizer for bipolar patients who have not responded to lithium or divalproex (Depakote) and for patients unable to tolerate either of the others. Carbamazepine, in a dosage range of 100 to 300 mg at bedtime, can be used to treat restless legs syndrome. Carbamazepine is sometimes used to relieve the pain of trigeminal neuralgia.

Oxcarbazepine may be used as monotherapy or adjunctive therapy in the treatment if partial seizures in adults. Oxcarbazepine is approved as monotherapy for partial seizures in children age 4 and older, and adjunctive therapy for children age 2 and older with partial seizures.

Monitoring

Patients taking carbamazepine and oxcarbazepine should be monitored for seizure activity, severity, and duration. Adverse effects should be monitored, including CNS depression and suicidality or behavioral changes.

Table 15–7 ⸭ Drug Interactions: Carbamazepine and Oxcarbazepine (Anticonvulsants)

Drug	Interacting Drug	Possible Effect	Implications
Carbamazepine	Anesthetics	Hepatic or renal damage	Ensure anesthetist is aware of carbamazepine use
	Cimetidine, propoxyphene, isoniazid, calcium channel blockers, fluoxetine, valproic acid, erythromycin, paroxetine, fluvoxamine, danazol grapefruit juice, influenza vaccine olanzapine, loxapine, ritonavir, nicotinamide	Increased plasma level of carbamazepine	Monitor plasma level
	Hydantoins, barbiturates, primidone, felbamate, rifampin, cisplatin, theophylline	Decreased plasma level of carbamazepine	Monitor level for possible dosage increase; monitor for seizure activity
	MAOIs	Hyperpyretic crisis	Do not give during or within 14 d of MAOI use
	Doxycycline, anticoagulants, warfarin, theophylline, haloperidol, acetaminophen, alprazolam, clozapine, anticonvulsants, clomipramine, phenytoin, primidone	Decreased effect of interacting drug	Monitor plasma levels when able; monitor for signs and symptoms of condition for which interacting drug was prescribed
	Lithium	Increased risk of neurotoxicity	Monitor plasma levels of both drugs; monitor for CNS-related adverse events
	Oral contraceptives	May decrease ethinyl, estradiol, and levonorgestrel availability	Use other birth control measures

Table 15–8 ⊗ **Dosage Schedule: Carbamazepine and Oxcarbazepine (Anticonvulsants)**

Drug	Indications	Dosage	Available Dosage Forms
Carbamazepine (Tegretol, Carbatrol)	Partial complex seizure disorder	*Adults and children >12 yr:* Initially 200 mg bid; increase by 200 mg/d at weekly intervals to maximum of 1,000 mg/d for children 12–15 yr; maintenance range: 800–1,200 mg/d 3–4 times/d *Children <12 yr:* Initially 100 mg bid; increase by 100 mg/d tid qid at weekly intervals to maximum of 1,000 mg/d: may also give at 20–30 mg/kg/d tid qid; maintenance range 400–800 mg/d	Tablets: 100, 200, 300, 400 mg Chewable tablets: 100, 200 mg Suspension: 100 mg/5 mL
	Trigeminal neuralgia	*Adults:* 100 mg bid on first day; increase by 200 mg/ at 100 mg every 12 h to maximum of 1,200 mg/d; maintenance range 200–1,200 mg/d, usually 400–800 mg/d: decrease dosage or discontinue every 3 mo	
	Bipolar disorder, aggressive/assaultive behavior	Same dosage guidelines as above until severe mood swings are stabilized and plasma level is within therapeutic range	
Oxcarbazepine (Trileptal)	Monotherapy or adjunctive therapy of partial seizures	*Adults PO:* 300 mg bid increased by 600 mg/d weekly up to 1,200 mg bid PO *Children* (4–16 yr): 4–5 mg/kg bid, increased over 2 wk	Tablets 150, 300, 600 mg Oral suspension 300 mg/5mL

Plasma carbamazepine levels should be monitored on a regular basis. The therapeutic range is 4 to 12 mcg/mL. Higher levels can lead to toxic symptoms consisting of the initial adverse effects and also hypertension, tachycardia, electrocardiogram (ECG) changes, stupor, agitation, nystagmus, urinary retention, respiratory depression, seizures, and coma. Children and elderly patients may develop toxicity at levels below 12.

Oxcarbazepine does not require serum level monitoring. Serum sodium levels should be monitored for the first 3 months of therapy, especially if the patient is taking other drugs that may cause hyponatremia.

Patient Education

Patients taking carbamazepine should be instructed to report to the clinician any symptoms such as skin lesions, bruising, fever, or sore throat. Carbamazepine should then be discontinued and another drug substituted. Tell the patient that administration with food may increase absorption, and because carbamazepine can be sedating, care should be exercised in situations in which mental and physical alertness is required for safety.

Oxcarbazepine may cause hyponatremia; therefore, patients should be educated regarding symptoms of hyponatremia, which include nausea, fatigue, headache, confusion, and increased seizures. Patients should report swelling of face, eyes, lips, or tongue, which may be symptoms of angioedema. Rash or mouth sores may be early symptoms of Stevens–Johnson syndrome.

Advise the patient that it is important to take the medication exactly as directed. If a dose is missed, the patient should take it as soon as possible but not right before the next scheduled dose and should not take double doses. Advise the patient to carry medical identification for the seizure disorder. Patients should report any mood changes or suidical thoughts.

SUCCINIMIDES

The succinimides are used for the treatment of absence seizures in children and adults. The succinimides include ethosuximide (Zarontin) and methsuximide (Celontin).

Pharmacodynamics

The succinimides exert their anticonvulsant effects by decreasing nerve impulses and transmission in the motor cortex. This produces a variety of effects, including an increase in the seizure threshold and reducing the electroencephalogram (EEG) spike-and-wave pattern of absence seizures.

Pharmacokinetics

Absorption and Distribution

Succinimides are administered orally and are thoroughly absorbed from the GI tract.

Metabolism and Excretion.

Succinimides are metabolized in the liver and excreted through the urinary tract, although a small amount of phensuximide is excreted in bile.

Onset, Peak, and Duration

There is a wide difference in half-lives, ranging from 30 hours in children and 60 hours in adults for ethosuximide, and 2.6 to 4 hours for methsuximide. Peak plasma levels are reached in 1 to 4 hours for methsuximide and in 3 to 7 hours for ethosuximide. Methsuximide has an onset of action of 15 to 30 minutes and a duration of 3 to 4 hours.

Pharmacotherapeutics

Precautions and Contraindications

Anticonvulsants in general are associated with fetal defects, but the succinimides, with careful monitoring of plasma levels, appear to be safe for use during pregnancy and are Pregnancy Category C. They are contraindicated, as are other anticonvulsants, during lactation.

Although uncommon, succinimides have caused blood dyscrasias and use should be preceded by a CBC with differential repeated at frequent intervals initially and less often as the patient continues on the medication without adverse effects. Liver function tests should also be obtained prior to instituting treatment.

Adverse Drug Reactions

The most common adverse reactions to the succinimides are GI distress, which can be relieved by taking the medication with food or milk, and CNS depression, characterized by sedation, ataxia, and lethargy. Other adverse reactions may include headache, rash, pruritus, and mood changes. Symptoms of toxicity are a worsening of these adverse reactions. Cases of systemic lupus erythematosus have been reported with the use of succinimides. All AEDs increase risk of suicidal ideation.

Drug Interactions

The most significant drug interactions are those that increase CNS depression, such as alcohol, opioid agonists, benzodiazepines, and CNS depressants. Succinimides may be given concurrently with other anticonvulsants but may antagonize them and contribute to tonic-myoclonic breakthrough seizures, therefore requiring the need for a higher dose of the other anticonvulsant.

Avoid concurrent use with TCAs and phenothiazines because an antagonistic effect on succinimides may lower the patient's seizure threshold. Haloperidol may change the pattern or frequency of seizures, necessitating an adjustment in dosage of the anticonvulsant. Succinimides may decrease the effectiveness of oral contraceptives; thus, the patient should be advised to use a backup birth control method.

Clinical Use and Dosing

Table 15-9 presents the indications, dosage schedules, and available dosage forms of succinimides.

Rational Drug Selection

Succinimides are the treatment of choice for childhood absence seizure disorders. They are sometimes used for the treatment of absence seizures in adults, but valproic acid becomes the primary treatment in adults. Methsuximide is equally effective as ethosuximide but may have more adverse reactions.

Monitoring

Plasma levels should be monitored. The normal therapeutic range of ethosuximide is 40 to 100 mcg/mL; levels over 150 mcg/mL are considered toxic. The therapeutic range for methsuximide is 10 to 40 mcg/mL, with levels greater than 40 mcg/mL considered toxic. In addition to monitoring seizure activity, evaluate liver, renal, and hematological studies periodically for adverse effects.

Patient Education

Advise the patient to avoid alcohol and, if sedation occurs, to avoid hazardous activities. To decrease stomach distress, succinimides should be taken with milk or food. Because adverse mood changes can occur while taking these medications, advise the client to report any behavioral changes to the clinician. Caution the client that withdrawal of the medication may precipitate absence seizures. Inform the client taking phensuximide that harmless changes in urine color may occur.

DRUGS THAT AFFECT GABA

The AEDs that affect gamma aminobutyric acid (GABA) include the benzodiazepines, gabapentin (Neurontin), topiramate (Topamax), and tiagabine (Gabitril). The AEDs that affect the inhibitory neurotransmitter GABA are also used for pain, including neuropathic pain (gabapentin) and migraine (topiramate).

Pharmacodynamics

The mechanism of action of the drugs that affect GABA is not well understood. Gabapentin is thought to be a GABA analogue that binds to unknown receptors in the brain; it does not bind to GABA receptors, nor does it mimic GABA. Topiramate may block sodium channels or potentiate GABA. Tiagabine may potentiate the action of GABA by blocking GABA reuptake into presynaptic neurons, allowing for more

Table 15–9 ⊗ **Dosage Schedule: Succinimides (Anticonvulsants)**

Drug	Indications	Dosage	Available Dosage Forms
Ethosuximide (Zarontin)	Absence seizures (petit mal)	*Adults and children >6 yr:* 500 mg daily or 250 mg bid; may increase by 250 mg every 4–7 d to maximum of 1.5 g/d	Capsules: 250 mg
		Children <6 yr: 250 mg daily or 125 mg bid; optimal dose 20 mg/kg/d; maximum dose 1.5 g/d	Syrup: 250 mg/5 mL
Methsuximide (Celontin)	Absence seizures (petit mal); second choice	*Adults and children:* Initially 300 mg/d; may increase by 300 mg/d increments at weekly intervals to maximum of 1.2 g/d in divided doses	Capsules: 150, 300 mg

GABA to be available to bind to postsynaptic neuronal receptors.

Pharmacokinetics

Absorption and Distribution

All the AEDs that affect GABA are rapidly absorbed after oral administration, and gabapentin plasma concentration peaks in 2 to 3 hours. Food increases absorption of gabapentin by 14% percent. Topiramate peaks 2 hours after oral administration and is not affected by food intake. Tiagabine peaks 45 minutes after ingestion if taken on an empty stomach. The drugs that affect GABA are widely distributed, including in the CNS and in breast milk. The pharmacokinetics of drugs that affect GABA are found in Table 15-10.

Metabolism and Excretion

Gabapentin is not metabolized; it is excreted unchanged in the urine (75% to 80%) and the feces (10% to 20%). Topiramate is not extensively metabolized, with minor amounts metabolized in the liver via hydroxylation, hydrolysis, and glucuronidation. The percentage of topiramate metabolized in the liver increases when coadministered with drugs that are enzyme inducers. Topiramate is eliminated 70% unchanged in the urine. Tiagabine is extensively metabolized in the liver, primarily by CYP 3A4, and undergoes enterohepatic recirculation. Tiagabine is eliminated as metabolites, 25% in the urine and 63% in the feces.

The half-life of gabapentin is 4.7 hours in infants and children and 5.3 hours in adults. In adults with renal insufficiency (CrCl less than 30 mL/min), it may have a half- life of 52 hours.The half-life of topiramate in adults is 21 hours and in adults with renal impairment the half-life is 59 hours. The half-life of tiagabine in adults is 7 to 9 hours. In children age 3 to 10 years, the mean half-life is 5.7 hours. In children who are on enzyme-inducing AEDs, the half-life of tiagabine is 3.2 hours and in adults on enzyme-inducing AEDs the half-life is 2 to 5 hours.

Pharmacotherapeutics

Precautions and Contraindications

Gabapentin

Gabapentin is contraindicated in patients who are hypersensitive to it. Gabapentin should not be abruptly discontinued because it may precipitate status epilepticus; the dose should be decreased over at least a week.

Neuropsychiatric events such as behavior problems, hostility, aggressive behavior, thought disorder, including changes in school performance and hyperkinesias, have been reported in pediatric patients ages 3 to 12 years taking gabapentin. The safety and effectiveness of gabapentin has not been established in children younger than age 3 years.

AEDs including gabapentin increase the risk of suicidal behavior and ideation; patients should be monitored for emergence or worsening of depression, suicidal thoughts, or changes in behavior.

Gabapentin is Pregnancy Category C. Gabapentin is excreted in breast milk, and nursing infants may be exposed to up to 1/mg/kg/day. Gabapentin should be used in nursing women only if the benefits outweigh the risks. Monitor the infant for lethargy or other neurological effects.

Topiramate

Patients taking topiramate may have decreased concentrations of serum bicarbonate due to inhibition of carbonic anhydrase and increased renal bicarbonate loss, leading to hyperchloremic metabolic acidosis. In adults, doses as low as 50 mg per day of topiramate may result in low serum bicarbonate, with the incidence of decreased serum bicarbonate 30% in clinical trials when topiramate dosage was 400 mg per day. Low serum bicarbonate levels in children 2 to 16 years of age were reported in up to 67% of children receiving 6 mg/kg/day. Severe metabolic acidosis has been reported in infants receiving a topiramate dose of 5 mg/kg/day. Serum bicarbonate should be monitored at baseline and periodically throughout therapy.

Table 15–10 ⊞ Pharmacokinetics: Tricyclic Antidepressants

Drug	Onset	Peak	Duration	Half-Life	Excretion
Amitriptyline HCl	45 min	2–12 h	Long-acting	31–46 h	Urine, feces
Amoxapine	90 min	2–4 wk	Long-acting	8–30 h	Urine
Clomipramine	4-7 h	2–4 wk	Long-acting	19–37 h	Urine
Desipramine HCl	2–5 d	2–3 wk	Long-acting	12–24 h	Urine
Doxepin HCl	2–8 d	2–4 wk	Long-acting	8–24 h	Urine
Imipramine HCl	2–4 h	2–4 wk	Long-acting	11–25 h	Urine, feces
Nortriptyline HCl	—	2–4 wk	Long-acting	18–44 h	Urine
Protriptyline HCl	8–12 h	24–30 h	Long-acting	67–89 h	Urine
Trimipramine maleate	—	—	Long-acting	9–11 h	Urine

An ocular syndrome consisting of acute myopia and angle closure glaucoma has been reported in adults and children taking topiramate. Symptoms usually occur within 1 month of starting topiramate. Patients who have eye pain or blurred vision should contact their provider immediately. The treatment is to discontinue topiramate as soon as possible.

A rare adverse effect of topiramate is oligohidrosis (decreased sweating) and hyperthermia. Most cases were reported in children and were associated with vigorous exercise and/or high environmental temperatures. Patients, especially children should be monitored for decreased sweating and hyperthermia, especially in warm weather. Use caution when prescribing drugs that predispose patients to heat-related disorders (anticholinergic drugs and carbonic anhydrase inhibitors).

AEDs including topiramate increase the risk of suicidal behavior and ideation; patients should be monitored for emergence or worsening of depression, suicidal thoughts, or changes in behavior.

Topiramate should not be abruptly discontinued because that may precipitate status epilepticus; it should be withdrawn gradually.

Topiramate is Pregnancy Category D and has been found to be teratogenic in animal studies. There is an increased risk of cleft lip and/or cleft palate in infants born to women who take topiramate during pregnancy. Topiramate is excreted in breast milk, with infant plasma concentrations of 10% to 20% of maternal concentrations. Infants ingesting topiramate via breast milk should be monitored for drowsiness, weight gain, and developmental milestones (Toxnet, 2011).

Tiagabine

Tiagabine is contraindicated in patients who are hypersensitive to it or any of its components. Post-marketing reports have shown that patients without epilepsy who are prescribed tiagabine may have seizure or status epilepticus. Seizures have been reported in doses as low as 4 mg per day. Most of these patients were taking other medications concomitantly, such as antidepressants, antipsychotics, stimulants, or narcotics. It is thought the concomitant drug lowered the seizure threshold. Seizures occurred soon after a dosage increase. Dosing recommendations for tiagabine are based on a study sample that was also taking enzyme-inducing AEDs, such as carbamazepine, phenytoin, primidone, and phenobarbital, leading to lower plasma tiagabine levels. Tiagabine should not be abruptly discontinued because that may precipitate increased seizure activity; it should be withdrawn gradually.

AEDs including tiagabine increase the risk of suicidal behavior and ideation; patients should be monitored for emergence or worsening of depression, suicidal thoughts, or changes in behavior.

Tiagabine is Pregnancy Category C. It has been found to be teratogenic in fetal rats. There are no adequately well-controlled studies in pregnant women. Tiagabine is excreted in breast milk and is not recommended in lactating women unless there are no other options for maternal treatment. Infants should be monitored for adequate weight gain and developmental milestones.

Tiagabine has been minimally studied in children and is not labeled for use in children younger than age 12.

Adverse Drug Reactions

The most common CNS adverse effects of gabapentin include somnolence (28% in clinical trials) and dizziness (21%). Less common CNS effects include ataxia (3.3%) and abnormal thinking (2.7%). In children 3 to 12 years of age, neuropsychiatric adverse effects of gabapentin include emotional lability (6%), hostility (5.2%), hyperkinesias (4.7%), and thought disorder, including problems with concentration and school performance (1.7%).

Peripheral edema occurred in 8.3% of patients taking gabapentin in clinical trials versus 2.2% in the control group.

The CNS adverse effects of topiramate include ataxia, parathesia, dizziness, somnolence, and difficulty concentrating. Patients in the treatment group also reported anorexia, difficulty with memory, confusion, depression, mood problems, and psychomotor slowing. In children, the most common CNS adverse effects are somnolence and fatigue. Weight loss was reported in 6% of patients taking 50 mg/day of topiramate and 16% of patients taking 400 mg/day.

There is an increase in incidence of kidney stones (2% to 4% greater than expected in clinical trials) in patients taking topiramate. Kidney stones were more prevalent in men and also occurred in children during clinical trials.

Hyperammonemia with and without encephalopathy has been observed in in clinical trials and in post-marketing reports in patients who were taking topiramate both with and without concomitant valproic acid use. Topiramate inhibits carbonic anhydrase, leading to renal bicarbonate loss, and may cause metabolic acidosis.

The adverse drug reactions most commonly reported for tiagabine were related to the CNS, including difficulty with concentration or attention, dizziness, light-headedness, somnolence, confusion, asthenia or lack of energy, and nervousness or irritability. Suicidal thinking has been reported, as previously mentioned.

Drug Interactions

Gabapentin does not interfere with the metabolism of commonly coadministered AEDs. Coadministration of naproxen increases absorption of gabapentin 12% to 15%. Gabapentin may increase the effects of alcohol and other CNS depressant drugs. Gabapentin may cause a false-positive urinary protein level with the N-Multistik SG test.

Clinical Use and Dosing

Dosing of gabapentin for seizures in children older than age 12 and in adults is 300 mg 3 times a day, which is titrated upward to the usual dose of 900 to 1,800 mg 3 times a day. Dosages up to 2,400 mg per day have been tolerated in long-term studies. Initial gabapentin dosing for children 3 to 12 years is 10 to 15 mg/kg/day divided into three doses per day; the dose is titrated up to a usual dose of 40 mg/kg/day in children 3 to 4 years, and 25 to 35 mg/kg/day in children 5 to 12 years. Neuropathic pain is treated in adults with a starting dose of 100 mg 3 times a day, with the dose titrated upward

300 mg per day at weekly intervals to a dose of at least 900 mg per day. The usual gabapentin dosage range for neuropathic pain is 1,800 to 2,400 mg per day, divided into three doses. The dose of gabapentin to treat post-herpetic neuralgia in adults is an initial dose of 300 mg per day; on day 2 the dose is 300 mg twice a day and on day 3 the dose is 300 mg 3 times a day. The dose is titrated up to 600 mg 3 times a day as needed to relieve pain. Dosage adjustment of gabapentin is required in patients with renal failure.

When topiramate is used as monotherapy for epilepsy in children age 10 years or older and in adults, the recommended dose is 400 mg per day in two divided doses. Patients should be titrated up to the recommended dosage. The topiramate starting dose is 25 mg twice a day for a week, then the dose is increased to 50 mg twice a day for a week. In week 3 the dose is 75 mg twice a day, and in week 4 the dose is 100 mg twice a day. In week 5 the topiramate dose is increased to 150 mg twice a day, and in week 6 the goal dosage of 200 mg twice a day is achieved. The recommended total daily dose in patients with partial onset seizures or Lennox–Gastaut Syndrome is 200 to 400 mg daily. In pediatric patients age 2 to 16 years with partial onset seizures, primary generalized tonic-clonic seizures, or seizures associated with Lennox–Gastaut syndrome, the topiramate dose is approximately 5 to 9 mg/kg/day in two divided doses. Pediatric dosing is started at 1 to 3 mg/kg/day (maximum 25 mg/day) in two divided doses and titrated up by 1 to 3 mg/kg/day at 1 to 2 week intervals to achieve clinical response. The usual maintenance dose of topiramate in children is 5 to 9 mg/kg/day, divided into twice-a-day dosing. In patients with renal impairment, half the usual dosage is recommended.

Tiagabine dosing depends on whether a patient is concurrently taking an enzyme-inducing AED. Use of tiagabine in patients not taking enzyme-inducing AEDs may result in serum concentration up to twice that of patients on enzyme-inducing AEDs. Tiagabine dosage adjustment is needed if an enzyme-inducing drug is added, discontinued, or has a dosage change. Avoid loading doses or rapid escalation of dose. The initial dose of tiagabine in adolescents age 12 to 18 years is 4 mg once daily for a week, then in week 2 the dose is 4 mg twice a day (8 mg/day total). Dosage is increased by 4 to 8 mg daily at weekly intervals until clinical response is achieved. The maximum dose of tiagabine in adolescents is 32 mg per day. The dosage for adults on enzyme-inducing AEDs is 4 mg once daily in week 1, then it is increased by 4 to 8 mg per day increments until the maximum daily dose of 32 to 56 mg per day divided in two to four doses is achieved. If a dose is missed, the patient should skip that dose and administer the next dose at the regularly scheduled time. Patients should not double the dose to catch up. If multiple doses of tiagabine have been missed, possible retitration may be required.

Rational Drug Selection

Drug selection of drugs that affect GABA is based on the type of seizure and possible drug interactions that may affect therapy.

Monitoring

Seizure frequency, duration, and severity are monitored with all AEDs, as should mood changes, signs of depression, anxiety, and suicidal thoughts. Patients taking gabapentin, topiramate and tiagabine do not require routine monitoring of serum drug levels.

Patients taking topiramate should have serum electrolyte, including sodium bicarbonate, monitored at baseline and periodically. Weight is monitored in all patients on topiramate as are body temperature and the ability to sweat, especially in warm weather. Serum ammonia levels should be drawn in any patient taking topiramate who exhibits any change in level of consciousness, unexplained lethargy, or vomiting.

Patient Education

Administration

Patients taking AEDs that affect GABA should take the medication exactly as prescribed to maintain consistent therapeutic levels. Missing doses may cause an increase in seizures. Withdrawal seizures may occur if any of these medications is abruptly discontinued; therefore, patients need to be warned to take their medication as scheduled and to not stop without discussing cessation with their provider.

Adverse Reactions

Patients and family members of patients taking AEDs should be warned about the potential neuropsychiatric adverse drug reactions (ADRs), including suicidal thoughts and action, and behavioral changes. Any changes should be reported to the prescriber immediately. Patients should also be warned about the possibility of somnolence, dizziness, or balance issues when starting on AEDs that affect GABA.

Patients taking topiramate will need to monitor their ability to sweat and monitor their temperature in warm weather. Any signs of confusion, unexplained vomiting, or mental status change in patients taking topiramate require investigation for elevated ammonia levels or metabolic acidosis.

Lifestyle Management

Patients who have seizures should get adequate sleep and exercise and avoid stressful situations that may trigger seizures.

LEVETIRACETAM

Levetiracetam (Keppra) is an antiepileptic indicated as an adjunct drug in the treatment of partial onset seizures in children and adults. It is its own unique drug class because it is chemically unrelated to other AEDs.

Pharmacodynamics

The exact mechanism of action of levetiracetam is not known. It does not appear to inhibit or affect GABA, nor does it affect calcium or sodium currents or channels. In vitro and in vivo recordings of epileptiform activity during clinical trials have shown that levetiracetam inhibits burst firing without affecting normal neuronal excitability, suggesting that levetiracetam may prevent epileptiform burst firing and spread of seizure activity.

Pharmacokinetics

Absorption and Distribution

Levetiracetam is almost completely absorbed after oral administration. Time to peak concentration is 1 hour in immediate-release tablets and 3 hours in extended-release tablets. Intake of a high-calorie, high-fat meal before administration delays time to peak in the extended-release levetiracetam by up to 2 hours. It is less than 10% protein bound.

Metabolism and Excretion

Levetiracetam is not extensively metabolized and does not use the cytochrome P450 enzymes. It is metabolized by hydrolysis of the acetamide group, which produces an inactive carboxylic acid metabolite. The half-life of levetiracetam is 7 hours. Levetiracetam is 68% eliminated renally; renal clearance is impaired in patients with renal dysfunction.

Pharmacotherapeutics

Precautions and Contraindications

The only absolute contraindication to the use of levetiracetam is sensitivity to the drug. Patients taking AEDs, including levetiracetam, are at increased risk for suicidal thoughts, depression, and unusual changes in mood and behavior. The mood changes can occur as early as 1 week from the onset of therapy and persist throughout the duration of therapy. Patients and caregivers should be informed of the risk for neuropsychiatric changes while taking levetiracetam and to report any changes in mood, suicidal thoughts, or behavioral changes. Levetiracetam may cause somnolence, fatigue, dizziness, and muscle coordination difficulties. Patients should be warned not to drive or operate heavy machinery until they know the effects of levetiracetam. There is a potential for withdrawal seizures if levetiracetam is abruptly stopped. Levetiracetam should be withdrawn slowly to prevent these.

Levetiracetam may cause a transient decrease in white blood count (WBC), with 3.2% of patients in the clinical trials experiencing a decreased WBC and 2.4% experiencing a decreased neutrophil count. Neutrophil counts returned to normal after continued use.

Levetiracetam is Pregnancy Category C, although there are no well-controlled trials in pregnant women. Administration of levetiracetam to rats led to minor fetal skeletal abnormalities. Altered pharmacokinetics during pregnancy may affect levetiracetam serum concentrations; with decreased serum concentration reported during pregnancy. Discontinuing AEDs during pregnancy may be harmful to the mother, so consultation with a perinatologist is warranted. Pregnant women who take levetiracetam during pregnancy should be reported and enrolled in North American Antiepileptic Drug Pregnancy Registry (888-233-2334).

Levetiracetam is FDA-approved for use in children age 1 month or older as adjunct therapy in partial seizures and as adjunctive therapy in children age 6 years and older with primary generalized tonic-clonic seizures.

Adverse Drug Reactions

The most common ADR reported in clinical trials of levetiracetam was somnolence, reported in 15% of patients. Dizziness is another common ADR (9% of patients). Behavioral changes are uncommon but significant in patients taking levetiracetam, including nervousness (4% of patients), anxiety (2%), hostility (2%), and emotional lability. Alopecia has been reported in post-marketing surveillance of levetiracetam, with recovery reported once the drug was discontinued.

As previously mentioned, suicidal thinking or behavior may occur in patients taking AEDs. In clinical trials of 11 different AEDs, patients randomized to one of the AEDs had approximately twice the risk of suicidal thoughts or behavior of the controls.

Drug Interactions

Levetiracetam is mostly unbound and does not use CYP 450 enzymes for metabolism, thereby decreasing the likelihood of drug interactions. Levetiracetam does not interact with phenytoin, valproate, carbamazepine, gabapentin, lamotrigene, or phenobarbital. It also does not interact with oral contraceptives or warfarin.

Clinical Use and Dosing

Levetiracetam is prescribed as adjunct therapy in adults and children age 1 month or older with partial onset seizures. It is indicated as adjunctive therapy in the treatment of primary generalized tonic-clonic seizures in adults and children age 6 years or older, and as adjunctive therapy for myoclonic seizures in adult patients and adolescents age 12 or older with juvenile myoclonic epilepsy Levetiracetam is added to a stable dosing regimen of an AED.

Rational Drug Selection

There are two forms of levetiracetam available, immediate-release and extended-release (Keppra XR) tablets. The immediate-release form is available in suspension or as tablets. The extended-release formula is FDA-approved for age 16 years and older. There is a significant cost difference between generic levetiracetam and the brand-name Keppra, with 60 tablets of 1,000 mg generic levetiracetam priced at $42 and 60 tablets of 1,000 mg Keppra priced at $848 (CostCo, www.costco.com).

Monitoring

Routine laboratory monitoring of patients on levetiracetam is not necessary. Efficacy is determined by a decrease in the mean weekly frequency of partial onset seizures.

Patient Education

Administration

Patients should take levetiracetam exactly as prescribed. Missing doses may cause an increase in seizures. Withdrawal seizures may occur if levetiracetam is abruptly discontinued; therefore, patients need to be warned to take their medication as scheduled and to not stop without discussing cessation with their provider.

Adverse Reactions

Patients and family members of patients taking levetiracetam should be warned about the potential neuropsychiatric ADRs, including suicidal thoughts and action, and behavioral changes. Any changes should be reported to the prescriber immediately. Patients should also be warned about the possibility of somnolence, dizziness, or balance issues when starting on levetiracetam.

Lifestyle Management

Patients who have seizures should get adequate sleep and exercise and avoid stressful situations that may trigger seizures.

LAMOTRIGINE

Lamotrigine (Lamictal) is used as adjunctive therapy in adults and children age 2 or older in the treatment of partial seizures, primary generalized tonic-clonic seizures, and generalized seizures associated with Lennox–Gastaut syndrome. Lamotrigine is approved for maintenance treatment of bipolar 1 disorder to delay occurrence of mood episodes in adults age 18 or older.

Pharmacodynamics

The exact mechanism of action of lamotrigine is not known. It is thought that lamotrigine affects voltage-sensitive sodium channels and inhibits presynaptic release of glutamate and aspartate in the neuron. The mechanism of action of lamotrigine in the treatment of bipolar disorder is not known.

Pharmacokinetics

Absorption and Distribution

Lamotrigine is well absorbed after oral administration. Lamotrigine chewable tablets have the same rate of absorption whether chewed or dissolved in water. Orally disintegrating tablets and regular tablets taken with water have the same rate and extent of absorption. Immediate-release lamotrigine peaks in 2 hours. Some patients may have a second peak at 4 to 6 hours due to enterohepatic recirculation. Extended-release lamotrigine peaks in 4 to 11 hours. The mean volume of distribution of lamotrigine is 0.9 to 1.3 L/kg after oral administration. Lamotrigine is 55% protein bound. It crosses the placenta and is excreted in breast milk.

Metabolism and Excretion

Lamotrigine is metabolized extensively in the liver via glucuronic acid conjugation. When lamotrigine is given alone, after multiple doses it induces its own metabolism resulting in a 25% decrease in half-life. Ninety-four percent of lamotrigine is excreted as metabolites in the urine and 2% is excreted in the feces.

Pharmacotherapeutics

Precautions and Contraindications

Lamotrigine is contraindicated in patients hypersensitive to the drug or its ingredients. Life-threatening hypersensitivity

reactions have occurred; these include multiorgan failure or dysfunction, hepatic abnormalities, and disseminated intravascular coagulation. Early symptoms of hypersensitivity, such as fever or lymphadenopathy, require evaluation and discontinuation if the reason for symptoms cannot be established. Blood dyscrasias, including neutropenia, leukopenia, anemia, thrombocytopenia, pancytopenia, and aplastic anemia have been reported in patients taking lamotrigine.

Lamotrigine has a Black-Box Warning regarding life-threatening rashes, including Stevens–Johnson syndrome, toxic epidermal necrolysis, and rash-related death. Pediatric patients are more likely to have serious rash than adults. Coadministration with valproate may increase the risk of rash. Exceeding recommended initial doses or exceeding recommended dosage escalation of lamotrigine increases risk of rash. Lamotrigine should be discontinued at the first sign of rash, unless clearly not drug related.

Patients taking AEDs, including lamotrigine, are at increased risk for suicidal thoughts, depression, and unusual changes in mood and behavior. The mood changes can occur as early as 1 week from the onset of therapy and persist throughout the duration of therapy. Patients taking lamotrigine for bipolar disorder may experience worsening of depression and emergence of suicidal ideation. Patients and caregivers should be informed of the risk for neuropsychiatric changes while taking lamotrigine and to report any changes in mood, suicidal thoughts, or behavior changes.

There is a potential for withdrawal seizures if lamotrigine is abruptly stopped. Lamotrigine should be withdrawn slowly (over at least 2 weeks) to prevent seizures.

Lamotrigine is Pregnancy Category C. Although not specifically found to be teratogenic, it decreases folate levels in animal studies. Lamotrigine should only be prescribed to pregnant women if the benefit outweighs the risk. Pregnant women who take lamotrigine during pregnancy should be referred to enroll in the North American Antiepileptic Drug Pregnancy Registry (888-233-2334). Providers may enroll patients in the Lamotrigine Pregnancy Registry by calling 1-800-336-2176.

Lamotrigine is excreted in breast milk. Breastfed infants of women taking lamotrigine have measurable serum levels of lamotrigine, which may be 30% to 50% of maternal levels. Neonates have limited ability to metabolize lamotrigine, placing them at higher risk of exposure. Lamotrigine has low protein binding, and maternal plasma levels may rise in the postpartum period, leading to elevated milk levels (LactMed, 2014). If there are no other therapeutic options to maternal lamotrigine use, then the infant should be monitored closely for drowsiness, poor suck, apnea, and rash. Consider measuring serum lamotrigine levels and platelet count in the infant. Infants may exhibit withdrawal symptoms if breastfeeding is abruptly discontinued (LactMed, 2014).

Lamotrigine is FDA-approved for use in children age 2 or older for the treatment of generalized tonic-clinic seizures, partial seizures, and Lennox–Gastaut syndrome. The safety and effectiveness in the treatment of bipolar disorder in patients younger than 18 has not been established.

Adverse Drug Reactions

As discussed in the Precautions and Contraindications section, lamotrigine has a Black-Box Warning regarding serious, possibly life-threatening rashes, including Stevens–Johnson. The incidence in pediatric patients age 2 to 16 years is 0.8% (8 in 1,000) and it is 0.3% in adults taking lamotrigine as adjunctive therapy. Any unexplained rash requires discontinuation of lamotrigine and investigation.

Multiorgan failure has been reported in patients taking lamotrigine, including hepatic failure. Blood dyscrasias may occur in patients taking lamotrigine. Reported abnormalities include neutropenia, anemia, thrombocytopenia, and pancytopenia. Rare reactions include aplastic anemia and red cell aplasia.

Patients taking lamotrigine for any reason may have increased suicidal thoughts or behavior. Monitor patients for mood changes or suicidal thoughts, especially those taking lamotrigine for bipolar disorder.

Abruptly discontinuing lamotrigine may cause withdrawal seizures. Patients may exhibit withdrawal seizures if they are taking lamotrigine for bipolar disorder also. To avoid withdrawal seizures, lamotrigine should be tapered off over 2 weeks.

Lamotrigine may cause increased seizures, including status epilepticus.

Drug Interactions

There are many drug interactions with lamotrigine due to enzyme induction that affect drug levels of both lamotrigine and the concurrently administered drugs. For example, the enzyme inducers carbamazepine, phenytoin, phenobarbital, and primidone decrease lamotrigine concentrations by approximately 40%.

Oral estrogen-containing contraceptives decrease lamotrigine levels by approximately 50%. If the patient is already taking lamotrigine and an oral contraceptive is started, the lamotrigine dose may need to be twice the normal dose. Lamotrigine decreases levonorgestrel levels by 19% when taken with combined oral contraceptives.

Rifampin decreases lamotrigine concentrations by 40% when taken concurrently.

The most concerning interaction with lamotrigine is with valproate. When valproate is administered concurrently with lamotrigine, there is an increased risk of life-threatening rash, such as Stevens–Johnson, developing. Valproate also increases lamotrigine levels by more than 2-fold.

Clinical Use and Dosing

Dosing of lamotrigine is dependant on the concurrent medications the patient may be taking. It is critical to follow recommendations for initial dosing and the escalation schedule to avoid the development of life-threatening rashes. There are Lamictal starter kits and Lamictal ODT Patient Titration kits available for the first 5 weeks of treatment if adherence to the escalation schedule is a concern.

Tablets should not be crushed or chewed. There is a chewable tablet that may be dissolved in water or juice if needed or oral disintegrating tablets (ODT). Do not prescribe partial portions of either regular or chewable tablets.

Dosing in Treating Seizures

Patients Not Taking Enzyme-Inducing AEDs

Patients age 12 or older and adults who are not taking enzyme-inducing AEDs (carbamazepine, phenytoin, primidone, or valproate) are started on 25 mg every day for 2 weeks. In weeks 3 and 4, the dosage is increased to 50 mg per day. In week 5, the lamotrigine dosage is increased 50 mg per day, and dosage increases by 50 mg per day every 1 to 2 weeks until the usual maintenance dose of 225 mg to 375 mg per day in two divided doses.

The dosage for children age 2 to 12 years with epilepsy who are not taking an enzyme-inducing AED begins with 0.3 mg/kg per day in one or two divided doses in weeks 1 and 2. The dosage should be rounded down to the nearest whole tablet and tablets should not be cut. In weeks 3 and 4, the dosage is 0.6 mg/kg per day in two divided doses rounded down to the nearest whole tablet. Starting in week 5, the dose is increased every 1 to 2 weeks by calculating 0.6 mg/kg/day, rounded down to the nearest whole tablet and added to the previously administered daily dose. The dose is titrated to effect, with an average daily dose of 4.5 to 7.5 mg/kg per day. A maintenance dose may need to be increased by as much as 50% in children who weigh less than 30 kg.

Patients Taking Enzyme-Inducing AEDs

For patients age 12 years and older taking carbamazepine, phenytoin, phenobarbital, or primidone and not taking valproate, the dose for the initial 2 weeks is 50 mg per day. In weeks 3 and 4, the dose is 100 mg per day in two divided doses. Beginning in week 5, the dose of lamotrigine is increased by 100 mg/day every 1 to 2 weeks to the usual maintenance dose of 300 to 500 mg per day in two divided doses.

The dosage in pediatric patients age 2 to 12 years taking carbamazepine, phenytoin, phenobarbital, or primidone and not taking valproate is 0.6 mg/kg/day in two divided doses, rounded down to the nearest whole tablet for the first 2 weeks. In weeks 3 and 4, the dose is 1.2 mg/kg/day in two divided doses, rounded down to the nearest whole tablet. Beginning in week 5, the dose of lamotrigine is increased by 1.2 mg/kg/day, rounded down to the nearest whole tablet and added to the previously administered daily dose. The usual daily maintenance dose is 5 to 15 mg/kg per day, with a maximum of 400 mg per day in two divided doses. The maintenance dose of lamotrigine may need to be increased by as much as 50% in children who weigh less than 30 kg.

Patients Taking Valproate

Valproate inhibits glucuronidation and decreases clearance of lamotrigine; therefore, the escalation schedule is slower. The initial dose of lamotrigine in patients older than age 12 is 25 mg per day for the first 4 weeks. Beginning in week 5, the dosage is increased 25 to 50 mg per day every 1 to 2 weeks. The usual maintenance dose of lamotrigine in patients taking valproate alone is 100 to 200 mg per day. If patients are taking

valproate and other drugs that induce glucuronidation, the usual maintenance dose is 100 to 400 mg per day.

Children age 2 to 12 years taking valproate are started on 0.15 mg/kg per day of lamotrigine in one or two divided doses, rounded down to the nearest whole tablet for the first 2 weeks. Children who weigh more than 6.7 kg and less than 14 kg are given 2 mg of lamotrigine every other day for weeks 1 and 2. The dose for weeks 3 and 4 is 0.3 mg/kg/day in one or two divided doses, rounded down to the nearest whole tablet. Beginning in week 5, calculate 0.3 mg/kg/day of lamotrigine, rounded down to the nearest whole tablet and added to the previously administered daily dose. The usual maintenance dose of lamotrigine in children taking valproate is 1 to 5 mg/kg per day, with a maximum of 200 mg per day. The maintenence dose of lamotrigine may need to be increased by as much as 50% in children who weigh less than 30 kg.

Dosing in Bipolor Disease

The initial dosage of lamotrigine in adult patients with bipolar disorder who are not taking enzyme-inducing AEDs or valproate is 25 mg daily for the first 2 weeks. During weeks 3 and 4, the dose is increased to 50 mg per day. In week 5, the dose of lamotrigine is increased to 100 mg per day. In week 6, the dose is increased to 200 mg per day, which is the maintenance dose of lamotrigine.

For patients taking carbamazepine, phenytoin, phenobarbital, or primidone and not taking valproate, the dose to treat bipolar disease for the initial 2 weeks is 50 mg per day. In weeks 3 and 4, the dose is 100 mg daily in divided doses. In week 5, the dose increases to 200 mg per day. The dose is increased to 300 mg per day in week 6, with the dose divided into two doses per day. In week 7, the lamotrigine dose is increased to up to 400 mg per day in divided doses.

In bipolar patients taking valproate, the initial dose of lamotrigine is 25 mg every other day for the first 2 weeks. In weeks 3 and 4, the dose is increased to 25 mg daily. The lamotrigine dose is increased to 50 mg per day in week 5. In week 6, the lamotrigine is increased to the maintenance dose of 100 mg daily.

Patients Taking Oral Contraceptives

Oral estrogen-containing contraceptives decrease lamotrigine levels by approximately 50%. If the patient is already taking lamotrigine and an oral contraceptive is started, the lamotrigine dose is increased 50 mg per day weekly. The lamotrigine dose may need to be twice the normal dose.

Rational Drug Selection

Lamotrigine is the only drug in its class. Its use is determined by the type of seizures, concurrent medications, and patient profile. Consultation with a neurologist is warranted when prescribing lamotrigine.

Monitoring

Patients should be monitored closely for any newly occurring rash and for hypersensitivity reactions. Complete blood count and differential should be monitored, as well as renal and hepatic function. Patients need to be instructed to monitor seizure activity. Concurrent AED levels should be monitored as should signs of suicidality or mood changes. Bipolar patients should be monitored for worsening depressive symptoms.

Patient Education

Administration

Patients need to be instructed to take lamotrigine exactly as prescribed and should follow the escalation schedule exactly. Tablets should not be crushed or chewed. Chewable tablets are chewed and washed down with a small amount of juice or water or may be dissolved in a small amount of water or juice.

Adverse Drug Reaction

Any rash needs to be reported to the provider immediately and the patient examined. Patients and family members of patients taking levetiracetam should be warned about the potential neuropsychiatric ADRs, including suicidal thoughts and action and behavioral changes. Any changes should be reported to the prescriber immediately.

Lifestyle Management

Patients who have seizures should get adequate sleep and exercise and avoid stressful situations that may trigger seizures.

ANTIDEPRESSANTS

The antidepressants are usually identified in five classes: tricyclics (TCAs), selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), norepinephrine reuptake inhibitors (NRIs), and miscellaneous drugs that do not easily fit one of the other categories.

As of 2007, all categories of antidepressants carry an FDA Black-Box Warning regarding increased risk of suicidal thought and behavior. This is most likely to occur in children, adolescents, and young adults to age 24 and is most likely to occur in the first 2 months of treatment. It is emphasized that depression and other serious psychiatric illnesses are themselves important causes of suicide. Providers and patients and their families must weigh benefits versus risks and if antidepressants are prescribed, monitor closely for suicidal ideation and behavior.

TRICYCLIC ANTIDEPRESSANTS (TCAs)

The development of TCAs grew out of work with phenothiazines, to which they are structurally related. Prior to TCAs' availability in the 1960s, depression had been treated with stimulants and tranquilizers, both of which had some utility but left the basic mood disorder essentially unchanged. They were not overshadowed until the late 1980s, when the new SSRIs began to be widely marketed.

Although now used less frequently than in the past, amitriptyline (Elavil), nortriptyline (Pamelor, Aventyl),

imipramine (Tofranil), doxepin (Sinequan), trimipramine maleate (Surmontil), amoxapine (Asendin), desipramine (Norpramin, Pertofrane), protriptyline HCL (Vivactil), and clomipramine (Anafranil) still have their individual usefulness. Essentially, the TCAs are equally efficacious as the newer drugs in treating depression, cost less, but have much more troublesome side effects. Also the TCAs are less safe in treating depression in those who are at high risk for suicide, because overdose can be fatal, whereas the newer antidepressants are much less likely to be fatal.

Pharmacodynamics

The TCAs act on the neurotransmitters serotonin and norepinephrine by inhibiting their reuptake at the presynaptic neuron. However, they also act on histamine (contributing to drowsiness and weight gain) and acetylcholine. Loxapine, an active metabolite of amoxapine, acts as an antipsychotic by blocking the dopamine receptor.

Pharmacokinetics

Absorption and Distribution

All the TCAs are administered orally, thoroughly absorbed, and highly lipophilic and protein bound. They have a fairly long half-life of elimination; therefore, steady state is achieved in approximately 5 days. There is a lag time of 2 to 4 weeks before remission of depressive symptoms becomes apparent. Half-life ranges from 8 to 90 hours but averages 24 to 36 hours. Table 15-10 includes the pharmacokinetics of TCAs.

Metabolism and Excretion

The TCAs undergo first-pass metabolism by the liver and are excreted by the kidneys. At least two (amitriptyline and imipramine) of the TCAs are metabolized into active metabolites that further extend the half-life and contribute to the difficulty in overdosage.

Pharmacotherapeutics

Precautions and Contraindications

Due to their direct alpha-adrenergic blocking effect and quinidine-like effect on the myocardium, TCAs are contraindicated with cardiovascular disorders. Similarly, due to their acetylcholine blocking effect they should be used with caution in those who have glaucoma, prostatic hypertrophy, or urinary incontinence. They should not be prescribed in combination with MAOIs or to individuals who have demonstrated hypersensitivity in this class.

Safety of use in pregnancy is unclear. TCAs are Pregnancy Category C and are excreted in low doses in breast milk.

Although rare, tardive dyskinesia and neuroleptic malignant syndrome have been reported, and are more likely with amoxapine use due to its dopaminergic effect.

As with any drug that affects the CNS, the TCAs should be titrated gradually in either direction. Nausea, headache,

vertigo, malaise, and nightmares have been noted following abrupt discontinuance of the drug or after large dose decreases.

The most significant risks related to TCA use are cardiac conduction disorder. At highest risk are children and the elderly; therefore, baseline ECG and periodic monitoring should be performed. The most common cardiovascular effect is sinus tachycardia due to the inhibition of norepinephrine reuptake and anticholinergic action. In addition, TCAs contribute to slowing of depolarization of the cardiac muscle, contributing to prolongation of the QRS complex and the PR/QT intervals.

TCAs can lower the seizure threshold of those with a seizure disorder or those taking medications that also decrease the seizure threshold. Because the index between therapeutic and toxic levels is narrow, great care needs to be taken when prescribing for a person who is depressed and has suicidal ideas. When treating such a person, the nurse practitioner needs to be alert for an energizing effect that precedes depressive symptom remission because this may contribute to sufficient activation to follow through with a suicidal plan. Such patients need to be monitored on a weekly basis, especially regarding suicidal thoughts and behaviors, and medication should be dispensed in only small amounts until suicidal risk decreases.

Finally, TCAs should be used with extreme caution if at all with the elderly. Due to their anticholinergic and norepinephrine effects, they can contribute to confusion, orthostatic hypotension, and falls.

Adverse Drug Reactions

Anticholinergic adverse effects are common and can include dry mouth, constipation, urinary hesitancy or retention, blurred vision, sedation, orthostatic hypotension, weight gain, nausea and vomiting, gynecomastia, and changes in libido. Patients newly prescribed a TCA should be cautioned about safety in a situation in which mental alertness is required until the full effect of the drug has been determined.

Drug Interactions

The most significant drug interactions are those that increase the plasma level of the TCA and thereby increase the risk of cardiotoxicity, such as can occur with the concurrent use of SRIs, cannabis, and sympathomimetics. Hyperpyrexia can occur with MAOIs and TCAs. Table 15-11 presents drug interactions.

Clinical Use and Dosing

The TCAs have shown efficacy in a variety of clinical conditions, including depression, panic disorder, enuresis, and chronic neuropathic pain. Due to their serotonergic and noradrenergic effects, they are especially helpful with anxiety disorders such as obsessive-compulsive disorder (clomipramine) and panic disorder (imipramine). Some TCAs, especially secondary and tertiary amines, contribute to significant drowsiness as a side effect; therefore, they are more commonly used for insomnia than they are for depression. Most notable of the TCAs used for insomnia include doxepin (Sinequan), amitriptyline (Elavil), and trazodone (Desyrel). Amitriptyline and imipramine are useful for neuropathic pain. Dosages are shown in Table 15-12.

Table 15–11 ▦ **Drug Interactions: Tricyclic Antidepressants**

Drug	Interacting Drug	Possible Effect	Implications
All TCAs	SSRIs, anorexiants, cimetidine, oral contraceptives, charcoal, calcium channel blockers, protease inhibitors, propoxyphene, methylphenidate	Increased plasma level of TCA and increased risk of cardiotoxicity	Use with caution; monitor plasma levels of TCA
	Narcotics, barbiturates, antihistamines, alcohol, benzodiazepines, antipsychotics	Increased CNS depression; increased TCA plasma level; increased risk of cardiotoxicity	Use with caution; monitor plasma level of TCA
	Anticholinergics	Increased anticholinergic adverse reactions	Avoid concurrent use if possible
	Dicumarol	Increased prothrombin time	Monitor
	Carbamazepine, phenytoin	Increased plasma level of anticonvulsant	Monitor blood levels of anticonvulsants
	MAOIs	Hyperpyretic crisis, convulsions	Avoid concurrent use
	Guanethidine	Hypotension	Monitor blood pressure
	Clonidine	Hypertension	Monitor BP
	Levodopa	Hypertension, dyskinesia	Use different type of antidepressant
	Tamoxifen, nicotine, rifampin	Decreased TCA effect	May require higher dose
	Sympathomimetics	Hypertension, risk of arrhythmias	Avoid if possible
	Cannabis	Increased risk of cardiotoxicity, tachycardia, light-headedness, confusion, mood lability, delirium	Avoid

Table 15–12 ⊗ **Dosage Schedule: Tricyclic Antidepressants**

Drug	Indications	Dosage	Available Dosage Forms
Amitriptyline (Elavil)	Depression, insomnia	*Adult:* 75 mg/d in divided doses to maximum of 150 mg/d; may give entire dose at bedtime; hospitalized patients may require 200–300 mg/d.	Tablets: 10, 25, 50, 75, 100, 150 mg
		Adolescents and older adults: 10 tid or 25 mg at bedtime; maximum 100 mg/d.	Syrup: 10 mg/5 mL
Amoxapine (Asendin)	Depression, psychotic depression	*Adults and children >16:* 50 mg bid tid, gradually increasing to 200–300 mg/d/ if needed; maximum 400 mg/d. If total dose equals 300 mg or more, give in divided doses. *Older adults:* 25 mg bid tid; may gradually increase to maximum of 300 mg/d	Tablets: 25, 50, 100, 150 mg
Clomipramine (Anafranil)	OCD	*Adults:* 25 mg/d initially; increase over 2 wk to maximum or 250 mg/d. Give with food to minimize GI distress. May divide dose initially; give at bedtime for maintenance.	Capsules: 25, 50, 75 mg
		Children and adolescents: 25 mg/d initially; may gradually increase over 2 wk to maximum of 3 mg/kg/d or 100 mg, whichever is smaller, or for adolescents, to maximum of 3 mg/kg/d or 200 mg, whichever is smaller.	
Desipramine HCl (Norpramin)	Depression	*Adults:* 100–200 mg/d in single or divided dose; maximum 300 mg/d *Adolescents and older adults:* 25–100 mg/d maximum 150 mg/d	Tablets: 10, 25, 50, 75, 100, 150 mg
Doxepin HCl (Sinequan)	Depression, insomnia	*Adults:* 75–150 mg/d, preferably at hs; maximum 300 mg/d. Dilute concentrate with 120 mL of milk, water, or juice.	Capsules: 10, 25, 50, 75, 100, 150 mg Concentrate; 10 mg/mL
Imipramine HCl (Tofranil, Tofranil PM)	Depression, enuresis in children >6 yr	*Adults:* 50–150 mg/d at hs; maximum 200 mg/d. Hospitalized patients may require 250–300 mg/d.	Tablets: 10, 25, 50, 75
		Adolescents and older adults: 30–40 mg/d to maximum of 100 mg/d	Capsules: 75, 100, 125, 150

Continued

Table 15–12 ⊗ Dosage Schedule: Tricyclic Antidepressants—cont'd

Drug	Indications	Dosage	Available Dosage Forms
		Children: 1.5 mg/kg/d tid to maximum of 5 mg/kg/d. Increase by increments of 1–15 mg/kg/d at 3 to 5 d intervals.	
Nortriptyline HCl (Pamelor, Aventyl)	Depression	*Adults:* 25 mg tid qid to maximum of 100 mg/d	Capsules: 10, 25, 50, 75 mg
		Adolescents and older adults: 30–50 mg/d in divided doses	Solution: 10 mg/5 mL
Protriptyline HCl (Vivactil)	Depression	*Adults*: 100–200 mg/d in single or divided dose; maximum 60 mg/d. Make increase in a.m.	Tablets: 5, 10 mg
		Adolescents and older adults: 25–100 mg/d: maximum 150 mg/d	
Trimipramine maleate (Surmontil)	Depression	*Adults:* 75–150 mg/d in divided doses; maximum 200 mg/d. Hospitalized patients may require 250–300 mg/d. *Adolescents and older adults:* 50–100 mg/d	Capsules: 25, 50, 100 mg

Rational Drug Selection

Indications for the use of TCAs are depression, anxiety with sleep disturbance, enuresis in children 6 years or older, obsessive-compulsive disorder (OCD), and eating disorders. Prior to prescribing, the nurse practitioner needs to obtain a patient and family history of suicide and cardiovascular disease, as these are risk factors for adverse events. These drugs should be avoided with the elderly and used with caution with children.

Monitoring

A preliminary ECG should be done with QT correction and repeated after 3 weeks. Plasma levels can be assessed to assure delivery of an adequate dosage and to support patient adherence. Drugs with secondary active metabolites will show the plasma level in terms of each metabolite as well as a total level. Again, suicidal ideation must be monitored carefully during the first month after initiation, then periodically if residual depressive symptoms remain.

Patient Education

Advise the patient to avoid engaging in hazardous activities or using heavy machinery if drowsy or sedated. If the patient develops dry mouth, advise him or her to use sugarless candy or gum. If constipation develops, advise the patient to increase fluid and fiber intake and to use a bulking agent or stool softener.

MONOAMINE OXIDASE INHIBITORS (MAOIs)

MAOIs are infrequently used today in mental health nursing and psychiatry because safer drugs that are equally efficacious are available. If the nurse practitioner decides to prescribe these drugs, it is advisable to do so with expert consultation. These drugs are primarily reserved for the treatment of refractory unipolar depression. There are four MAOIs available: phenelzine (Nardil), isocarboxazid (Marplan), tranylcypromine (Parnate), and selegiline (Emsam), a transdermal preparation.

Pharmacodynamics

The MAOIs exert their effect by irreversibly inactivating the enzymes that metabolize norepinephrine, serotonin, and dopamine, thereby increasing the bioavailability of these neurotransmitters. In addition, they prevent the breakdown of tyramine, found in many foods that are aged or fermented. Because tyramine is toxic to humans, contributing to rapid extreme hypertension, these drugs require careful dietary restrictions. Selegiline transdermal (Emsam) requires dietary restriction only for doses above 9 mg in 24 hours.

Pharmacokinetics

Absorption and Distribution

The MAOIs are administered orally and are rapidly and thoroughly absorbed from the GI tract.

Metabolism and Excretion

There is a major first-pass effect of liver metabolism, and most of these drugs have P450 2D6 as a substrate. They are metabolized by the liver. Half-life is variable within 1 to 3 hours. TCA metabolites are excreted by the kidneys.

Onset, Peak, and Duration

Whereas SRIs and TCAs have long half-lives, requiring 3 to 4 weeks before full therapeutic benefits are evident, patients taking MAOIs may begin to experience relief of their depressive symptoms immediately or within approximately 14 days. Onset is 1 to 2 weeks; the peak for isocarboxazid and tranylcypromine is 0.7 to 3 hours and 1 to 2 hours for phenelzine.

Pharmacotherapeutics

Precautions and Contraindications

Contraindications include liver or kidney disease, hypersensitivity, congestive heart failure or arteriosclerotic disease, and age over 60 years. They should not be used with patients who are impulsive, cognitively impaired, or cannot follow the necessary dietary restrictions.

These drugs are rated Pregnancy Category C. They are excreted in breast milk, and safety has not been established. They have not been approved for use with children.

Postural hypotension and suppression of myocardial pain may occur.

Adverse Drug Reactions

Initial adverse effects may include insomnia, anxiety, and agitation as a result of the delayed metabolism of dopamine. In addition, dry mouth, blurred vision, urinary retention, and constipation occur because of anticholinergic activity. Most common side effects include dizziness, headache, insomnia, restlessness, and hypotension.

Clinical Use and Dosing

Because safer and more convenient drugs are available, the MAOIs are reserved for drug-resistant, refractory depressions.

Drug and Food Interactions

Because MAOIs inhibit the metabolism of norepinephrine, hypertensive crisis can occur if they are administered concurrently with other drugs or foods that raise blood pressure, including anticholinergics, sympathomimetics, stimulants, and foods containing tyramine. Tyramine is a precursor to dopamine, norepinephrine, and epinephrine. Foods that have been aged or fermented are rich in tyramine; therefore, dietary restrictions apply during use or within 14 days following discontinuance of the MAOI.

Symptoms of hypertensive crisis include headache, heart palpitations, stiff or sore neck, chest tightness, tachycardia, sweating, and dilated pupils. The crisis needs to be managed immediately, and the patient should remain standing until it is. Usual treatment is phentolamine (Regitine) 5 mg IV and then 0.25 to 0.5 mg IM every 4 to 6 hours. The prolonged metabolism of norepinephrine and the pressor effect of other drugs can lead to interactions resulting in hypotension and heart failure.

The 14-day restriction discussed previously also applies to initiating SRI or SNRI drug treatment. The increased amount of serotonin available due to inhibition of its metabolism by the MAOI leads to a risk of the potentially fatal serotonin syndrome. As a result of other drug interactions, particularly with meperidine, CNS depression can also occur. Table 15-13 presents drug interactions.

Rational Drug Selection

Use of MAOIs should be limited to conditions that are resistant to other forms of pharmacotherapy. Most notably, MAOIs have been used with treatment-resistant unipolar depression, panic disorder, and atypical depression associated with borderline personality disorder.

Monitoring

Periodic liver function tests should be performed and the drug discontinued if any abnormalities are found.

Patient Education

Advise the patient that strict dietary restrictions need to be followed. Provide a written list of foods to be avoided, including cheese, yogurt, sour cream, aged meat and meat products, dried fish and herring, alcoholic beverages, fermented vegetables such as sauerkraut, soy sauce, miso soup, bean curd, fava beans, avocados, bananas, raisins, caffeine, chocolate, and ginseng.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIs)

The SSRIs were first approved by the FDA in 1985 with the introduction of fluoxetine (Prozac) and quickly followed by paroxetine (Paxil), sertraline (Zoloft), fluvoxamine (Luvox), citalopram (Celexa), and most recently escitalopram (Lexapro).

Table 15–13 ▦ **Drug Interactions: Monoamine Oxidase Inhibitors**

Drug	Interacting Drug	Possible Effect	Implications
All MAOIs	Anorexiants, venlafaxine, SSRIs, bupropion, bromocriptine, L-dopa, L-tryptophan, MAO-B inhibitor, sumatriptan	Increased serotonergic effect, possible serotonin syndrome	Avoid
	CNS depressants, meperidine, antipsychotics	Increased CNS depression	Use cautiously in hazardous situations
Amphetamines	Buspirone, L-dopa, reserpine, tetrabenazine, guanethidine, meperidine	Increased blood pressure and possible hypertensive crisis	Monitor blood pressure; avoid if possible
	Antihypertensives, propoxyphene, meperidine, diuretics, nitroglycerin, dextromethorphan	Hypotension agitation diaphoresis, vascular collapse	Monitor blood pressure; avoid concurrent administration if possible
	Insulin, sulfonylureas	Hypoglycemia	Monitor blood glucose and for signs and symptoms of hypoglycemia
	Carbamazepine	Increased carbamazepine level	Monitor level; use alternative anticonvulsant if possible
	TCAs and SSRIs	Seizures and delirium	Avoid

Vortioxetine (Brintellix), the newest SSRI, was approved by the FDA in 2013. Because of their safety and equitable efficacy, their use has exceeded the use of TCAs and MAOIs.

Pharmacodynamics

All the SSRIs affect the serotonin neurotransmitter in the synaptic cleft by blocking the serotonin transporter from returning remaining serotonin to the presynaptic cell. Although traditionally these drugs are referred to as *selective* serotonin reuptake inhibitors, each one has different effects on other neurotransmitters. For example, fluoxetine significantly affects dopamine that contributes to the development of side effects. Citalopram and escitalopram are probably the closest to a true serotonin selective reuptake inhibitor. Through this mechanism, more serotonin is available to bind with the postsynaptic receptors.

Pharmacokinetics

Absorption and Distribution

All of the SSRIs are given orally and thoroughly absorbed through the GI tract. They are all highly protein bound with variable biodistribution, ranging from 12 to 40 L/kg. Peak plasma levels range from 1 to 8 hours and have a positive correlation with parent half-life.

Metabolism and Excretion

The SSRIs have a significant first-pass effect in the liver and are metabolized predominantly by the CYP450 system. Consideration of the half-life requires consideration of active metabolites as well as the possibility of inhibiting the SSRI's

own metabolism. For example, fluoxetine as the parent drug has a half-life of 1 to 3 days and its first metabolite, norfluoxetine, has an additional half-life of 4 to 16 days, resulting in an overall half-life of 4 to 16 days. Similarly, sertraline has a half-life of 24 to 26 hours but inhibits the P450 2D6 enzyme that is also the substrate for metabolism. Vortioxetine is metabolized primarily via CYP450 isozymes CYP2D6, CYP3A4/5, CYP2C19, CYP2C9, CYP2A6, CYP2C8 and CYP2B6. CYP2D6 poor metabolizers have approximately twice the vortioxetine plasma concentration of extensive 2D6 metabolizers. Table 15-14 presents the pharmacokinetics of SSRIs. Excretion of the SSRIs is primarily by the kidneys.

Pharmacotherapeutics

Precautions and Contraindications

Contraindications to use are limited to hypersensitivity to any of the drugs and concurrent or within 14 days of the administration of an MAOI. They should be used cautiously in patients with severe hepatic or renal impairment and should be avoided in the first and last trimesters of pregnancy. Although safety of use during pregnancy has not been definitively established, sertraline in particular has been used without adverse consequences. Risk versus benefit needs to be carefully considered, as it does during lactation as well. Caution is recommended. Fluvoxamine and vortioxetine are Pregnancy Category C, paroxetine is Pregnancy Category D, and the others are Category B. High doses of SSRIs have caused malformations and fetal death in animal studies. Neonates exposed to SSRIs in the late third trimester have demonstrated complications soon after birth, requiring hospitalization, respiratory support, and tube feedings.

Table 15–14 ✛ **Pharmacokinetics: SNRIs, SSRIs, and Other Antidepressants**

Drug	Peak	Half-Life	Excretion
Trazodone	1–2 h	3–9 h	Urine, feces
Fluoxetine HCl	6–8 h	1–384 h	Urine
Fluvoxamine maleate	3–8 h	16 h	Urine
Levomilnacipran	6–8 h	12 h	Urine
Milnacipran	2–4 h	6-8 h	Urine
Nefazodone HCl	1 h	2–18 h	Urine, feces
Mirtazapine	12 h	20–40 h	Urine, feces
Bupropion HCl	2 h	21–37 h	Urine
Paroxetine HCl	5.2 h	21–33 h	Urine
Sertraline HCl	4.5–8 h	26 h	Urine
Venlafaxine	1–3 h	5–11 h	Urine
Vortioxetine	7–11 h	66 h	Urine
Citalopram	4 h	35 h	Urine
Escitalopram	5 h	27–32 h	Urine

All of the SSRIs have been studied in children and FDA-labeled according to safety and effectiveness. Fluoxetine is labeled effective for major depression in children age 8 to 17 years and effective in treating OCD in children age 7 to 17 years. The safety and effectiveness of escitalopram have been established for treating major depression in adolescents age 12 to 17 years. Fluvoxamine is approved for treating OCD in children and adolescents age 8 to 17 years; it is not approved for treating depression in children or adolescents. Paroxetine is not approved for use in children after studies indicated it is not effective for them. Sertraline is approved for the treatment of OCD in children age 6 to 17 years, but not for treatment of depression or panic disorder in children. Vortioxetine has not been studied for safety or effectiveness in children or adolescents.

Although clinical drug trials do not substantiate a link between SSRIs and suicidal thinking, there is clearly a greater risk of suicide within the first 3 weeks of taking SSRIs and other antidepressants. This is related to the lag time in receiving the full therapeutic effect while there is an increase in neurocognitive activation early in initiation of the drug. Therefore, patients have greater energy to act on suicidal thoughts.

Adverse Drug Reactions

Adverse reactions to this group of drugs depend on which receptors are affected but are usually relatively minor and transient. Most common are nausea and sometimes vomiting, headache, light-headedness, dizziness, dry mouth, increased sweating, weight gain or loss, exacerbation of anxiety, and agitation. Sexual side effects may occur in up to 35% of patients and manifest as diminished, delayed, or absent orgasm; premature ejaculation; and decreased libido. A patient may not experience the same sexual side effects with other SRIs, and it is reasonable to decrease the dosage or change to another medication if they develop.

A significant adverse effect is serotonin syndrome, which occurs in the presence of excessive serotonergic activity. Therefore, maximum recommended doses must be adhered to, adjunctive combinations of serotonergic agents must be avoided, and adequate time for titration when changing from one serotonergic to another must be provided. A safe guideline when making such a change is to allow five half-lives per dose decrease, so that titrating off a 20 mg dose of paroxetine would need 5 days at 10 mg before starting another serotonergic drug. Symptoms of serotonin syndrome are nausea, diarrhea, chills, sweating, hyperthermia, hypertension, myoclonic jerking, tremor, agitation, ataxia, disorientation, confusion, and delirium. It can progress to coma and death.

Several years after the SSRIs had been on the market, it became apparent that some have a significant withdrawal syndrome that can be very disturbing to patients. In fact, the shorter half-life drugs such as paroxetine, sertraline, citalopram, and escitalopram can show withdrawal symptoms with just one missed dose. These symptoms are nausea, dizziness, and paresthesias such as electric shock sensations or visual tracers with eye movements. Fluoxetine is the only SSRI that does not require gradual and slow tapering because of its long half-life and active metabolites. In fact, a single dose of fluoxetine as the last step in tapering off other SSRIs is helpful in avoiding withdrawal symptoms.

Drug Interactions

Significant drug interactions may occur. As previously mentioned, the most significant are with MAOIs and other serotonergic drugs. With MAOIs there needs to be at least a 14-day washout period before initiating an SSRI and at least a 21 day washout of fluoxetine before initiating an MAOI. Drugs that inhibit the P450 2D6 will increase the effects of the SRI, and many SRIs inhibit the 2D6 and 3A3/4 and will interact with drugs that use these enzymes as substrates. CNS depression can occur with alcohol, antihistamines, and opioid analgesics. Concomitant use of St. John's wort and/or SAMe (S-adenosylmethionine) may contribute to serotonin syndrome. SSRIs should not be prescribed with TCAs and require washout between drugs. The SSRI may increase the plasma level of the TCA, which increases the risk of cardiac conduction complications. Table 15-15 includes the drug interactions with the SRIs.

Clinical Use and Dosages

Table 15-16 includes the indications, dosages, and available dosage forms for the SRIs and non-TCA antidepressants.

Rational Drug Selection

The SRIs, with the exception of fluvoxamine, are indicated for the treatment of depressive, anxiety, and panic disorders; OCD; and bulimia. Fluvoxamine is FDA-approved for the treatment of OCD, although it is likely to be as effective as the others for the listed disorders. More recently, the FDA has approved the indication for premenstrual dysphoric disorder, post-traumatic disorder (PTSD), generalized anxiety disorder, and social phobia. Off-label uses include the treatment of anorexia, the depressive phase of bipolar disorder, chronic headaches and other types of pain, impulse control disorders, and trichotillomania.

The patient needs to be monitored closely during the first 2 to 3 weeks of initiation of SRIs, including regular assessment of suicidal thinking. There should be at least telephone contact on a weekly basis with an agreement to notify the prescriber immediately if suicidal thoughts occur or persist.

Monitoring

No specific monitoring is required, other than ongoing assessment of mood.

Patient Education

Advise the patient that these drugs may take as long as 3 to 4 weeks until their full therapeutic benefits become evident and that the initial adverse reactions, commonly including nausea, intermittent light-headedness, sedation, muscle restlessness, and sleep disruptions, should be minor and transient. Also, tell the patient to assess the level of sedation the drug can initially cause before engaging in hazardous activities. Patients also need to be reminded not to miss a dose or let their prescription run out before seeking a refill because of the withdrawal syndrome.

Table 15–15 ▦ **Drug Interactions: Selective Serotonin Reuptake Inhibitors (SSRIs)**

Drug	Interacting Drug	Possible Effect	Implications
All (SSRIs)	Anorexiants, ergotamine, tryptophan	Serotonin syndrome	Avoid; or use with caution
	MAOIs	Hypertensive crisis	Contraindicated
	Valproate carbamazepine	Increased level of anticonvulsant	Monitor plasma levels
	TCAs	Increased level of TCA, increased risk of cardiotoxicity	Monitor blood levels of TCA; use with caution
	Benzodiazepines	Increased plasma level of benzodiazepines with sedation and psychomotor/cognitive impairment	Avoid long-term use of benzodiazepines
	Beta blockers	Bradycardia, syncope, increased serum levels of SSRI	Warn patient
	Insulin	Increased insulin sensitivity	Monitor blood glucose
	Neuroleptics	Increased plasma level of neuroleptic	Monitor for adverse reactions
	Zolpidem	Hallucinations and delirium	Avoid
	Aspirin, NSAIDs	Risk of bleeding increased	Caution
	Alcohol	May potentiate alcohol effects	Avoid

Table 15–16 � **Dosage Schedule: Non-TCA Antidepressants**

Drug	Indications	Neurotransmitters Affected	Dosage	Available Dosage Forms
Bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL)	Depression, Seasonal Affective Disorder	Dopamine, norepinephrine	*Adolescents and adults:* 75–450 mg/d; give 2–3 times/d with 6 h intervals in between; no single dose to exceed 150 mg; increase at 3 to 4 d intervals Wellbutrin XL 150–300 mg qAM	Tablets: 75, 100 mg Sustained-release tablets: 75, 100 mg Extended-release: 150, 300 mg
Citalopram (Celexa)	Depression, anxiety (off-labeled)	Primary: serotonin Secondary: norepinephrine and dopamine	*Adults:* 20 mg qd; may increase in 20 mg increments at weekly intervals; maximum 60 mg/d *Older adults:* 20 mg/d	Tablets: 10, 20, 40 mg
Desvenlafaxine (Pristiq)	Depression	Serotonin Norepinephrine	*Adults:* 50 mg qam, max 100 mg/d	Tablets, extended-release: 50, 100 mg
Duloxetine (Cymbalta)	Depression, diabetic neuropathy, fibromyalgia, anxiety	Serotonin and norepinephrine	*Adults:* 40–60 mg/d max 60 mg 60 mg for neuropathy and fibromyalgia	Tablets: 20, 30, 60 mg
Escitalopram (Lexapro)	Depression, anxiety	Serotonin	*Adults:* 10 mg qam, max 20 mg qd *Children 12 and up:* 10 mg, may increase to 20 mg after 3 wk	5, 10, 20 mg tabs Oral solution 1 mg/mL
Fluoxetine (Prozac)	Depression, OCD, bulimia, panic disorder	Primary: serotonin Secondary: norepinephrine	*Adolescents and adults:* 20–80 mg/d; may increase slowly at 5 d intervals after 3 to 4 wk trial at lower dose; OCD may require a higher dose *Children 8–17:* 10 mg qd, increase by 10 mg in 1 wk. Slower titration with lower-weight children *Older adults:* Half dose	Capsules: 10,0 mg, 40 Liquid: 20 mg/5 mL Delayed-release capsules: 90 mg

Table 15–16 ✖ Dosage Schedule: Non-TCA Antidepressants—cont'd

Drug	Indications	Neurotransmitters Affected	Dosage	Available Dosage Forms
Fluvoxamine (Luvox)	OCD, social anxiety disorder Depression (off-labeled)	Primary: serotonin Secondary: norepinephrine	*Adults:* 50–300 mg/d; dose >100 mg should be divided; increase in 50 mg increments every 4–7 d *Older adults:* half dose	Tablets: 50, 100 mg
Levomilnacipran (Fetzima)	Major depression	Serotonin and norepinephrine	*Adults:* 40 to 120 mg daily. Titration schedule: 20 mg qd x 2 days; then 40 mg qd. Adjust dose in increments of 40 mg q 2d. Maximum 120 mg daily.	Capsules: 20, 40, 80, or 120 mg
Milnacipran (Savella)	Fibromyalgia	Serotonin and norepinephrine	*Adults:* 100 mg (50 mg bid). Titration schedule: day 1: 12.5 mg once; days 2–3: 25 mg/d (12.5 mg bid); days 4–7: 50 mg/d (25 mg bid); after day 7: 100 mg/d (50 mg bid)	Tablets: 12.5 mg, 25 mg, 50 mg, 100 mg
Mirtazapine (Remeron, Remeron Soltabs)	Depression	Primary: histamine Secondary: serotonin and norepinephrine	*Adults:* 15–45 mg/d, preferably at bedtime Disintegrating Soltab: 15, 30, 45 mg Lower doses may increase sedation	Tablets: 15, 30, 45 mg
Nefazodone	Depression	Primary: serotonin Secondary: adrenergic	*Adults:* 200–600 mg/d in 2 divided doses; increase in 100–200 mg/d increments at weekly intervals	Tablets: 50, 100, 150, 200, 250 mg
Paroxetine (Paxil, Paxil CR)	Depression, OCD, panic disorder, social phobia, PTSD, anxiety, PMDD (CR)	Primary: serotonin; Secondary: norepinephrine	*Adolescents and adults:* 20–60 mg/d; panic disorder and OCD may require higher doses; taper off slowly *Older adults:* half dose	Tablets: 10, 20, 30, 40 mg Controlled-release: 12.5, 25 mg Oral suspension: 10 mg/5 mL
Sertraline (Zoloft)	Depression, OCD, GAD, PMDD, PTSD, social anxiety disorder	Primary: serotonin Secondary: norepinephrine	*Adolescents and adults:* 50–200 mg/d; increase at weekly intervals *Older adults:* half dose	Tablets: 25, 50, 100 mg Concentrate: 20 mg/mL
Trazodone (Desyrel)	Depression, off label for sleep	Primary: serotonin Secondary: adrenergic	*Adults:* 50–400 mg/d; increase in 50 mg increments every 3–4 d; take with food	Tablets: 50, 100, 150, 300 mg
Venlafaxine (Effexor)	Depression, PTSD, GAD, social anxiety disorder, panic disorder	Primary: serotonin Secondary: norepinephrine	*Adults:* 75–375 mg/d in divided doses. When discontinuing, taper off over a 2 wk period; increase in 75 mg increments at 4 d intervals; take with food Extended-release: 37.5, 75, 150 mg	Tablets: 25, 37.5, 50, 75, 100 mg
Vortioxetine (Brintellix)	Major depression	Serotonin	*Adults:* 10 mg/d, may increase to 20 mg/d	Tablet: 5, 10, 15, or 20 mg

SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS (SNRIs)

In the United States there are six SNRIs that have been approved by the FDA: venlafaxine (Effexor and Effexor XR), desvenlafaxine (Pristiq), duloxetine (Cymbalta), Milnacipran (Savella), and levomilnacipran (Fetzima). Milnacipran (Savella) was approved by the FDA in 2009 to treat fibromyalgia. Levomilnacipran (Fetzima) is the newest SNRI, approved for major depression in 2013. Nefazodone is a serotonin antagonist and reuptake inhibitor that also inhibits the reuptake of norepinephrine. It is available only in generic

form. In 2004, the FDA added a Black-Box Warning related to liver toxicity in 1 out of 250,000 cases of those taking nefazodone and 21 deaths related to liver failure. It will not be discussed in detail in this chapter.

Pharmacodynamics

Venlafaxine and duloxetine both block the serotonin and norepinephrine transporters, thereby inhibiting the reuptake of the neurotransmitter and increasing the availability to bind with the postsynaptic receptors. At lower doses (75 mg), venlafaxine predominantly affects serotonin reuptake, contributing to greater reduction of anxiety more so than reduction of depressive symptoms. Duloxetine, however, appears to be a more potent and equal serotonin and norepinephrine reuptake inhibitor than venlafaxine is. The exact mechanism of action of milnacipran and levomilnacipran are unknown, but it is thought that they inhibit reuptake of serotonin and noepinephrine.

Pharmacokinetics

Absorption and Distribution

These drugs are rapidly absorbed after oral intake and metabolized extensively in the liver. The time needed to reach maximum plasma concentration is 2 hours for both venlafaxine and duloxetine. Venlafaxine has only 30% protein binding, whereas duloxetine has greater than 90%.

Metabolism and Excretion

Venlafaxine is metabolized by CYP450 2D6 with one active metabolite (O-desmethylvenlafaxine) and two less-active metabolites. Duloxetine is metabolized by CYP450 2D6 and 1A2. Venlafaxine has a half-life of 5 hours, and the active metabolite has a half-life of 11 hours. Steady state is achieved in 3 to 4 days. Duloxetine has a half-life of 12 hours, reaching steady state in 3 days. Both drugs are excreted mostly in the urine. Levomilnacipran is catalyzed primarily by CYP3A4 and is excreted renally. Fifty-five percent of milnacipran is excreted unchanged in the urine. Milnacipran is also metabolized into inactive metabolites that are excreted in the urine.

Pharmacotherapeutics

Precautions and Contraindications

As with other drugs used to treat depression, a major precaution is increased suicidal thinking during the first few weeks of initiation and change in dosage of the medication. The patient must be monitored at least weekly and assessed for suicide risk each time. Patients need to be monitored for mood lability and switching into a manic or hypomanic state. In addition, hypersensitivity contraindicates use.

The SNRIs venlafaxine, duloxetine, levomilnacipran, and milnacipran are rated as Pregnancy Category C. There are no well-controlled studies in pregnant women taking SNRIs. There have been reports of fetal mortality and skeletal malformations in rats and rabbits. Neonates of women who took SNRIs in the third trimester have developed complications

soon after birth, requiring prolonged hospitalization, respiratory support, and tube feeding.

Both venlafaxine and duloxetine have been found in breast milk. There are no proven adverse effects in infants exposed to venlafaxine via breast milk, but it is recommended infants be monitored for weight gain and excessive sedation (LactMed, 2014). There is little information on the effects of duloxetine in breastfed infants. It is recommended that exclusively breastfed infants of mothers who take duloxetine be monitored for adequate weight gain, drowsiness, and developmental milestones (LactMed, 2014). Levomilnacipran is excreted in breast milk in rats, but has not been studied in lactating women, and the manufacturer recommends nursing women not take the medication while breastfeeding (LactMed, 2014). Milnacipran is excreted in breast milk and in a single study where lactating women were administered a single 50 mg dose of milnacipran, the maximum estimated infant dose via breast milk was 5% of maternal dose (Forest Laboratories, 2013).

Duloxetine may exacerbate narrow-angle glaucoma and should be used cautiously with these patients. Duloxetine has also shown increased serum transaminase levels and should not be used with patients with liver disorders.

Adverse Drug Reactions

The most common side effects with both venlafaxine and duloxetine include headache, somnolence, dizziness, insomnia, nervousness, nausea, dry mouth, constipation, and abnormal ejaculations. Appetite and weight decreases may occur. At higher doses, both drugs may contribute to elevated blood pressure. There was no effect shown to the QTc interval with either of these drugs.

The most common adverse effect of milnacipran in clinical trials was nausea in 37% of patients. Other common adverse effects include headache (18%), constipation (16%), hot flush (12%), dizziness (10%), hyperhidrosis (9%), and palpitations (7%). Male patients reported erectile dysfunction, decreased libido, and ejaculation failure.

Levomilnacipran most commonly may cause nausea (17%), constipation (9%), hyperhidrosis (9%), tachycardia (6%), erectile dysfunction (6%), and urinary hesitation (4%). Erectile dysfunction and urinary hesitation increase as the dose increases.

Drug Interactions

Drugs that inhibit CYP450 2D6 will interact with both venlafaxine and duloxetine, including fluoxetine and quinidine. With duloxetine, drugs that inhibit 1A2 will also interact, especially fluvoxamine and some quinolone antibiotics. There seems to be no interaction between alcohol and either venlafaxine or duloxetine; however, frequent use of alcohol may affect the liver function, and therefore duloxetine should not be used with patients who abuse or are dependent on alcohol.

Drugs that inhibit CYP3A4 (i.e., ketoconazole) may require adjustment of levomilnacipran dosage. Alcohol may cause an accelerated release of levomilnacipran extended-release, and it is recommended that levomilnacipran not be taken with alcohol.

Serotonin syndrome may occur if milnacipran is used concurrently with a triptan. If a triptan is clinically indicated,

patients should be monitored closely. The catecholamines epinephrine and noepinephrine may cause paroxysmal hypertension and dysrhythmias if cominstered with milnacipran, because milnacipran inhibits the reuptake of norepinephrine. Patients taking milnacipran and digoxin have reported postural hypotension and tachycardia. Clonidine's antihypertensive effect may be inhibited by milnacipran owing to inhabitation of norepinephrine reuptake.

Clinical Use and Dosing

These drugs are indicated in treating major depressive disorders and bipolar mood disorders. Venlafaxine is also approved for treating anxiety disorders such as generalized anxiety disorder, social phobia, and PTSD. Duloxetine is also approved to treat neuropathic pain and overactive bladder. It is likely that duloxetine, owing to its neurophysiological action, will eventually be approved for treating anxiety disorders as well.

Venlafaxine is available in extended-release (XR) form as well as in immediate-release form. The immediate-release form must be taken at least twice a day and has uncomfortable discontinuation symptoms if doses are missed, including paresthesias, dizziness, nausea, and vomiting. The initial dose for venlafaxine XR is 75 mg/day, which is increased to 150 to 300 mg/day in increments of 75 mg every 4 days. Severely depressed patients may require a higher dosage of 375 to 450 mg/day in divided doses to prevent side effects.

The initial dose of duloxetine is 20 mg/day, which is increased to 60 mg/day in increments of 20 mg every 4 days. There is no evidence that doses higher than 60 mg/day produce better results than 60 mg/day. Desvenlafaxine (Pristiq), an active metabolite of venlafaxine, is available only in extended-release capsules.

Levomilnacipran is indicated for major depressive disorder, with the recommended dose range of 40 mg to 120 mg daily. Patients should be started on 20 mg once daily for 2 days, then increased to 40 mg daily. The dose may be adjusted in increments of 40 mg every 2 days until efficacy is determined. The maximum dose is 120 mg daily. Withdrawal symptoms may be seen if levomilnacipran is discontinued abruptly; therefore it should be tapered if discontinued.

Milnacipran is indicated for treatment of fibromyalgia, with a recommended dose of 100 mg/day (50 mg twice daily). Patients may tolerate milnacipran better if the dose is titrated based on the following schedule: day 1: 12.5 mg once; days 2–3: 25 mg/day (12.5 mg BID); days 4–7: 50 mg/day (25 mg BID); after day 7: 100 mg/day (50 mg BID). Withdrawal symptoms are seen if milnacipran is abruptly discontinued; therefore it should be tapered when discontinuing.

Rational Drug Selection

Initially, it was thought that duloxetine would be especially effective for patients with melancholic depressions or the type of depressions with low energy, hypersomnia, low motivation, and social withdrawal. However, the results have been inconclusive about this selective and difficult-to-treat population. Both venlafaxine and duloxetine are more activating than the SSRIs and therefore are first-line drugs to use with patients who have the more sluggish types of depression. Venlafaxine also seems effective with adults who have both depression and attention deficit-hyperactivity disorder. Milnacipran is only used for fibromyalgia.

Monitoring

No specific serum level monitoring is available for the SNRIs. With duloxetine, liver function should be monitored once weekly, once monthly, biannually, and finally annually. All patients taking antidepressants need to be carefully monitored for suicidal risk as well as activation of hypomanic or manic symptoms.

Patient Education

Patients should be given written descriptions of side effects and ways to relieve them. Women of childbearing age need to be told to report if pregnant and should be tapered off medication, especially in the third trimester. As with the SSRIs, sudden discontinuation frequently results in uncomfortable withdrawal symptoms; and patients need to request refill prescriptions in an adequate amount of time to avoid running out.

ANTIPSYCHOTICS (APS)

Since 1952, when chlorpromazine (Thorazine) was first used to treat psychosis, there has been a substantial increase in the types of antipsychotic agents available. Antipsychotic drugs (APs) are generally divided into two major categories, although numerous specific classes exist. The older APs are variably termed *conventional*, *traditional*, or *typical* antipsychotics. They are also referred to as *neuroleptics* or *major tranquilizers*. The newer APs are generally termed *atypical antipsychotics*. In this chapter, the older APs will be termed typical APs and the newer agents will be termed atypical APs. The specific classes of APs and examples of these include the benzisoxazoles (paliperidone, risperidone, ziprasidone), piperidinyl-benzisoxazole (iloperidone), benzisothiazol (lurasidone), butyrophenones (haloperidol), dibenzoxazepines (loxapine), dibenzo-oxepino pyrroles (asenapine), dibenzodiazepines (clozapine), dibenzothiazepines (quetiapine), dihydroindolones (molindone), diphenylbutylpiperidines (pimozide), phenothiazines (chlorpromazine), quinolinones (aripiprazole), thienobenzodiazepines (olanzapine), and thioxanthenes (thiothixene).

Traditionally, it was believed that overstimulation of dopamine (D) receptors was at the heart of schizophrenia. This theory, called the dopamine hypothesis, formed the basis for understanding the effect of typical APs in reducing the positive symptoms of schizophrenia, such as hallucinations and delusions. A more current hypothesis is that schizophrenia involves overactivity of D_2 receptors in the basal ganglia, hypothalamus, limbic system, brainstem, and medulla, and underactivity of D_1 receptors in the prefrontal cortex. The overactivity of these D_2 receptors is thought to contribute to the positive symptoms of schizophrenia, whereas the underactivity of D_1 receptors explains the negative symptoms of schizophrenia, such as lack of motivation and social isolation. As new knowledge of the brain

evolves, it is apparent that it is not a simple question of too much or too little of a neurotransmitter (NT), but where is there too much, too little, or an imbalance of neurotransmitters.

TYPICAL ANTIPSYCHOTICS

The phenothiazine group of typical APs includes chlorpromazine (Thorazine), thioridazine (Mellaril), fluphenazine (Prolixin), and fluphenazine decanoate, perphenazine (Trilafon), and trifluoperazine (Stelazine). Nonphenothiazine typical APs include haloperidol (Haldol) and haloperidol decanoate, thiothixene (Navane), loxapine (Loxitane), and molindone (Moban).

Pharmacodynamics

The typical APs block D_2 receptors in the basal ganglia, hypothalamus, limbic system, brainstem, and medulla and reduce the positive symptoms of schizophrenia. Typical APs, however, are less effective in treating the negative symptoms of schizophrenia, such as flat affect, decreased motivation, withdrawal from interpersonal relationships, and poor grooming and hygiene. Clinical effectiveness occurs when 60% to 70% of D_2 receptors are blocked. Too much dopamine blockade, however, leads to symptoms resembling those of parkinsonism. Prolactin elevation appears beyond 72% D_2 occupancy. As D_2 occupancy nears 78%, extrapyramidal symptoms (EPSs) are more prominent.

Pharmacokinetics

Absorption and Distribution

Typical APs are usually administered orally, although parenteral versions and long-acting decanoate forms of haloperidol and fluphenazine are available. The drugs are absorbed rapidly and distributed widely to adipose tissue. Onset of action varies among agents. Onset of oral agents is generally within 1 to 2 hours, IM injections within 10 to 30 minutes, and decanoate forms within 1 to 9 days.

Metabolism and Excretion

Typical APs are metabolized in the liver and excreted in the urine. Half-life varies widely among agents and types of agents. Because of their lipid solubility, several weeks may be required before their antipsychotic benefits become evident. Table 15-17 presents the pharmacokinetics.

Pharmacotherapeutics

Precautions and Contraindications

Typical APs may be grouped according to whether they are high or low potency. High-potency drugs such as haloperidol and fluphenazine carry an increased risk of causing EPSs, whereas low-potency drugs such as chlorpromazine and thioridazine carry less risk of EPSs but more risk of anticholinergic adverse reactions (dry mouth, constipation, urinary retention, blurred vision) and antiadrenergic effects (orthostatic hypotension).

Contraindications for use may include narrow-angle glaucoma, bone marrow depression, and severe liver or cardiovascular disease. These agents should be used cautiously in the presence of CNS tumors, epilepsy, diabetes mellitus, respiratory disease, and prostatic hypertrophy. Safety is not established in pregnancy and lactation.

All antipsychotic medications now have an FDA Black-Box Warning regarding increased mortality in elderly patients with dementia-related psychosis and are not approved for the treatment of such patients.

Adverse Drug Reactions

Typical APs have many adverse effects that make compliance a common issue. A life-threatening adverse reaction is

Table 15–17 ⊞ Pharmacokinetics: Typical Antipsychotics

Drug	Onset	Peak	Duration	Half-Life	Excretion
Chlorpromazine HCl	Erratic	2–4 h	Up to 6 mo	10–30 h	Urine
Fluphenazine	1 h	—	6–8 h	4.7–15.3 h	Urine
Fluphenazine decanoate	1 h; 1–3 d	2–4 h; 2–3 d	6–8 h; up to 4 wk	6.8–14.3 d	Urine
Perphenazine	Erratic	2–4 h	6 h	12–24 h	Urine
Trifluoperazin	Erratic	2–4 h	4–6 h	13 h	Urine and feces equally
Thioridazine HCl	Erratic	2–4 h	4–6 h	24–36 h	Urine
Thiothixene	Slow	2–8 h	Up to 12 h	34 h	Urine
Loxapine	20–30 min	2–4 h	12 h	5–19 h	Urine
Pimozide	—	6–8 h	—	55 h	Urine
Haloperidol	2 h	2–6 h	8–12 h	21–24 h	Urine
Haloperidol decanoate	3–9 d	—	Up to 4 wk	12–36 h; 3 wk	Urine, bile
Molindone HCl	Erratic	1.5 h	24–36 h	10–20 h	Urine and feces equally

neuroleptic malignant syndrome (NMS), characterized by fever up to 107°F, elevated pulse, diaphoresis, rigidity, stupor or coma, and acute renal failure. EPSs are among the most troublesome side effects and include pseudoparkinsonism (shuffling, pill-rolling, cog-wheeling, tremors, drooling, rigidity), akathisia (restlessness), dystonia (involuntary, painful movements), and tardive dyskinesia (TD) (involuntary buccolingual movements, difficulty speaking and swallowing, which may be irreversible). Antiparkinson, antihistamine, and anticholinergic drugs are given to counter EPSs. Other side effects of typical APs include sedation, weight gain, anticholinergic effects, photosensitivity, reduction of seizure threshold, orthostatic hypotension, sexual dysfunction, galactorrhea, and amenorrhea.

Drug Interactions

Drug interactions are many and varied, the most serious of which is CNS depression with concomitant use of CNS depressants. There may be additive hypotension with antihypertensives. Lithium in combination with a phenothiazine increases the risk of EPSs and masks the early signs of lithium toxicity. There is an inc reased risk of anticholinergic effects with other agents having anticholinergic properties. Table 15-18 presents drug interactions.

Clinical Use and Dosing

Typical APs are more effective in reducing the positive than they are the negative symptoms of schizophrenia. Typical APs may be more effective than atypical APs in treating very severe psychosis. Patients who need rapid control of agitation and dangerous psychosis can be treated with IV haloperidol. IM chlorpromazine also provides rapid sedation. Table 15-19 presents the indications and dosage schedules of typical APs.

Rational Drug Selection

The choice of a specific agent can be guided by past response to the medication, initial response, family history, and side-effect profile of the medication. Usually, EPSs can be decreased or eliminated by the addition of drugs such as benztropine (Cogentin), diphenhydramine (Benadryl), trihexyphenidyl (Artane), atenolol (Tenormin), or amantadine (Symmetrel). A decrease in the dose or a change to a different type of antipsychotic may also counter these effects. Some anticholinergic effects, such as constipation, can be addressed by nonpharmacological measures, such as increased fluid intake and dietary bulk.

The depot or decanoate form of medication may be used if compliance is an issue. It is usually administered every 2 to 4 weeks.

Monitoring

The motor function of individuals taking typical antipsychotics should be routinely assessed with the Abnormal Involuntary Movement Scale (AIMS), which rates various movements such as joint rigidity and balance numerically, thereby enabling the clinician, over time, to detect changes

Table 15–18 ▦ **Drug Interactions: Typical Antipsychotics**

Drug	Interacting Drug	Possible Effect	Implications
All typical antipsychotics	Alcohol, antihistamines, barbiturates, hypnotics, narcotics, benzodiazepines	CNS depression	Avoid; monitor for adverse reactions
	Lithium	Increased risk of neurotoxicity and EPS	Monitor lithium levels and signs and symptoms of toxicity
	Lithium, antacids, cimetidine	Decreased antipsychotic effect	May require increased antipsychotic dose
	Anticholinergics	Increased anticholinergic effect; increased risk of hyperthermia	Monitor temperature
	Beta blockers	Increased effect of both drugs	Monitor for adverse reactions
	Dopaminergics	Antagonize antipsychotic effect	Avoid concurrent use
	Hypoglycemics	Decreased diabetic control	Monitor blood glucose closely
	Phenytoin	Increased toxicity of phenytoin	Monitor blood level of phenytoin; lower dose of antipsychotic may be needed
	Trazodone	Increased hypotension	Monitor postural hypotension; warn patient to change position slowly
	Diazoxide	Hyperglycemia	Monitor blood glucose
	TCAs	Increased sedation, risk of seizures, anticholinergic effect, serum levels of TCA, risk of arrhythmias	Use SSRI
	SSRIs	Increased antipsychotic levels	Monitor dose of antipsychotic
	Nicotine	Decreased antipsychotic levels	Monitor dose of antipsychotic

Table 15–19 ⊗ Dosage Schedule: Typical Antipsychotics

Drug	Indications*	Dosage	Available Dosage Forms
Chlorpromazine HCl (Thorazine)	Psychosis; acute severe agitation	*Adults:* PO: 25 mg tid, increase gradually to maximum of 400 mg/d IM: 25 mg initially; may repeat with 25–50 mg in 1 h: maximum 400 mg IM every 4–6 h; substitute with oral as soon as possible; give concentrate with 60 mL or more of diluent *Children:* PO: 0.5 mg/kg every 4–6 h as needed Rectal: 1 mg/kg every 6–8 h as needed IM: 0.5 mg/kg every 6–8 h as needed	Tablets: 10, 15, 25, 50, 100, 150, 200 mg Solution: 30, 100 mg/mL
Fluphenazine (Prolixin)	Psychosis; acute severe agitation	*Adults:* PO: 0.5–10 mg/d in divided doses at 6 to 8 h intervals *Older adults:* PO 1–2.5 mg/d: IM one-third to one-half oral dose starting with 1.25 mg Decanoate: 12.5–25 mg deep IM every 1–3 wk	Tablets: 1, 2.5, 5, 10 mg Elixer: 2.5 mg/5 mL
Perphenazine (Trilafon)	Psychosis; acute severe agitation	*Adults:* 4–16 mg 2–4 times daily to maximum of 64 mg/d. Prolonged dosage of greater than 24 mg/day should be reserved for hospitalized patients who can be monitored for EPS. *Older adults:* One-third to one-half adult dose *Children >12 yr:* Lowest adult dose possible	Tablets: 2, 4, 8, 16 mg Concentrate: 16 mg/5 mL Injection: 5 mg/mL
Trifluoperazine (Stelazine)	Psychosis; acute severe agitation	*Adults:* 2–5 mg bid to maximum of 40 mg/d. Most are managed on 15–20 mg/day. IM: 1–2 mg every 4–6 h has needed *Older adults:* Low end of adult dose *Children >6 yr:* 1 mg 1–2 times daily; adjust according to weight	Tablets: 1, 2, 5, 10 mg Concentrate: 10 mg/mL Injection: 2 mg/mL
Thioridazine (Mellaril)	Psychosis; acute severe agitation	*Adults:* 50–100 mg tid to maximum of 800 mg/d *Children >2 yr:* 0.5 to maximum of 3 mg/kg/d	Tablets: 10, 15, 25, 50, 100, 150, 200 mg 25, 100 mg/5 mL 30, 100 mg/mL
Thiothixene (Navane)	Psychosis; acute severe agitation	*Adults:* Initial dose of 2 mg tid (5 mg tid in severe conditions). The usual optimum dose is 15 mg/day in milder conditions and 20–30 mg/d in more severe cases; maximum 60 mg/d	Capsules: 1, 2, 5, 10, 20 mg Concentrate: 5 mg/mL
		IM: 16–20 mg 2–4 times/d to maximum of 30 mg/d	Injection: 2 mg/mL
Loxapine (Loxitane)	Psychosis; acute severe agitation	*Adults and children >15 yr:* 10 mg bid initially; may increase rapidly over 7–10 d to 60–100 mg/d to control symptoms. Lower dose to lowest to control symptoms, maintenance dose 20–60 mg/d.	Tablets: 5, 10, 25, 50 mg Concentrate: 25 mg/mL Injection: 50 mg/mL
		IM: 12.5–50 mg every 4–6 h until desired response; then start oral	
Pimozide (Orap)	Motor and phonic tics in patients with Tourette's disorder	*Adults and children >12 yr:* 1–2 mg/d in divided doses. Increase every other day to max of 10 mg/d. Doses above 4 mg/d (0.05 mg/kg/d in children) require CYP 2D6 genotyping; do not exceed 4 mg/d in poor CYP 2D6 metabolizers. ECG at baseline and periodically thereafter.	Tablets: 1, 2 mg
Haloperidol (Haldol)	Psychosis; acute severe agitation	*Adults:* 0.5–5 mg 2–3 times daily to usual maximum dose of 30 mg/d; some adults require 100 mg/d IM: 2–5 mg; may repeat after 60 min; substitute with oral as soon as feasible. First oral dose should be administered 12–24 h following last IM dose. Decanoate: Deep IM every 4 wk; initial dose 10–15 times oral dose; not to exceed 100 mg *Older adults:* Lower doses and slower titration *Children:* 0.05–15 mg/kg/d; may give in divided doses	Tablet: 0.5, 1, 2, 5, 10, 20 mg Concentrate: 2 mg/mL Injection solution: 5 mg/mL IM injection solution decanoate: 50, 100 mg/mL
Molindone HCl (Moban)	Psychosis; acute severe agitation	*Adults and children >12 yr:* 50–75 mg/d. Increase in 3 to 4 days to maximum of 225 mg/d. Maintenance: Mild: 5–15 mg 3–4 times daily; moderate 10–25 mg 3–4 times a day; severe 225 mg/d may be required	Tablet: 5, 10, 25, 50 mg Concentrate: 20 mg/mL

*Not for dementia-related psychosis in the elderly.

that represent early EPSs. Table 15-20 presents an AIMS checklist that the nurse practitioner may use to evaluate patients.

Typical APs may elevate prolactin levels because dopamine, which inhibits prolactin, is blocked. Patients should be monitored for the consequences of chronic prolactin elevation, such as galactorrhea, gynecomastia, amenorrhea, and sexual dysfunction.

Patient Education

Anticipate the need for refills before the patient runs out of medication. Teach the patient to avoid sudden withdrawal of the medication because EPSs can occur. Emphasize that it is important to take the medication as prescribed, because noncompliance is the leading cause of increased symptoms and hospitalization. Advise the patient to report any side effects of EPSs, TD, or NMS. Advise the patient to rise slowly to minimize orthostatic hypotension. Caution the patient to avoid taking alcohol or other CNS depressants concurrently with these drugs and to avoid driving or other activities requiring alertness, because medication may cause drowsiness. Advise the patient to wear sunscreen and protective clothing because photosensitivity and changes in skin pigmentation may occur.

ATYPICAL ANTIPSYCHOTICS

A number of atypical APs have been marketed since 1990. These drugs include aripiprazole (Abilify), asenapine (Saphris), clozapine (Clozaril), iloperidone (Fanapt), lurasidone (Latuda), olanzapine (Zyprexa, Zyprexa Zydis, IM), paliperidone (Invega, Invega Sustenna), quetiapine (Seroquel), risperidone (Risperdal, Risperdal M-Tabs, Risperdal Consta), and ziprasidone (Geodon). Atypical APs address both the positive and negative symptoms of schizophrenia. Some of the superiority in treating negative symptoms, as compared to typical APs, may be related to less interference with cognitive functioning. Because there is better patient tolerability than with the typical APs, patients are more likely to continue taking the atypical APs. These newer agents are characterized by less risk for EPSs, TD, and elevation of prolactin levels. The atypical APs, however, are associated with unhealthy weight gain, which leads to a metabolic syndrome (abdominal obesity, high blood pressure, high cholesterol levels, and insulin resistance). Schizophrenia itself, as well as the atypical APs, increases the risk of diabetes. Before starting any atypical antipsychotic, patients should be assessed for waist circumference, body mass index (BMI), blood pressure (BP), fasting plasma glucose, and lipid profile. The practitioners should recheck BMI monthly and order laboratory work-ups at 3 months. After 3 months, the BMI should be checked quarterly and BP, laboratory work-ups, and waist circumference annually.

Pharmacodynamics

Although the mechanism of action for these APs is not precisely understood, the atypical APs are thought to block serotonin receptors in the cortex, which blocks the usual ability of serotonin to inhibit the release of dopamine. Thus, more dopamine is released to the prefrontal cortex, which reduces the negative symptoms of schizophrenia. All drugs with antipsychotic properties block dopamine D_2 receptors, but atypical APs generally have less D_2 blockade than the typical APs. Drugs with the least D_2 blockade (clozapine, olanzapine) have the lowest incidence of EPSs. Most of the atypical APs also variously affect adrenergic, histaminic, and cholinergic receptors. Drugs that are potent histamine H_1 receptor antagonists (olanzapine, clozapine) produce more weight gain and sedation. Drugs that block noradrenergic receptors (clozapine) produce more hypotension.

Pharmacokinetics

Absorption and Distribution

These drugs are commonly administered orally and are rapidly and completely absorbed. Parenteral or long-acting decanoate forms of olanzapine, risperidone, and ziprasidone also exist. Orally disintegrating tablets of olanzapine and risperidone are available and helpful when "cheeking" of medication is suspected.

Table 15–20 **Abnormal Involuntary Movement Scale (AIMS) Checklist**

Instructions: Rate on a scale from 1 to 5, with 1 being none and 5 being severe. Rate at each appointment initially, then decrease frequency unless patient is a male under age 25 or a female over age 70.

Abnormal Involuntary Movement	Scale	Notes
Holding arms outstretched to sides		
Arms outstretched to front with hands flat and paralle		
Walking in a straight line		
Fluidity of shoulder and elbow joints		
Touching each finger with thumb of both hand		
Sticking tongue out straight		
Rolling head laterally, front and back		

Metabolism and Excretion

All are metabolized in the liver and primarily excreted through the renal system.

Onset, Peak, and Duration

Onset of action is within a few days to a few weeks. These drugs reach their peak activity in approximately 1 to 6 hours and steady state within a few days. Half-lives vary widely. For example, clozapine peaks in 2.5 hours and has a half-life of 8 to 12 hours, whereas olanzapine peaks in 6 hours and has a half-life of 21 to 54 hours.

Pharmacotherapeutics

Precautions and Contraindications

Most atypical APs are not recommended in pregnancy (Pregnancy Category C), lactating women, or young children. Lurisidone is Pregnancy Category B. APs should be prescribed cautiously in the presence of hepatic or renal disease. Analysis of risk versus benefit is indicated in individuals who have hepatic or renal disease but who also have poor quality of life without treatment with an antipsychotic. Because of liver function decline, the geriatric population generally requires smaller doses. An additional contraindication is hypersensitivity.

Adverse Drug Reactions

Although the risk of developing EPSs, tardive dyskinesia, and neuroleptic malignant syndrome exists with any antipsychotic, it is significantly less with the atypical APs than it is with the typical APs. Atypical APs do have significant negative adverse effects, including seizures, weight gain, diabetes, hyperprolactinemia, dizziness, orthostatic hypotension, tachycardia, sleep disturbance, constipation, and rhinitis.

Specific adverse reactions may occur with individual agents. Because of the risk of potentially fatal agranulocytosis, clozapine is reserved for the treatment of severe schizophrenia refractory to complete trials of at least two different types of antipsychotics. Clozapine is available only through a patient management system in which a clinician and patient are both registered. A baseline CBC with differential is obtained prior to treatment, then monitored weekly or biweekly, depending on the length of time the patient has been taking clozapine, before the next week's medication is dispensed by the pharmacy. Monitoring should be continued for 4 weeks after clozapine is discontinued. The clinician must be aware of the indications of a falling white blood count (WBC) (fever, lethargy, bruising, sore throat, flu-like symptoms). A precipitous onset of agranulocytosis is potentially lethal within 24 to 72 hours and requires immediate attention.

Aripiprazole is relatively weight neutral and lacks any significant effect on QT intervals. It has good antidepressant properties but may be unpleasantly activating to some patients. Side effects include agitation, akathisia, nausea, tremor, insomnia, and headache.

Asenapine may cause somnolence and dose-related akathesia. Patients taking 10 mg daily of asenapine for bipolar disorder may report oral hypoesthesia (5% of patients versus 0% of placebo).

The most common adverse effects reported in clinical trials of iloperidone included tachycardia (12% in patients taking 20 to 24 mg/day), nausea and dry mouth (10%), dizziness (20% in patients taking 20 to 24 mg/day), somnolence (15% in patients taking 20 to 24 mg/day), and orthostatic hypotension (5%). There is a slight increase in EPS symptoms in patients taking iloperidone over placebo (13.5% to 15.1% versus 11.6% in placebo).

The dosage of risperidone should be titrated up slowly over a few days or longer to minimize adverse effects. Adverse effects may include orthostatic hypotension, bradykinesia, akathisia, agitation, and elevation of prolactin levels. Weight gain with risperidone is generally less than it is with clozapine or olanzapine.

The most problematic adverse effects of long-term use of olanzapine are sedation and weight gain. This weight gain appears to be associated with increased appetite, with much of the weight gain occurring in the first 6 months of drug therapy. Olanzapine is very sedating and should be taken at bedtime if possible. Olanzapine has a low incidence of EPSs.

The most common adverse effects of paliperidone reported in clinical trials included tachycardia (14% versus 7% in placebo), somnolence (11%), akathesia (10% versus 4% in placebo), and EPS symptoms (18% to 20%).

The most common side effects of quetiapine are dizziness and somnolence. Other side effects may be weight gain and orthostatic hypotension.

Ziprasidone appears to be well tolerated in general. It is unique among the atypical APs in that it does not cause significant weight gain, and may even result in weight loss and reduced triglyceride levels. Ziprasidone has a low incidence of EPSs. The most common side effects are drowsiness, dyspepsia, dizziness, constipation, and nausea. One concern with ziprasidone is that it is associated with mild to moderate QT interval prolongation in about 5% of patients taking this drug. Patients with a known history of arrhythmia should have a baseline and repeat ECG.

Drug Interactions

Concurrent use with fluvoxamine (1A2 inhibitor) may increase atypical AP levels. Use with alcohol and other CNS depressants results in increased sedation and orthostasis. Use with antihypertensives may increase orthostasis. Carbamazepine decreases serum levels of olanzapine and is contraindicated with clozapine. Ciprofloxacin (Cipro) is a potent 1A2 inhibitor and increases atypical antipsychotic levels. Smoking increases the rate of metabolism of APs, thereby potentially decreasing their effect. Combinations of APs may increase the risk of TD and NMS. Table 15-21 presents drug interactions.

Clinical Use and Dosing

Table 15-22 presents the indications, dosages, and available dosage forms of atypical APs.

Rational Drug Selection

Indications for use of the atypical APs include schizophrenia, schizoaffective disorder, depression or mania with psychotic

Table 15–21 ▦ **Drug Interactions: Atypical Antipsychotics**

Drug	Interacting Drug	Possible Effect	Implications
All atypical antipsychotics	Antihypertensives CNS depressants Ciprofloxacin (Cipro	Hypotension Increased CNS depression Potent 1A2 inhibitor	Monitor blood pressure, orthostasis Warn patient about drowsiness Increase atypical antipsychotic levels
Clozapine	Anticholinergics	Increased anticholinergic effect	Increase fluid intake; use hard candies fo dry mouth; stool softener if needed; monitor for urinary retention
	Caffeine	Increased effect of clozapine	Monitor CNS depression, WBC
	Lithium	Increased risk of neurotoxicity and agranulocytosis	Monitor lithium level, WBC, and for signs and symptoms of neurotoxicity
	Carbamazepine	Decreased serum levels of olanzapine	Contraindicated with clozapine
Quetiapine	Glucocorticoids	Decreased effect of quetiapine	Avoid concurrent use
Clozapine, quetiapine	Phenytoin	Increased toxicity of phenytoin; decreased antipsychotic effect	Monitor phenytoin blood levels and for increased psychotic symptomatology
	Erythromycin, ketoconazole, itraconazole, fluconazol	Increased effect of antipsychotics	Monitor for increasing CNS depression
Olanzapine, quetiapine	Rifampin, SSRIs	Decreased effect of antipsychotics	Monitor for increased psychotic symptomatology
Olanzapine, quetiapine, risperidone	Carbamazepine	Increased toxicity of carbamazepine	Monitor plasma levels of carbamazepine
Paliperidone	Carbamazepine	Coadministration may decrease paliperidone levels	Monitor effectiveness of paliperidone and increase dose if necessary
	Dopaminergic	Antagonistic to effect of antipsychotics	Do not use if possible; increased dose may be required
Olanzapine, quetiapine, clozapine	Cimetidine	Increased effect of antipsychotics	Monitor for increasing CNS depression
Aripiprazole, iloperidone	Ketoconazole or other CYP3A4 inhibitors	Decreases metabolism and increases effects of antipsychotic	Reduce aripiprazole or iloperidone dose by 50%
Ziprasidone	Drugs that prolong QT interval	Potentially life-threatening cardiac changes	ECG monitoring
Lurasidone	Strong CYP 3A4 inducers (rifampin, avasimibe, St. John's wort, phenytoin, carbamazepine) Moderate CYP 3A4 inducers		Do not use concurrently May need to increase lurasidone dose
Lurasidone	Strong CYP3A4 inhibitors (ketoconazole, clarithromycin, ritonavir, voriconazole, mibefradiol, grapefruit and grapefruit juice) Moderate CYP3A4 inhibitors (diltiazem, atazanavir, erythromycin, fluconazole, verapamil)		Avoid concomitant use Reduce lurasidone dose by one-half
Iloperidone	Inhibitors of CYP 2D6: fluoxetine, paroxetine	Increased iloperidone levels	Reduce iloperidone level by one-half when coadministering
Asenapine	CYP 2D6 inhibitors or substrates	May enhance inhibitory effects	Coadminister with caution
Asenapine	Fluvoxamine	Increased asenapine levels	Coadminister with caution
Aripiprazole	Carbamazepine and other CYP3A4 inducers	Reduced aripiprazole levels	Double dose of aripiprazole if carbamazepine added
Aripiprazole	Quinidine or other 2D6 inhibitors (fluoxetine or paroxetine)	Increase levels of aripiprazole	Reduce aripiprazole by one-half original dose

Table 15–22 ⊗ **Dosage Schedule: Atypical Antipsychotics**

Drug	Indications	Dosage	Available Dosage Forms
Aripiprazole (Abilify)	Schizophrenia, psychotic disorders, acute agitation, acute mania, bipolar maintenance, adjunct to antidepressant treatment for major depression	*Adult dose:* 10–15 mg/d single dose, may increase dose at 2 wk intervals up to 30 mg/d Bipolar: 15 mg q d initially Depression adjunct: 2–5 mg/d, may increase by 5 mg q wk to max 15 mg *Children:* Schizophrenia age 12–17 yr 2 mg/d, increase to 5 mg after 2 d, then to target dose of 10 mg after 2 d, then 5 mg q d if needed to max 30 mg Bipolar age 10–17: 2 mg/d, increase to 5 mg after 2 d, then in 2 d, if needed to max of 10 mg. Abilify injection: 9.75 mg IM, may repeat in 2 h, max 30 mg/d	Tablets: 2 mg 5 mg 10 mg 15 mg 20 mg 30 mg Oral solution: 1 mg/mL Discmelt: 10, 15 mg Injection: 7. 5 mg/mL (IM)
Asenapine (Saphris)	Schizophrenia, acute bipolar mania	*Adults:* 5 mg bid, max 10 mg bid For acute mania: Initial 10 mg bid	Oral disintegrating tablets: 5, 10 mg
Clozapine (Clozaril)	Refractory severe schizophrenia	*Adults:* Initial dose: 25–50 mg/d increasing by 25 mg increments/d until target range of 300–450 mg/d; maximum dose 900 mg/d; can give once daily or in divided doses; do not increase dose until adequate time for response has been provided, usually a few weeks. See pharmacy titration schedule.	Tablets: 25, 100 mg
		Maintenance: Lowest dose possible to resolve psychotic symptoms Discontinuation: Taper slowly over 1–2 wk	25 mg (G) 100 mg (G)
Lurasidone (Latuda)	Schizophrenia	40 mg daily (maximum 80 mg/daily)	Tablet: 20 mg, 40 mg, 60 mg, 80 mg, 120 mg
	Depressive episodes associated with bipolar I disorder	20 mg daily as monotherapy or as adjunctive therapy with litihium or valproate. Maximum dose 120 mg daily.	
Iloperidone (Fanapt)	Schizophrenia	*Adults:* Start with 1 mg bid, increase to 2 mg bid on second day, then by 2 mg bid q day to target dose of 12–24 mg bid on day 7	1-, 2-, 4-, 6-, 8-, 10-, 12 mg tablets
Olanzapine (Zyprexa, Zyprexa Zydis (oral-disintegrating form) Zyprexa (IM)	Psychotic disorders, severe agitation, acute mania, bipolar maintenance	Schizophrenia: 5–10 mg daily in single dose; dosage adjustment should occur no less often than once weekly; 5 mg/d in debilitated patients or those with predisposition to hypotension Bipolar: Initially 10–15 mg qd, may increase by 5 mg/d to target dose 20 mg/d Bipolar maintenance: 5–20 mg/d Acute agitation: IM 2.5–10 mg/dose deep IM, 3 doses 2–4 h apart up to 3 in 24 h	Tablets: 2.5 mg 5 mg 7.5 mg 10 mg 15 mg 20 mg Zydis: 5 mg 10 mg 15 mg 20 mg IM: 10 mg vial (before reconstitution)
Paliperidone (Invega, Invega Sustenna)	Schizophrenia Schizoaffective disorder	*Adults:* 6 mg qam, increase by 3 mg q 4–5 days to max of 12 mg (lower doses for renal impairment) Invega Sustenna (IM): First establish tolerability with oral treatment, deep deltoid 234 mg day 1, in 1 wk, 156 mg. Maintenance injection: deltoid or gluteal 117 mg monthly (range 39–234 mg (lower doses for renal impairment).	Tabs (extended-release): 3, 6, 9 mg Invega Sustenna extended-release injection: 39, 78, 117, 156, 234 mg
Risperidone (Risperdal) (Risperidal M-TAB) (oral-disintegrating form) Risperdal Consta (IM)	Psychotic disorders, severe agitation, acute mania, autism-related irritability in children	Schizophrenia: *Adults:* Initial dose: 1 mg bid; increase (q 24 h) by 1 mg per dose to target dose of 4–8 mg/d; most efficacious in range of 4–6 mg/d *Children 13–17 yr:* 0.5 mg qd, increase by 0.5 mg q 24 h to target of 3 mg/d. Divide dose if somnolence occurs.	Tablets: 0.25 mg 0.5 mg 1 mg 2 mg 3 mg 4 mg

Table 15–22 ⊗ **Dosage Schedule: Atypical Antipsychotics—cont'd**

Drug	Indications	Dosage	Available Dosage Forms
		(Debilitated patients should begin with 0.5 mg bid and have the dose increased in 0.5 mg increments.) For bipolar I maintenance or adjunct to lithium or valproate: *Adult:* Range 1–6 mg/d *Children 10–17 yr:* 0.5 mg/day; increase dose after 4 days to 1.0 mg/day; target 2.5 mg/d, max 6 *For irritable autism symptoms age 5–16 yr:* 15 to 20 kg, 0.25 mg/d; increase in 4 d to 0.5 mg. Remain for 14 d, then may increase 0.25 mg q 2 wk. >20 kg: 0.5 mg; may increase in 4 d to 1 mg. Remain for 14 d then may increase 0.5 mg q 2 wk. Risperdal Consta for adults: After trial with oral only, give IM deep gluteal or deltoid. Give injection with oral dose for 3 wk, then stop oral. Every 2 wk, 25 mg IM; adjust q 4 wk if needed to max 50 mg q 2 wk injection.	Solution: 1 mg/1 mL M-TAB: 0.5 mg 1 mg 2 mg Consta: Long-acting injectable: 25 mg 37.5 mg 50 mg
Quetiapine (Seroquel, Seroquel XR)	Psychotic disorders, severe agitation, schizophrenia, acute mania, bipolar maintenance, bipolar depression, adjunct to major depressive disorder antidepressant treatment	*Adults:* Schizophrenia Seroquel: Initially 25 mg bid, day 1 and increase q d by 25–50 mg in divided doses to target of 300–400 mg/d (divided) by day 4. Then increase by 25–50 mg in 2-d intervals to max 800 mg; lower in the elderly or with hepatic impairment. XR formulation: Initially 300 mg in p.m. (3–4 h before hs), increase by 300 mg/d to range 400–800/d. Mania: 100 mg/d divided, increase by 100 mg/d (divided) to 400 mg by day 4, then 200 mg increments to 800 mg (divided) by day 6. Depression: 50 mg day 1 at hs, then increase by 100 mg qhs until 300 mg on day 4. May increase to 400 mg day 5 and 600 mg day 8 if needed. XR formulation: Mania— 300 mg in p.m. day 1, then 600 mg in p.m. day 2. Day 3 titrate to effective dose (range 400–800) Depression—50 mg day 1, 100 mg day 2, 200 mg day 3, and 300 mg day 4 Give evening dose 3–4 h before hs.	Tablets: 25 100, 200, 300, 400 mg XR tablets: 50, 150, 200, 300, 400 mg
Ziprasidone (Geodon)	Schizophrenia, severe agitation, mania	*Adults*: Must be taken with full meal for proper absorption. *Schizophrenia:* Initial dose: 20 mg bid may increase at 2-d intervals up to 80 mg bid *Mania*: Initial dose 40 mg bid, day 2 60–80 mg bid Injection: Severe agitation 10–20 mg IM to max 40 mg per day (10 mg q 2 h or 40 mg q 4 h), not to exceed 3 days	Capsules: 20 mg 40 mg 60 mg 80 mg IM: 20 mg vial (before reconstitution)

features, and severe agitation and delusions with dementia. Selecting one atypical antipsychotic over another may be based on specific patient risk factors, history of response to specific medications, or adverse effects experienced by the patient. Change from one AP to another should be accomplished by slowly titrating off the first medication and onto the second, with a washout period in between if possible. If the presence of psychotic symptoms makes a washout period unfeasible, overlap of medications should be at the lowest doses and for the shortest period of time possible.

Monitoring

No specific blood tests are available to determine the plasma level of these medications. Dosages are adjusted based on subjective information provided by the patient and the clinician's objective observations of the client.

Patient Education

Patients need to be informed of the possible adverse reactions that may be associated with individual agents. Patients taking clozapine, for example, need to know the signs and

symptoms of agranulocytosis so that these symptoms can be promptly reported to the clinician. Advise the patient to change position slowly to prevent orthostatic hypotension. Provide safety instructions for driving and other activities that require alertness. Sugarless gums, candies, or ice chips may be used to alleviate symptoms of dry mouth. Alert the patient to avoid the use of alcohol or other CNS depressants. Advise of the potential for significant weight gain and increase in triglycerides, and assist the client in modifying diet and exercise regimes to counter these undesirable effects.

DOPAMINERGICS

The dopaminergics, also known as dopamine agonists, are the pharmacological treatment of choice for Parkinson's disease. These agents include amantadine (Symmetrel), bromocriptine (Parlodel), carbidopa-levodopa (Sinemet), carbidopa-levodopa-entacarpone (Stalevo), selegiline hydrochloride (Eldepryl), pramipexole (Mirapex), rasagiline (Azilect), ropinirole (Requip), and tolcapone (Tasmar). Amantadine is occasionally used to treat the parkinsonism-like EPS of the antipsychotic drugs, but to give a dopamine-enhancing drug to a patient with schizophrenia might cause psychotic symptoms to increase.

Pharmacodynamics

Dopamine and acetylcholine are the neurotransmitters primarily responsible for balance and coordinated musculoskeletal functioning, and each needs to balance the other for smooth functioning to take place. When dopamine depletion occurs, either idiopathically as in Parkinson's disease or because of inadequate synthesis or impaired storage, transmission, or reuptake, the classic signs of muscular rigidity, tremors, and psychomotor retardation appear. Excessive amounts of dopamine are thought to produce the positive symptoms of schizophrenia, such as hallucinations and delusions.

Amantadine is effective because it releases dopamine from storage, whereas the dopamine precursors levodopa and carbidopa-levodopa increase dopamine synthesis. When entacapone is given with levodopa and carbidopa, the plasma levels of levodopa increase and are higher and more sustained when given with just carbidopa. Bromocriptine and pergolide act as dopamine agonists at the postsynaptic receptor sites. Selegiline inactivates monoamine oxidase (MAO), which then leads to increased amounts of dopamine available in the CNS. Similarly, rasagiline acts as a selective, irreversible MAO inhibitor. Pramipexole and ropinirole act by stimulating dopamine receptors in the brain. The exact mechanism of action of tolcapone is unknown, but it is thought to enhance the pharmacokinetics of levodopa.

Pharmacokinetics

Absorption and Distribution

Dopaminergics are administered orally and are relatively rapidly and completely absorbed. These agents are widely distributed and enter breast milk.

Metabolism and Excretion

Variations occur in metabolism; for example, bromocriptine, levodopa, rasagiline, and tolcapone are metabolized in the liver, but amantadine is excreted unchanged in the urine. Selegiline has three active metabolites, including amphetamine and methamphetamine, and deaths have occurred when selegiline has been taken concurrently with meperidine. Dopaminergics are excreted through urine and feces. Table 15-23 presents the pharmacokinetics of dopaminergics.

Pharmacotherapeutics

Precautions and Contraindications

These agents are contraindicated in hypersensitivity and should be used cautiously in patients with a history of cardiac, psychiatric, or ulcer disease. Dopaminergics are Pregnancy Categories B and C; their safety of use during lactation and in children has not been determined. Selegiline is contraindicated with concurrent administration of meperidine. Renal impairment should be carefully assessed before using amantadine because it is excreted unchanged through the kidneys. Patients with underlying cardiac arrhythmias who have taken pergolide have experienced bradycardia and sinus tachycardia. Ropinirole and pramipexole should be used cautiously

Table 15–23 ❖ Pharmacokinetics: Dopaminergics

Drug	Onset	Peak	Duration	Half-Life	Excretion
Amantadine (Symmetrel)	48 h	4 h	—	18–24 h	Urine
Bromocriptine mesylate (Parlodel)	—	1–3 h	4–8 h	3–8 h	Feces (85%–98%), Urine
Carbidopa-levodopa (Sinemet)	—	1–3 h	4–6 h	—	Urine
Selegiline HCl (Eldepryl)	—	0.5–2 h	—	18–20 h	Urine
Pergolide (Permax)	—	—	—	—	Urine
Pramipexole (Mirapex)	—	2 h	8 h	8 h	Urine
Ropinirole (Requip)	—	—	8 h	6 h	Urine

in geriatric patients because of the increased risk of hallucinations. Carbidopa-levodopa is contraindicated in narrow-angle glaucoma and malignant melanoma. Tolcarpone is contraindicated in patients with liver disease.

Adverse Drug Reactions

Adverse effects may include nausea and vomiting, dizziness, postural hypotension, abdominal pain, dyspepsia, constipation, dry mouth, depression, insomnia, confusion, and hallucinations. Pramipexole and ropinirole may cause sleep attacks in which the patient has unexpected episodes of falling asleep. Tolcapone may cause severe hepatocellular injury, including liver failure.

Drug Interactions

Drug interactions among the dopaminergic agents are many and varied. For example, administration with MAO inhibitors may cause hypertensive crisis. Concurrent use with antihypertensives may increase hypotension. Concurrent use with antihistamines, phenothiazines, quinidine, and tricyclic antidepressants may increase anticholinergic effects. Phenothiazines, haloperidol, and phenytoin may decrease the effect of levodopa. Concurrent use of levodopa with pramipexole increases the risk of hallucinations and dyskinesia. Ropinirole is extensively metabolized by the liver's CYP450 CYP1A2 enzyme systems; thus, drugs that alter the activity of these enzyme systems may affect the activity of ropinirole. Concurrent administration of rasagiline and meperidine may lead to serotonin syndrome. Concurrent

administration of rasagiline and dextromethorphan may lead to psychosis or bizarre behavior. Table 15-24 presents drug and food interactions.

Clinical Use and Dosing

Table 15-25 presents the indications and dosage schedule of dopaminergics.

Rational Drug Selection

Treatment with a dopamine agonist such as bromocriptine, pergolide, pramipexole, or ropinirole is recommended as the first-line therapy for patients with mild to moderate parkinsonism symptoms. As symptoms worsen over time, levodopa may be introduced. Combinations such as levodopa with amantadine or carbidopa-levodopa with selegiline may provide improved response over a single drug or in cases of deterioration in status. In late-stage therapy, a controlled-release preparation (Sinemet CR) may relieve "wearing off," the recurrence of severe symptoms hours after the dose of medication. Patients who take levodopa for several years may experience a decrease in the effectiveness of the drug and require a drug holiday to restore effectiveness. Some newer dopamine agonists, such as pramipexole, have been used in the treatment of resistant depression.

Monitoring

Monitor the effectiveness of the drug in managing parkinsonism symptoms. Assess for the "on-off" phenomenon in which symptoms suddenly worsen or improve. Monitor

Table 15–24 ⬛ Food and Drug Interactions: Dopaminergics

Drug	Interacting Drug or Food	Possible Effect	Implications
All dopaminergics	Antihypertensives	Increased antihypertensive effect	Monitor for postural hypotension, blood pressure
	Oral contraceptives	Decreased effectiveness of oral contraceptives	Use backup contraception
	MAOIs, TCAs, opioids	Hypertensive crisis	Avoid concurrent use
Carbidopa-levodopa	Food	Increased plasma level of carbidopa-levodopa with sustained-release form	Avoid taking with food
	Anticholinergics	Increased adrenocorticotropic hormone (ACH) adverse effects and decreased effect of levodopa	Monitor eye pain/vision; effect of dopaminergic
	Haldol, hydantoins	Decreased effect of levodopa	Monitor eye pain/vision; effect of dopaminergic
Pramipexole, ropinirole	Levodopa	May increase effect of levodopa	Monitor for hallucinations, dyskinesia (may allow dosage reduction of levodopa)
Tolcapone	Drugs metabolized by COMT (methyldopa, apomorphine, dobutamine, isoproterenol)	May increase the effects of methyldopa, apomorphine, dobutamine, isoproterenol	Consider dosage reduction of concurrent drug
Rasagiline	Dextromethorphan	Psychosis/bizzare behavior	Avoid concurrent use
Rasagiline	Meperidine	Serious, sometimes fatal reactions	Wait 14 days between giving

Table 15–25 ⊗ Dosage Schedule: Dopaminergics

Drug	Indications	Dosage	Available Dosage Forms
Amantadine (Symmetrel)	Parkinson's disease; drug-induced EPS; parkinsonism syndrome following carbon monoxide poisoning	*Adults:* 100–200 mg bid; may increase to maximum of 400 mg/d in divided doses after several weeks without response after lower dose In conjunction with levodopa: 100 mg qd bid	Capsules: 100 mg Syrup: 50 mg/5 mL
Bromocriptine mesylate (Parlodel)	Parkinson's disease	*Adult:* Initial dose 1.25 mg bid with meals; if dosage increase needed after 2 wk, increase by 2.5 mg/d in divided doses with meals; maintain at lowest dose producing optimal response; usual range 10–40 mg/d	Tablets: 2.5 mg Capsules: 5 mg
Carbidopa-levodopa (Sinemet)	Parkinson's disease; parkinsonism syndrome following carbon monoxide or manganese poisoning	*Adult:* 1 tab (25 mg carbidopa and 100 mg levodopa) tid or 1 tab (10 mg carbidopa and 100 mg levodopa) tid qid; may increase by 1 tab daily or every other day until maximum of 8 tabs/d. Tablets of various ratios may be used but maintain 70–100 mg carbidopa/d. CR form: 1 tab bid with minimum of 6 h between doses; increase as above; do not crush or chew tabs	Tablets: 10 mg carbidopa/100 mg levodopa 25 mg carbidopa/100 mg levodopa 25 mg carbidopa/250 mg levodopa Sustained-release tablets: 25 mg carbidopa/100 mg levodopa 50 mg carbidopa/200 mg levodopa
Selegiline HCl	Adjunctive treatment of Parkinson's disease with carbidopa-levodopa	*Adult:* 5 mg bid with breakfast and lunch; after 2–3 d, decrease dose of carbidopa-levodopa	Tablet: 5 mg
Pramipexole	Parkinson's disease	*Adult:* 0.125 mg tid initially, may increase 5–7 d up to 1.5–4.5 mg/d in 3 divided doses	Tablet: 0.125, 0.25, 0.5, 1,1.5 mg
Ropinirole	Parkinson's disease	*Adult:* 0.25 mg tid for 1 wk, then 0.5 mg tid for 1 wk, then 0.75 mg tid for 1 wk, then 1 mg tid for 1 wk; then may increase by 1.5 mg/d each wk up to 9 mg/d; then may increase by up to 3 mg/d each wk up to 24 mg/d	Tablet: 0.25, 0.5, 1, 2, 4, 5 mg
Levodopa, carbidopa, entacapone (Stalevo)	Idiopathic Parkinson's disease	May substitute Stalevo for equal dose of carbidopa-levodopa. Individualize dose.	Tablet: Stalevo 50: 12.5 mg of carbidopa, 50 mg of levodopa and 200 mg of entacapone Stalevo 75: 18.75 mg of carbidopa, 75 mg of levodopa, and 200 mg of entacapone Stalevo 100: 25 mg of carbidopa, 100 mg of levodopa, and 200 mg of entacapone Stalevo 125: 31.25 mg of carbidopa, 125 mg of levodopa, and 200 mg of entacapone Stalevo 150: 37.5 mg of carbidopa, 150 mg of levodopa, and 200 mg of entacapone Stalevo 200: 50 mg of carbidopa, 200 mg of levodopa, and 200 mg of entacapone
Rasagiline (Azilect)	Idiopathic Parkinson's disease	*Adults:* 0.5 to 1.0 mg/d	Tablet: 0.5 mg, 1.0 mg
Tolcapone (Tasmar)	Used as adjunct to levodopa and carbidopa for idiopathic Parkinson's disease	*Adults:* 100 mg tid. Maximum 600 mg/d. Monitor liver function.	Tablet: 100 mg

CR = controlled release.

hepatic and renal function in patients on long-term therapy. Monitor patients on pramipexole and ropinirole for the occurrence of drowsiness and sleep attacks.

Patient Education

Advise the patient to exercise care when changing position to prevent postural hypotension and to avoid hazardous activities if drowsy or dizzy. Explain that gastric irritation may be decreased by taking medication with food but that high-protein meals may impair levodopa's effects. Caution patient to monitor skin lesions for any changes, because carbidopa-levodopa may activate malignant melanoma. Advise the patient that large amounts of vitamin B (pyridoxine) may interfere with the action of levodopa.

ANXIOLYTICS (ANTIANXIETY) AND HYPNOTICS

Drugs used to treat anxiety can be divided into three groups based on their pharmacological action: serotonergics, gaba-ergics, and dopaminergics. Traditionally, however, the benzodiazepines, such as diazepam or alprazolam, were regarded as the anxiolytics. The benzodiazepines affect the gamma amino butyric acid (GABA) receptors at a particular site within the receptor, whereas other gaba-ergics affect the receptor more globally. The net effect of inhibiting GABA is to slow down neurotransmission and thereby produce reduction in anxiety. Serotonin as a neurotransmitter has a calming effect as well, owing to the areas of the brain where there are high concentrations of these pathways. Finally, dopaminergics have an anxiolytic effect in a fashion similar to that of serotonin but in more specific areas of the brain. Therefore, the prescriber needs to select a drug based not only on the general class of drugs but also on the specific symptomatology produced by the neurophysiology.

Because the SSRIs and serotonin-dopamine antagonists are discussed elsewhere in this chapter, this section focuses on the gaba-ergics, including the benzodiazepines. There is one exception and that is buspirone (BuSpar), which is a partial serotonin receptor agonist. For greater depth of discussion regarding the treatment of anxiety, see Chapter 29.

BENZODIAZEPINES

Benzodiazepines have been frequently prescribed to treat anxiety and insomnia. However, because of the increased potential for tolerance and dependence on the newer variations, the CNS depressant-related adverse effects, and the development of buspirone, many clinicians are more cautious in assessing risks versus benefits for their patients than they might have been previously. The drugs in this class include the following:

- Alprazolam (Xanax, Xanax XR)
- Chlordiazepoxide (Librium)
- Clonazepam (Klonopin)
- Clorazepate (Tranxene)
- Diazepam (Valium)
- Halazepam (Paxipam)
- Lorazepam (Ativan)
- Oxazepam (Serax)

Benzodiazepines have also been extensively used as a muscle relaxant and for preanesthesia sedation, prevention and treatment of panic attacks, acute agitation and dystonia, emergency treatment of uncontrollable seizures, and treatment of restless leg syndrome.

Pharmacodynamics

Benzodiazepines are thought to exert their anxiolytic and sedative effects by increasing the action of GABA, an inhibitory neurotransmitter, thereby decreasing the effect of neuronal excitation. Within the GABA receptor is an area that the benzodiazepines bind to, referred to as the benzodiazepine receptor.

Pharmacokinetics

Absorption and Distribution

Benzodiazepines are rapidly and widely distributed following oral administration and reach their peak levels within 30 minutes to 6 to 8 hours. Chlordiazepoxide (Librium) and diazepam (Valium) are slowly and inconsistently absorbed after intramuscular administration, but lorazepam (Ativan) and midazolam are rapidly absorbed and widely distributed after IM injection. These drugs are lipid-soluble and highly protein bound, which means that they may have prolonged activity in obese people and compete with other protein-bound drugs for receptor sites.

Metabolism and Excretion

Benzodiazepines are metabolized in the liver and biotransformed by oxidation. Some (lorazepam and temazepam) are biotransformed by conjugation. These two mechanisms may influence the patient's reaction to the drug. Benzodiazepines that are metabolized by conjugation are better tolerated by patients with impaired liver function or who are elderly or are smokers, whereas those drugs metabolized by oxidation may have a prolonged effect in the elderly. Duration of effect is influenced by the lipid solubility and the half-life of the active metabolites more than the parent drug. Half-lives and active metabolites are included in Table 15-26.

Pharmacotherapeutics

Precautions and Contraindications

The development of dependence, which can be psychological as well as physical, is of concern with the benzodiazepines. Although dependence is usually related to dose (high) and duration of use (more than a few weeks), it can occur in the absence of these parameters. It is thought that alprazolam (Xanax) and lorazepam (Ativan) are more likely to cause dependence because of their high potency and rapid, short-term action but clonazepam (Klonopin) is less likely because of its long action.

Symptoms of withdrawal, which usually occur 1 to 2 days after the last dose of short-acting benzodiazepines and 5 to

Table 15–26 ⚏ Pharmacokinetics: Benzodiazepines

Drug	Onset	Peak	Duration	Half-Life	Excretion
Alprazolam	Intermediate	1–2 h	Intermediate	8–37	Urine
Chlordiazepoxide	Intermediate	0.5–4 h	Long	5–30 h	Urine
Clonazepam	Intermediate	1–4 h	Long	30–40	Urine
Clorazepate	Fast	1–2 h	Long	40–50 h	Urine
Diazepam	Very fast	0.5–2 h	Long	20–80 h	Urine
Lorazepam	Intermediate	2–4 h	Intermediate	10–20 h	Urine
Oxazepam	Slow	2–4 h	Intermediate	5–20 h	Urine

10 days after the last dose of the long-acting compounds, resemble withdrawal symptoms of other CNS depressants. Use of the drug should be gradually tapered rather than abruptly discontinued because of the risk of severe withdrawal symptoms. One strategy for tapering is to decrease the dose by 0.5 mg per week, and then by 0.25 mg per week for the last few weeks. Another is to substitute a long-acting benzodiazepine such as clonazepam in an equivalent dose for a short-acting one and then titrate down.

Benzodiazepines are contraindicated in pregnancy and lactation and in the presence of hepatic and renal disease, and they are not recommended for children younger than 6 years. Other contraindications include hypersensitivity to benzodiazepines and acute narrow-angle glaucoma.

Geriatric patients generally should not be prescribed benzodiazepines; if they are prescribed, they should be in very low doses due to their decreased rate of metabolism and consequent potential for accumulation.

These drugs are not the treatment of choice for depression or psychosis or in the absence of anxiety signs and symptoms.

Adverse Drug Reactions

Major adverse effects are due to the drugs' action as CNS depressants. The same concerns apply to their use as with other CNS depressants: excessive sedation, particularly initially, in a situation requiring mental and physical alertness, and the potential for cardiac and respiratory depression, especially in combination with other CNS depressants. Paradoxical anxiety, agitation, and acute rage may occur with benzodiazepines. Clonazepam may increase salivation. Other common side effects include dizziness, confusion, blurred vision, and hypotension.

Drug Interactions

Drug interactions of greatest concern are those involving other CNS depressants, such as barbiturates, alcohol, antihistamines, and neuroleptics, because of their additive effects. Benzodiazepines also increase the blood levels of TCAs and digitalis preparation. Table 15-27 includes drug interactions and possible effects.

Clinical Use and Dosing

Benzodiazepines are indicated for the short-term treatment of anxiety and anxiety-related disorders. Additional uses include muscle relaxants, emergency treatment of status epilepticus, irritable bowel syndrome, chemotherapy-induced nausea and vomiting, and restless leg syndrome. Because they have cross-sensitivity with alcohol and act as an anticonvulsant, the benzodiazepines are especially useful in alcohol withdrawal and delirium tremens. Table 15-28 includes dosages and available dosage forms for the benzodiazepines.

Rational Drug Selection

Diazepam is the treatment of choice for status epilepticus, administered by a parenteral route, preferably IV, because of the rapidity of absorption and effect. In acute alcohol withdrawal, care must be exercised so that cross-tolerance does not develop. Because dependence has occurred after as little as 4 to 6 weeks of use, these drugs should be not be used beyond the acute stage of alcohol withdrawal and should be slowly tapered to avoid withdrawal symptoms.

All of the benzodiazepines are equally efficacious and drug selection depends on the patient's and prescriber's preference and the patient's side-effect profile. For long-term treatment of anxiety, other classes of drugs should be considered first (e.g., buspirone or SSRIs); and if the benzodiazepine is necessary, then clonazepam is preferred due to its long half-life and daily dosing ability.

Monitoring

Increased blood levels of TCAs and digitalis may occur with concurrent use of benzodiazepines and should be monitored. In long-term use, periodic assessment of liver function and complete blood cell counts should be performed.

Patient Education

Advise the patient to avoid alcohol. Because drowsiness and impaired cognition may be an adverse effect, tell the patient to avoid taking a benzodiazepine before or during situations in which mental or physical alertness is required to maintain safety. Patients should also be advised to report ocular pain or changes in vision immediately.

Drugs Affecting the Central Nervous System   •   269

Table 15–27 ⚏ **Drug Interactions: Benzodiazepines**

Drug	Interacting Drug	Possible Effect	Implications
All benzodiazepines	Digoxin	Increased level of digoxin	Monitor level; take pulse before giving digoxin
	TCAs	Increased plasma level of TCAs	Monitor level of TCA
	Barbiturates, nefazodone, fluoxetine fluvoxamine, MAOIs, sertraline antihistamines	Increased CNS depression	Avoid concurrent administration
	Clozapine	Increased sedation, salivation, hypotension, delirium, respiratory arrest	Avoid concurrent administration
Alprazolam	Cimetidine oc, disulfiram, omeprazole, macrolide antibiotics		Warn of increased effects
	Grapefruit juice	Decreased metabolism and increased effect of alprazolam	Use alternative juice
	Ketoconazole		Concurrent use contraindicated
Alprazolam, clonazepam	Carbamazepine	Decreased plasma level of benzodiazepines	Use alternative anticonvulsant
Clonazepam	Lithium	Increased sexual dysfunction	Warn of possible adverse effects
Clonazepam, diazepam, chlordiazepoxide	Phenytoin	Decreased plasma level and toxicity of phenytoin	Use alternative anticonvulsant
		Decreased clinical effect of benzodiazepines	Monitor phenytoin blood level; may need lower dose
Clonazepam, lorazepam	Valproate	Decreased metabolism and increased effect of benzodiazepines	May require lower dose of benzodiazepine
Diazepam	Phenobarbital	Additive CNS depression; increased metabolism of diazepam	May affect treatment of status epilepticus

SEROTONERGIC ANXIOLYTICS

Neurophysiologically, it makes sense that enhancing serotonin would contribute to relief of anxiety because of the areas of the brain that are heavily innervated by serotonin. However, there are 15 subtypes of serotonin receptors, some of which may actually contribute to anxiety. Buspirone is a serotonergic that is a member of the azapirones, a relatively new group of anxiolytics. Other drugs in this group are ipsapirone and gepirone, neither of which is approved for use in the United States for treatment of anxiety. These drugs exert their effects without the CNS depression and sedation of barbiturates and benzodiazepines but also without the anticonvulsant or muscle-relaxant qualities. Buspirone has little risk of dependence and few drug interactions, and it is considered relatively safe, even in high doses.

Pharmacodynamics

Buspirone has a similar chemical structure to butyrophenone antipsychotics such as haloperidol (Haldol) and was thought to be an atypical antipsychotic similar to clozapine (Clozaril) without the EPSs. However, further human studies showed that it had greater efficacy as an anxiolytic, through its action on the serotonin-1A (5-HT 1a) presynaptic and postsynaptic receptors. At the presynaptic 5-HT 1a receptor, buspirone is a full agonist, that is, it contributes to the channel's opening and permitting serotonin binding, thereby inhibiting neuron firing. Buspirone also is a partial agonist at the postsynaptic 5-HT 1a receptors. When there is an excess of serotonin, buspirone acts as an antagonist, but in a deficit state such as is presumed in anxiety and depression, it acts as an agonist.

Remembering that buspirone was originally thought to be an atypical antipsychotic, it is not surprising that buspirone inhibits the increase in dopamine D_2 receptors. However, the dopaminergic action is minor compared to the serotonergic effects. Buspirone has no effect on the GABA receptor and cannot be used as a substitute for benzodiazepines in withdrawal treatment.

Pharmacokinetics
Absorption and Distribution

Buspirone is rapidly absorbed and undergoes extensive first-pass metabolism. When taken with food, buspirone has a reduced first-pass effect, allowing for more active drug going directly into

Table 15–28 ⊗ **Dosage Schedule: Benzodiazepines**

Drugs	Indications	Dosage	Available Dosage Forms
Alprazolam (Xanax)	Anxiety disorder, panic disorder	Anxiety: 0.25–0.5 mg tid, maximum 4 mg/d Panic disorder: 0.5 mg tid, titrate q 3–4 d to 1–10 mg/d (mean 5–6 mg/d) Wean off slowly when discontinuing	Tablets: 0.25 mg, 0.5 mg, 1 mg, 2 mg Orally disintegrating tablets: 0.25 mg
			Intensol solution: 1 mg/mL concentrated solution to be mixed with liquid or semisolid food, using only the provided calibrated dropper Extended-release tablets (Xanax XR): 0.5 mg, 1 mg, 2 mg, 3 mg
Chlordiazepoxide (Librium)	Anxiety, alcohol withdrawal	Mild to moderate anxiety: 5–10 mg tid Severe anxiety: 20–25 mg tid Older adults: 5 mg 2–4 times daily	Capsules: 5, 10, 25 mg Powder for injection: 5, 10, 25, 100 mg
Clonazepam (Klonopin)	Seizure disorders, panic disorder,	Seizure disorder: 1.5 mg/d, increase 0.5 mg to 1.0 mg q3d to maxiumum of 20 mg/d Panic disorder: 0.25 mg bid, may increase q 3 d to a maximum of 1 mg/d	Tablets: 0.5 mg, 1 mg, 2 mg
Diazepam (Valium, Diastat)	Anxiety, alcohol withdrawal, skeletal muscle spasm, status seizures	Anxiety: 2–10 mg 2–4 times a day Acute alcohol withdrawal: 10 mg tid or qid during first 24 h, then 5 mg tid or qid Muscle spasms: 2–10 mg tid or qid Seizures: Age 2–5 yr: 0.5 mg/kg; age 6–11 yr: 0.3 mg/kg; ≥ 12 yr: 0.2 mg/kg	Tablets: 2, 5, 10 mg Oral solution: 5 mg/5 mL Intensol solution: 5 mg/5 mL Injection: 5 mg/5 mL Rectal gel: 10 mg, 20 mg rectal delivery system
Lorazepam (Ativan)	Anxiety	Anxiety: Initial dose: 2–3 mg/d divided bid or tid, increase to usual range of 2–6 mg/d Elderly: 1–2 mg/d in divided doses Short-term insomnia due to anxiety: 2–4 mg at bedtime	Tablets: 0.5, 1, 2 mg Intensol solution: 2 mg/mL Injection: 2 or 4 mg/mL
Oxazepam(Serax)	Anxiety, alcohol withdrawal	Mild to moderate anxiety: 10–15 mg tid or qid Severe anxiety: 15–30 mg tid or qid Older patients: 10 mg tid Alcohol withdrawal: 15–30 mg tid or qid	Capsules: 10 15, 30 mg

circulation. It has many metabolites that have no effect on anxiety symptoms, but at least one metabolite has noradrenergic effects, which may explain why buspirone is contraindicated in panic attacks (Schatzberg & Nemeroff, 2009). It has a short half-life, ranging from 1 to 10 hours, but a slow onset of action (up to 6 weeks); therefore, it requires multiple dosing during the day. It is highly protein bound and lipid-soluble, therefore having broad distribution in brain and adipose tissue.

Metabolism and Excretion

Buspirone is metabolized by oxidation in the liver and is a substrate for the CYP450 3A4 enzyme. It does not inhibit any of the CYP450 enzymes; therefore, it has few drug interactions. It is excreted in the urine and feces.

Onset, Peak, and Duration

For unknown reasons it takes 1 to 2 weeks for the onset of anxiolytic effects of buspirone and up to 6 weeks for maximum effects. It peaks in circulation in 0.7 to 1.5 hours and has an intermediate duration.

Pharmacotherapeutics

Precautions and Contraindications

Buspirone is contraindicated in patients with known hypersensitivity or in those with severe hepatic or renal disease. As mentioned previously, it is contraindicated in the treatment of panic disorder both because of its prolonged onset and possibility of exacerbating panic.

Buspirone is considered Pregnancy Category B. The extent of excretion in breast milk is not clear and use during lactation should be avoided. Although buspirone is not commonly thought to be sedating, as with other anxiolytics, drowsiness should be assessed prior to use in situations requiring cognitive or motor alertness in order to maintain safety.

Adverse Drug Reaction

Adverse effects are few and usually resolve with continued use. Most common are light-headedness, headache, insomnia, nausea, nervousness, and dry mouth. Akathisia and involuntary movements are possible although rare.

Drug Interactions

Interactions between buspirone and other serotonergic drugs such as MAOIs and SSRIs have the potential to cause serotonin syndrome with symptoms of nausea, diarrhea, chills, sweating, elevated temperature and blood pressure, agitation, ataxia, coma, and death.

Interactions with antipsychotic drugs, especially haloperidol, contribute to increased serum levels of haloperidol due to competition for metabolism. When combined with trazodone, there may be an increased ALT (alanine transaminase).

Drugs that inhibit CYP3A4 (erythromycin, ketoconazole, nefazodone, intraconazole, ritonavir) and grapefruit juice may increase serum levels of buspirone. Drugs that induce CYP3A4 (rifampin, dexamethasone, phenytoin, phenobarbital, carbamazepine) decrease buspirone levels.

Clinical Use and Dosing

Used primarily for anxiety, buspirone's usual dose is 15 mg per day (7.5 mg BID). Initially, the patient takes 5 mg 2 or 3 times a day for 4 days; then the dose is increased by 5 mg each dose to a maximum dose of 60 mg per day. It is available in 5, 10, and 15 mg tablets, bisected or trisected for easy titration. The tablets are small and may be difficult to handle for those with hand mobility problems.

Rational Drug Selection

Although buspirone can be used as the sole pharmacotherapeutic modality for anxiety, it is frequently used adjunctively with SSRIs in treatment-resistant depression because of the combined serotonergic mechanisms, that is, postsynaptic reuptake inhibition and receptor agonism. Buspirone is indicated in treating generalized anxiety disorder, depression with an overlay of anxiety, and situational anxieties that are long-lasting. It is essential, however, that the drug be taken daily; it cannot be used on an as-needed basis.

A positive response may begin within 7 to 10 days of starting the drug, but maximum benefits may not become evident for 3 to 6 weeks. It may be necessary to add a benzodiazepine in very low doses initially to relieve the patient's anxiety and fear about the anxiety.

Monitoring

No monitoring other than periodic reassessment of the drug's continued effectiveness is required.

Patient Education

To maintain safety, advise the patient to try the medication and observe the effects, especially drowsiness, before engaging in activities requiring mental or physical alertness. The patient also needs to be told of the prolonged onset and be offered nonpharmacological strategies for anxiety management during this time.

BARBITURATES

Before the benzodiazepines became standard treatment, anxiety was treated with a variety of drugs with different mechanisms of action. Barbiturates have been used historically as anxiolytics, sedative-hypnotics, and anticonvulsants. Because of tolerance and dependence problems associated with their use, the indications for short-acting barbiturates are limited to preanesthesia sedation, short-term treatment of insomnia, and uncomfortable seizure activity, such as status epilepticus. Long-acting phenobarbital (Solfoton, Mebaral) is the drug of choice for some types of epilepsy, the only indication for its long-term use.

Pharmacodynamics

Barbiturates are CNS depressants and can be short- (30 minutes to 4 hours), intermediate- (6 to 8 hours), or long-acting (10 to 12 hours). They produce sedation and sleep by decreasing sensitivity to stimuli in the reticular formation, a primitive area deep in the brainstem through which all the sensorimotor nerve tracts pass. They bind to $GABA_A$ receptors at a site other than the benzodiazepines and contribute to prolonged opening of the chloride ion channel. With a prolonged activation of the GABA in the reticular activating system, decreased motor stimulation and increased sleep would be expected.

Pharmacokinetics

Absorption and Distribution

Barbiturates are administered by oral, parenteral, and rectal routes. Their rate of absorption depends on the route of administration, but generally, salts are absorbed more rapidly than are acid forms. They are widely distributed, particularly to brain, kidney, and liver tissue and fluid.

Metabolism and Excretion

Barbiturates are metabolized in the liver by CYP450 2C19 enzymes. They induce their own metabolism, thereby increasing the rate of their metabolism and increasing the potential for tolerance. They are excreted in the urine, although up to 50% is eliminated unchanged. Table 15-29 includes the pharmacokinetics of the barbiturates.

These drugs are FDA Pregnancy Category D and should be avoided during pregnancy. Infant sedation has occurred when the lactating mother has used barbiturates. For women of childbearing age, care is needed to maintain birth control to prevent unwitting teratogenicity in the first trimester.

Pharmacotherapeutics

Precautions and Contraindications

Barbiturates combined with alcohol have contributed to many deaths, whether suicide or accident, because of the additive depressive effect each has on the other. Caution should be exercised in prescribing them for patients with a history of depression, suicide attempts, or alcoholism. If the clinician has any doubts about the patient's safety and there is no other medication option, no more than a week's worth of the drug should be supplied at a time and for as short a period as possible.

Because of the anxiolytic effect of the short-acting barbiturates, known as "downers" on the street, they may be abused. In addition to the hazard associated with the narrow

Table 15–29 ⊞ Pharmacokinetics: Barbiturates

Drug	Onset	Peak	Duration	Half-Life	Excretion
Pentobarbital	10–15 min	—	3–4 h	15–50 h	Urine, feces
	IV immediate				
Secobarbital	10–15 min	—	3–4 h	15–40 h	Urine, feces
	IV immediate				
Amobarbital	45–60 min	—	6–8 h	16–40 h	Urine, feces
Butabarbital	45–60 min	—	6–8 h	66–140 h	Urine, feces
Phenobarbital	30 min or more		10–16 h	53–118 h	Urine, feces
	IV: less than 5 min	IV: 15 min or more			

therapeutic index and the risk for combining them with other CNS depressants, particularly alcohol, the short-acting barbiturates secobarbital (Seconal) and pentobarbital (Nembutal) can cause physiological dependence quickly. Tolerance leads the individual to increase the dose. One gram can cause toxic adverse effects, and 2 to 10 grams can be fatal.

Withdrawal and detoxification are potentially fatal and should be accomplished extremely slowly. Withdrawal symptoms usually begin 8 to 12 hours after the last dose and can range from nausea and vomiting, confusion, and tremors to delirium and seizures, with the latter beginning approximately 16 hours after the last dose. If untreated, symptoms can last for several days.

Barbiturates are not recommended for children younger than 6 years. Other contraindications include barbiturate sensitivity, severely impaired liver function, nephritis, impaired pulmonary function with dyspnea or obstruction, and history of dependence on barbiturates, hypnotics, or alcohol. They should not be administered subcutaneously or intra-arterially.

Adverse Drug Reactions

Adverse reactions are due to the CNS depressant effects of the drug and can consist of persistent sedation and drowsiness, leading to safety concerns for patients in situations requiring alertness. Although respiratory depression and cardiac depression are dose-related, they are always a concern, especially in combination with other CNS depressants. Other adverse reactions may include agitation, particularly in young children and older adults, confusion, headache, insomnia, ataxia, skin rash, nausea and vomiting, bradycardia, dyspnea, and somnolence.

Rebound status epilepticus may follow abrupt withdrawal of barbiturates during daily administration for treatment of seizure disorders.

Drug Interactions

As discussed earlier, CNS depression may occur with concurrent use of drugs such as antihistamines, alcohol, benzodiazepines, valproic acid, and MAOIs. Table 15-30 includes the drug interactions with barbiturates.

Barbiturates may also decrease the efficacy of beta blockers, steroids, hormones, doxycycline, theophylline, protease inhibitors, dicumarol, exogenous corticosteroids, and vitamins K and D, due to the P450 enzyme induction of 2C19.

Clinical Use and Dosing

Phenobarbital and mephobarbital are effective in the treatment of some types of epilepsy—primarily tonic-clonic,

Table 15–30 ⊞ Drug Interactions: Barbiturates

Drug	Interacting Drug	Possible Effect	Implications
Barbiturates	Anticoagulants	Induces metabolism of anticoagulants and rebound bleeding when barbiturate stopped	Monitor bleeding times
	Antihistamines, alcohol, benzodiazepines	Increases CNS depression	Avoid concurrent administration
	Neuroleptics	Decreases effect of neuroleptic	Monitor for increase in psychotic symptoms
	Beta blockers, steroids, estrogen, doxycycline, protease inhibitors, valproate, theophylline, griseofulvin, quinidine, phenylbutazone	Induces metabolism and decreases effectiveness of drugs	Monitor blood levels where appropriate and assess effectiveness if concurrent administration unavoidable
	Caffeine	Antagonizes sedation and increases insomnia	Avoid coffee, tea, cola, and chocolate

simple partial, and complex partial seizures—because the reduction of response to stimuli raises the threshold of seizure activity. In addition to epilepsy, other indications for use include preanesthetic sedation and short-term treatment of insomnia. The latter indication, however, is a last resort because of the risk of dependence and the comorbidity of sleep disturbance and depression, raising the risk for suicide.

Other than parenteral administration of phenobarbital in medical emergencies such as eclampsia and status epilepticus, barbiturates are generally given orally. The short-, intermediate-, and long-acting forms have an onset of action ranging from 10 to 60 minutes, a duration of action from 3 to 16 hours, and half-lives from 24 to 100 hours. Table 15-31 includes the indications, dosage schedules, and available dosage forms for the barbiturates.

Rational Drug Selection

Although efficacious in the treatment of partial, tonic-clonic, and cortical focal seizures, phenobarbital and mephobarbital are not considered the first-line treatment of the medical

Table 15–31 ⚗ Dosage Schedule: Barbiturates

Drug	Indications	Dosage	Available Dosage Forms
Amobarbital sodium (Amytal)	Sedation, hypnotic, preanesthetic, acute convulsive episodes	Sedative: 30–50 mg bid to tid Hypnotic: 65–200 mg IM: 65–500 mg IV: do not exceed 50 mg/min *Children 6–12 yr:* 65–500 mg Single dose not to exceed 1 g	Injection: 0.5 g vials
Butabarbital sodium (Butisol)	Sedation, hypnotic, preanesthetic, acute convulsive episodes	Sedation: 15–30 mg tid to qid Hypnotic: 50–100 mg hs* Pre-operative sedation: 50–100 mg 60–90 min before surgery *Children:* 2–6 mg/kg/d; not to exceed 100 mg	Tablets: 30, 50 mg Solution: 30 mg/5 mL
Pentobarbital sodium (Nembutal)	Sedation, hypnotic, preanesthetic	IV: Initial dose of 100 mg in adult with proportional decrease of dose for children or debilitated adults. Wait for a full minute to assess effect before adding more. Not to exceed 200–500 mg for healthy adult. IM: Usual adult dose is 150–200 mg *Children:* 2–6 mg/kg as single injection; not to exceed 100 mg	Injection: 1 g/20 mL vial
Phenobarbital	Sedation, hypnotic, preanesthetic, treatment of partial and generalized tonic-clonic and cortical focal seizures status epilepticus	Epilepsy *Adults:* 60–100 mg/d *Children:* 3–6 mg/kg/d Acute convulsions *Children:* 200–320 mg IM/IV, repeat q6h prn *Children:* 4–6 mg/kg/d IM/IV for 7–10 d to blood level of 10–15 mcg/mL	Oral tablets: 15, 30, 100 mg Elixer: 20 g/5 mL
		Sedation *Adults:* 30–120 mg/d in divided doses; not to exceed 400 mg/24 h *Children:* 8–32 mg Hypnotic *Adult:* 100–200 mg *Children:* Dose based on age and weight Pre-operative sedation *Adults:* 100–200 mg IV 60–90 min before surgery *Children:* 1–3 mg/kg IM or IV Status epilepticus 15–20 mg/kg IV over 10–15 min; may require 15 min or more to achieve peak	
Secobarbital sodium (Seconal)	Sedation, hypnotic, pre-operative sedation, status epilepticus	Pre-operative sedation *Adult:* 200–300 mg 1–2 h before surgery or 1 mg/kg IM 10–15 min before surgery *Children:* 2–6 mg/kg not to exceed 100 mg or 4–5 mg/kg IM Hypnotic *Adult:* 100 mg at bedtime Status epilepticus *Children:* 15–20 mg/kg IV over 15 min	Capsules: 100 mg

*hs = *hora somni* (at bedtime).

emergencies mentioned previously, which also include seizures associated with meningitis and tetanus. The first choice in such situations is intravenous diazepam (Valium).

Phenobarbital for the treatment of epilepsy is usually prescribed in low doses so that dependence and tolerance are not significant concerns. Adults are treated with 50 to 100 mg 2 to 3 times per day, and children are prescribed 3 to 5 mg/kg per day. For uses other than treatment of tonic-clonic seizures and focal epilepsy, safer drugs are available.

Short-acting barbiturates are Schedule II controlled drugs and therefore may not be available to some nurse practitioners. Phenobarbital is Schedule IV and may be included on a state nurse practitioner formulary, depending on the individual state's rules and regulations.

Monitoring

The difference between therapeutic and toxic plasma levels is not wide, and levels should be monitored frequently. The therapeutic range is 15 to 40 mcg/mL. It is necessary to closely monitor blood levels when prescribing barbiturates with other drugs metabolized by CYP450 2D19.

Sedative-Hypnotics

Insomnia can be either a symptom within a syndrome or a specific type of sleep disorder. However, it should not be treated as an illness by itself. When patients complain about difficulty sleeping, it is necessary to further assess the kind of difficulty, that is, is the difficulty falling asleep (initial or onset insomnia), difficulty staying asleep (sleep maintenance insomnia), waking up too early and not being able to return to sleep (late or terminal insomnia), or waking up tired and not rested. Each of these components indicates different problems and is treated differently.

Onset insomnia frequently is a symptom of anxiety or agitated depression and better treated by sleep hygiene measures. Terminal insomnia again is common in depression and improves when the depression remits. Waking up tired and waking up several times during the night may be depression, pain, or other physical problem such as overactive bladder. Finally, other medical conditions (e.g., fibromyalgia, chronic obstructive pulmonary disease [COPD], cardiac arrhythmias) or medications (e.g., beta blockers, corticosteroids, bronchodilators) may contribute to sleep disturbances.

Insomnia may occur transiently, lasting only a few days; short-term, lasting 2 to 3 weeks; or chronic, lasting longer than 3 weeks and even years. Transient and short-term insomnia can often be treated with sleep hygiene only. Chronic insomnia should be treated with medication for a few months; then the patient should be tapered off the medication. If the problem persists, however, the practitioner should refer the patient for a sleep laboratory study before continuing with treatment.

Whatever the cause of the insomnia, sleep disturbance can contribute to other health problems and requires attentive decision making. Prior to considering medication, sleep hygiene measures should be the first resort. This includes limiting the bedroom and bed to purposes of sleep and sex only. Working in bed, watching television, eating in bed are all activities that disturb sleep and contribute to the perception that the bed is a battleground on which to fight sleep. In addition, the patient may be advised to establish a bedtime routine that includes comforting and relaxing measures an hour before going to bed. These may include a hot bath, a warm noncaffeine drink or high tryptophan snack, light reading, and relaxation or mild stretch exercises. More vigorous exercise should be avoided within 4 hours of going to bed, as should eating. If not asleep within 30 minutes, the patient should get up and read or do some simple tasks and return to bed when sleepy.

BENZODIAZEPINE HYPNOTICS

If sleep is still a problem after treating the underlying problem, the most common sedatives or hypnotics include benzodiazepines and nonbenzodiazepine gaba-ergics. The benzodiazepines most commonly used for sleep include the rapid-onset, slow-acting triazolam (Halcion); delayed-onset, intermediate-acting temazepam (Restoril) and estazolam (Prosom); and rapid-onset, long-acting flurazepam (Dalmane) and quazepam (Doral). They all have the potential for dependence and tolerance and should not be used more than 3 weeks at a time of daily dosing and no more than 3 times a week for no more than 3 months. The pharmacodynamics and pharmacokinetics are the same as for the benzodiazepine anxiolytics shown in Table 15-26.

NONBENZODIAZEPINE HYPNOTICS

Pharmacodynamics

There are three categories of nonbenzodiazepine hypnotics used to induce sleep. Nonbenzodiazepine hypnotics also act at the GABA receptor but not at the benzodiazepine site. There are four drugs in this class, including zolpidem (Ambien, Edluar, Intermezzo), zaleplon (Sonata), and eszopiclone (Lunesta) (zopiclone is not available in the United States). Ramelteon (Rozerem) is a melatonin receptor agonist with high affinity for melatonin MT1 and MT2 receptors, similar to exogenous melatonin.

The first orexin receptor antagonist suvorexant (Belsorma) was approved in 2014. Orexin, a neurotransmitter that regulates wakefulness, arousal, and appetite, is produced in the hypothalamus. The neurotransmitter, also called hypocretin, was discovered in 1998. An orexin receptor mutation is thought to cause narcolepsy. Suvorexant blocks the binding of orexin to the orexin A and orexin B recptors, promoting sleep.

Pharmacokinetics

Absorption and Distribution

The nonbenzodiazepine hypnotics are rapidly absorbed through oral administration and are protein bound differentially; that is, zaleplon is minimally protein bound but zolpidem is 92% protein bound. They have short half-lives, ranging from 1 hour (zaleplon) to 5.8 hours (eszopiclone) and short duration. Peak onset occurs in 0.5 to 1 hour. Ramelteon is rapidly absorbed after oral administration with a peak in 0.75 hours (range 0.5 to 1.0 hours); it is 82% protein bound. After oral administration on an empty stomach, suvorexant peaks in 2 hours

(range 30 minutes to 6 hours). Peak onset of suvorexant is delayed by 1.5 hours if it is taken on an empty stomach.

Metabolism and Excretion

Zolpidem, zaleplon, and eszopiclone are extensively metabolized by aldehyde oxidase and the CYP450 3A4 isoenzymes. They are excreted by the kidneys. Ramelteon is metabolized by CYP1A2 and excreted in the urine (84%) and feces (4%). Suvorexant is metabolized primarily by CYP3A4, with CYP2C19 contributing to a minor portion of metabolism, and is excreted in the feces (66%) and urine (23%).

Pharmacotherapeutics

Precautions and Contraindications

All of the nonbenzodiazepine drugs are within Pregnancy Category C and should not be used during pregnancy or lactation. Use of sedative-hypnotics may lead to worsening of depression. Zolpidem, eszopiclone, and zaleplon are associated with withdrawal signs and symptoms when discontinued. All the drugs in this class may lead to abnormal thinking and behavioral changes, including bizarre behavior and complex behaviors such as "sleep driving" or other behaviors (eating food, having sex, making phone calls). Rare cases of angioedema have been reported with ramelteon. Suvorexant is contraindicated in patients with narcolepsy and should be used cautiously in patients with respiratory compromise. No sleeping medication should be used acutely beyond 3 weeks or chronically beyond 3 months without careful evaluation of the treatment plan. None of these medications is approved for use in children.

Adverse Drug Reactions

The most common side effects of nonbenzodiazepine hypnotics include headache, mild transient anterograde amnesia, dizziness, somnolence, and nausea. There may be daytime drowsiness, especially if taken 6 hours or less before it is necessary to awaken. Abnormal behaviors such as "sleep driving" or worsening of depression may occur. Older adults may be more sensitive to the adverse effects of these medications. Women are more sensitive to the effects of zolpidem and should be prescribed lower doses than men.

   A dose-related worsening of suicidal ideation was reported in clinical trials of suvorexant. Mild cataplexy, including periods of leg weakness lasting seconds to minutes, may occur day or night. Sleep paralysis, the inability to move or speak, may occur for up to several minutes during the sleep-wake transition. Hypnagogic or hypnopompic hallucinations may occur with suvorexant.

   Zolpidem, eszopiclone, and zaleplon are Schedule IV drugs and all exhibit withdrawal symptoms when used chronically and abruptly discontinued. Ramelteon is not a controlled substance and does not appear to cause physical dependence. Suvorexant is Schedule IV due to potential for abuse, but does not cause physical dependence.

Drug Interactions

The nonbenzodiazepine drugs have an additive effect with CNS depressants including benzodiazepines and alcohol. Drugs that induce CYP450 3A4 will decrease the blood levels of these hypnotics, including cimetidine, phenytoin, rifampin, and carbamazepine. Drugs that inhibit CYP450 3A4 will increase the blood levels of these hypnotics, including ketoconazole, clarithromycin, erythromycin, and protease inhibitors. Fluvoxamine, a strong CYP 1A2 inducer, increases the serum levels of ramelteon significantly and they should not be administered concurrently. Ketoconazole, a strong CYP3A4 inhibitor, increases ramelteon levels when coadministered. Concominent use of suvorexant and strong CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, posaconazole, clarithromycin, nefazodone, ritonavir, saquinavir, nelfinavir, indinavir, boceprevir, telaprevir, telithromycin and conivaptan) should be avoided. The dose of suvorexant is decreased if a patient is on a moderate CYP3A4 inhibitor (e.g., amprenavir, aprepitant, atazanavir, ciprofloxacin, diltiazem, erythromycin, fluconazole, fosamprenavir, grapefruit juice, imatinib, verapamil). Likewise, fluconazole (CYP2C9 inhibitor) increases ramelteon levels. Suvorexant levels will be decreased when administered with CYP3A4 induducers.

Clinical Use and Dosing

The primary use of the nonbenzodiazepine gaba-ergics in this class is for sedation during episodes of insomnia. All have rapid onset and the patient should be warned to take the medication within 30 minutes of bedtime. Lower doses of all these drugs should be used with the elderly. The dose of zaleplon is 10 mg, and 5 mg in the elderly or small adults. Zolpidem is dosed at 5 mg for the elderly or women and 10 mg for men. The dose of Ambien CR (zolpidem extended-release) is 12.5 mg before bed, with elderly patients prescribed 6.5 mg daily. Zolpidem is available as a sublingual tablet for middle-of-the-night awakening with the maximum dose of 1.75 mg for women and elderly patients and 3.5 mg for men. The daily dose of eszopiclone is 2 to 3 mg before bed, with elderly patients prescribed 1 to 2 mg. The dose of the melatonin receptor agonist ramelteon is 8 mg taken 30 minutes before bed.

   The recommended initial dose of suvorexant is 10 mg, taken within 30 minutes of bedtime and with at least 7 hours before wakening time. Only 1 dose of suvorexant should be taken each night. If 10 mg is tolerated but not effective, the dose can be increased to 20 mg once daily before bed. If the patient is on a moderate CYP3A4 inhibitor, the initial dose is 5 mg and should not exceed 10 mg once day.

Rational Drug Selection

There is little to distinguish between the nonbenzodiazepine drugs other than individual response. Ramelteon (Rozerem) is not a controlled substance and does not cause dependence; therefore it may be preferred for some patients. Care must be taken with patients who have a drug or alcohol abuse history that may contribute to psychological dependence.

Monitoring

No drug monitoring is needed or available. Ongoing monitoring of use is necessary to determine overuse.

Patient Education

Patients should be advised to take these drugs immediately before bedtime and to get at least 6 hours of sleep (7 hours with

suvorexant). They should be advised to use caution if driving a vehicle or operating hazardous machinery until they know what effect the drug has for them. Patients should not combine these drugs with over-the-counter sleeping aids or alcohol.

MOOD STABILIZERS

Mood stabilizers are used with patients who have bipolar disorders with evidence of depressive and manic or hypomanic episodes. Bipolar disorders are distinctive from unipolar depression by virtue of mood swings and require medication not just for depression but to restore balance in the moods. Neurophysiologically, this is achieved by maintaining a regularity in nerve firing as opposed to the erratic firing that produces changes in behavior and mood. An oversimplified analogy is that bipolar disorder is like epilepsy, but the erratic firing occurs between the limbic system and the frontal cortex as opposed to the motor strip in clonic seizures. The most direct way to achieve regularity is by affecting the calcium channel on the nerve axon that permits influx of ions and stimulates the release of GABA.

Traditionally, bipolar disorder has been treated with lithium salts, first introduced in the mid-19th century and reintroduced in 1960. Although at the time it was not understood how it worked, more recently theories focus on lithium exchanging with sodium ions to propel the nerve impulse along the cell membrane. Currently, the theory underlying neuromodulation is that the catecholaminergic, indolaminergic, cholinergic, and gamma aminobutric acid systems interact to alter the pre- and postsynaptic receptors and postsynaptic activity. The most direct manner of affecting these systems is with the anticonvulsant drug classes; therefore, this section will focus on the anticonvulsants used in mood stabilization. Chapter 29 addresses additional approaches to the prominent depressive episodes.

Although traditionally medications to stabilize mood in bipolar disorders included lithium and anticonvulsants, more recently the atypical APs demonstrate mood stabilization through the combination neurotransmitter effects on dopamine and serotonin. A product released in 2003 departs from the standard because it combines fluoxetine and olanzapine in the brand-name form of Symbyax to provide mood stabilization. Because this drug is predominantly used in patients with mixed bipolar disorder, it will be discussed in greater detail in Chapter 29 along with anxiety and depression.

LITHIUM

Lithium's stabilizing effect on manic individuals was discovered in the mid-1940s, making it the earliest psychotropic drug available for use. Until recently it was considered the treatment of choice for classic bipolar mood disorder and is used as an adjunct for treatment-resistant unipolar depression.

Pharmacodynamics

Lithium carbonate (Lithobid, Eskalith) is a naturally occurring substance, similar to sodium in its lack of metabolism, its excretion through the renal system, and its affinity for the same binding sites. Both are widely distributed and interchangeable.

The relationship between sodium, lithium, and body fluid is inverse in that when sodium and fluids are depleted, as can occur during severe vomiting, prolonged heavy sweating, and diuretic use, the level of lithium is increased. The opposite also occurs, for example, as a result of water intoxication, which has the effect of decreasing the lithium level. Such variations in lithium concentration can also be the product of abrupt dietary changes or seasonal weather changes.

Lithium's mechanism of action is not completely understood but, because of the two substances' ability to substitute for each other, it is believed that lithium replaces sodium during depolarization in neuronal pathways, effectively stopping the transmission of electrical impulses. Additionally, it is suspected that lithium acts on the second messenger system postsynaptically to inhibit either the inositol monophosphatase enzyme to modulate the G proteins or the messenger RNA to alter the protein kinase C (Stahl, 2009).

Pharmacokinetics

Absorption and Distribution

Lithium is quickly absorbed through the GI tract after oral administration and shows no protein binding. Ingestion of food does not affect absorption. It is widely distributed throughout the body according to water volume. Distribution across the blood–brain barrier is slow.

Metabolism and Excretion

Lithium is one of the few psychopharmacological agents that is not metabolized by the liver and is essentially excreted into the urine unchanged. Because it is excreted by the kidneys, kidney function is critical in the use of lithium in treatment. The excretion half-life is between 10 and 50 hours.

Onset, Peak, and Duration

Lithium reaches maximum blood level within 0.5 to 3 hours and has a half-life of 17 to 36 hours. Steady state is achieved in 5 to 7 days.

Pharmacotherapeutics

Precautions and Contraindications

Because lithium is almost completely excreted through the renal system, it is essential that the presence of kidney disease be assessed before starting lithium. Baseline blood chemistry, including creatinine, blood urea nitrogen (BUN), and TSH levels, should be obtained. In the event of positive findings, a different drug should be used.

Lithium is contraindicated in children younger than 12 years because of insufficient clinical trials with young children. Lithium is rated Pregnancy Category C and should not be used with pregnant or lactating women without serious balancing of risks and benefits. When taken in the first trimester, there is a 10% chance of fetal abnormalities, including

Epstein's cardiac anomaly and tricuspid valve prolapse. When taken in the third trimester, there is a significant risk for neonatal lithium toxicity, hypertonicity, congenital hypothyroidism, and congenital goiter (Williams & Oke, 2000).

Extreme caution should be used when prescribing lithium to patients with sodium depletion or to those taking diuretics. Hypothyroidism and kidney failure may occur with long-term administration.

Adverse Drug Reactions

Early, transient adverse reactions may occur, including most commonly fine tremors of the fingers, nausea, dry mouth, headache, and drowsiness. Lithium may be taken with food to minimize GI distress, and the form of the drug may be changed to sustained release to minimize adverse effects associated with dosage peaks. Even at therapeutic blood levels, some patients may have ECG changes that are not necessarily indicative of underlying cardiac disease but should be monitored.

The index between therapeutic and toxic levels is narrow at the upper end, requiring frequent monitoring initially and in the event of significant changes in fluid balance, as often as daily if necessary. The therapeutic range is 0.6 to 1.5 mEq/L.

Indicators of toxicity, which can also occur at therapeutic levels, are coarse tremors of the hands that impair function, nausea and vomiting, diarrhea, confusion, stupor, polydipsia and polyuria, muscle weakness, and ataxia. If the lithium level is elevated enough, coma and death can result. Treatment for overdose is supportive, including ensuring adequate hydration and even dialysis. Because lithium overdose may contribute to arrhythmias, ECG monitoring is necessary.

Drug Interactions

Because the liver does not metabolize lithium, drug interactions due to the CYP450 system are not an issue. However, drug interactions associated with altering fluid balance and lithium concentrations may increase the risk for lithium toxicity. Diuretics may increase sodium excretion and increase lithium concentrations. NSAIDs and COX 2 inhibitors reduce renal elimination and elevate serum lithium levels. Lithium prolongs the effects of neuromuscular-blocking agents used before surgery and during electroconvulsive treatments (ECT). Concurrent use of etronidazole increases risk of lithium toxicity due to decreased renal excretion.

Decreased lithium levels may result with theophylline, concurrent use of sodium salts, and bulking agents such as Metamucil. Concurrent administration with anticonvulsants may increase toxicity of both drugs. Table 15-32 includes the drug interactions with lithium.

Clinical Use and Dosing

Table 15-33 includes the indications, dosage schedule, and available dosage forms for lithium.

Rational Drug Selection

Because of its long half-life, lithium takes 10 to 14 days to reach maximum efficacy; therefore, it is not indicated in the treatment of acute mania. Rather, it is indicated for maintenance of mood stability and prevention of mania or hypomania. A strategy for responding to acute mania would be to start a patient on lithium supplemented initially with a dopaminergic or serotonergic-dopaminergic drug such as haloperidol or risperidone and to discontinue the neuroleptic, if possible, when the required length of time for lithium to be become efficacious has elapsed and the mania has abated. Some clinicians raise the dosage initially to achieve a serum level of 1.2 mEq/L during an acute stage and back down to 0.8 mEq/L for maintenance. As a patient achieves and maintains stability, levels need not be obtained as frequently.

Table 15–32 ⚏ Drug Interactions: Lithium

Drug	Interacting Drug	Possible Effect	Implications
Lithium	Angiotensin-converting enzyme (ACE) inhibitors, antibiotics (ampicillin, doxycycline, tetracycline, spectinomycin), antihypertensives, metronidazole, NSAIDs, antimicrobials, diuretics, fluoxetin	Increased lithium level	Monitor lithium blood levels and for signs and symptoms of toxicity Avoid NSAIDs
	Caffeine, psyllium, urinary alkalizers, theophylline	Decreased lithium level	Monitor lithium blood level and recurrence of manic signs and symptoms for need to increase dose
	Anticonvulsants, calcium channel blockers, phenothiazines, haloperidol, methyldopa	Increased neurotoxicity	Avoid coadministration
	Benzodiazepines	Sexual dysfunction	Avoid
	SSRIs	Serotonin syndrome	Keep SSRI dose low
			Monitor for signs and symptoms of serotonin excess
	Acetazolamide, osmotic diuretics, theophyllines, urinary alkalizers	Increased renal excretion	Monitor PT response and lithium blood levels, adjust lithium dose
	Neuromuscular blocking agents, TCAs	Increased pharmacological effects of additive drugs	Adjust dosage accordingly

Table 15–33 ⊗ **Dosage Schedule: Lithium**

Drug	Indications	Dosage	Available Dosage Forms
Lithium (Lithobid, Eskalith, lithium carbonate, Lithotabs)	Treatment of manic phase of bipolar disorders and prevention of manic episodes	Acute mania; 600 mg tid or 900 mg bid Extended-release Maintenance: 300 mg tid qid or 450 mg bid Controlled-release	Capsules (G): 150 mg 300 mg 600 mg Tablets: 300 mg Controlled-release tablets: 300 and 450 mg Syrup: 300 mg/15 mL Slow-release capsules 150 and 300 mg

Refractory unipolar depression = 300–600 mg daily.
G = generic.

Lithium is also prescribed for patients who have been resistant to adequate trials of the usual antidepressants based on the theory that the resistance is due to an underlying bipolar pathology. Adjunctive doses of lithium are frequently lower than they would be for bipolar disorder, with concomitantly lower risks.

Monitoring

Because signs and symptoms of toxicity may occur even at subtoxic blood levels, patients should always be assessed for tremors, nausea, and drowsiness. Lowering the dose will usually be sufficient to resolve the problems.

Blood levels should be obtained 14 days after beginning treatment and 14 days after every dosage change. Generally, routine blood levels are obtained every 3 to 6 months after stability is achieved. In the event of patient illness involving severe vomiting, diarrhea, prolonged high fever, or heatstroke, more frequent monitoring is needed as would also be the case in a planned dietary change or weight-loss plan. The procedure for obtaining an accurate lithium level is to have the sample drawn 12 hours after the last dose, usually the bedtime dose, before any morning dose has been taken. The patient need not be fasting, but the timing needs to be accurate within an hour to ensure standardization of interpretation of the results.

Routine blood counts with differential, chemistry screens, and thyroid panels should be obtained yearly. In addition, there should be a baseline ECG and annual ECG to ascertain arrhythmias.

Patient Education

Patients should be informed of the procedure for obtaining an accurate lithium level as described above. Advise the patient to report any illness involving severe vomiting, diarrhea, or prolonged fever. Also tell patients engaging in activities that produce copious sweating to increase their water intake and maintain an adequate salt intake. Women of childbearing age need to be advised of contraceptive strategies and that unplanned pregnancies may result in congenital malformations.

VALPROATES

Although valproate (Depakote) was approved for treatment of seizures in the 1960s, the FDA did not approve its use in mania until 1995. It is currently seen as the first- or second-choice drug in the treatment of bipolar disorder, especially in acute mania and maintenance for bipolar, manic disorder.

Pharmacodynamics

Although the exact mechanism is unknown, valproate blocks GABA uptake into presynaptic neurons without affecting the benzodiazepine binding site. It appears to enhance GABA function, thereby slowing down repolarization and reducing glutamate functioning at the sodium and calcium channels.

Pharmacokinetics

Absorption and Distribution

Valproate is administered orally and is rapidly absorbed by the GI tract. It has also been approved for IV administration for immediate treatment of seizures, but this route has not been used in rapid treatment of mania. It is 100% bioavailable with high protein binding. It reaches peak levels in 1 to 4 hours and has a half-life of 6 to16 hours. Valproate may be displaced by carbamazepine and warfarin, contributing to toxic side effects.

Metabolism and Excretion

Valproate is metabolized by the liver with several active metabolites. It is metabolized by P450 2C9, 2C19, and 2A6; possibly induces 2C9 and 2C19; and inhibits 2C9, 2D6, and 3A4. Such a complicated metabolism contributes to many drug interactions, as described below. It is excreted by the kidneys.

Onset, Peak, and Duration

Peak plasma levels occur within 1 to 4 hours, although when administered by syrup, the drug peaks sooner. Conversely, the enteric-coated version delays absorption and peaking.

Pharmacotherapeutics

Precautions and Contraindications

Contraindications include hypersensitivity and hepatic disease.

Use of these drugs during the first trimester of pregnancy is associated with neural tube defects including spina bifida. They are Pregnancy Category D. Their use should be

restricted to cases in which the woman's life would be endangered without them and then only beyond the first trimester. They should be used with caution during lactation.

The plasma level range is 50 to 100 mcg/mL. Levels above 100 mcg/mL are thought to be toxic, although symptoms of toxicity can occur at blood levels within the normal range, and patients have been maintained on levels above 100 mcg/mL without apparent toxicity. Therefore, valproate has a wider safety margin than lithium. Symptoms of toxicity include dizziness, hypotension, tachycardia or bradycardia, drowsiness, visual hallucinations, and respiratory depression. Coma and death may result.

Although relatively uncommon, valproate may impair platelet aggregation so that bleeding time may be prolonged, and it may suppress bone marrow production. For this reason, a CBC with differential and platelets should precede use and be repeated with regularity initially and less frequently beyond the first 3 months as the patient continues to take the medication without adverse events.

Rare cases of hepatotoxicity and liver failure have occurred, primarily in children younger than 2 years who have been on combination antiepileptic drug therapy. Because bipolar disorder has not yet been diagnosed in children younger than 2 years, valproate has not been used for mood stabilization in this population.

Patients with diabetes taking valproate may show falsely positive ketone urine tests because the drug is partially excreted in the urine as a ketone metabolite. Any patient may have initially elevated liver enzymes, but this is usually transitory.

Adverse Drug Reactions

Valproate is well tolerated, and most adverse effects, such as GI distress, heartburn, and CNS depression, are mild and transient. Safety in situations requiring mental alertness is of concern initially, and the patient should be instructed to avoid potentially dangerous situations until the effect of the drug can be assessed. Alopecia has also been reported but the hair usually grows back, although with a different texture.

Drug Interactions

Many common drug interactions have to do with the competition with protein-binding sites and the P450 enzyme involvement. Valproates in combination with other CNS depressants can lead to an additive depressant effect. Bleeding time can be increased in combination with anticoagulants. Combinations of TCAs and valproates can lead to increased risk of cardiotoxicity. Combinations of valproates with carbamazepine or hydantoins may result in increased levels of these drugs and reduced efficacy of valproate. Chlorpromazine, cimetidine, erythromycin, rifampin, and salicylates may increase valproate serum levels. Table 15-34 includes the drug interactions with the valproates.

Clinical Uses and Dosages

Table 15-35 includes the indications, dosage schedule, and available dosage forms for the valproates.

Rational Drug Selection

Valproate psychiatric indications include the treatment of bipolar disorder, particularly the rapid cycling or mixed types, both for acute mania and prevention. It can be given in large doses in an acute state with minimal concern for toxicity.

Other uses include treatment of mood stability associated with borderline personality disorder or PTSD, anger and aggression, and adjunctive treatment for drug-resistant unipolar depression.

The usual adult dose is 750 to 3,000 mg/day taken initially in divided dose then once daily at bedtime if side effects are

Table 15–34 Drug Interactions: Valproates

Drug	Interacting Drug	Possible Effect	Implications
Valproic acid and derivatives	CNS depressants	Increased sedation and disorientation	Warn patient about safety issues; avoid if possible
	Anticoagulants	Increased bleeding time	Monitor bleeding time
	Anticonvulsants	May increase plasma level of anticonvulsant, decrease valproate efficacy	Monitor plasma levels
	TCAs, barbiturates, diazepam, ethosuximide	Increased blood level and increased risk of cardiotoxicity	Monitor blood level
	Clonazepam	Increased risk of absence seizure	
	Lithium	Increased tremors	Decrease lithium dose
	Typical antipsychotics	Increased risk of neurotoxicity, sedation, EPS	Monitor for signs and symptoms of toxicity
	Antiviral	Decreased valproate level	Monitor plasma level of valproate
	Cimetidine, salicylates, rifampin, erythromycin	Increased plasma level and half-life of valproate	Monitor plasma level of valproate
	Lamotrigine	Decreased valproic levels, increased lamotrigine levels	Monitor plasma levels

Table 15–35 ⊗ **Dosage Schedule: Valproates**

Drug	Indications	Dosage	Available Dosage Forms
Valproic acid (Depakote, Depakene; Depacon)	Complex partial, simple (petit mal), absence seizure epilepsy; mania; migraine headache	*Adults:* 750 mg daily in divided doses; may increase rapidly to control acute mania to maximum of 60 mg/kg/d For migraine headache: 250 mg bid *Children and older adults:* Reduce dose Sprinkle capsule should not be chewed and not stored for future use once opened; take with food to prevent GI distress For acute mania: 60 mg IV infusion (20 mg/min or less) at same frequency as oral dose	Depakene: 250 mg capsule 250 mg/5 mL syrup Generic: 250 mg capsules 250 mg/5 mL syrup Depakote enteric-coated tablet: 125 mg 250 mg 500 mg 125 mg sprinkle capsule Extended-release Depakote 250 and 500 mg Depacon: 5 mg injection

tolerable. Maximum daily dosage is 60 mg/kg/day. Because it inhibits its own metabolism after reaching steady state, the drug begins to maintain a consistent blood level sufficient for single daily dosing.

Monitoring

Plasma levels should be assessed to help guide dosage adjustments, with a trough concentration of 50 to 125 mcg/mL. CBCs and chemistries should be obtained prior to onset of treatment and then every 3 months for 1 year. After 1 year, monitoring can be done annually.

Patient Education

Patients should be advised about the side effects, especially the possibility of bruising and delayed clotting initially. Patients who are prone to falls should especially be advised to tell their primary care provider and family members. Patients should be advised to avoid hazardous activities until their level of sedation is determined. Also, advise patients not to discontinue the drug abruptly.

NONCLASSIFIED MOOD STABILIZERS

The nonbenzodiazepine gaba-ergics used in the treatment of epilepsy have shown effectiveness in treating bipolar states, as might be expected based on the data about valproates. These include lamotrigine (Lamictal), gabapentin (Neurontin), and topiramate (Topamax). Only lamotrigine has been approved by the FDA for this use.

Pharmacodynamics

All of these drugs act in some way on GABA as well as other mechanisms. Lamotrigine also acts as a 5-HT$_3$ blocker and glutamate modulator as well as inhibits the sodium channels to slow down depolarization. Gabapentin does not act directly on GABA but instead seems to act as a GABA transporter inhibitor, thereby increasing the availability of GABA. As with lamotrigine, gabapentin decreases the excitatory amino acid neurotransmitter, glutamate. Finally, topiramate acts in a manner similar to gabapentin to enhance GABA functioning and interfere with glutamate by means of the sodium and calcium channels.

Pharmacokinetics

Absorption and Distribution

All three of the gaba-ergic drugs are readily absorbed through the GI tract and have between 80% to 90% bioavailability. Gabapentin's bioavailability decreases as the dose increases, however. Lamotrigine has the longest half-life at 25 hours, topiramate has 21 hours, and gabapentin is at 5 to 8 hours. Food does not alter absorption for any of these drugs.

Metabolism and Excretion

Lamotrigine is metabolized by glucuronidation; however, all three drugs are essentially excreted by the kidneys relatively unchanged. Neither gabapentin nor topiramate undergoes metabolism at all.

Pharmacotherapeutics

Precautions and Contraindications

All three of these drugs are rated Pregnancy Category C. Based on the pregnancy registry, there is no evidence of harm to the fetus; however, the database is insufficient to determine the risk. The prescriber would need to balance the risks and the benefits of treating a pregnant woman with these drugs. If it is necessary to use them, it serves the fetus best to wait until the second trimester. Although no detrimental effects have been reported to the breastfeeding newborn, each of these drugs is excreted in breast milk and exposes the healthy neonate unnecessarily to the drug.

These drugs have not been tested in children and should not be used to treat children younger than 2 years. There are no age-related differences in safety; however, dosages may need to be changed in the elderly to accommodate changes in renal clearance.

Topiramate has shown the effect of hyperchloremic non-anion gap metabolic acidosis and should be used cautiously with patients with eating disorders.

Adverse Drug Reactions

The gaba-ergic drugs have relatively few side effects. Those most commonly seen are somnolence, dizziness, ataxia, and fatigue. Gabapentin is associated with weight gain, whereas

topiramate and to a lesser extent lamotrigine are associated with weight loss. In addition, diplopia, blurred vision, nausea, and rhinitis are not uncommon. Lamotrigine and topiramate have a rare incidence (0.8% in children; 0.3% in adults) of Stevens–Johnson syndrome occurring within the first 2 to 8 weeks of therapy that can be fatal. Topiramate has a 1% occurrence of renal calculi.

Drug Interactions

The gaba-ergics are minimally metabolized by the liver; there are few drug interactions. When given in conjunction with other antiepileptic drugs, such as carbamazepine or phenytoin, the half-life of lamotrigine is decreased, but with valproate the half-life is increased. Gabapentin reduces the bioavailability of antacids, but cimetidine increases the bioavailability of gabapentin. Gabapentin also increases the serum levels of contraceptives. Topiramate decreases the effectiveness of oral contraceptives, and carbonic anhydrase inhibitors may increase the risk of kidney stones.

Clinical Use and Dosing

The primary use of these non-benzodiazepine gaba-ergics is for epilepsy; however, lamotrigine has been approved for use in acute mania, maintenance and prophylaxis of mood lability, and may even reduce the incidence of depression in bipolar disorders. Gabapentin and topiramate have not been approved to treat bipolar disorders; however, indication for this is likely to be approved in the near future.

Rationale Drug Selection

Currently these three drugs are seen as a third line for the treatment of bipolar disorder and are often used in conjunction with other therapies for treatment-resistant bipolar conditions. They are safe and easy for patients to maintain treatment.

Monitoring

No routine serum levels are necessary. Patients should monitor skin appearances and report any rashes within the first 2 months of therapy, especially if blisters form. Weight monitoring is important, especially with gabapentin.

Patient Education

Patients must be informed of the risks and benefits of these drugs as well as the possible side effects. Patients taking topiramate need to be advised to drink plenty of water owing to the risk of kidney stones. Advise patients of the potential for Stevens–Johnson syndrome and what to do if a rash appears.

MUSCLE RELAXANTS AND ANTISPASMOTICS

Muscle relaxants and antispasmotic drugs are used to treat severe muscle spasms and the associated pain. The two categories of muscle relaxants are those that act in the CNS and the direct-acting drugs or antispasmotics. The commonly used centrally acting muscle relaxants include baclofen (Lioresal), carisoprodol (Soma), chloraxazone (Paraflex, Parafon Forte), cyclobenzaprine (Flexeril), methocarbamol (Robaxin), orphenadrine (Banflex, Norflex), and tizanidine (Zanaflex). The benzodiazepines (diazepam) that are centrally acting muscle relaxants have been previously discussed. The direct-acting antispasmotics include dantrolene (Dantrium) and botulinum toxin type A (Botox). Muscle relaxants and antispasmotics are often combined with nonpharmacological measures such as stretching, massage, and heat or cold to relieve muscle spasms and pain.

CENTRALLY ACTING MUSCLE RELAXANTS

Pharmacodynamics

The exact mechanism whereby the centrally acting muscle relaxants relieve muscle spasms is not well understood. The centrally acting medications appear to act on the monosynaptic and polysynaptic spinal reflexes, rather than on the muscles themselves. Inhibiting the synaptic reflex arcs impacts the messages that are producing and maintaining the skeletal muscle spasm. Centrally acting muscle relaxants also have a sedative effect, which causes drowsiness and may enable a patient with muscle spasms to relax and sleep. Tizanidine is a centrally acting alpha$_2$-adrenergic agonist that produces presynaptic inhibition of motor neurons in the spinal cord, reducing muscle spasticity.

Pharmacokinetics

Absorption and Distribution

The centrally acting muscle relaxants baclofen, carisoprodol, chloraxazone, cyclobenzaprine, methocarbamol, and tizanidine are rapidly absorbed after oral administration. Metaxalone is more slowly absorbed and has an onset of 3 hours after oral dose on an empty stomach. The centrally acting muscle relaxants are distributed into the CNS (site of action). The pharmacokinetics of orphenadrine is not described.

Metabolism and Excretion

Most of the centrally acting muscle relaxants are metabolized in the liver and excreted in the urine. Carisoprodol is metabolized in the liver by CYP2C19 into the active metabolite meprobamate, which has antianxiety properties. Cyclobenzaprine is subject to enterohepatic circulation and will accumulate if dosed 3 times a day, with steady-state plasma levels significantly higher than when given in a single dose. Tizanidine is metabolized via CYPO 1A2 into inactive metabolites, which are excreted in the urine.

Pharmacotherapeutics

Precautions and Contraindications

The centrally acting muscle relaxants may cause CNS sedation and increase the risk of falls and injury. Patients should not drive or use any other CNS sedating drug while taking

muscle relaxants. Many of the centrally acting muscle relaxants (carisoprodol, chlorzoxazone, cyclobenzaprine, methocarbamol, and orphenadrine) are on the Beer's list of medications to be avoided in the elderly.

Baclofen's only true contraindication is hypersensitivity to baclofen. Baclofen should be used cautiously in patients with decreased renal function, as it is excreted primarily via the kidneys. Patients with seizure disorder should be prescribed baclofen carefully, with seizure control and EEG monitored because of a deterioration in seizure control associated with baclofen use. Baclofen is Pregnancy Category C and should be avoided in pregnancy due to increased incidence of omphaloceles in fetal rats and unossified forelimbs and hindlimbs in rabbits. Case reports of neonatal withdrawal have been reported. Limited information on use of baclofen during lactation indicates there are low levels of baclofen in breast milk, but not enough to cause adverse effects in the infant (LactMed, 2014). Breastfed infants should be monitored for sedation.

Carisoprodol is contraindicated in patients with porphyria or hypersensitivity to carisoprodol or its active metabolite meprobamate. Carisoprodol (Soma) may cause physical dependence and abuse or result in criminal diversion. Abuse of carisoprodol may lead to overdose, CNS and respiratory depression, and death. Carisoprodol is Pregnancy Category C. It is known to cross the placenta, and animal studies indicate adverse effects on fetal growth but no clear teratogen effects. Carisoprodol and its metabolite meprobamate can be measured in human breast milk, with mild sedation noted in breastfed newborns of women taking the drug (LactMed, 2014). Carisoprodol is not approved for use in children younger than age 16 years.

Rare reports of hepatoxocity have been noted with chlorzoxazone use. Chlorzaxone is Pregnancy Category C. Safety in lactation or in children has not been established.

Cyclobenzaprine is contraindicated in patients with hyperthyroidism or in the acute recovery phase of a myocardial infarction or who have heart failure, dysrhythmias, or conduction disturbances. Serotonin syndrome has been reported with cyclobenzaprine use. Owing to its anticholinergic effects, cyclobenzaprine should be used cautiously in patients with urinary retention, angle-closure glaucoma, or increased intraocular pressure. Patients with hepatic impairment are not able to metabolize cyclobenzaprine well; therefore, those with mild liver dysfunction should be prescribed small doses (5 mg) and those with moderate to severe liver dysfunction should not be prescribed cyclobenzaprine. Cyclobenzaprine is Pregnancy Category B, with no impact on pregnancy or the fetus recorded. There is no available information regarding the use of cyclobenzaprine while breastfeeding; therefore, it should be used with caution and the infant monitored for sedation. The safety and efficacy of cyclobenzaprine in children younger than age 15 years have not been established.

Metaxalone is contraindicated in patients with known hypersensitivity and those with significantly impaired renal or hepatic function. If administered to a patient with liver dysfunction, serial liver function studies should be performed. Metaxalone does not have a pregnancy category assigned, and safe use in pregnancy has not been determined. It is not known whether metaxalone is excreted in breast milk. The safety and effectiveness in children younger than age 12 years have not been established.

Methocarbamol is contraindicated in patients who are hypersensitive to the drug. Patients with renal or hepatic dysfunction should be prescribed methocarbamol with caution. Methocarbamol is Pregnancy Category C. Rare reports of fetal malformations have been recorded following in utero exposure. It is not known whether methocarbamol is excreted in human breast milk, although it has been measured in dog milk. The safety and efficacy in children younger than age 16 years have not been established.

Orphenadrine has significant anticholinergic effects and therefore should not be used in patients with urinary retention, prostatic hypertrophy, glaucoma, or achalasia. Orphenadrine is Pregancy Category C. Safety during lactation or in children has not been established.

Tizanidine is contraindicated in patients who are hypersensitive or who are taking CYP1A2 inhibitors (fluvoxamine or ciprofloxacin). Anaphylaxis and angioedema has been reported with tizanidine use. Tizanidine is hepatotoxic and should be used cautiously in patients with liver dysfunction. Liver function should be monitored during use. Older adults or patients with renal dysfunction should be prescribed tizanidine cautiously due to increased adverse effects. Tizanidine is an alpha$_2$-adrenergic agonist and patients who abruptly stop taking the medication may experience hypertension or tachycardia. Tizanidine is Pregnancy Category C. There are no human studies, but animal studies have noted developmental retardation and fetal loss. Safety and efficacy in children or during lactation have not been established.

Adverse Drug Reactions

As previously noted, all the muscle relaxants cause CNS sedation to some extent, with some causing significant sedation, drowsiness, and dizziness. Baclofen may cause neuropsychiatric effects, including confusion, headache, insomnia, and seizures.

Carisoprodol causes significant CNS and respiratory depression, which is worsened by coadministration of other CNS depressants. Carisoprodol may cause headache, tachycardia, vertigo, atazia, syncope, insomnia, and seizures. Physical dependence on carisoprodol may occur, as well as leukopenia or pancytopenia.

Chlorzaxazone may be hepatotoxic and may rarely cause angioedema or anaphylaxis. Gastrointestinal effects of chlorzaxazone include nausea, vomiting, diarrhea or constipation, heartburn, or gastrointestinal bleeding.

Patients taking cyclobenzaprine may experience dry mouth, fatigue, nausea and vomiting, constipation, hallucinations, and blurred vision. Cyclobenzaprine may cause dysrhythmias or prolonged QT syndrome.

The adverse effects of metaxalone include confusion, headache, anxiety, nausea, dry mouth, or gastrointestinal

upset. Metaxalone may also cause leukopenia or hemolytic anemia.

Methocarbamol may cause significant sedation and dizziness. Anaphylaxis, urticaria, and rash may occur. Blurred vision, headache, leukopenia, jaundice, nausea, and vomiting have also been reported in patients taking methocarbamol.

Orphenadrine may cause CNS excitation, agitation and hallucinations, dry mouth, tachycardia, syncope, palpitation, blurred vision, nausea and vomiting, and abdominal cramps. Anaphylaxis may occur with orphenadrine use.

Tizanidine may cause dry mouth (49% in clinical trials), asthenia (weakness), fatigue, constipation, hypotension, and bradycardia. Tizanidine may be hepatotoxic and liver function should be monitored.

Drug Interactions

All of the muscle relaxants have additive sedation with other CNS depressants and patients should be warned not to consume alcohol or antihistamines while taking these medications.

Coadministration of carisoprodol and CYP2C19 inhibitors (omeprazole, fluvoxamine, aspirin) may result in increased carisoprodol levels.

Cyclobenzaprine may have a life-threatening interaction with MAO inhibitors. Coadministration of cyclobenzaprine with serotinergic drugs (SSRIs, SNRIs, TCAs, bupropion, MAOIs) may cause serotonin syndrome.

Mecthocarbamol decreases the effect of pyridostigmine. Use cautiously in patients taking anticholinesterase medications, such as those with myasthenia gravis.

Tizanidine's effects may be increased if taken concurrently with fluvoxamine, ciprofloxacin, or alpha $_2$-adrenergic antihypertensives, leading to hypotension, increased drowsiness, and increased impairment. Concurrent use with CYP 1A2 inhibitors is contraindicated—including zileuton, fluroquinolones, amiodoarone, mexiletine, propafenone, verapamil, cimetidine, famotidine, oral contraceptives, acyclovir, and ticlopidine—due to increased levels of tizanidine that lead to increased risk of hypotension and sedation. Alcohol increases tizanidine blood levels and additionally causes additive sedation.

Clinical Use and Dosing

Baclofen is prescribed to relieve spasticity associated with multiple sclerosis, spinal cord injuries, and occasionally cerebral palsy. Baclofen dosage is individualized to the patients, with slow titration to desired effect. Adult patients are started at 5 mg TID and increased every 3 days until desired effect to a maximum of 80 mg/day. Baclofen is also delivered intrathecally via pump to treat spasticity in both children and adults.

Carisoprodol (Soma) is dosed at 250 to 350 mg 3 times a day for a maximum of 2 to 3 weeks. Limiting the length of treatment to 3 weeks helps avoid dependence and abuse.

Chlorzoxazone (Parafon Forte) in addition to rest and physical therapy is indicated for the treatment of painful musculoskeletal conditions. The usual adult dose is 500 mg 3 to 4 times a day. The dose may be increased to 750 mg 3 to 4 times a day if needed, but the dose should be reduced as soon as improvement occurs.

Cyclobenzaprine (Flexeril) is used for the short-term treatment of painful muscle spasms that impact activities of daily living. The recommended dose of cyclobenzaprine is 5 mg 3 times a day for 2 to 3 weeks. The dosage may be increased to 10 mg 3 times a day if indicated. Lowered or less frequent doses are recommended for the elderly or patients with hepatic impairment. Cyclobenzaprine should not be prescribed for longer than 3 weeks.

Metaxalone (Skelaxin) is indicated for the short-term treatment of acute, painful musculoskeletal conditions. It is to be used in conjuction with rest and other measures to relieve muscle pain. The recommended adult dose is 800 mg 3 to 4 times a day.

Methocarbamol (Robaxin) is prescribed for short-term treatment of acute painful musculoskeletal conditions in adults or adolescents age 16 years or older. The initial dose of methocarbamol for muscle spasms is 1.5 g 4 times a day for 2 to 3 days. The maintenance dose is 1.0 g 4 times a day or 1.5 g 3 times a day. Dosage should be adjusted downward in patients with renal or hepatic impairment. Intravenous methocarbamol is used to treat tetanus.

Orphenadrine (Norgesic or Norgesic Forte) is used for short-term relief of moderate pain associated with musculoskeletal disorders in conjunction with rest and other measures to relieve muscle pain. The dose of Norgesic (orphenadrine 25 mg with aspirin 385 mg and caffeine 30 mg) is one to two tablets 3 to 4 times a day. The dose of Norgesic Forte (orphenadrine 50 mg with aspirin 770 mg and caffeine 60 mg) is one-half to one tablet 3 to 4 times daily.

Tizanidine (Zanaflex) is used for spasticity and is recommended only when spasticity is affecting activities of daily living. Tizanidine may be taken with or without food, but once a patient decides it should be taken consistently with or without food because pharmacokinetics differ depending on food intake. The recommended initial dose of tizanidine is 2 mg every 6 to 8 hours, for a maximum of three doses in 24 hours. The dose may be increased by 2 mg per dose every 1 to 4 days to a maximum of 36 mg per 24 hours. Lower doses should be prescribed for patients with renal or hepatic impairment. Patients are at risk for rebound when discontinuing tizanidine; therefore, they should be tapered slowly (2 to 4 mg per day taper) to prevent rebound hypertension, tachycardia, and hypertonia.

Rational Drug Selection

Drug selection is dependent on the patient's underlying condition and health status. The evidence for the use of muscle relaxants is lacking, and they have not been proven to be more effective than acetaminophen or NSAIDS for low back pain. Elderly patients and those with hepatic impairment should be prescribed the antispasmotics with caution. Tizanidine and cyclobenzaprine are sedating and may be

helpful if muscle spasms cause insomnia. Methocarbamol is less sedating if patients need to take it during the day, but the patient should not drive while using the drug.

Monitoring

It is important to monitor for adverse reactions to muscle relaxants, as discussed previously. The clinician should monitor that the amount of drug used is consistent with the amounts prescribed and dispensed.

Patient Education

Patients being prescribed muscle relaxants should be educated on the appropriate use and adverse effects. All of the muscle relaxant drugs are sedating, and patients should be cautioned not to drive or combine them with other sedating medications or alcohol. Muscle relaxants are for short-term use; therefore nonpharmacological therapies should be addressed, including heat/cold, physical therapy, and back exercises.

DIRECT-ACTING ANTISPASMOTICS

Pharmacodynamics

The direct-acting antispasmotics dantrolene (Dantrium) and botulinum toxin type A (Botox) have unique uses based on their pharmacodynamics. Dantrolene is administered orally or via IV and is used to treat spasticity associated with upper neuron disorders, including spinal cord injury, stroke, cerebral palsy, and multiple sclerosis. Botulinum toxin type A is injected to provide localized reduction in muscle activitiy.

Dantrolene causes muscle relaxation by interfering with the release of calcium from the sarcoplasmic reticulum, affecting the fast muscle fibers more than the slow fibers. The intensity of the skeletal muscle relaxation is dose-related. Botulinum toxin type A acts locally to block neuromuscular transmission by binding to receptor sites on the motor or sympathetic nerves, depending on site of injection. At the nerve terminal, botulinum toxin type A works to inhibit the release of acetylcholine. When injected intradermally, botulinum toxin type A causes temporary denervation of the sweat glands, causing decreased production of sweat locally. When injected into the detrusor muscle, botulinum toxin type A affects the afferent pathways of the detrusor muscle by inhibiting acetylcholine release.

Pharmacokinetics

Absorption and Distribution

Absorption of dantrolene after oral administration is incomplete but not well described. The half-life of dantrolene is 8.7 hours after a 100 mg dose, with the duration of action related to dosage. Botulinum toxin type A is not absorbed and is not detected in the blood after intramuscular injection.

Metabolism and Excretion

Dantrolene is metabolized into a 5-hydroxy analog and an acetamido analog and excreted in the urine.

Pharmacotherapeutics

Precautions and Contraindications

Dantrolene is contraindicated in patients with active liver disease such as hepatitis or cirrhosis. Dantrolene may induce potentially fatal hepatocellular disease, with a higher risk noted in female patients and those over age 35. The elderly may have an increased likelihood of fatal hepatoticity, possibly due to concomitant illness or interacting medications.

Botulinum toxin type A may spread from the site of injection to produce effects similar to botulinum toxin. Symptoms may appear hours to weeks after injection and include muscle weakness, dysphagia, dysphonia, urinary incontinence, and breathing difficulties. If muscles of the respiratory system are involved, the patient may need intubation and mechanical ventilation. If the muscles of the oropharynx or esophagus are affected, patients may aspirate. Antitoxin is available for overdose from the Centers for Disease Control and Prevention. Intradetrusor injection with botulinum toxin type A is contraindicated in patients with a urinary tract infection or urinary retention.

Dantrolene is Pregnancy Category C. There is no long-term data on use during lactation; therefore it should not be used during breastfeeding (LactMed, 2014). Botulinum toxin type A is Pregnancy Catetory C.

Adverse Drug Reactions

Although dantrolene is a direct-acting antispasmotic, the major ADRs involve CNS sedation, including drowsiness, dizziness, weakness, fatigue, and malaise. These adverse effects can be reduced by starting at a low dose and slowing the increase to the target dose. Other CNS effects include mental depression, confusion, nervousness, headache, insomnia, drooling, and alteration in taste. Patients may experience diarrhea that may be severe and require the temporary cessation of therapy. If diarrhea recurs when dantrolene is restarted, the patient may not be able to tolerate the medication. Less common GI adverse effects include constipation, abdominal cramps, anorexia, nausea, and vomiting. Patients may also experience hepatitis, tachycardia, heart failure, urinary frequency, hematuria, erectile dysfunction, or urinary incontinence or retention. Hematologic adverse effects are not common but include aplastic anemia, anemia, leukopenia, and thrombocytopenia.

Adverse effects of injected botulinum toxin type A are mostly related to the effects of the spread of the toxin, including dysphagia and breathing difficulties when treating cervical dystonia and bronchitis and upper respiratory tract infections in patients treated for spasticity. Patients being treated with intradetruser injections for bladder dysfunction experienced urinary tract infection (18%), urinary tract retention (6%), and residual urine volume (3%). Patients with diabetes who were treated with 100 units of intradetruser botulinum toxin type A injections had a 31% incidence of urinary tract infections. Patients being treated for chronic migraines reported neck pain (9%), eyelid ptosis (4%), muscular weakness (4%), and musculoskeletal stiffness (4%).

Drug Interactions

Administration of dantrolene and other CNS depressants will lead to additive sedation. Estrogen may increase risk of hepatotoxicity, so dantrolene should be used concomitantly with caution. Combining IV dantrolene and verapamil has led to ventricular fibrillation and cardiovascular collapse in anesthetized pigs; therefore, the combination of dantrolene and calcium channel blockers is not recommended during the management of malignant hyperthermia.

Aminoglycosides and anticholinergic drugs may potentiate the effects of botulinum toxin type A. Muscle relaxants may lead to exaggerated weakness when given before or after administration of botulinum toxin type A. A second dose or type of botulinum toxin should not be administered until the effects of the first dose resolve because excessive neuromuscular weakness may occur.

Clinical Use and Dosing

Dantrolene is gradually titrated to optimum dose to decrease adverse effects. Adult patients are started on 25 mg daily for 7 days then increased to 25 mg 3 times a day for 7 days. If the patient tolerates that dose, it is increased to 50 mg 3 times a day for 7 days and can be increased to a maxiumum of 100 mg 3 to 4 times daily if necessary. The maximum dose is 100 mg 4 times a day. In children over age 5, the patient is started on 0.5 mg/kg dantrolene daily for 7 days, then increased to 0.5 mg/kg 3 times a day for 7 days. If the patient is tolerating the dose, the dantrolene is increased to 1 mg/kg 3 times a day. The patient may take 2 mg/kg 3 or 4 times a day, with a maximum dose of 100 mg 4 times a day.

The dantrolene dose for malignant hyperthermia is 4 to 8 mg/kg/day (divided in three or four doses) for 1 or 2 days prior to surgery. The dose of dantrolene after a malignant hyperthermia crisis is 4 to 8 mg/kg/day (divided in three to four doses) for 1 to 3 days to prevent recurrence.

Botulinum toxin type A (Botox) injections require providers skilled in proper technique to prevent accidental paralysis. The use of Botox is reserved for specialty practice and is outside the scope of this text.

Rational Drug Selection

Dantrolene and botulinum toxin type A are unique drugs with specific, unique uses and are the only drugs for their respective uses.

Monitoring

Patients who are taking dantrolene should be monitored for effectivess of the medication as seen by decreasesd spasticity and for adverse effects, including excessive drowsiness, dizziness, and fatigue. Diarrhea may occur and requires dantrolene be stopped and restarted once symptoms resolve.

Patients who have received botulinum toxin type A injections should be monitored for the effects of toxin spread and hypersensitivity.

Patient Education

The titration schedule for dantrolene needs to be explained to patients carefully and written down. They should be advised of the adverse effects and to not drive or participate in hazardous activities. Patients should avoid CNS sedating drugs and alcohol.

Patients being injected with botulinum toxin type A (Botox) should be educated on the expected effects of the medication and the adverse effects. Patients should be warned of life-threatening adverse effects, including respiratory paralysis and problems swallowing. The effects of botulinum toxin type A may last for several months and may occur hours or weeks after injection.

OPIOID ANALGESICS AND THEIR ANTAGONISTS

When nonopioid agents are ineffective for pain relief, opioids are a next logical step in the treatment of pain. These agents alter the perception of and response to painful stimuli. This group of drugs includes natural opium alkaloids, synthetic agents, and a combination of the two. Most of these drugs are Schedule II narcotics under federal law. And although many states allow prescription of these agents by nurse practitioners, state laws may vary.

Opioids are generally classified as agonists, mixed agonist-antagonists, or partial agonists. Agonists include codeine (Tylenol #3 or #4), fentanyl (Sublimaze, Duragesic), hydrocodone (Vicodin, Lortab), hydromorphone (Dilaudid), levorphanol (Levo-Dromoran), meperidine (Demerol), methadone (Dolophine), morphine (MSIR, Roxanol, MS Contin, Oramorph, Kadian), oxycodone (Percocet, Percodan, Roxicodone, OxyContin), and propoxyphene (Darvon, Darvocet). Propoxyphene (Darvon, Darvocet) was removed from the U.S. and European markets in 2010 owing to its role in altering cardiac conduction, which can result in serious adverse effects including sudden cardiac death. Some of these agents, such as hydrocodone and codeine, are typically combined with acetaminophen or an NSAID. Opiate antagonists include naloxone HCL (Narcan), naltrexone HCL (Revia), and nalmefene HCL (Revex).

Mixed agonist-antagonists include butorphanol (Stadol), nalbuphine (Nubain), and pentazocine (Talwin). Partial agonists include buprenorphine (Buprenex) and dezocine (Dalgan). Suboxone is a combination of a partial opioid agonist, buprenorphine and an antagonist, naloxone.

Pharmacodynamics

Narcotic analgesics are active at various opioid receptor sites and act as agonists, partial agonists, or mixed agonist-antagonists of endogenously occurring opioid peptides (eukephalins, endorphins). Opioids interact with mu, kappa, delta, or sigma receptors, producing both the desired and adverse effects of opioids. The primary receptors associated with analgesia are the mu and kappa receptors. Activation of these receptors is thought to create an analgesic effect by inhibiting adenyl cyclase activity, which results in a reduction in intracellular cyclic adenosine monophosphate. In addition to an analgesic effect, activation of mu receptors may cause euphoria, physical dependence, and respiratory depression. Activation

of kappa receptors may cause miosis, sedation, and respiratory depression. Activation of delta and sigma receptors accounts for many of the adverse effects of opioids, such as dysphoria, hallucinations, and respiratory and vasomotor stimulation. Mixed agonist-antagonists can cause withdrawal symptoms when given to narcotic-dependent individuals because of their preference at specific opioid receptor sites.

Narcotic antagonists block or reverse opioids by competing at their receptor sites and reverse respiratory depression, hypotension, and sedation. Indications for use are narcotic overdose and prolonged surgical use of narcotics.

Pharmacokinetics

Absorption and Distribution

Opioid analgesics may be administered via oral, parenteral, rectal, sublingual, and transdermal routes. The rate of absorption depends on the route used. Oral drugs are convenient and have a slower onset of action, delayed peak time, and a longer duration of action than drugs administered parenterally. Overall, the onset of action of opioid analgesics is rapid and varies from 2 or 3 minutes up to 60 minutes, depending on the route of administration. Half-life is generally up to 6 hours, although some are longer, for example, levorphanol with a half-life of 12 to 16 hours and methadone with a half-life

of 15 to 30 hours. Meperidine has an active metabolite, normeperidine, with a half-life of 15 to 30 hours.

The opioid antagonists nalmefene HCL, naloxone HCL, and naltrexone HCL are indicated for acute crises and are given parenterally. Their onset of action is within 2 to 15 minutes, with duration of action of 1 to 4 hours. Because their half-lives can be shorter than the narcotic they are reversing, patients must be closely monitored for symptoms of a recurrence of respiratory depression.

Metabolism and Excretion

Opioid analgesics and antagonists are metabolized in the liver and excreted in urine. Codeine is metabolized into morphine, which is metabolized and excreted in the urine. Table 15-36 presents the pharmacokinetics.

Pharmacotherapeutics

Precautions and Contraindications

Because of the respiratory depressant effect of these drugs, compromised pulmonary function is a contraindication. Cautious use is indicated in the case of head injury, increased intracranial pressure, and acute abdominal conditions because of the drugs' capacity to mask symptoms of pain and to increase cerebrospinal fluid pressure.

Table 15–36 ⚕ **Pharmacokinetics: Opioid Analgesics and Antagonists**

Drug	Onset	Peak	Duration	Half-Life	Excretion
Alfentanil	Immediate	—	—	1–2 h	Urine
Codeine	10–30 min	0.5–1 h	4–6 h	3 h	Urine
Fentanyl IM transdermal	7–15 min; 6 h	20–30 min; 12–24 h	1–2 h; 72 h	1.5–6 h	Urine
Hydromorphone	15–30 min	0.5–1 h	4–5 h	2–3 h	Urine
Levorphanol	30–90 min	0.5–1 h	6–8 h	1–16 h	Urine
Meperidine	10–45 min	0.5–1 h	2–4 h	3–4 h	Urine
Methadone	30–60 min	0.5–1 h	4–6 h	15–30 h	Urine
Morphine	15–60 min	0.5–1 h	3–7 h	1.5–2 h	Urine
Oxycodone	15–30 min	1 h	4–6 h	—	Urine
Oxymorphone	5–10 min	0.5–1 h	3–6 h	—	Urine
Propoxyphene	30–60 min	2–2.5 h	4–6 h	6–12 h	Urine
Sufentanil	1.3–3 min	—	—	2.5 h	Urine
Nalmefene	5–15 min	1.5–2.3 h	—	1–10.8 h	Urine
Naloxone	2 min	—	1–4 h	30–81 min	Urine
Naltrexone	Rapid	Within 1 h	—	4–13 h	Urine
Buprenorphine	15 min	60 min	6 h	2.2–3.5 h	Urine
Butorphanol	<10 min	30–60 min	3–4 h	2.5–4 h	Urine
Dezocine	<15–30 min	30–150 min	2–4 h	2.4 h	Urine
Nalbuphine	15–30 min	30–60 min	3–6 h	5 h	Urine
Pentazocine	15–30 min	15–60 min	3 h	2.2–3.5 h	Urine

Safety of use in pregnant and nursing women is not established, and they are classified as Pregnancy Category C. Infants born to addicted mothers suffer sedation, respiratory depression, and withdrawal. Oxycodone, methadone, oxymorphone, and hydromorphone should not be used in children.

Narcotic analgesics carry the risk of physical tolerance and dependence, as well as having street value. Thus, the prescribing clinician needs to obtain a clear history of current substance use because of the dangers of cross-tolerance and additive CNS depression. These agents have been implicated in suicide or accidental death, particularly in combination with alcohol. As indicated previously, mixed agonist-antagonists should not be prescribed for narcotic-addicted individuals because of the risk of physical withdrawal. Patients wishing treatment of narcotic addiction with methadone should be referred to an appropriate treatment facility.

Careful titration of opioid antagonists is required, because the blockade of opioids by antagonistic action means that the individual may experience withdrawal symptoms, called *acute abstinence syndrome*, at about the time the next narcotic dose would be due. Achieving a balance between reversing CNS depression and preventing acute withdrawal is delicate and requires careful titration in small increments. This situation applies equally to the drug-affected neonate. In addition to these concerns, attention is also needed in post-operative situations in which the antagonist's action may leave the patient in severe, acute pain.

The FDA issued a Safety Alert regarding the use of codeine in children, particularly after tonsillectomy and/or adenoidectomy because of reports of respiratory depression. Codeine is metabolized in the liver to morphine via CYP 2D6 and ultrametabolizers may be at risk of toxicity. Lactating women who are ultrametabolizers and take codeine may have increased levels of morphine in the breast milk.

Adverse Drug Reactions

Adverse reactions to opioids include respiratory depression, hypotension, confusion, sedation, nausea, vomiting, dizziness, visual disturbances, hallucinations, euphoria, lethargy, uncoordinated movements, constipation, agitation, depression of cough reflexes, and paresthesias. Most patients experience constipation when taking an opioid agonist.

Adverse reactions to antagonists include nausea, vomiting, tachycardia, hypertension, fever, and dizziness. Naltrexone is particularly hepatotoxic and can be injurious to the liver when used in high doses. Individuals with impaired liver function should be assessed carefully for signs of further damage.

Drug Interactions

Some interacting drugs, such as alcohol, sedative-hypnotics, barbiturates, antihistamines, and antipsychotics, can create additive CNS-depressant effects. Others, such as cimetidine, hydantoins, nicotine, and droperidol, can interfere with narcotic effects. Other drug interactions, for example, with carbamazepine and warfarin, may decrease the effect of the interacting drug. Use with extreme caution with MAOIs because severe, even fatal, reactions may occur. Table 15-37 presents drug interactions.

Clinical Use and Dosing

Table 15-38 presents the indications and dosage schedules of opioid analgesics and antagonists.

Rational Drug Selection

Indications for the use of opioid analgesics are the control of pain, primarily acute pain as in the case of post-operative situations, cancer, and obstetric pain. Opioid analgesics are also used in the treatment of chronic pain, which is not alleviated with nonopioid agents. In selecting among available agents, the degree and duration of pain must be considered as well as the patient variables of subjective therapeutic response to an agent and adverse effects experienced. Morphine is the standard against which other opioids are measured and is considered the drug of choice for cancer pain.

For the treatment of mild to moderate pain not alleviated by nonopioids, treatment can start with a lower-potency opioid, such as codeine, often given in combination with acetaminophen. If pain is not alleviated by codeine, the derivatives of codeine, oxycodone and hydrocodone, are approximately 8 times more potent. These drugs are available in combination with aspirin and acetaminophen, which limit the overall dose of the opioid that can be given. Caution should be taken to instruct patients regarding proper dosing to avoid acetaminophen toxicity.

For patients with moderate to severe pain who have not been treated with opioids, treatment can begin with a short half-life agonist (morphine, hydromorphone, oxycodone).

Table 15–37 Drug Interactions: Opioid Analgesics and Antagonists

Drug	Interacting Drug	Possible Effect	Implications
Opioids	CNS depressants, alcohol, hypnotics, barbiturates, benzodiazepines, antipsychotics	Additive CNS depression	
	Cimetidine, hydantoins, rifampin, droperidol, charcoal, nicotine	Decreased effect of opioid	Increased doses of opioid may be required
	Carbamazepine, warfarin, MAOIs, furazolidone, nitrous oxide	Decreased effect of interacting drug	Monitor blood levels when possible
Nalmefene	Flumazenil	Seizures	Use with caution
Naltrexone	Thioridazine	Decreased effect of thioridazine	Higher dose may be required

Table 15–38 ⊗ **Dosage Schedule: Opioid Analgesics and Antagonists**

Drug	Indications	Dosage	Available Dosage Forms
Alfentanil HCl (Alfenta)	Anesthetic adjunct only	—	Injection: 500 mcg/mL
Codeine	Mild to moderate pain; coughing	*Adults:* PO, IM, IV, SC: 15–60 mg every 4 h to maximum of 360 mg/24 h; usual dose is 30 mg *Children >1 yr:* PO, IM, SC: 0.5 mg/kg every 4–6 h	*Tablet:* 15, 30, 60 mg *Acetaminophen and No. 3 codeine tablet:* 300 mg acetaminophen and 30 mg codeine *Acetaminophen and codeine solution:* Acetaminophen 120 mg and codeine 12 mg per 5 mL *Aspirin and codeine:* Aspirin 325 mg/codeine 30 mg, aspirin 325 mg/codeine 60 mg
Fentanyl (Sublimaze, Duragesic, Oralet)	Anesthesia; post-operative analgesia; management of chronic pain	*Adults:* Post-operative analgesia: 0.05–0.1 mg IM every 1–2 h Transdermal: 25, 50, 75, 100, 125, 150, 175, 200, 225, 250, 275, and 300 mcg/h system; change once every 72 h Titrate dose upward first time only in 3 d thereafter at 6 d intervals	*Injection:* 0.05 mg/mL *Film for buccal application:* 200, 400, 800, 1,200 mcg *Patch:* 12, 25, 50, 75, 100 mcg/h *Tablet, sublingual:* 100, 200, 300, 400, 800 mcg
Hydromorphone HCl (Dilaudid)	Moderate to severe pain	*Adults:* PO: 2–4 mg every 4–6 h Parenteral: 1–4 mg every 4–6 h; slow IV over 1–5 min Rectal: 3 mg every 6–8 h	*Liquid:* 1 mg/mL *Tablet:* 2, 4, 8 mg *Injection:* 10 mg/mL
Levorphanol tartrate (Levo-Dromoran)	Management of opioid dependence	*Adults:* PO, SC: 2–3 mg	*Tablets:* 2 mg
Meperidine (Demerol)	Moderate to severe pain; pre-operative sedation	*Adults:* PO, IM, SC: 50–150 mg every 3–4 h *Children:* PO, IM, SC: 1–1.8 mg/kg (0.5–0.8 mg/lb) every 3–4 h	*Tablets:* 50, 100 mg *Oral solution:* 50 mg/5mL *Injection:* 25 mg/mL
Methadone (Dolophine)	Severe pain; management of opioid dependence	*Adults:* PO, IM, SC: 2.5–10 mg every 3–4 h; oral dose is half of parenteral	*Oral concentrate:* 10 mg/mL *Oral solution:* 5 mg/5 mL *Tablet:* 5 mg, 10 mg
Morphine sulfate (Astramorph PF, Duramorph, Infumorph, MSIR, MS Contin, Oramorph SR, Roxanol, OMS concentrate, MS/L, RMS)	Moderate to severe acute and chronic pain; preanesthetic sedation	*Adults:* PO: 10–30 mg every 4 h Controlled-release: 30 mg every 8 h; do not crush or chew SC/IM: 5–20 mg/70 kg every 4 h IV: 2.5–15 mg/70 kg in 4–5 mL water for injection over 4–5 min Continuous IV pump infusion: 0.1–1 mg/mL in 5% dextrose Rectal: 10–20 mg every 4 h *Children:* SC, IM: 0.1–0.2 mg/kg to maximum of 15 mg every 4 h	*Capsule:* 30, 45, 60, 75, 90, 120 mg *Oral solution:* 1 mg/mL *Tablet:* 15, 30 mg *Extended-release tablet:* 15, 30, 60, 100, 200 mg *Injection:* 0.5 mg/mL
Oxycodone (Roxicodone, OxyContin)	Moderate to moderately severe pain	*Adults:* 2.5 to 5 mg *Children:* 0.1-0.2 mg/kg/dose q 4–6 h prn	*Tablet:* 5, 7.5 mg *Oral solution:* 5 mg/5 mL
Oxymorphone (Numorphan)	Moderate to severe pain; preanesthetic sedation; relief of anxiety/dyspnea in pulmonary edema and left ventricular failure	*Adults:* SC, IM: 1–1.5 mg every 4–6 h IV: 0.5 mg Rectal: 5 mg every 4–6 h	*Injection:* 1 mg/mL
Buprenorphine (Buprenex, Subutex, Zubsolv) Buprenorphine/naloxone (Suboxone)	Moderate to severe pain Maintenance of opioid dependence	*Adults and children >13 yr:* IM, IV: 0.3 mg every 6 h; may repeat once 30–60 min later if needed; compatible with most IV solutions	*Tablet:* 2, 8, 12, 16 mg *Injection solution:* 0.3 mg/mL *Sublingual film:* Buprenorphine/naloxone 2 mg/0.5 mg, buprenorphine/naloxone 4 mg/1 mg, buprenorphine/naloxone 8 mg/ 2 mg, buprenorphine/naloxone 12 mg/3 mg *Sublingual tablet:* 2 mg/0.5 mg, 8 mg/2 mg

Table 15–38 ⊗ **Dosage Schedule: Opioid Analgesics and Antagonists—cont'd**

Drug	Indications	Available Dosage Forms	Dosage
Butorphanol tartrate (Stadol)	Pain; preanesthesia sedation	*Adults:* IM: 1–4 mg every 3–4 h to nonambulatory patients IV: 0.5–2 mg every 3–4 h Nasal: 1 mg = 1 spray in each nostril; may repeat if needed in 60–90 min; may repeat 2 dose sequences in 3–4 h	*Injection:* 1 mg/mL, 2 mg/mL
Nalbuphine (Nubain)	Moderate to severe pain; preoperative sedation	*Adults:* SC, IM, IV: 10 mg/70 kg every 3–6 h to maximum of 20 mg/dose or 160 mg/24 h	*Injection:* 10, 20 mg/mL
Pentazocine (Talwin, Talwin NX)	Moderate to severe pain; pre-operative sedation	*Adults:* PO: 50–100 mg every 3–4 h to maximum of 600 mg/24 h; initial dose 50 mg IM, SC, IV: 30 mg every 3–4 h to maximum of 360 mg/24 h	*Injection:* 30 mg/mL
Pentazocine combinations	Mild to moderate pain	*Adults:* 12.5 mg with 325 ASA (Talwin compound caplets): 2 tabs tid qid 25 mg with acetaminophen 650 mg (Talacen caplets): 1 tab every 4 h to maximum of 6 tabs/24 h	
Nalmefene	Reversal of opioid effects	Opioid-dependent patients: Initial challenge dose of 0.1 mg/70 kg. If no signs or symptoms of withdrawal within 2 min, use following guidelines: Non–opioid-dependent patients: Initial dose of 0.25 mg/kg followed by 0.25 mcg/kg doses at 2–5 min intervals until degree of opioid reversal is attained Give IV; if no IV access is available, give 1 mg SC or IM as single dose	Injection: 100 mcg/mL, 1 mg/mL
Naloxone (Narcan)	Reversal of opioid depression	*Adults:* IV, IM, SC For overdose: 0.4–2 mg IV; may repeat at 2–3 min intervals Post-operative: 0.1–0.2 mg IV at 2–3 min intervals; may repeat in 1–2 h intervals if needed *Children:* For overdose: 0.01 mg/kg IV; may follow with 0.1 mg if needed; if no IV access, give IM or SC in divided doses Post-operative: Initial dose of 0.005–0.01 mg IV repeated at 2–3 min increments if needed	*Injection:* 0.02, 0.4, 1 mg/mL
Naltrexone (ReVia)	Blocks effects of opioids; treatment of alcohol dependence	Alcoholism: 100 mg PO once daily Opioid dependence: do not give until patient has been abstinent for 10 d, then give challenge dose of 25 mg once; if no withdrawal signs and symptoms occur, continue with maintenance dose; if signs and symptoms occur, repeat challenge in 24 h Maintenance: 50 mg every 24 h; dosing may be flexible (e.g., 100 mg on Mon an Wed; 150 mg on Fri)	Tablets: 50 mg

These drugs are easier to titrate than those with a longer half-life, such as methadone or levorphanol. Morphine is the drug of choice for severe pain. Sustained-release preparations such as MS Contin and Oramorph SR provide pain relief for 8 to 12 hours. Morphine has the advantage of a wide range and flexibility of dosing.

Chronic stable pain may be managed with sustained-release morphine, oxycodone, methadone, or transdermal fentanyl. Methadone has the advantage of low cost and oral efficacy, but it can cause excessive sedation. Methadone has the ability to antagonize NMDA (N-methyl-D-aspartate) receptors and is particularly useful in the treatment of chronic and neuropathic pain. Fentanyl is a potent opioid, available as a transdermal patch that provides up to 3 days of continuous analgesia. Fentanyl must be titrated carefully, however, to avoid oversedation. Meperidine is not recommended for chronic pain because it has a short half-life and has a toxic metabolite, normeperidine, that causes CNS excitability as manifested by dysphoria, tremors, seizures, and irritability.

Partial agonists and mixed agonist-antagonists are limited by a dose-related ceiling effect, but they are effective in treating moderate to severe pain. These agents are useful for patients who are intolerant of morphine or meperidine. Mixed agonist-antagonists are contraindicated in patients receiving full agonist opioids because they reverse some of the pain control provided by the full agonist. These agents may cause less respiratory depression than morphine, however, which is a consideration for patients with compromised pulmonary function.

In addition to pain relief, some of these opioids may be utilized for other purposes, such as antitussive or antidiarrheal effects. For example, camphorated tincture of opium (paregoric) is used in the treatment of diarrhea. Codeine possesses both antitussive and antidiarrheal properties.

Further discussion of pain management is found in Chapter 52.

Monitoring

It is important to monitor for adverse reactions, as discussed previously. It is also important to monitor for opioid withdrawal. Symptoms of opioid withdrawal resemble a flu-like syndrome manifested by muscle cramps, dilated pupils, lacrimation, rhinorrhea, yawning, sneezing, anxiety, anorexia, nausea, vomiting, diarrhea, and gooseflesh.

Patient Education

Patients should be warned about the potential for physical dependence and advised that these agents should primarily be used for relief of acute, severe pain. Long-term use for chronic pain can result in tolerance and hypersensitivity to pain. Patients should be instructed to avoid the concurrent use of alcohol and other CNS depressants. To prevent overdose patients should also avoid using acetaminophen with acetaminophen/opioid combinations. Opioid analgesics may cause drowsiness and, for safety reasons, should not be used when mental or physical alertness is required. Advise the patient to change position slowly to minimize postural hypotension. Because these agents may cause constipation, patients should be advised to increase daily intake of fluid and fiber. Opioids may be taken with food to prevent nausea. Because opioids are controlled substances, patients should be cautioned to prevent use or theft of these agents by unauthorized persons.

STIMULANTS

The FDA approved the use of stimulants in treating attention deficit-hyperactivity disorder (ADHD), narcolepsy, and weight reduction. In therapeutic ranges, these drugs improve alertness, mood, attention, wakefulness, vigilance, and psychomotor performance and have an anorexiant effect. The prototype stimulant drug is amphetamine, which was developed more than 100 years ago. It has been used to treat depression, obesity, narcolepsy, and respiratory depression and as an energizer during World War II. Because of these same foci, amphetamines are notorious street drugs of abuse.

The stimulants amphetamine, dextroamphetamine, methylphenidate, and, less commonly, methamphetamine (Desoxyn) are used in the treatment of ADHD and narcolepsy. Primarily, methylphenidate (Ritalin, Methylin, Metadate, Concerta, Focalin, Daytrana patch) and Adderall, a combination of dextroamphetamine (Dexedrine) and amphetamine salts, are used. In addition, atomoxetine (Strattera), a norepinephrine reuptake inhibitor, is available as an alternative to stimulants for ADHD. Other stimulants such as caffeine found in over-the-counter cold medicines are significant because of the additive stimulant effects they have in combination with other stimulants.

Pharmacodynamics

The CNS stimulants are sympathomimetic amines that act as dopamine agonists and indirectly release and prevent the reuptake of dopamine, serotonin, and norepinephrine in presynaptic nerve endings. This action stimulates the cerebral cortex, brainstem, and reticular activating system and appears to stimulate the reward center in the brain that consists of the nucleus accumbens, the amygdala, and the ventral tegmentum. The dopamine and norepinephrine (and to a lesser extent the serotonin) nerve fibers connect these regions of the brain to the prefrontal cortex to coordinate thinking, feeling, and responding to emotional stimuli. When receptors in the reward center are occupied, there is a sense of well-being; it is because of this response that these drugs have considerable potential for abuse.

Pharmacokinetics

Absorption and Distribution

Taken orally, these drugs are quickly and thoroughly absorbed, with a rapid onset of action. Depending on the formulation, peak plasma levels occur in fewer than 1 to 4 hours. Their half-lives are from 1 to 12 hours. Although biodistribution is unknown for methylphenidate, atomoxetine is highly protein bound.

Metabolism and Excretion

Dextroamphetamine and methylphenidate are metabolized in the liver by de-esterification without the influence of the P450

system, whereas atomoxetine is predominantly metabolized by 2D6 and 2C19. In addition, atomoxetine has an equally potent metabolite that circulates in a lower concentration. All three are excreted by the kidneys. Urine acidity affects the rate of excretion of amphetamine in that increased alkalinity increases its half-life, a fact that can be important in drug overdose. Table 15-39 presents the pharmacokinetics of these stimulants.

Pharmacotherapeutics

Precautions and Contraindications

Contraindications to use include arteriosclerotic and symptomatic heart disease, hypertension, hyperthyroidism hypersensitivity to sympathomimetic amines, glaucoma, motor tics, agitation, history of drug abuse, and during or within 14 days of use of an MAOI.

Stimulants are contraindicated for pregnant (Pregnancy Category C) and lactating women. Methylphenidate is found in high concentrations in breast milk. Stimulants may cause insomnia and should therefore be taken no closer than 6 hours before bedtime. Concerta should be used cautiously in patients with esophageal motility disorders, as there is an increased risk of obstruction.

Adverse Drug Reactions

Undesirable effects include insomnia, undesired weight loss, growth retardation in children, tachycardia, palpitations, restlessness, irritability, euphoria, headache, blurred vision, tremor, increased libido with impaired ability, hypertension, and arrhythmias. Some individuals may experience a paradoxical drowsiness.

Drug Interactions

Various undesirable drug interactions may occur, perhaps the most significant being the risk of hypertensive crisis if stimulants are taken within 14 days of an MAOI. Additive sympathomimetic effects occur if these agents are taken concurrently with other adrenergics, including vasoconstrictors and decongestants. Metabolism of warfarin, anticonvulsants, and tricyclic antidepressants may be decreased and their effects increased.

Due to the P450 involvement, atomoxetine has a different interaction profile than methylphenidate or dextroamphetamine. CY2D6 inhibitors (e.g., fluoxetine) will increase the plasma levels of atomoxetine, and pressor agents will contribute to increased effects on blood pressure. Atomoxetine needs to be used with caution with albuterol due to the potentiation of the cardiovascular effects of albuterol. Table 15-40 presents drug interactions.

Clinical Use and Dosing

Table 15-41 presents the indications, dosage schedules, and available dosage forms of stimulants.

Rational Drug Selection

With the exception of atomoxetine, stimulants are on the Drug Enforcement Agency's (DEA) Schedule II and can be

Table 15–39 Pharmacokinetics: Stimulants

Drug	Onset	Peak	Duration	Half-Life	Excretion
Dextroamphetamine	30 min	1–3 h	4–20 h	10–30 h	Urine
Methamphetamine HCl	30 min	1–3 h	3–6 h	4–5 h	Urine
Methylphenidate HCl	30–60 min	1.9–4.7 h	4–6 h	1–3 h	Urine
Atomoxetine	—	1–2 h		5–22 h	Urine

Table 15–40 Drug Interactions: Stimulants

Drug	Interacting Drug	Possible Effect	Implications
All stimulants	MAOIs	Increased risk of hypertensive crisis and stroke	Avoid
	CNS depressants, alkalinizing agents	Decreased effect of stimulant	Dosage may need adjustment
	Antidepressants	Increased effect of antidepressant, especially with TCAs; increased risk of cardiotoxicity in children	Avoid use of TCAs
	Guanethidine	Increased hypotensive effect	Warn patient about dizziness and syncope
	Hypoglycemic agents	Increased glucose lability and decreased control	Monitor blood glucose
	Acidifying agents	Decreased effect of stimulant	Dosage adjustment may be required
	Phenytoin	Increased plasma level of phenytoin	Monitor plasma level
Atomoxetine	Fluoxetine, paroxetine, and quinidine	Increased plasma level of atomoxetine	Increase dosage only after 4 wk

Table 15–41 ⊗ Dosage Schedule: Stimulants

Drug	Indications	Dosage	Available Dosage Forms
Dextroamphetamine (DextroStat, Dexedrine ER)	ADHD, narcolepsy, exogenous obesity	*Adults:* 10 mg daily; may increase by 10 mg increments every week to maximum of 30 mg/d; give individual doses at 4–6 h intervals *Children age 3–5:* 2.5 mg/d; increase by 2.5 mg daily at weekly intervals to range of 0.1–0.5 mg/kg/d; give in morning *Children >5 yr:* 5 mg 1–2 times/d; may increase in 5 mg increments weekly to maximum of 40 mg/d; usual range 0.1–0.5 mg/kg/d *Extended-release: Adult and child 6 and older:* 5 mg qam, increase by 5 mg/d qwk Max 40 mg/d	Tablets: 5, 10 mg Sustained-release spansules: 5, 10, 15 mg
Methamphetamine HCl (generic)	ADHD, narcolepsy, exogenous obesity	*Adults and children >12 yr:* 5 mg 1–2 times/d; may increase at 5 mg increments weekly to maximum of 25 mg/d, may be twice-daily dosing	5, 10, 20 mg tab
Amphetamine and dextroamphetamine (Adderall, Adderall XR)	ADHD Narcolepsy XR for ADHD only	*Age 3–5:* 2.5 mg qd, increase by 2.5 mg/wk *Age 6 and up:* 5 mg qd or bid, then increase by 5 mg q wk. Not to exceed 40 mg *Narcolepsy: Children 6–12 yr:* 5 mg daily up to 60 mg/d max *Sustained-release for age 6 and up only:* 6–12, 10–30 mg qd *Age 12–18:* 10–20 mg qd *Adults:* 20 mg qd	Adderall: 5, 7.5, 10, 12.5, 15, 20, 30 mg tabs Adderall XR: 5, 10, 15, 20, 25, 30 mg caps
Lisdexamfetamine (Vyvanse)	ADHD	*Age 6 and up:* 30 mg qam, increase by 10–20 mg/d every 7 days. Not to exceed 70 mg total qd for any patient May dissolve contents in water, drink immediately, do not subdivide caps	20, 30, 40, 50, 60, 70 mg caps
Methylphenidate HCl (Ritalin, Ritalin SR, Ritalin LA, Methylin, Methylin ER, Daytrana patch)	ADHD, narcolepsy (Ritalin and Ritalin SR)	*Ritalin and Methylin: Adults:* 10–30 mg/d in 2–3 divided doses; maximum 60 mg/d in divided doses. *Children >6 yr:* 5 mg bid before breakfast and lunch, with increase of 5–10 mg at weekly intervals; maximum 60 mg/d in divided doses. Stop drug if no improvement in 4 wk. *All ages:* Ritalin SR tabs taken in morning may be supplemented with afternoon regular tablets, if needed, no later than 6 p.m. *Ritalin LA: age 6 and up:* Whole or sprinkled in applesauce, 20 mg qam, increase by 10 mg weekly to max 60 mg/d *Methylin ER:* *Child age 6 and up:* 10 mg qam, increase weekly by 10 mg/d to max 60 mg in divided doses. *Adults:* 10–20 mg qam, increase by 10 mg weekly to max of 60 mg in divided doses. *Daytrana patch: 6–12 yr:* 10 mg patch to hips 2 h before desired effect. Remove 9 h after application, earlier if shorter duration needed. Titrate dose q week. Rotate application site.	Ritalin tablets: 5, 10, 20 mg Methylin tabs: 5, 10, 20 mg Methylin chews: 2.5, 5, 10 mg Methylin oral solution: 5 mg/ 5ml, 10 mg/5 ml. Ritalin SR Sustained-release tablets: 20 mg Ritalin LA: Extended-release caps:10, 20, 30, 40 mg (half immediate-release, half extended-release beads) Methylin ER: 10, 20 mg tabs Daytrana patch: 10, 15, 20, 30 mg delivered over 9 h
Methylphenidate (Concerta)	ADHD	*Age 6-12:* Start at 18 mg qd, max 54 mg/d *Age 13–17:* Start at 18 mg/d, max 72 mg/d *Adults:* 18–36 mg/d, max 72 mg/d For patients already on methylphenidate: 5 mg bid/tid = 18 mg 10 mg bid/tid = 36 mg 15 mg bid/tid = 54 mg 20 mg bid/tid = 72 mg/d	18, 27, 36, 54 mg extended-release

Table 15–41 ⊗ **Dosage Schedule: Stimulants—cont'd**

Drug	Indications	Dosage	Available Dosage Forms
Metadate ER	ADHD, Narcolepsy	*Metadate ER: Age 6 and up:* swallow whole, 10 mg qam, increase by 10 mg q week. Max 60 mg/d in divided doses.	Metadate ER:10, 20 mg tabs
Metadate CD	ADHD	*Metadate CD: Age 6 and up:* swallow whole or sprinkle on applesauce: 20 mg before breakfast, increase weekly by 10–20 mg/d. Max 60 mg once daily.	Metadate CD: 10, 20, 30, 40, 50, 60 mg caps (immediate-release and extended-release beads)
Dexmethylphenidate (Focalin, Focalin XR)	ADHD	*Age 6 and up:* 2.5 mg bid, increase by 2.5 mg at weekly intervals. Max 20 mg/d. *Extended-release:* Once daily in a.m. Swallow whole or sprinkle onto applesauce. *Age 6 and up:* 5 mg/d, may increase by 5 mg/wk. *Adults:* Start at 10 mg/d, increase by 10 mg weekly. Max dose for adults and children 20 mg/d.	2.5, 5, 10 mg tablets XR: 5, 10, 15, 20 mg caps. (contains immediate- and extended-delayed release beads)
Atomoxetine (Strattera)	Drug-resistant depression	*PO Adults and Children >70 kg:* Start w/40 mg/d and increase dose every 3 days to target 80 mg. After 2–4 wk dose may be increased to 100 mg/d.	Capsules: 10, 18, 20, 25, 40, 60, 80, 100 mg
Modafinil (Provigil)	ADHD Narcolepsy, and excessive sleepiness due to sleep apnea and shift work	*Age 16 and up:* 200 mg qd in a.m. Max 400 mg/d in divided doses. For shift work, take dose 1 h before work.	100, 200 mg tabs

ER, XR = extended release,
CD = continuous release, SR = sustained release.

prescribed only by nurse practitioners whose state permits Schedule II prescribing. Because they are Schedule II drugs, the pharmacy requires a new hard copy of the prescription every month. Stimulants can be prescribed only without refills, although states may have a mechanism for providing more than 1 month's prescription at a time. Providers should check with the state's regulatory authorities.

To prevent anorexia and slowed growth in children, providers should maintain records of growth and weight and consider drug holidays to permit the child to catch up on growth. Some children may exhibit symptoms of ADHD as the drug begins to wear off and may do better on a sustained-release formulation, especially if they must complete homework in the afternoon or early evening. If symptom coverage with extended release is not adequate, a short-acting formulation after school may be needed.

CNS stimulants are indicated for the treatment of ADHD, narcolepsy, and exogenous obesity refractive to other forms of treatment. The use of stimulants in the treatment of adolescent and residual adult ADHD is a matter of some controversy, given the street value of these drugs, the increase in societal abuse of these drugs, and the association of these agents with violent behavior. Because atomoxetine seems to stimulate the reward center less than do other agents and has a delayed onset of action, it is less useful as a drug of abuse but may also be less effective therapeutically. These agents should be given cautiously to emotionally unstable patients, including those with a history of drug or alcohol abuse,

because such patients may be more likely to increase their doses unnecessarily.

Monitoring

It is important to monitor for adverse reactions, as discussed previously. The clinician should monitor that the amount of drug used is consistent with the amounts prescribed and dispensed.

Patient Education

Stimulant agents may cause insomnia, so patients should not take them within 6 hours of bedtime. Abrupt cessation of stimulants may cause extreme fatigue and mental depression. These agents may cause dizziness or blurred vision, so caution patients to avoid driving or other hazardous activities until their response to the medication is known. To reduce anorexia and growth retardation in children, these agents should be given with or after meals. Parents should notify the school nurse of the medication regimen and need to be aware that these drugs have street value and should be stored safely in the home. Children and teens require an explanation of why these drugs are appropriate for their disorder as distinct from drugs of abuse and assistance in handling peers' responses to their use of these medications.

DRUGS AFFECTING THE CARDIOVASCULAR AND RENAL SYSTEMS

Marylou V. Robinson

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS, ANGIOTENSIN II RECEPTOR BLOCKERS, AND DIRECT RENIN INHIBITORS

Angiotensin-converting enzyme inhibitors (ACEIs), angiotensin II receptor blockers (ARBs), and direct renin inhibitors (DRI) have multiple uses related to the cardiovascular system. Their action on the renin-angiotensin-aldosterone (RAA) system lowers blood pressure (BP) and reduces the adverse affects of diabetes on the kidney. The DRIs are related but act uniquely by direct blocking of renin itself, not on its genesis or on the angiotensin components of the RAA. ACEIs improve oxygenation to heart muscle and decrease inappropriate remodeling of heart muscle after myocardial infarction (MI) or with heart failure (HF). Their mild and usually transient adverse effects and their ease of dosing make them

popular drugs. ARBs have similar roles and profiles in hypertension (HTN). The DRIs and most ARBs do not have HF indications except candesartan and valsartan.

Pharmacodynamics

As shown in Figure 16-1, inhibition of ACE activity (ACEIs) results in decreased production of both angiotensin II (AT II) and aldosterone. AT II has multiple roles in the cardiovascular system. It increases vasomotor tone by direct stimulation of vascular smooth muscle contraction and through the inhibition of endothelial nitric oxide and prostaglandin release, raising BP and decreasing blood flow through arteries, including the coronary arteries. AT II increases intravascular volume through its stimulation of sodium and water retention (with aldosterone), shifting of the pressure-natriuresis relationship, and altering glomerular hemodynamics. It is also produced in response to tissue injury. This latter action results in stimulation of smooth muscle cell and fibroblast proliferation with thickening of the vessel wall (remodeling). This action, combined with its inhibition of the endothelium's ability to resist monocyte and platelet adhesion, promotes intravascular inflammation and clotting and contributes to the atherosclerotic process. Finally, in the heart, AT II also causes remodeling, resulting in hypertrophy and fibrosis of myocardial tissue after ischemic injury or in response to persistent afterload. This is a primary mechanism in HF.

ACE also has a role in the kinin-kallikrein-bradykinin system. Bradykinin in low doses causes dilation of vessels and acts with prostaglandin to produce pain and cause extravascular smooth muscle contraction, increased vascular permeability, and increased leukocyte chemotaxis. Bradykinin has a primary role in inflammation. ACE facilitates the breakdown of bradykinin into inactive fragments, thus reducing these actions. High levels of bradykinin are thought to be a factor in the cough associated with ACEI use.

ARBs do not affect ACE activity but rather act by blocking the AT II receptor. They have similar action to ACEIs on vasoconstriction and aldosterone secretion, but no activity related to bradykinin. ACEIs and ARBs do not affect cardiac output and so do not produce reflex tachycardia. DRIs directly impact renin levels with subsequent AT I and AT II reductions. The suppression of AT II levels actually triggers a feedback mechanism that increases renin production. The drug effect is more than adequate to offset this rise.

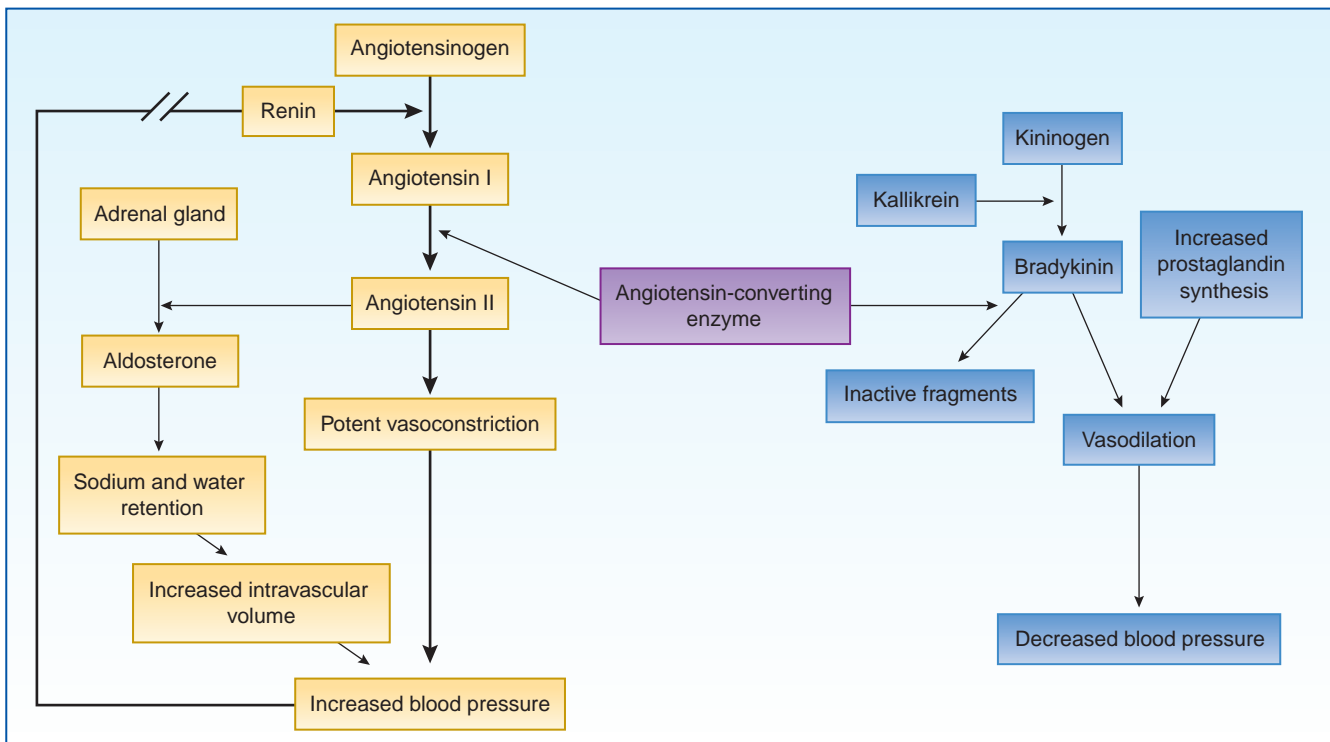
ACEI are reno-protective for individuals with proteinuria but is not as protective in renal patients without proteinuria (Kent et al., 2007). The effectiveness of ACEIs in preventing diabetic nephropathy probably results from decreased glomerular efferent arteriolar resistance and a reduction in intraglomerular capillary pressure, which causes improved renal hemodynamics, diminished proteinuria, retarded glomerular hypertrophy, and a slower rate of decline in glomerular filtration rate (GFR). These drugs do not affect glucose metabolism or raise serum lipid levels, but they do


Figure 16–1. Renin-angiotensin-aldosterone system. Renin acts on angiotensinogen to create the inactive decapeptide angiotensin I. Angiotensin I is then converted, primarily in the lung, to angiotensin II, a potent vasoconstrictor, through the activity of angiotensin-converting enzyme (ACE). Angiotensin II stimulates aldosterone secretion, causing retention of sodium and water and loss of potassium by the kidney. ACE is also involved in the inactivation of bradykinin, a vasodilator. Together, these systems help to control blood pressure.

improve insulin sensitivity; all of these are important issues in type 2 diabetes mellitus. ARBs do not prevent diabetic nephropathy but do suppress the rate of progression (ADA, 2015). DRIs in diabetic (DM) patients who already have nephropathy do not preserve renal function (Parving et al, 2012). DRIs are not to be used in diabetic patients with renal function of less than 60 mL/min.

Pharmacokinetics

Absorption and Distribution

The ACEIs and ARBs are well absorbed orally, with some variation in bioavailability based on the presence of food in the gut (Table 16-1). Captopril (Capoten), the prototype drug for the ACEI class, is rapidly absorbed, with a bioavailability of about 70% when taken on an empty stomach. Bioavailability is decreased to 30% to 40% if taken with food. Losartan (Cozaar), the prototype drug for the ARB class, undergoes extensive first-pass metabolism, resulting in 33% bioavailability. It may be taken without regard to food. Distribution is to most body tissues except the central nervous system (CNS). ACEIs and ARBs cross the placenta and are found in breast milk. Alsikren, the only DRI at this time, is poorly absorbed, which is made worse by high-fat meals. Bioavailability is 55%. Its presence in breast milk is yet to be determined.

Metabolism and Excretion

Except for captopril and lisinopril (Zestril, Prinivil), all ACEIs are prodrugs converted to active metabolites by hydrolysis, primarily in the liver. Losartan has both an active drug and an active metabolite (5-carboxylic acid) hydrolyzed by the liver. Captopril is metabolized by the liver to inactive compounds. The kidney is the primary organ of excretion for all ACEIs except fosinopril (Monopril) and moexipril (Univasc), and impaired renal function can significantly prolong their half-lives. ARBs have significant excretion in feces. The percentage excreted in feces varies from 50% to more than 97%. Alsikren is not a prodrug and is mostly eliminated via the feces. Mild to moderate renal impairment does not require dose changes.

Captopril, with a half-life of less than 2 hours, is the only short-acting ACEI. It requires two or three doses daily with steady state achieved in 2 to 3 days. All other members of the class have 6 to12 hour half-lives and require more time to achieve steady state but can be given daily. Losartan has a 2 hour half-life, and its active metabolite has a 6 to 9 hour half-life. Dosing may be daily or in two divided doses. Steady state is achieved in 3 to 6 weeks. Alsikren has a 24 hour half-life with full therapeutic effect seen in 2 weeks.

Pharmacotherapeutics

Precautions and Contraindications

There are only three absolute contraindications to the use of these three drug classes: bilateral renal artery stenosis, angioedema, and pregnancy. In bilateral renal artery stenosis, increased vascular pressure and vasoconstriction appear to be required to sufficiently overcome the stenotic blood flow to perfuse the kidney. The vasodilating effect of these meds prevents the kidney from maintaining its perfusion, and ischemic renal failure may develop; therefore, ACEIs, ARBs, and DRIs should be used cautiously with patients who have impaired renal function, *especially older adults.* Hypovolemic or hyponatremic states also require cautious use of all three. Adequate hydration is required to maintain an appropriate GFR and must be adequate before starting these drugs to prevent renal dysfunction. Hyperkalemia contraindicates use because reduced aldosterone secretion may worsen this electrolyte imbalance. Hyperkalemia risk increases for patients with chronic heart failure (HF) because of the reduced blood flow to the kidneys. Patients should have their serum potassium level checked prior to initiating therapy and within one week to note trends.

Hepatic impairment also requires cautious use. For ACEIs, fosinopril metabolism is cut in half; the maximum concentration (C_{max}) is cut in half and the area under the curve (AUC) is increased 300% for moexipril; plasma concentrations are 50% higher for perindopril; and plasma concentrations are reduced for quinapril. For ARBs, losartan total plasma clearance is about 50% lower and bioavailability is twice as high; the AUC is increased 60% for olmesartan; the AUC is twice that for valsartan and increased 40% for eprosartan. DRIs are not significantly impacted by hepatic issues.

Because ACEIs, ARBs, and DRIs can cause fetal and neonatal morbidity and mortality, they are Pregnancy Category C in the first trimester of pregnancy and Pregnancy Category D in the second and third trimesters and during lactation. Safety and efficacy in children have been established for some drugs, as indicated in Table 16-2.

Adverse Drug Reactions

Angioedema occurs in approximately 0.2% of patients taking ACEIs and DRIs. It can be life-threatening. The physiological reason for this adverse response appears to be related to an increase in bradykinin level associated with inhibition of ACE. It is not known if DRIs interact with bradykinin, but they have caused angioedema. It usually occurs with the first dose or within the first month of therapy and is more common in the longer-acting ACEI agents. Because this is a class phenomenon, the ACEI or DRI must be discontinued, and no other drug in this class may be used. ARBs do not affect the bradykinin system and should not cause this adverse response; however, administration of an ARB in a patient who exhibited angioedema with an ACEI is to be done with close observation.

Adverse reactions for ACEIs, ARBs, and DRIs are usually transient, mild, and more common in longer-acting agents. Most common are those associated with hypotension (dizziness, headache, fatigue, orthostatic hypotension). Tachyphylaxis frequently occurs with continued therapy. Also common and often cited as the reason for discontinuance of ACEIs is a dry, hacking cough that usually occurs in the first week of therapy. This is a class phenomenon, but changing to a newer-generation ACEI has been associated with less cough.

Table 16–1 ⚕ Pharmacokinetics: Angiotensin-Converting-Enzyme Inhibitors Angiotensin II Receptor Blockers, and Direct Renin Inhibitors

Drug	Onset(h)	Peak (h)	Duration (h)	Protein Binding	Bioavailability (BA)	Effect of Food on Absorption	Active Metabolite	Half-Life (h)	Elimination
ACE Inhibitors									
Benazepril	1	2–4	24	95%	37%	Slows	Benazeprilat	NRF: 10–11 IRF: prolonged	20% in urine; 11%–12% in bile
Captopril	0.25	0.5–1.5	6–12	25%–30%	75%	Reduced by 30%–40%	—	NRF: <2 IRF: 3.5–32	>90% in urine

Direct Renin Inhibitor									
Aliskiren	UK	1–3	UK	UK	3%	Reduced by fat	UK	24	Feces

NRF = normal renal function; IRF = impaired renal function; nd = no data; UK = unknown.

Table 16–2 ⊗ Dosage Schedules: Angiotensin-Converting-Enzyme Inhibitors and Angiotensin II
Receptor Blockers and Direct Renin Inhibitors

Drug	Indication	Dose Form	Initial Dose	Maintenance Dose
ACEI				
Benazapril (Lotensin) (G)	HTN (not recommended for children <6 years of age)	Tablets: 5 mg (not Lotensin); 10, 20, 40 mg	10 mg daily (if not on a diuretic; 5 mg if on diuretic or older adult) 5 mg daily (for Ccr <30 mL/min) *Children:* 0.2 mg/kg once daily (up to 10 mg)	20–40 mg daily in a single or divided dose *Max Dose:* 80 mg/d 40 mg/d *Children:* 0.1–0.6 mg/kg (up to 40 mg)
Captopril (no brand name) (G)	HTN (adult)	Tablets: 12.5, 25, 50, 100 mg	25 mg 2 or 3 times daily (6.25–12.5 mg twice a day if older adult)	Increase to 50 mg twice daily to 3 times daily after 2 weeks if BP not controlled. If BP still not controlled, add 25 mg/d HCTZ. *Max Dose:* 450 mg/d (300 mg if older adult).
	Heart failure		6.25–12.5 mg 3 times daily (if previous or concurrent diuretic or older adult) 25 mg 3 times daily (adult)	Titrate every 2 wk Increase to 50 mg 3 times daily in 2 wk if no improvement *Max:* 450 mg/d
	Diabetic nephropathy		25 mg 3 times daily	25 mg 3 times daily *Max:* 450 mg/d
	LVD/post-MI		6.25 mg for one dose (3 d post-MI)	12.5 mg 3 times daily, then increase to 25 mg 3 times daily with a target of 50 mg 3 times daily over several weeks *Max:* 450 mg/d
	HTN in children		Infant: 0.15– 3 mg/kg/dose Child: 0.3– 0.5 mg/kg/dose Older child: 6.25– 12.5 mg/kg/dose every 12–25 hours Teen: 12.5–25 mg/dose	Infant: titrate to *Max:* 6 mg/kg/d in 1–4 divided doses Child: same *Max* as infant Older child: *Max* as infant Teen *Max:* 450 mg/day
Enalapril (Vasotec) (G)	HTN (may use for children 1 month–16 yr)	Tablets: 2.5, 5, 10, 20 mg	2.5–5 mg daily *Children:* 0.08 mg/kg (up to 5 mg) once daily	Increase at 4 d intervals to 10–40 mg/d as single or two divided doses. *Max:* 40 mg/d *Children:* 0.58 mg/kg (upto 40 mg)
			2.5 mg daily (if serum creatinine >1.6 mg/dL **or** on a diuretic)	Increase by 2.5 mg/d at 4 d intervals. *Max:* 40 mg/d
	Heart failure (unlabeled for children)		2.5 mg once or twice daily	Increase to 40 mg/d over wks
	LVD (no symptoms)		2.5 mg two doses daily	Increase over wk to 20 mg/d in divided doses

Table 16–2 ⊗ **Dosage Schedules: Angiotensin-Converting-Enzyme Inhibitors and Angiotensin II Receptor Blockers and Direct Renin Inhibitors—cont'd**

Drug	Indication	Dose Form	Initial Dose	Maintenance Dose
Fosinopril (Monopril) (G)	HTN *Children:* Not recommended for children <6 yr or <50 kg	Tablet: 10, 20, 40 mg	10 mg daily *Children:* 5–10 mg/d	20–40 mg/d Can divide dose if not adequate to control BP *Max:* 80 mg/d *Child Max:* 40 mg/d
	Heart failure		10 mg daily (5 mg with renal issues)	Increase over wk to 20–40 mg/d *Max:* 40 mg/d
Lisinopril (Prinivil or Zesteril) (G)	HTN *Peds:* Not recommended for children <6 yr	Tablets: 2.5 mg (not Prinivil); 5, 10, 20, 30 mg (not Prinivil); 40 mg (not Prinivil)	10 mg daily 5 mg daily (if Ccr ≥10 <30 mL/min **or** on diuretic) 2.5 mg daily (if Ccr <10 mL/min or older adult) *Children:* ≥6 yr old: 0.07 mg/kg/d (up to 5 mg)	20–40 mg/d to max of 80 mg/d *Max:* 40 mg/d *Max:* 40 mg/d *Max Children:* 0.61 mg/kg/d (up to 40 mg/d)
	Heart failure (decrease afterload)		2.5–5 mg daily	Titrate over 2 wk no more than 10 mg at a time up to 5–40 mg *Max:* 40 mg;
	24 h post-MI survival and/or post-MI LV dysfunction		5 mg at time of MI followed by 5 mg 24 h later, then 10 mg after 48 h	*Max:* 10 mg daily Continue for 6 wk
Moexipril (Univasc) (G)	HTN	Tablets: 7.5, 15 mg	7.5 mg prior to meal once daily or 3.5 mg if taking diuretics	7.5–30 mg/d in single or divided doses; 1 h prior to meal *Max:* 60 mg/d
			3.75 mg (if Ccr <40 mL/min)	7.5–15 mg/d *Max:* 15 mg/d
Perindopril (Aceon) (G)	HTN	Tablets: 2, 4, 8 mg	4 mg daily	4–8 mg in single or divided doses titrated weekly *Max:* 8 mg/d
Quinapril (Accupril) (G)	HTN	Tablets: 5, 10, 20, 40 mg	10–20 mg/d (5 mg if on diuretic)	20–80 mg/d Increase at 2 wk intervals based on peak and trough levels *Max:* 80 g/d
	Heart failure		5 mg once or twice daily	20–40 mg in divided doses. Increase at weekly intervals. *Max:* 40 mg/d
Ramipril (Altace) (G)	HTN	Tablets: 1.25, 2.5, 5, 10 mg	2.5–5mg daily	2.5–20 mg/d in single or divided doses *Max:* 20mg/d
			1.25 mg daily (if Ccr <40 mL/min)	1.25 mg in two doses daily *Max:* 5 mg/d
	LV dysfunction post-MI		2.5 mg twice daily 1.25 mg in two doses daily (if Ccr <40 mL/min)	Increase in 1 wk to 5 mg in two doses daily; *Max:* 10 mg/d 1.25 mg in two doses daily *Max:* 2.5 mg in two doses daily

Table 16–2 ⚭ **Dosage Schedules: Angiotensin-Converting-Enzyme Inhibitors and Angiotensin II Receptor Blockers and Direct Renin Inhibitors—cont'd**

Drug	Indication	Dose Form	Initial Dose	Maintenance Dose
	Reduce risk MI, stroke, and CV death		2.5 mg daily for 1 wk, then 5 mg for next 3 wk	Titrate to 10 mg (if on diuretic, reduce dose of diuretic)
Trandolapril (Mavik) (G)	HTN	Tablets: 1, 2, 4 mg	1 mg/d (2 mg/d in blacks) 0.5 mg/d (if Ccr <40 mL/min)	Increase dose at 1 wk intervals to 2–4 mg/d *Max:* 8 mg/d
	Heart failure, post-MI or LVD		1 mg/d	Increase dose at 1 wk intervals to 4 mg/d *Max:* 8 mg/d
Candesartan (Atacand) (B)	HTN	Tablets: 4, 8, 16, 32 mg	16 mg daily *Children: 1-6 yr:* 0.2 mg/kg/d in 1–2 divided doses *Children: 6-16 (<50 kg) yr:* 4–8 mg/kg in 1–2 divided doses; *>50 kg* 8–16mg/d in 1–2 divided doses	8–32 mg Increase dose at 2 wk intervals *Max:* 32 mg/d *Child range:* 0.05 mg– 0.4 mg/kg/d *Max:* 0.4 mg/kg/d *Child 6–16:* titrate in 2 wk to range 2–16 mg/day • *50 kg:* titrate in 2 wk to 4–32 mg/d • *Max:* 32 mg/d
	Heart failure NYHA II–IV		4 mg daily	Double dose at 2 wk intervals; target 32 mg daily
Eprosartan (Teveten) (B)	HTN	Tablets: 400 mg (B) 600 mg (G, B)	600 mg daily	400–800 mg. Increase dose at 2 wk intervals *Max:* 800 mg/d
Irbesartan (Avapro) (G)	HTN diabetic nephropathy in type II not taking insulin	Tablets: 75, 150, 300 mg	150 mg daily	300 mg/d in single dose *Max:* 300 mg/d
	HTN		150 mg daily *Children: 6– 12 yr:* 75 mg daily; over age 13 use adult dosing	As above *Children:* Titrated to *Max* of 150 mg
Losartan Cozaar) (G)	HTN *Children:* Not recommended for children <6 yr of age	Tablets: 25, 50, 100 mg	50 mg daily *Children:* 0.7 mg/kg (up to 50 mg) once daily	25–100 mg in single or divided doses *Max:* 100 mg/d *Max Children:* 1.4 mg/kg (up to 100 mg)
			25 mg/d (if volume depleted or diuretics)	Increase dose at 1 wk intervals
	Stroke risk reduction in HTN with LVD		50 mg/d	Add HCTZ 12.5 mg/d and increase dose at 1 wk intervals to *Max* of 100 mg/d
	Diabetic nephropathy		50 mg/d	Increase at 1 wk intervals to *Max* of 100 mg/d
Olmesartan (Benicar) (B)	HTN	Tablets: 5, 20, 40 mg	20 mg/d *Children: 6–16 yr:* 10 mg daily	20–40 mg/d. Increase dose at 2 wk intervals *Max:* 40 mg/d *Children:* Titrate after 2 wk *Max:* 20 mg/d
Telmisartan (Micardis) (B)	HTN	Tablets: 20, 40, 80 mg	40 mg/d (lower if volume depletion)	20–80 mg/d. Increase dose at 2 wk intervals *Max:* 80 mg/d

Table 16–2 ⊗ **Dosage Schedules: Angiotensin-Converting-Enzyme Inhibitors and Angiotensin II Receptor Blockers and Direct Renin Inhibitors—cont'd**

Drug	Indication	Dose Form	Initial Dose	Maintenance Dose
	CV risk reduction	Tablets: 20, 40, 80 mg	80 mg daily	80 mg daily
Valsartan (Diovan) (B)	HTN *Children:* Not recommended for children <6 yr of age	Tablets: 40, 80, 160, 320 mg	80 mg/d *Children:* 1.3 mg/kg (up to 40 mg) once daily	80–160 mg/d. Increase dose at 2 wk intervals. *Max* 320 mg/d. Adding diuretic has greater effect than doses above 80 mg/d. *Max Children:* 2.7 mg/kg (up to 160 mg)
DRI Aliskiren (Tekturna) (B)	HTN	150 mg and 300 mg	150 mg daily	150–300 mg/day *Max:* 300 mg/day

LVD = left ventricular dysfunction; (G) = generic available; (B) brand-name only. All maintenance doses are titrated to target blood pressure. Lowest dose that meets target is used.

Because the action of bradykinin may be responsible for the adverse reactions of cough, changing to an ARB provides benefits similar to those of the ACEI with less likelihood of cough. DRIs sometimes produce this cough. Less common adverse reactions with ACEIs include a rash that is most common with captopril and neutropenia that increases with high doses, renal impairment, and concomitant collagen diseases. Enalipril, quinapril, and ramipril can cause photosensitivity reactions. Valsartan is the only ARB noted to also do this (Drucker & Rosen, 2011).

Drug Interactions

Losartan levels are significantly lowered by inhibitors of cytochrome P450 (CYP450) 3A4 and 2C9. Irebesartan has a similar problem with CYP450 2C9. Drugs that inhibit this system (e.g., cimetidine) may cause increased levels of free drug. The clinical significance of these inhibitions is negligible, however, because the active metabolite is unaffected. Alsikren has minor issues in the CYP 3A4 system but greater ones in other meds with *P*-glycoprotein (e.g., cyclosporine and itraconazole).

Typically, additive hypotensive effects occur with diuretics, but the DRIs make furosemide less effective. Additive hypotension may also occur with other antihypertensives, nitrates, phenothiazines, and acute alcohol ingestion. Due to the interference with aldosterone secretion, the concurrent use of potassium supplements, potassium-sparing diuretics, or cyclosporine may result in hyperkalemia. The antihypertensive response is reduced by NSAIDs because of their effect on prostaglandins. Other specific drug interactions and the appropriate actions to prevent them are given in Table 16-3.

Table 16–3 ▦ **Drug Interactions: Angiotensin-Converting-Enzyme Inhibitors, Angiotensin II Receptor Antagonists, and Direct Renin Inhibitors**

Drug	Interacting Drug	Possible Effect	Implications
All ACEIs	Lithium	Increased serum lithium levels and symptoms of toxicity	Monitor lithium levels more closely.
Captopril	Diuretics	Hypotension and renal dysfunction	Discontinue 2–3 days before initiating therapy with ACEI or initiate with low dose. Ensure adequate hydration prior to first dose and warn about potential for dizziness.
Enalapril	Antihypertensives, nitrates, alcohol, phenothiazines	Hypotension	Warn patient. Avoid concurrent use if possible. Avoid or reduce alcohol use.
Losartan	Potassium supplements, potassium-sparing diuretics	Hyperkalemia	Avoid concurrent use. Teach patient that salt substitutes often are high in potassium. Read label and check with provider before using.
Telmisartan	NSAIDs	Blunted antihypertensive effects	Avoid concurrent use or monitor for need to increase ACEI dose. Teach patient not to take over-the-counter drugs (OTCs) without informing provider.
All ARBs	Antacids	Decreased absorption of ACEI; increased risk for digoxin or lithium toxicity	Avoid use or separate doses by at least 1 h.

Continued

Table 16–3 Drug Interactions: Angiotensin-Converting-Enzyme Inhibitors, Angiotensin II Receptor Antagonists, and Direct Renin Inhibitors—cont'd

Drug	Interacting Drug	Possible Effect	Implications
	Allopurinol	Increased risk of hypersensitivity reactions	Avoid concurrent use.
	Capsaicin	Increased incidence of cough	Avoid concurrent use.
	Probenecid	Decreased elimination and increased levels of captopril	Monitor for need to increase dose of enalapril or select a different ACEI.
	Rifampin	Decreased effectiveness of enalapril	Fluconazole does not affect eprosartan. Select different antifungal or use eprosartan.
	Fluconazole	May inhibit metabolism of losartan causing increased antihypertensive and adverse effects	Avoid concurrent use. Select different ARB.
	Indomethacin	Reduced hypotensive effects of losartan	Avoid concurrent use. Select different ARB.
	Digoxin	Median increase in digoxin peak concentration (49%) and trough concentration (20%)	Select different histamine$_2$ blocking agent.
	Cimetidine	Increased effects of ARB	If use is necessary, monitor for need to change ARB dose.
	Phenobarbital	May decrease effects of ARB	Same as for ARBs.
	Diuretics, especially thiazide diuretics	Hypotension	
DRI meds	Furosemide	Less effective diuresis	Use other loop or thiazide diuretic.
	Atorvastatin, cyclosporine, ketoconazole	Increased level of aliskiren	Avoid concurrent use if possible.
	Ibesartan	Decreased DRI effect	HTN is less controlled.

Clinical Use and Dosing

Hypertension

Primary HTN has no identifiable cause; therefore, the treatment depends on interfering with normal physiological mechanisms that regulate BP. ACEIs, ARBs, and DRIs act on the RAA system to reduce pressure by decreasing sodium and water retention (aldosterone action), by decreasing vasoconstriction (angiotensin direct action), and by increasing vasodilation (bradykinin action). ACEIs and ARBs are the drugs of choice for patients who are younger and white and for patients with diabetes, HF, or MI, for whom they are most effective and have the lowest incidence of adverse reactions. They are generally not as effective for black patients; however, the interracial differences in BP-lowering observed with any drug class are mitigated when the drugs are combined with a diuretic. Despite noted differences in BP response at the population level, race alone is a poor predictor of BP response to any particular class of drugs if they are given in adequate doses and with sufficient time to work. Literature on the DRIs has not mentioned altered ethnic group responses of significance.

Racial differences in adverse responses may occur. African Americans and Asians, for example, have a 3- to 4-fold higher risk of angioedema (Wright et al, 2009), and more cough in these groups has been attributed to ACE than in whites (Elliot, 1996). Unfortunately, insufficient numbers of Hispanics, Native Americans, or Asian/Pacific Islanders have been included in most of the major clinical trials to make strong recommendations about adverse response patterns.

No specific difference related to gender has been shown (National High Blood Pressure Education Program [NHBPEP], 2003). Doses for HTN vary with each drug, but adverse reactions increase with higher doses. The first dose may cause a steep drop in BP, especially for patients taking diuretics. Diuretics should be stopped for 2 to 3 days to allow rehydration before starting an ACEI, ARB, or DRI. All three drug classes increase in effectiveness when given with a diuretic. Diuretics should be reintroduced after the monotherapy dose has been stabilized. Because reduced aldosterone secretion may result in potassium retention, thiazide diuretics make an excellent combination owing to their tendency to foster potassium loss. The best approach is to start low and go slow. Begin with the lowest dose recommended and increase the dose at 1 to 2 week intervals until BP is controlled. Table 16-4 provides dosage schedules for each of the combination drugs based on their indications. For further information, see Chapter 40 on HTN.

Hypertensive Proteinuric Diabetes

To prevent diabetic nephropathy or slow its progression, ACEIs or ARBs should be selected to treat the HTN (AACE Hypertension Task Force, 2006; American Diabetes Association, 2015). The use of DRIs for proteinuria is still

Table 16–4 ❊ Indication and Dosage Forms: Selected ACEI and ARB Combinations

Drug	Indication	Dosage Form	Initial Dosing	Maintenance Dosing
ACEI				
Benazepril + HCTZ (Lotensin HCT) (G)	HTN (not for initial tx)	Tablets: 5 mg/6.2.5 mg (not brand); 10/12.5 mg; 20/12.5mg; 20/25 mg	10–20/12.5 mg daily. For those s BP on 25 mg HCTZ, but K loss: 5 mg/6.25 mg	Titrate 2–3 wk intervals
			Cr <30 not recommended	Give loop
Amlodipine + Benazapril (Lotrel) (G)		Caps: 2.5 mg/10 mg; 5/10 mg; 5/20 mg; 5/40 mg; 10/40 mg	2.5–10 mg amlodipine and 10–40 mg benazapril daily	*Max*: amlodipine 10 mg and 80 mg Benazapril
		Cr <30 not recommended		
Captopril +HCTZ (no longer brand name)	HTN	Tablets: 25 mg/15 mg; 25 mg/25 mg; 50 mg/15 mg; 50 mg/25 mg	25 mg/15 mg daily	*Max dose* of captopril is 150 mg and *Max dose* of HCTZ is 50 mg
Enalapril + HCTZ (Vaseretic) (G)	HTN	Tablets: 5 mg/12.5 mg (not vaseretic); 10 mg/25 mg	5–10 mg enalapril + HCTZ	*Max*: 40 mg/d enalapril and 50 mg/d HCTZ
Lisinopril+ HCTZ (Prinzide or Zestoretic) (G)	HTN	Tablets: 10 mg/12.5 mg; 20 mg/12.5 mg (not available as prinzide brand); 20 mg/25 mg	10 mg/12.5 mg	Increases of either or both drugs per BP response *Max*: 80 mg lisinopril or 50 mg HCTZ
Moexipril + HCTZ (Uniretic) (G)	HTN (not for initial tx)	Tablets: 7.5 mg/12.5 mg; 15 mg/12.5 mg; 15 mg/25 mg	7.5–30 mg of moexipril in one to two divided doses with HCTZ dose less than 50 mg	
Quinapril + HCTZ (Accuretic)	HTN (not for initial tx)	Tablets: 10 mg/12.5 mg; 20 mg/12.5 mg; 20 mg/25 mg	10 mg/12.5 mg	20 mg/12.5 mg daily
Trandolapril + Verapamil (Tarka) (G)	HTN (not initial tx)	Tablets: 1 mg/240 mg; 2 mg/180 mg; 2 mg/240 mg; 4 mg/240 mg	Start at equivalent dose of monotherapy daily	Individualize dose
ARB				
Candesartan + (Atacand HCT) (B)	HTN (not of initial tx)	Tablets: 16 mg/12.5 mg; 32 mg/12.5 mg; 32 mg/25 mg	Substitute dose for original agents in one to two divided doses	Max effect in 4 wk at 16–32 mg/d for the candesartan and at 12.5–25 mg for the HCTZ
Eprosartan + HCTZ (Teveten HCT) (B)	HTN (not initial tx)	600 mg/12.5 mg; 600 mg/25 mg	600 mg/12.5 mg daily	*Max*: 600 mg/25 mg daily
Irbesartan + HCTZ (Avalide) (G)	HTN	Tablets: 150 mg/12.5 mg; 300 mg/12.5 mg	Initial Tx: 150 mg/12.5 mg Add-on Tx: 150 mg/12.5 mg	Can titrate as soon as 1 wk; max effect seen in 2 wk *Max*: 300 mg/25 mg
Losartan + HCTZ (Hyzaar) (G)	HTN	50 mg/12.5 mg; 100 mg/12.5 mg; 100 mg/25 mg	Individualized based on individual drug impact	May be titrated after 2–4 wk
	Stroke risk reduction HTN + LVD		50 mg daily	
Olmesartan + HCTZ (Benicar HCT) (B)	HTN (not initial tx)	Tablets: 20 mg/12.5 mg; 40 mg/12.5 mg; 40 mg/25 mg	Substitute for previously effective doses For noncontrolled: Lowest available dose	Titrate at 2–4 wk *Max*: 40 mg/25 mg
Telmisartan + HCTZ (Micardis HCT) (B)	HTN (not for initial tx)	Tablets: 40 mg/12.5 mg; 80 mg/12.5 mg; 80 mg/25 mg	*Currently only on Telmisartan 80 mg:* 80 mg/12.5 mg *Currently only on HCTZ 25 mg:* 80 mg/12.5mg	Titrate to 160 mg/25mg prn Titrate to 160 mg/25 mg after 2–4 wk

Table 16–4 ❀ Indication and Dosage Forms: Selected ACEI and ARB Combinations—cont'd

Drug	Indication	Dosage Form	Initial Dosing	Maintenance Dosing
Telmisartan + Amlodipine (Twynsta) (B)	HTN	40 mg/5 mg; 40 mg/10 mg; 80 mg/5 mg; 80 mg/10 mg	*Initial tx*: 40 mg/5 mg daily *Replacement dosing*: 40–80 mg/5–10 mg daily	*Initial tx*: Titrate 2 wk to 80 mg/10 mg *Max*: 80 mg/10 mg Titrate after 2 wk *Max*: 80 mg/10 mg
Valsartan + HCTZ (Diovan HCT) (B)	HTN	Tablets: 80 mg/12.5 mg; 160 mg/12.5 mg; 160 mg/25 mg; 320 mg/12.5 mg; 320 mg/25 mg	Initial Rx: 160 mg/12.5 mg daily Add-on RX; 80–160 mg valsartan and 12.5–25mg HCTZ	Titrate after 1–2 wk *Max*: 320 mg/25 mg Titrate after 3–4 wk *Max*: 320 mg/25 mg
Amlodipine + Valsartan + HCTZ (Exforge HCT) (B)	HTN (not initial tx)	5 mg/160 mg/12.5 mg; 5 mg/160 mg/25 mg; 10 mg/160 mg/12.5 mg; 10 mg/160 mg/25 mg; 10 mg/320 mg/25 mg	Add-on or replacement dose: 5–10 mg/ 160–320 mg/ 12.5–25 mg daily	*Max*: 10 mg/320 mg/25 mg
Amlodipine +Valsartan (Exforge) (B)	HTN	5 mg/160 mg; 5 mg/320 mg; 10 mg/160 mg;10 mg/ 320 mg	5 mg/160 mg daily	Titrate after 1–2 wk *Max*: 10 mg/320 mg

(G) = generic; (B) = brand; (P) = Prinivil; (Z) = Zestril; tx = treatment

off-label. In patients with type 1 diabetes, with or without HTN, ACEIs have been demonstrated to significantly delay the progression of diabetic nephropathy. In patients with type 2 diabetes, HTN, and microalbuminuria, ACEIs and ARBs have been shown to delay the progression to macroalbuminuria. In diabetic patients with macroalbuminuria and renal insufficiency, ARBs have been shown to delay the progression to nephropathy (American Diabetes Association, 2015). Though dual blockade by combining an ACEI and an ARB has been shown to provide statistically significant reduction in albuminuria and BP, this combination is not recommended. (Remuzzi, Schieppati, & Ruggenenti, 2003; Wade & Gleason, 2004). Dosages generally used for HTN are appropriate for this indication. DRIs are typically not mixed with ACEIs or ARBs due to significant risks of hyperkalemia.

Angina and Ischemic Heart Disease

Angina is largely a problem of imbalance between myocardial oxygen supply (MOS) and myocardial oxygen demand (MOD). ACEIs affect both the MOS and the MOD sides of the equation. Their prevention of formation of AT II decreases peripheral-vascular resistance (PVR) and, thereby, MOD; decreases the thickening of coronary artery walls, resulting in increased MOS; and decreases the thickening of ventricular walls, resulting in decreased MOD. Their reduced secretion of aldosterone decreases the retention of sodium and water, thereby reducing extracellular fluid (ECF) volume and preload.

ACEIs are recommended for all symptomatic patients with chronic stable angina to prevent MI or death and to reduce symptoms (American College of Cardiology Foundation/American Heart Association [ACCF/AHA], 2009). They are also recommended to limit coronary artery disease (CAD) patients who also have diabetes or left ventricular

(LV) dysfunction. The ACCF/AHA recommend that ACEIs be considered in CAD patients even without LV dysfunction. The Institute for Clinical Symptoms Improvement (ICSI, 2011a) also states that ACEIs and ARBs are appropriate treatment options for stable CAD. Ample evidence exists for basing the use of both ACEIs and ARBs for long-term use in patients with CAD even without other comorbidities. Doses are found in Table 16-4. DRIs do not have this indication.

Postmyocardial Infarction

Survivors of acute MI have a risk for subsequent morbidity and mortality that is 1.5 to 15 times greater than that of the general population. A combination of an ACEI, a non-ISA beta blocker (BB), antiplatelet therapy, and lipid-lowering therapy after MI is appropriate. The reduced morbidity and mortality owing to the use of ACEIs results from: reduced AT II after myocardial injury, prevention of ventricular remodeling in noninfarcted myocytes, alteration of ventricular mass, and positive hemodynamic effects on BP and fluid and electrolyte balance. ARBs are also extremely effective here because they affect not only AT II but also AT I receptors. In addition, bradykinin has cardioprotective effects, and a combination of an ACEI and an ARB provides complete inhibition of AT II and increased levels of bradykinin, which may be more beneficial than either class alone

ACEIs, with or without ARBs, should be started early after MI in stable high-risk patients (anterior MI, previous MI, Killip class II). They should be continued indefinitely for all patients with LV dysfunction (ejection fractions less than 40%) or symptoms of HF and used as needed to manage BP or symptoms in all other patients. Dosages usual for treating HTN are used unless HF is present (see Table 16-4). DRIs do not have this post-MI indication because they do not contribute to positive outcomes more than standard care.

Heart Failure

CAD is the underlying cause in about two-thirds of patients with LV dysfunction, which begins with some injury to the myocardium and progresses even in the absence of additional myocardial insults. The principal mechanism relates to re-modeling. ACEIs and ARBs are useful in treating heart failure related to CAD, primarily for their role in reducing remodeling. Another underlying cause for HF is chronic HTN. ACEIs and ARBs are also effective in treating this underlying cause. DRIs do not carry an indication for HF.

ACEIs are a cornerstone of therapy for HF and are recommended for patients with a history of atherosclerotic vascular disease, diabetes mellitus, or HTN. They have been shown to improve symptoms, decrease morbidity, and increase life expectancy. Because they are the only drugs that address all of the pathological mechanisms that produce HF, they are appropriate for all subsets of patients unless these patients have an absolute contraindication. They are also useful for preventing the development of HF in patients with ventricular dysfunction but no overt symptoms. ACEIs are superior to all other drugs and drug combinations used to treat HF. They should be started immediately without waiting for symptoms to become overt.

For symptomatic HF, the dose is about half that used for HTN. Start low and go slow also applies here. In patients with congestive heart failure (CHF) and low ejection fractions (less than 40%), the vasodilating effect of ACEIs provides adequate perfusion even with SBP below 90 mm Hg. For patients who cannot tolerate an ACEI, hydralazine, in combination with a long-acting nitrate (ISDN), BiDil has been shown to be equally effective in reducing morbidity and mortality from HF. This is especially noted in African Americans (see Chap. 36).

Rational Drug Selection

Short-Acting versus Long-Acting

Adverse reactions such as angioedema and renal dysfunction usually occur within the first few doses. Instituting therapy with captopril, a short-acting form, enables rapid onset of action, assessment of patient tolerance, and the ability to clear the drug quickly should an adverse reaction occur. Captopril requires frequent dosing, and adherence is less likely with this treatment regimen in the long term. Other ACEIs have the advantage of once-daily dosing, and as soon as patient tolerance is determined, patients should be converted to these other agents to improve adherence. ARBs and DRIs also allow once-daily dosing.

Cost

Brand-name ACEIs and ARBs are expensive. Most have become generic, which has reduced costs. Combination drug formulations, if needed for control, can additionally reduce these costs. Initiate therapy with captopril for the reasons given previously and then change to the least-expensive long-acting form or to an ARB. DRIs are expensive brand names.

Difficulty in Swallowing

For patients who have difficulty in swallowing, ramipril (Altace) may be a good choice. The capsules may be opened and sprinkled on applesauce, added to apple juice, or dissolved in 4 oz water with no change in the effectiveness of the drug. Captopril may be crushed but may have a sulfurous odor and requires two or three doses daily. Available dosage forms are listed in Table 16-4.

Monitoring

Baseline BP and a pulse reading should be taken before initiating therapy and with each change in dosage. Weight and other indicators of fluid status should also be monitored. See Chapter 40 for further BP monitoring guidelines and other related chapters for monitoring guidelines for the various disease processes for which these drugs are used.

During administration of ACEIs, ARBs, and DRIs, monitoring renal function is important. Serum creatinine levels should be drawn before beginning therapy, after the first week of therapy, monthly during the first 3 months, and when increasing the dose. The ACEI dose should be reduced if serum creatinine is more than 2.5 mg/dL. Potassium levels are also obtained at baseline and with the other labs suggested.

CLINICAL PEARL

Many brand-name **ACEIs** have the same cost for different strengths. It is possible to prescribe a high strength of the drug and have the patient halve it to achieve the desired dose, resulting in considerable cost savings.

CLINICAL PEARL

If you hear an abdominal bruit in a patient known to have vascular disease, give **captopril**, a short-acting **ACEI**, and measure serum creatinine prior to the dose and within 1 or 2 days after the dose. A rapid rise in the creatinine level suggests renal artery stenosis. A slower rise probably indicates a problem with poor hydration that can be corrected by rehydrating the patient and discontinuing or lowering the dose of any **diuretics** the patient is taking.

For patients with renal impairment or receiving an ACEI or ARB that requires dosage adjustments for renal impairment, assess urine protein prior to initiation, every 2 to 4 weeks for the first 3 months of therapy, and regularly thereafter for up to 1 year. Increased proteinuria suggests reevaluation of ACEI therapy. For patients on ARBs, no change in dosage is required based on renal impairment. Initial ARB doses may be lower for patients with impaired hepatic function. Liver function tests (LFTs) should be performed prior to initiating therapy. The dose may be increased as tolerated. According to drug company literature, no patient has had to discontinue an ARB because of increased LFT values. DRIs need renal and potassium monitoring.

For ACEIs, the white blood cell (WBC) count with differential should be monitored prior to initiation of therapy, monthly for the first 3 to 6 months, and periodically for up to 1 year for patients at risk for neutropenia (renal impairment, collagen vascular disease, high doses). Therapy should be discontinued if the neutrophil count is less than 1,000/mm³.

Patient Education

Patient education focuses on administration of the drug, adverse reactions to expect and appropriate responses to each, and concomitant lifestyle management.

> **CLINICAL PEARL**
>
> Patients should be monitored for indications of angioedema. Suspect angioedema in any patient who calls the next morning after taking the first dose and complains of voice changes or swollen lips or tongue. Stop the drug immediately. The symptoms recede as the drug is eliminated. Protection of the airway is rarely needed, but careful assessment of airway status is required.

Administration

The drug should be taken exactly as prescribed, at the same time each day. Missed doses should be taken as soon as remembered unless it is almost time for the next dose. Doses should not be doubled. The ACEIs vary on whether food alters absorption (see Table 16-1). ARBs may be administered without regard to food intake. DRIs do not have a long enough use pattern for a definitive statement, except to avoid high-fat meals.

The patient should be educated to consult the health-care provider before taking any OTC drugs, especially cold remedies. NSAIDs should be avoided because they may counteract the effects of all three drug classes. Salt substitutes often contain potassium and should be avoided unless approved by the health-care provider.

Adverse Reactions

Education concerning hypotensive reactions can reduce the risk of falls. Changing position slowly, not exercising in hot weather, and keeping fluid intake at more than 2 L/day (non-caffeinated) will decrease these reactions. Fluid intake at this level may not be practical in patients with HF who need to limit their fluid intake, but ACEIs are not contraindicated in this situation (see Chap. 36). There is no effective treatment to date for ACEI-related cough. Changing to another ACEI or to an ARB may help. For the few patients who experience impairment in taste, this generally resolves in 8 to 12 weeks, even with continued therapy. Rash is rare and mostly occurs with captopril. It should be reported, and a different ACEI may be prescribed. DRI effects mirror the other two drugs in the group.

Patients also need to be aware of the serious adverse reactions, including angioedema and renal failure. If flushing or pallor of the face; hoarseness; swelling of the face, eyes, lips, or tongue; or difficulty in swallowing or breathing occurs, the patient should discontinue the drug and notify the health-care provider immediately. Swelling of the feet and ankles and decreased urine output should also be reported. Childbearing women need to understand that ACEIs, ARBs, and DRIs are contraindicated in pregnancy. This topic should be discussed and effective contraception instituted prior to prescription.

Lifestyle Management

Patients are directed toward a cardiac-healthy lifestyle that includes weight loss, aerobic exercise, tobacco avoidance, decreased dietary saturated fats, and moderation in alcohol and dietary sodium. Stress management is also important. They must be made aware that potassium-rich foods and supplements touted as being important for some of the other medications they might be taking should not be increased without provider direction.

CALCIUM CHANNEL BLOCKERS

Calcium is a vital component in the excitation-contraction process in muscles, in electrical excitation, and in facilitating myocardial relaxation. Calcium enters cells via three types of voltage-dependent calcium channels (L-type, N-type, and T-type). The L-type, or long-lasting, channels are predominant in cardiac and smooth muscle and are the ones blocked by most calcium channel blockers (CCBs). CCBs have multiple indications, including angina, HTN, and selected tachyarrhythmias. Unlabeled indications include migraine headache prophylaxis, Raynaud's syndrome, cardiomyopathy, and esophageal spasm. Laboratory evidence indicates that CCBs may interfere with platelet aggregation and reduce the development of atherosclerotic lesions.

Pharmacodynamics

As shown in Figure 16-2, contraction of smooth muscles is triggered by an influx of calcium through transmembrane calcium channels. CCBs directly block the influx of calcium at the onset of the cycle, like the sodium channel blockade in local anesthetics. The drugs act from the inner side of the membrane and bind to channels in depolarized membranes, converting the mode of operation of the channel from frequent openings to rare openings. The result is a marked decrease in transmembrane calcium content and prolonged vascular smooth muscle relaxation.

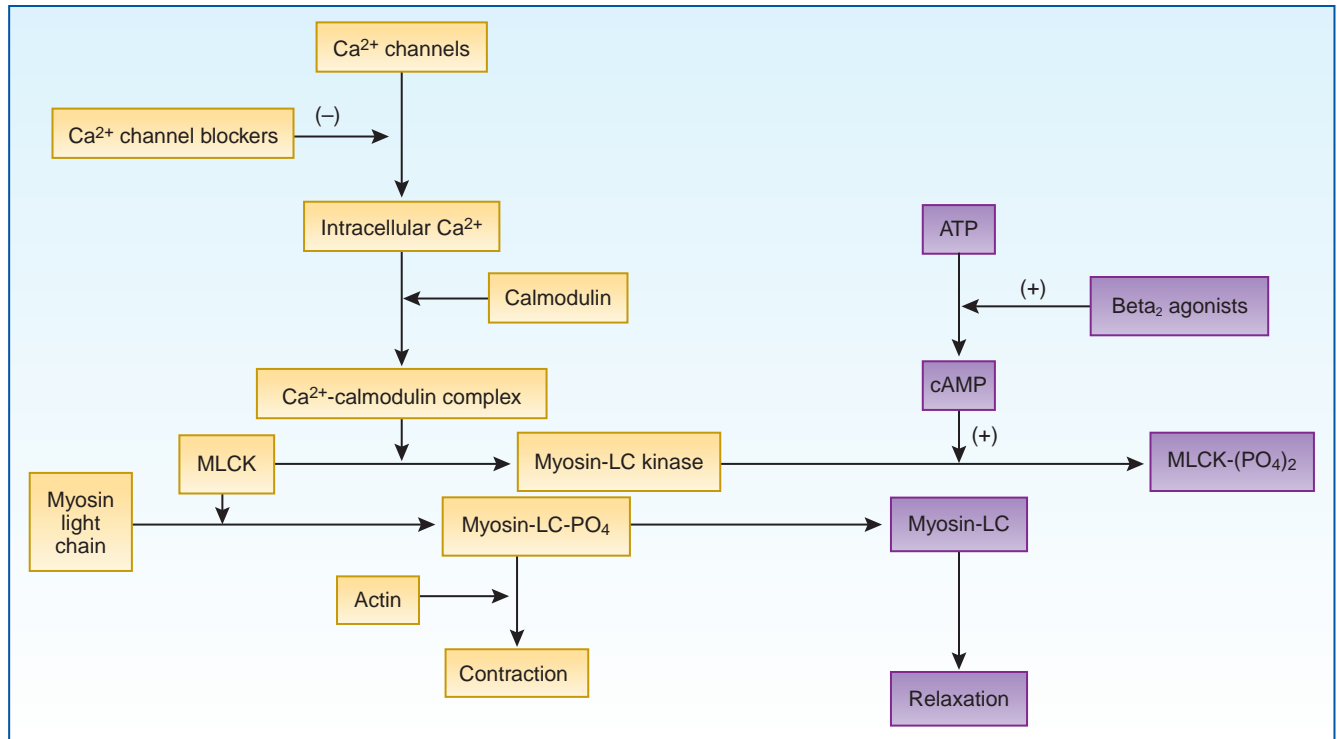
The blocking action of CCBs occurs via three different receptors: diphenylalkylamine-based and benzothiazepine-based (both type 1 receptors) and dihydropyridine-based (type 2 receptors). The physiological response in the calcium channel is different for these two receptor types, and these differences are important in the clinical choice of CCB. All CCBs relax arterial smooth muscle but have little effect on venous beds. This results in significant reduction in afterload but limited effect on cardiac preload. In cardiac


Figure 16–2. Control of smooth muscle contraction. Contraction is triggered by the influx of calcium (Ca) through transmembrane calcium channels. The calcium combines with calmodulin to form a complex that converts the enzyme myosin light-chain kinase (MLCK) to its active form. The latter phosphorylates the myosin light chains, initiating the interaction of myosin with actin that produces contraction. Relaxation begins with the reabsorption of calcium, removing it from interaction with the myosin system. Substances that increase cyclic adenosine monophosphate (cAMP), including beta agonists, may cause relaxation in smooth muscle by accelerating the inactivation of MLCK.

muscle, reduction in contractility (negative inotropism) and decreases in sinoatrial (SA) and atrioventricular (AV) nodal conduction velocity also occur. Although this is true of all classes of CCBs, the greater degree of vasodilation seen in the dihydropyridines causes sufficient reflex increase in sympathetic tone to overcome the negative inotropic effects.

The effect of a CCB on nodal conduction depends on whether it delays slow calcium channel recovery. Nifedipine (Adalat, Procardia) and the other dihydropyridines do not affect the rate of recovery of these channels. At doses used clinically, they do not affect conduction through the AV node. In contrast, verapamil (Calan, Isoptin) not only affects openings of calcium channels but also decreases the rate of recovery, resulting in depression of the SA node firing rate and slowing of AV nodal conduction. This is the basis of its use in treating supraventricular tachycardia. Verapamil is also a direct negative inotrope.

Pharmacokinetics

Absorption and Distribution

All CCBs are well absorbed orally, but there is variance in bioavailability among them (Table 16-5). Verapamil and diltiazem (Cardizem), prototype type 1 CCBs, are rapidly absorbed but rapidly metabolized to yield bioavailabilities of 20% to 35% and 40% to 65%, respectively. The dihydropyridines (type 2 CCBs) are absorbed at varying rates,

and their bioavailabilities vary from 65% to 90% for amlodipine (Norvasc) and to 15% for isradipine (DynaCirc). The presence of food in the gut does not affect bioavailability in any of these drugs. IV forms are available for some CCBs. This latter form is not used in primary care and is not discussed in this chapter.

Distribution is to most body tissues, with only nimodipine (Nimotop) crossing the blood–brain barrier. Because nimodipine has only one very restricted application in the acute care setting, it is not discussed further. All cross the placenta. Verapamil, diltiazem, and nicardipine (Cardene) are excreted extensively in breast milk. Nifedipine is excreted at less than 5% in breast milk, making it the drug of choice during lactation if a CCB is required.

Metabolism and Excretion

All CCBs are extensively metabolized by the liver via the CYP 3A4 channel. Inducers and inhibitors of that isoenzyme system can affect CCB metabolism. This is more of a problem for type 1 CCBs than for dihydropyridines. Many CCBs have elimination routes in both the urine and the feces (see Table 16-5). Dosage reduction based on renal impairment is recommended only for nicardipine.

Most CCBs have short-acting forms with half-lives between 2 and 8 hours and sustained-release forms with half-lives of 12 to 24 hours. Amlodipine is the exception, with a half-life of 30 to 50 hours. Reduced adverse reactions are seen with the use of sustained-release forms.

Table 16–5 Pharmacokinetics: Calcium Channel Blockers

Drug	Onset (h)	Peak (h)	Duration (h)	Protein Binding	Oral Bioavailability	Half-Life (h)	Elimination
Dihydropyridines							
Amlodipine	1 h	6–12	24+	>93%	65%–90%	30–50 (56 in hepatic impairment)	10% drug and 60% metabolite in urine
Felodipine	1 h	2.5–5	24	>99%	15%–20%	11–16	70% in urine; 10% in feces
Isradipine	<2 h	1.5	12	95%	15%–24%	8	60%–65% in urine; 25%–30% in feces
Isradipine CR	2 h	7–18	24	95%	15%–24%	8	60%–65% in urine; 25%–30% in feces
Nicardipine IR	20 min	1–2	8	95%	35%	2–4	<1% unchanged in urine
Nicardipine SR	UK	1–4	12	>95%	35%	2–4	60% in urine; 35% in feces
Nifedipine IR	20 min	0.5–1	6–8	90%	45%–70%	2–5	60%–80% in urine; 15% in feces
Nifedipine XL	20 min	6–8	24	92%–98%	85%–90%	2–5	60%–80% in urine; 15% in feces
Nisoldipine	UK	6–12	24	99%	5%	7–12	60%–80% in urine
Type 1 CCB							
Diltiazem IR	30 min	2–3	6–8	70%–80%	40%–65%	4.5	2%–4% unchanged in urine
Diltiazem ER	UK	10–14	24	70%–80%	40%	4–9.5	2%–4% unchanged in urine
Diltiazem SR/CD	30–60 min	6–11	24	70%–80%	67%	5–7	2%–4% unchanged in urine
Verapimil IR	30 min	0.5–1	3–7	90%	20%–35%	4.5–12	70% in urine; 16% in feces
Verapamil SR	1.2	5–7	24	88%–92%	20%–35%	4–12	70% in urine; 16% in feces
Verapamil ER	UK	11	24	>90%		4.5–12	70% in urine; 16% in feces

IR = immediate release; UK = unknown; SR = sustained release; CR = controlled release; ER = extended released; CD = continuous dosing.

Pharmacotherapeutics

Precautions and Contraindications

Verapamil has the strongest negative inotropic effect and should be avoided in HF, in which this effect can worsen the disorder. It also has the strongest effect on nodal conduction and can significantly worsen bradycardia. Diltiazem also affects nodal conduction and can worsen or cause bradycardia, although less than verapamil. None of the CCBs are drugs of choice immediately after MI, but diltiazem has shown some benefit in reducing mortality in non–Q-wave MI for a selected group of patients whose ejection fractions are above 40%. For those with ejection fractions below 40% and for all other patients early after MI, type 1 CCBs are contraindicated because of their negative inotropic and bradycardic effects. Patients with ventricular dysfunction, SA or AV nodal conduction disturbances, and SBPs below 90 mm Hg should not be treated with type 1 CCBs because of the high risk for induction of HF and significant hypotension.

The dihydropyridines are less dependent on the heart for their effects, but they are still not the drugs of choice after MI. Dihydropyridines should also be avoided for patients with significant peripheral edema. Their strong peripheral vasodilating effects result in peripheral pooling of blood and may lead to reflex tachycardia. They are also contraindicated in unstable angina because of their potential to cause tachycardia. If it is necessary to give a dihydropyridine to a patient who has peripheral edema or a tachyarrhythmia disturbance, the sustained-release forms are preferred. All CCBs should be used cautiously in severe hepatic impairment, with dosage reduction recommended for most agents.

Teratogenic and embryotoxic effects have been demonstrated in small animals. There are no adequate and well-controlled studies in pregnant women. These drugs are Pregnancy Category C. Female patients capable of childbearing should be made aware of the risks of these drugs, and contraception should be instituted before CCBs are prescribed. They should be used only when benefits clearly outweigh risks.

Verapamil, diltiazem, nifedipine, and nicardipine are all found in breast milk. They should not be given to nursing mothers. It is not known if amlodipine, isradipine, nislodipine (Sular), or felodipine (Plendil) are excreted in breast milk. For these drugs, the determination to continue nursing is based on the importance of the drug for the mother and the presence or absence of acceptable alternatives. Safety and efficacy of these drugs have not been established in children.

Adverse Drug Reactions

The more common adverse reactions of CCBs are extensions of their actions. Reduction in BP secondary to vasodilation may result in dizziness, headache, hypotension, and syncope. These lead to HF with congestion, shortness of breath, cough, and palpitations; though a potential class effect, HF is worse with verapamil, diltiazem, and nifedipine. Gastrointestinal (GI) symptoms can include dry mouth, nausea, vomiting, reflux, and constipation. Although not common, sexual dysfunction and gynecomastia may occur. Hyperglycemia is also uncommon but may affect the choice of the drug in patients with diabetes, especially with nifedipine, verapamil, and diltiazem at high doses. Photosensitivity and facial telangiectasia can occur with amlodipine, nifedipine, and diltiazem. These drugs are also associated with hyperpigmentation (Drucker & Rosen, 2011).

The highest rate of adverse reactions is found in the short-acting dihydropyridines (17%), with the lowest rate for this group being in amlodipine (less than 4%). All adverse drug reactions for CCBs are less common with sustained-release forms because the amount of drug in the system at any given time is more stable.

Drug Interactions

Additive hypotensive effects are major concerns with all CCBs given concurrently with other antihypertensives, nitrates, quinidine, or alcohol. Antihypertensive effects may be decreased with concurrent use of NSAIDs. Verapamil, diltiazem, and some dihydropyridines have an additive bradycardic effect with BBs or digoxin. Serum digoxin levels may be increased with risk of toxicity when it is concurrently used with verapamil, diltiazem, or nifedipine. Verapamil may decrease the effectiveness of rifampin, and the effectiveness of verapamil may be decreased by concurrent administration of vitamin D and calcium. Verapamil may also alter serum lithium levels.

CYP3A4 isoenzymes are involved in the metabolism of all CCBs. Drugs that inhibit this system, including grapefruit juice, may increase free drug levels. Both verapamil and diltiazem increase the risk of myalgia in simvastatin. Food interactions also occur for several of the CCBs. Specific drug and food interactions and appropriate actions to prevent them are found in Table 16-6.

Table 16–6 ▦ Drug Interactions: Selected Calcium Channel Blockers

Drug	Interacting Drug	Possible Effect	Implications
All CCBs	Histamine$_2$ blockers	Serum concentrations of CCB may increase	Monitor cardiovascular status closely. May need to adjust dose.
	Fentanyl, nitrates, antihypertensives, acute alcohol ingestion, quinidine	Additive hypotension	Monitor for orthostatic changes. Warn patient. Reduce or avoid alcohol use.
	NSAIDs	Decreased antihypertensive effects	Warn patient. Avoid concurrent use or monitor therapeutic response and adjust CCB dose.
Diltiazem and verapamil	Benzodiazepines, buspirone, carbamazepine	Serum concentrations of psychotropics increased	Monitor serum levels closely and adjust dose as needed.
	HMG-Co-A reductase inhibitors	Serum concentrations of statin may be elevated, except lovastatin, which may be reduced	Monitor clinical response and adjust dose as needed if concurrent use cannot be avoided. Lovastatin limited to 20 mg daily.
Verapamil, diltiazem, nifedipine	Digoxin	Increased serum digoxin levels	Monitor for digoxin toxicity. Teach signs and symptoms to report to provider.
	CYP-450 3A4 inhibitors (including grapefruit juice)	Decreased hepatic clearance of CCB with increased risk of toxicity to CCB	Monitor for orthostatic changes, rate and rhythm changes.
	Calcium salts, vitamin D	Reduced response to CCB	Avoid concurrent use. If use is necessary, monitor therapeutic response and adjust CCB dose.
	Cyclosporine, prazosin, quinidine, theophylline, carbamazepine	Decreased metabolism of these drugs and increased toxicity risk	Monitor therapeutic levels and signs and symptoms of toxicity.
Verapamil, diltiazem, felodipine, isradipine, nicardipine, nifedipine, nimodipine	Beta-adrenergic blockers, digoxin, disopyramide, phenytoin	Myocardial depression, bradycardia, conduction defects, CHF	Do not administer within 24 h of each other. If you must give both, monitor for heart failure and decreased peripheral perfusion.

Continued

Table 16–6 ⚏ **Drug Interactions: Selected Calcium Channel Blockers—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
Diltiazem	Phenobarbital, phenytoin	Increased metabolism and decreased effect of diltiazem	Avoid concurrent use. Select different anticonvulsant.
	Cyclosporine	Enhanced action of cyclosporine	Monitor renal function with blood urea nitrogen (BUN) and creatinine levels. Monitor cyclosporine levels.
Verapamil	Rifampin	Decreased effect of rifampin	Avoid concurrent use. Select different CCB if rifampin is needed to treat tuberculosis.
	Lithium	Altered serum lithium levels with increased toxicity risk	Avoid concurrent use. Select different CCB.
	Statins	Toxicity risk	Do not exceed simvastatin 10 mg; lovastatin 20 mg
Dihydropyridines	Azole antifungals	Increased concentrations of CCB	Monitor cardiovascular effects and adjust dose if concurrent use cannot be avoided.
Food Interactions			
Felodipine, nifedipine, nislodipine, verapamil, amlodipine	Grapefruit juice	Increased serum concentrations of CCB	Avoid concurrent use.
Diltiazem, felodipine, nislodipine	High-fat or high-carbohydrate meal	Drug taken with this kind of meal has increased AUC and C_{max} of CCB	Avoid taking drug and eating this type of meal concurrently.
Nicardipine	High-fat meal	Taken together results in decreased AUC and C_{max} for CCB	Avoid taking drug and eating this type of meal concurrently.

Clinical Use and Dosing

Chronic Angina

Both type 1 and type 2 CCBs are effective in the treatment of stable and exertional angina (Table 16-7). They act on both sides of the supply–demand equation: peripheral vasodilation and negative inotropism reduce oxygen demand; dilation of coronary arteries increases oxygen supply.

Among the dihydropyridines, nifedipine, nicardipine, and amlodipine are drugs of choice. The long-acting form of nifedipine (Procardia XL) is the most often prescribed. Combining this drug with propranolol (Inderal), a BB, has proved more effective than either agent given alone, possibly because the BB suppresses the reflex tachycardia that may occur with type 2 CCBs.

Nicardipine is structurally similar to nifedipine but less likely to cause hypotension and LV dysfunction. It is useful for patients with angina who also have mild HF or borderline HTN. Amlodipine is well tolerated, with less venous pooling and minimum reflex tachycardia. It is safe to use for patients with significant ventricular dysfunction. Its long half-life means it acts like a sustained-release form. Although sustained-release forms of the other drugs cannot be crushed, amlodipine can be crushed so that patients who have difficulty in swallowing or who have nasogastric (NG) tubes can use this drug and still benefit from the reduced adverse effects associated with sustained release. The dose is 5 mg initially. Doses higher than 10 mg have not demonstrated any increase in benefit. Amlodipine has been used in combination with several BBs to produce improved response. The long-acting form of each of these drugs offers once-daily dosing, which improves adherence.

● CLINICAL PEARL ●

Amlodipine can be crushed and put down a nasogastric (NG) tube, which is not possible with sustained-release preparations. This provides the clinical advantage of allowing **amlodipine** to act as if it were sustained-release with less venous pooling, less reflex tachycardia, and once-daily dosing.

● CLINICAL PEARL ●

Constipation is especially common with **verapamil,** with almost 100% of patients experiencing significant issues. Patients taking this drug should be encouraged to increase the fiber in their diet and may need to use a stool softener.

Table 16–7 ⊗ **Dosage Schedule: Selected Calcium Channel Blockers**

Drug	Indication	Dosage Forms	Starting Dose	Maintenance Dose
Amlodipine (Norvasc) (G)	HTN *Peds:* Not recommended for children <6 yr of age	Tablets: 2.5, 5, 10 mg	5 mg daily *Children:* 2.5–5 mg	5–10 mg daily; titrate over 7–14 d *Max:* 10 mg daily
	Angina		5–10 mg	10 mg
Diltiazem (Cardizem) (G)	Angina	Tablets: 30; 60, 90, 120 mg	30 mg 4 times/d	Titrate dose 1–2 d, 12–320 mg in divided doses
Diltiazem CD (Cardizem CD; Cartia XT) (G)	Angina	Capsule (CD): 120, 180, 240, 300, 360 mg	120 mg daily	120–180 mg daily Titrate over 1–2 wk *Max*: 480 mg/d
	HTN		180 mg	180–240 mg/d titrate *Max*: 480 mg/d
Diltiazem ER (Cardizem LA) (G)	Angina	Capsules (ER): 60, 90, 120, 180, 240, 300 mg Tablets: All as above except no 60 mg	Tab: 180 mg/d Caps: 120 mg/d	Tab:120–320 mg/d titrate every 1–2 wk *Max*: 360 mg/d Caps: 120–320mg/d *Max*: 480 mg/d
	HTN		Caps: 180–240 mg/d or 60–120 mg twice daily Tabs: 180 mg/d	Tabs: 120–540 mg/d Caps:180–480 mg/d Adjust after 2 wk *Max*: 480 mg/d
Felodipine (Plendil) (G)	HTN	Tablets: 2.5, 5, 10 mg (G)	2.5 mg daily	2.5–5 mg daily *Max*: 20 mg/d
Isradipine (DynaCirc CR) (G)	HTN	Capsules: 2.5, 5 mg Tablets: 5, 10 mg	Caps: 2.5 mg q12h Tabs: 5 mg daily	Increase caps 2.5–5 mg every 2–4 wk; increase tabs 5 mg every 2–4 wk 2.5–5 mg q12h *Max*: 20 mg/d
			Cr 30–80 has only 45% bioavailability Cr <10 drops to 20%–50% bioavail.	
Nicardipine (Cardene) (G)	Angina	Capsules: 20, 30 mg	20 mg 3 times/d	60–120 mg/d Increase every 3 d *Max*: 120 mg/d
	HTN		20 mg 3 times/d	20–40 mg 3 times daily
Nicardipine SR (Cardene SR) (G)	HTN	Capsules (SR): 30, 45, 60 mg	30 mg q12h	Titrate up to 60 mg q12h *Max*: 120 mg/d
Nifedipine (Procardia) (G)	Angina	Cap:	10 mg 3 times/d	10–20 mg 3 times daily; spasm may require 20–30 mg 4 times daily *Max*: 180 mg/d
Nifedipine (Procardia XL; Adalat CC)	HTN	Tablets ER: 30, 60, 90 mg (only Adalat, Procardia)	30 or 60 mg daily	Max 9–120 mg/d
	Angina		30 or 60 mg	30–60 mg daily *Max*: 120 mg/d
Nislodipine (Sular) (G) Sular Geomatrix is not = to generic extended release	HTN	Tablets: 8.5, 17, 20, 25.5 mg 30, 34, 40 mg	Tabs: 20 mg daily	Increase by 10 mg per wk; range 10–40 mg daily *Max*: 60 mg

Table 16–7 🕸 **Dosage Schedule: Selected Calcium Channel Blockers—cont'd**

Drug	Indication	Dosage Forms	Starting Dose	Maintenance Dose
		GeoMatrix form: 8.5, 17, 25.5, 34 mg	GeoMatrix: 17 mg	Increase 8.5 mg weekly; range 17–34 mg *Max:* 34 mg
Verapamil (Calan) (G)	Angina	Immediate release oral tab: 40 (not Calan), 80, 120 mg	40–80 mg 3 times daily	80–160 mg 3 times daily *Max:* 480 mg/d
	HTN		80 mg 3 times/d	80–320 mg/d in 2 divided doses
	AFib rate control		240–480 mg/d in divided doses	Range 120–360 mg/d in divided doses
Verapamil SR (Calan SR) (G except SR Caplet	HTN	Caplet (Calan SR): 120, 180, 240 mg Capsule (Verelan): 120, 180, 240, 360 mg Tablet SR (Isoptin SR): 120, 180, 240 mg	120–180 mg daily in the a.m.	120–480 mg daily or q12h *Max:* 240 mg/twice daily of Calan SR and Isoptin SR *Max:* 480 mg Verelan
Verapamil ER (G except ER controlled onset)	Angina	ER: Capsule:120, 180, 240 mg Tablet: 120, 180, 240 mg Controlled onset: Capsule (Verelan PM): 100, 200, 300 mg Tablet (Covera HS): 180, 240 mg	180 mg at bedtime (Covera HS)	Increase in weekly intervals to 240 mg daily, then 360 mg *Max:* 480 mg/d
	HTN		180 mg at bedtime (Covera Hs) or 200 mg (Verelan PM)	Increase weekly doses *Max* dose of 480 mg (Covera HS) or 400 mg (Verelan PM)

(G) = generic; (B) = brand; (ER), (CD), (HS), (XL), (XT), and (XR) = extended release forms are not interchangeable even within same brand.
(SR) = sustained release; (CR) = controlled release.

Diltiazem, also effective in angina therapy, is less likely to cause hypotension and other adverse responses associated with peripheral vasodilation (reflex tachycardia) than nifedipine. It has less negative inotropic activity than verapamil. The reduction in average daily heart rate improves coronary artery filling time and myocardial oxygen supply. Diltiazem is a good choice for patients who need to reduce their heart rate. Verapamil is more often prescribed for treatment of arrhythmias because it has the most potent negative inotropic effect and significantly slows AV nodal conduction. It is not used for patients with compromised LV function, bradycardia, or AV block. Verapamil might be chosen for patients with supraventricular tachycardia who also have angina.

Vasospastic (Variant, Prinzmetal's) Angina

CCBs that produce more coronary artery vasodilation and reduce vasospasm are the drugs of choice. Diltiazem, long-acting nifedipine, and amlodipine are the most commonly used.

Unstable Angina

Medical therapy for unstable angina involves nitrates, BBs, and heparin, which are effective in controlling pain, and aspirin, which reduces mortality. When vasospasm is a component of this angina, CCBs may offer an additional treatment. There is insufficient evidence whether this addition decreases mortality. Verapamil is the CCB of choice. Type 2 CCBs are contraindicated because they tend to increase heart rate and have less vasospastic protection. Because verapamil is often given in combination with other drugs that lower BP, hypotension is a serious potential adverse response.

Hypertension

Initial drug therapy for HTN is monotherapy. Because ACEIs, ARBs, and diuretics have been shown to reduce cardiovascular morbidity and mortality in controlled trials, all are considered first-line medications in the new "JNC-8" guidelines (James et al, 2013). BBs are no longer used as first-line treatment for reducing BP. They are used in the post-MI population or added to the plan if the first-line drugs have proved ineffective.

The guidelines indicate black patients as a group are more responsive to diuretics and CCBs than they are to RAAS medications. CCBs are also indicated for both severe (BP greater than 160/110) and nonsevere hypertension (BP 140 to 159/90 to 109) in pregnancy. Nifedipine capsules and Peripheral Arterial Dilator drugs are useful for both disorders (ACOG, 2012). CCBs would also be appropriate for patients

with certain concomitant pathologies (such as unstable asthma) in which BBs are contraindicated.

Amlodipine is especially good for HTN patients with LV dysfunction and CHF. Long-acting nifedipine, diltiazem, or verapamil may be used for patients with CAD. Long-acting nifedipine is a good choice as well for patients who also have peripheral-vascular disease (PVD) because of its peripheral vasodilating effect. For all CCBs, older adults should be started on half the usual dose, and increases in dosage should be gradual to reduce adverse drug responses. (See Chap. 40 for further discussion.)

Supraventricular Tachycardia and Atrial Fibrillation

Type 1 CCBs are useful in treating selected supraventricular tachycardias because they slow AV nodal conduction. Verapamil (80 to 120 mg orally) can be used to terminate the rhythm. Conversion usually occurs in about 1 hour. Diltiazem (40 to 80 mg orally) can also be tried. Prophylaxis with verapamil (240 to 480 mg/d) is effective for patients with paroxysmal supraventricular tachycardia (PSVT). It is important to be certain that the rhythm is not ventricular; verapamil may worsen ventricular rhythm disturbances because of its negative inotropic effects. Verapamil is also used as an alternative to digoxin to slow a rapid ventricular response in the treatment of atrial fibrillation through its direct effect on the AV node, prolonging its refractory period and conduction time. Doses are similar to those used for PSVT. If it must be used concurrently with digoxin, then the digoxin level must be evaluated frequently because verapamil slows the clearance of digoxin and may increase the risk of toxicity.

Patients with Wolff–Parkinson–White (WPW) syndrome can have ventricular responses that are dangerously rapid. Drugs commonly used to control ventricular response such as diltiazem, verapamil, and digoxin are ineffective in this situation and can facilitate conduction through the accessory pathway, increasing the risk for ventricular fibrillation (ACCF/AHA, 2012). The move away from only pharmaceutical intervention and toward physiologic ablation methods has diminished the risks somewhat in this population. In cases of second- and third-degree block, drugs with the rate and conduction alterations are typically contraindicated.

Migraine Headache Prophylaxis

Migraine prophylaxis is an unlabeled indication for CCBs. Of patients with frequent migraines for whom CCBs are prescribed, 30% report a 30% reduction in migraines. The CCB used most often is verapamil (240 to 480 mg/d). To facilitate adherence, it is best to use the sustained-release form to permit once-daily dosing. The trial to determine effectiveness should last at least 3 months. Failure to give an adequate dose or an adequate trial time with a sustained-release form is a common reason for failure of migraine prophylaxis.

Raynaud's Syndrome

Raynaud's syndrome is also an unlabeled indication. Type 2 CCBs are the choice for this disorder because of their peripheral vasodilating effects and some platelet inhibition. The drug most studied and the first choice is long-acting nifedipine. The initial dose is 10 mg orally given in the office to assess the effect on BP. If the patient does not experience a drop in SBP more than 20 mm Hg below baseline or a drop below 90 mm Hg, then 10 mg orally 3 times daily is prescribed. The dose may be increased by 10 mg/d every 3 to 4 days to a maximum of 30 mg 3 times daily to achieve the desired effect. Monitoring every 2 to 4 months is necessary because the initial response may be transient. If nifedipine does not work, diltiazem may be tried, beginning at 30 mg given four doses daily and increasing every 3 to 4 days until a maximum of four 120 mg doses daily is reached. Felodipine and isradipine are also powerful vasodilators and may be tried. Raynaud's syndrome symptoms are often present only during exposure to cold temperatures. Drugs may be stopped during the summer months in some patients.

Esophageal Spasm

Although this is an unlabeled indication, CCBs may offer transient improvement for patients with mild spasm. Diltiazem (90 mg, four doses daily) has been used. Because this drug makes GERD worse, this disorder might cause a CCB to be discontinued.

Rational Drug Selection

Short-Acting Versus Long-Acting Forms

Short-acting forms of CCBs have been associated with more adverse drug reactions. In several trials, the short-acting form of nifedipine was associated with increased mortality in post-MI patients. All type 2 CCBs cause vasodilation that results in reflex tachycardia and peripheral pooling of blood. These actions are greatly reduced in the long-acting forms. To reduce adverse drug reactions and improve adherence, long-acting forms are suggested.

Cost

Branded CCBs are expensive; the generics are less so. Verapamil is the least costly, but its adverse reaction profile includes significant constipation in almost 100% of patients. Although this reaction can be mitigated by the concurrent prescription of a stool softener, the cost advantage is lost by the additional cost of the stool softener. The sustained-release forms of diltiazem are the most expensive CCBs and must be given twice daily. The remaining drugs fall between these two. Cost may be a factor in choosing to use a CCB, but it is not a major factor in choosing among them.

Indication

Specific drugs are more appropriate for specific indications previously discussed. Any CCB should be chosen with these indications clearly in mind.

Difficulty in Swallowing or Nasogastric Tube Placement

Only amlodipine can be crushed and mixed with food for patients who have difficulty swallowing; it can also be put down an NG tube. The longer half-life allows daily dosing.

Monitoring

Liver function should be evaluated prior to initiating therapy. Dosage reductions for most CCBs are recommended with severe hepatic impairment because of the extensive metabolism of these drugs by the liver. Monitoring HR, peripheral edema, and for HF symptoms is critical as well.

Patient Education

Administration

The drug should be taken exactly as prescribed, at the same time each day. Sustained-release drugs taken once daily are best taken in the morning for therapeutic effect. Missed doses should be taken as soon as remembered unless it is almost the time for the next dose. Doses should not be doubled. Sudden withdrawal may precipitate myocardial ischemia, so withdrawal is gradual. CCBs cannot relieve acute anginal attacks; they only have a role in prevention. For patients taking isradipine or nifedipine, anginal attacks sometimes occur 30 minutes after administration because of reflex tachycardia. This is usually temporary and not necessarily an indication for stopping the drug, but this symptom should be reported to the health-care provider who needs to consider if other therapy is warranted.

Several of the CCBs come in more than one form, from short-acting drugs requiring multiple doses daily to long-acting drugs with once-daily dosing (see Table 16-7). The patient has to read the label carefully and follow the appropriate dosing schedule. This is especially important if a different form or a different CCB is prescribed and patients have old bottles at home.

Some CCBs have food interactions, especially with high-fat or high-carbohydrate meals and with grapefruit juice. The patient should be informed so that the interactions can be avoided. Drug interactions also occur with some OTC and prescription drugs and with alcohol. CCB can be taken safely with calcium supplements; the extra calcium does not impair drug effect.

Adverse Reactions

Hypotensive reactions are the most common. Orthostatic precautions, such as changing position slowly, not exercising in hot weather, and keeping intake of noncaffeinated fluids above 2 L/d, will decrease these reactions. Patients who must limit their fluid intake must have a lower dose if hypotensive reactions occur. Bradycardia is also possible, especially for patients on type 2 CCBs. Patients should learn how to monitor their own pulse rate and contact the health-care provider if the rate is less than 50 beats per minute (bpm) or if they have irregular beats. HF symptoms such as dyspnea, pronounced dizziness, or nausea, or more than the usual swelling of hands, feet, or ankles and/or decreased urine output should generate provider contact because CCB can increase HF risk.

Preventive action is required to alleviate the expected constipation. The patient should increase dietary fiber and fluid (if allowed). Stool softeners are prescribed prophylactically with verapamil and as needed with other CCBs.

Lifestyle Management

See the section "Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers." The cautions about K+ do not pertain. Wearing protective clothing, using sunscreen, and other sun-smart measures will reduce photosensitivity reactions.

CARDIAC GLYCOSIDES

Cardiac glycosides (CGs) are among the oldest known drugs. They have been medically recognized in the treatment of HF since 1785. Although there are three main glycosides available, digoxin is by far the most commonly prescribed because of its convenient pharmacokinetics, the alternative routes of administration, and the techniques for monitoring its serum level. It has lost the preeminence it once held but is still a major cardiac medication.

Pharmacodynamics

Mechanical Effects on Heart Muscle

All CGs are strong and highly selective inhibitors of the sodium-potassium-adenosine triphosphatase (ATPase) system: the "sodium pump." The preferential binding of CGs to ATPase occurs following phosphorylation of the alpha subunit of the enzyme. Extracellular potassium promotes dephosphorylation of the enzyme and decreases the affinity of the enzyme for the CG. This may explain why increased extracellular potassium reverses some of the toxic effects of these drugs.

The sodium pump is the major determinant of the concentration of sodium in the cell. As shown in Figure 16-3, inhibition of this pump results in sodium and calcium buildup inside the cell. The combination of the changes in sodium and calcium results in increased velocity of the shortening of cardiac muscle, with a shift upward and to the left in the ventricular function curve, causing an increase in stroke work for a given filling volume or pressure (positive inotropism).

Electrical Effects on Heart Muscle

A mixture of direct and autonomic actions produces the electrical effects (negative chronotropism) seen with CGs. At therapeutic levels, CGs decrease automaticity and conduction velocity (negative dromotropism) through the AV node via central vagal stimulation and facilitation of muscarinic transmission at the cardiac muscle cell. Because cholinergic innervation is more prevalent in the atria, these actions affect atrial and AV nodal response more than in the Purkinje fibers or ventricular system.

Figure 16–3. Effects of digoxin on the sodium–potassium pump. The sodium pump is the major determinant of the concentration of sodium in the cell. Inhibition of this pump results in sodium buildup inside the cell. The resultant decrease in sodium gradient reduces the sodium–calcium transport mechanism, and calcium ions also increase inside the cell. The influx of sodium through voltage-gated channels is a major determinant in cardiac action potentials. This influx is reduced when the sodium gradient is decreased. Ultimately, contraction of cardiac muscle results from the interaction of calcium with the actin–myosin system. Reduced extracellular calcium levels decrease this contraction.
Other Effects

Several studies suggest that digoxin may also decrease plasma renin activity, reduce plasma norepinephrine levels, and restore baroreceptor sensitivity, all of which are factors in HF pathology. CGs affect all smooth excitable tissues, including smooth muscle and the CNS. These actions on other tissues explain many of their adverse responses.

Pharmacokinetics

Absorption and Distribution

Digoxin is well absorbed orally (Table 16-8). Taking digoxin with food, fiber, or after meals results in slower absorption. Approximately 10% of individuals have intestinal bacteria that inactivate digoxin in the gut, greatly reducing bioavailability and requiring higher-than-average doses to produce a therapeutic response. Treatment of these individuals with antibiotics can cause a sudden increase in bioavailability, which results in toxicity. Product formulation may also be a factor in bioavailability. Generic tablet preparations have a bioavailability of 70% to 80%; the bioavailability is 90% to 100% for digoxin elixir and encapsulated gel. The narrow safety margin between therapeutic effect, loss of effect, and toxicity means that even small variations in bioavailability can have serious consequences. It is best to prescribe using the same manufacturer.

Once absorbed, CGs are widely distributed to tissues, including the CNS. Digoxin's volume of distribution is large (4 to 7 L/kg) and dependent on plasma protein-binding capacity. Its highest tissue concentration (10 to 50 times that in plasma) is found in the heart, kidney, and liver. Digoxin crosses the placenta, and drug levels in maternal and umbilical vein blood are similar. The principal tissue reservoir is skeletal muscle, so dosing is based on lean muscle mass. Neonates and infants require higher doses to achieve a therapeutic effect than do older children and adults. When skeletal mass reduces with cachexia or advancing age, dose adjustments are needed.

Metabolism and Excretion

Digoxin is not extensively metabolized and is excreted largely unchanged by the kidneys. Its half-life is 36 to 48 hours with

Table 16–8 ⊞ Pharmacokinetics: Cardiac Glycosides

Drug	Onset	Peak	Duration	Protein Binding	Oral Bioavailability	Half-Life	Time to Steady State	Volume of Distribution	Elimination
Digoxin	1–2 h	6–8 h	2–4 d	20%–40%	Tablets: 60%–80% Capsules: 90%–100% Elixir: 75%–85%	NRF: 36–48 h IRF: prolonged	1 wk or 4 doses	6.3 L/kg	Unchanged PO by kidney
Digoxin IM	30 min	4–6 h	2–4 d	20%–40%	50%–75%	NRF: 36–48 h IRF: prolonged	1 wk or 4 doses	6.3 L/kg	Unchanged by kidney

NRF = normal renal function; IRF = impaired renal function.

normal renal function. In the absence of oral or IV loading doses, steady state is achieved in about four half-lives or 1 week. Its clearance rate is proportional to the GFR. For patients with elevated serum creatinine levels, drug clearance closely parallels creatinine clearance. Improvement in cardiac output and renal blood flow through therapy with digoxin or other agents may increase renal digoxin clearance and require dosage adjustments. Several drugs (most notably quinidine, amiodarone, verapamil, and diltiazem) reduce clearance and can double the serum concentration, resulting in toxicity unless the dose of digoxin is reduced when those medications are introduced.

Pharmacotherapeutics

Precautions and Contraindications

CGs are contraindicated in AV blocks and uncontrolled ventricular arrhythmias because their action on the AV node may worsen the arrhythmia. They are used for rate control only after BB; verapamil or diltiazem cannot be used or are inadequate to achieve the desired rate range. Patients with idiopathic hypertrophic subaortic stenosis (IHSS) may develop worsening outflow tract obstruction with CG use owing to the action on myocardial contractility. CG use in cor pulmonale is questionable. Toxicity risk increases in the presence of hypoxia from any cause.

Because digoxin is excreted essentially unchanged by the kidneys, severe renal impairment effectively contraindicates its use. Patients with chronic kidney disease (CKD) have very labile creatinine levels, which can be easily disturbed, so it becomes very difficult to monitor these patients in primary care without frequent visits and constant lab testing. Hypothyroidism and CKD decrease digoxin's volume of distribution, necessitating a decrease in both loading and maintenance doses. Digoxin may be used safely in renal impairment as long as necessary dosage adjustments are made.

CGs are used cautiously for patients with electrolyte abnormalities because the concentrations of potassium, calcium, and magnesium in the extracellular compartment affect sensitivity to CGs and may result in toxicity. Digoxin may exacerbate atrial fibrillation due to WPW syndrome by facilitating conduction through the bypass tract and shortening its refractory period. It should not be used to treat this disorder (ACCF/AHA, 2012).

Because 20% to 30% of digoxin is bound to plasma proteins, diseases that lower serum albumin may require alterations in loading doses. Older adults are particularly at risk for toxic effects because of protein levels and chronically altered renal clearance; they require slower digitalization and careful monitoring. Most of the time loading doses are safely eliminated in this group.

Digoxin is a Pregnancy Category C drug. Although safety has not been formally established, digoxin has been used for many years without adverse effects to the fetus. The volume of distribution (Vd) of this drug, however, suggests that it will use fetal tissue as a distribution site. Blood volume also changes throughout pregnancy, and this may affect both maternal and fetal levels of digoxin. Blood levels should be monitored carefully during this time to avoid toxicity. Pregnant women who require digoxin are best managed by a specialist. Concentrations of digoxin in the mother's serum and milk are similar. However, the actual amount of drug the infant gets while nursing is relatively small, so no pharmacological effect is usually seen in the infant. Nonetheless, care should be taken in this case.

Newborns and premature and immature infants are particularly sensitive to the effects of digoxin. There are children's doses for this drug, but they must be highly individualized. Consultation or referral is suggested in these instances.

Adverse Drug Reactions

The GI tract is the most common site of adverse drug reactions, including anorexia, nausea, vomiting, and diarrhea. These result from CNS actions, including chemoreceptor trigger zone stimulation. Other CNS-based adverse responses include fatigue, disorientation, and hallucinations, especially in older adults, and visual disturbances, including yellow vision and green halos around lights. The visual disturbances are considered classic signs of toxicity but actually occur rarely. Atrial arrhythmias and atrial tachycardia with AV block are the most common signs of toxicity in children. Cardiac adverse reactions are extensions of the therapeutic action of these drugs (bradycardia, junctional and AV block arrhythmias, premature ventricular contractions [PVCs], and bigeminy). Gynecomastia is a rare adverse reaction.

Toxicity

Toxicity typically occurs with serum levels greater than 2 ng/mL. Toxicity is commonly caused by excessive administration of a CG, too much diuresis resulting in hypokalemia, concurrent development of renal insufficiency, or by administration of drugs that interfere with excretion of digoxin (see the section "Drug Interactions"). This is especially common in older adults who have polypharmacy changes. Each of these common etiologies and the patient's calcium and magnesium levels should be considered in the differential diagnosis.

Diagnosis of toxicity is based on both clinical and laboratory data. Serum levels alone are insufficient to diagnose toxicity. Patient tolerance plus cardiac output and vital sign outcomes are important considerations to determine if individuals actually need levels above or below common ranges. Providers are cautioned that a faster heart rate in a patient previously controlled on a CG may be a sign of toxicity, not the need for increasing the dose! Incorrect timing of lab draws can be a factor (see the Monitoring section for times to draw serum levels). Toxicity is an important differential diagnosis of arrhythmias and neurological and GI symptoms for patients taking CGs.

Treatment of toxicity depends on the problem. AV junctional and first-degree block rhythms, ventricular ectopic beats, or an excessively slow ventricular response to atrial fibrillation often requires CG dosage adjustment and careful monitoring. Potassium administration should be considered to reduce automaticity, even when serum potassium is in the normal range, unless a high-grade AV block is also present. Lidocaine has minimum effects on the AV node and may be used to treat ventricular ectopic beats that threaten hemodynamics. Bradycardia and second- or third-degree AV block usually respond to atropine. When toxicity is severe or life-threatening, the antidote for CG toxicity is antidigoxin immunotherapy, digoxin immune fab (Digibind). Patients who require this medication are hospitalized so that cardiopulmonary resuscitation equipment and medications are available when it is administered. A short holding of the next dose or two may be sufficient to return to normal values without using Digibind.

Any patient who becomes toxic on a CG should have the indications for that drug carefully reviewed. In some cases, it is possible to stop the drug altogether. There is new recognition that women fare worse on CG, so as a group they should be evaluated for treatment with other meds. Several studies, however, have shown negative consequences for withdrawal of digoxin, so the decision should be carefully made in consultation with cardiology.

Drug Interactions

Any drug that may cause hypokalemia, hypercalcemia, or hypomagnesemia increases the risk of toxicity. Several antiarrhythmic drugs (quinidine, amiodarone, verapamil, diltiazem, and propafenone) increase serum CG levels and toxicity risk. Drugs that induce bradycardia can exhibit additive bradycardia when given with CGs. This is especially a concern with BBs.

Interactions with Potassium, Calcium, and Magnesium

Potassium and CGs interact by inhibiting each other's binding to sodium-potassium-ATPase. Hyperkalemia reduces the enzyme-inhibiting actions of CGs, and hypokalemia facilitates these actions. Hyperkalemia, however, inhibits the abnormal cardiac automaticity seen in excessive doses of CGs so that moderately increased extracellular potassium reduces toxic effects of CGs. Calcium facilitates the toxic actions of CGs by overloading the intracellular calcium stores. Hypercalcemia increases the risk of CG-induced arrhythmias. Magnesium has the opposite effects to calcium. Hypomagnesemia is a risk factor for arrhythmias. Specific drug interactions and the appropriate actions to prevent them are given in Table 16-9.

Table 16–9 ⊞ Drug Interactions: Cardiac Glycosides

Drug	Interacting Drug	Possible Effect	Implications
CGs	Phenobarbital, phenytoin, rifampin	Decreases the effect of digoxin	Increase dose of digoxin or change to digoxin
	Thiazide and loop diuretics, mezlocillin, piperacillin, ticarcillin, amphotericin B, glucocorticoids	May cause hypokalemia and increase risk of CG toxicity	Monitor serum potassium levels and teach patient signs and symptoms of hypokalemia to monitor for and report. Administer potassium supplement prn and encourage diet high in potassium. Where possible, choose alternative drug, especially antibiotic.
	Calcium preparations	Facilitates toxicity by accelerating overloading of intracellular calcium stores	Monitor for indications of toxicity. Avoid concurrent administration. Separate administration of CG and milk intake by at least 30 min.
	Spironolactone	Increases digoxin half-life	Reduce dose of digoxin or increase dosing interval
	Beta-adrenergic blockers, quinidine, disopyramide	Additive bradycardia	Avoid concurrent use or teach patient to monitor pulse rate and report pulse <60 bpm. Monitor electrocardiogram (ECG) regularly.
	Antacids, colestipol, kaolin pectin, cholestyramine	Decreases absorption of CG if given concurrently	Separate administration by at least 1 h and give CG first
	Thyroid hormones	May decrease therapeutic effects and cause arrhythmias	Monitor for effectiveness. Monitor ECG at regular intervals.

Continued

Table 16–9 ⠿ Drug Interactions: Cardiac Glycosides—cont'd

Drug	Interacting Drug	Possible Effect	Implications
Digoxin	Quinidine, cyclosporine, amiodarone, verapamil, diltiazem, propafenone, diflunisal	Increases serum levels of digitalis and risk of toxicity	Avoid concurrent use or monitor serum levels 5–7 d after adding one of these drugs. Consider reducing digitalis dose by half if patient has signs of toxicity or a high normal digitalis level at initiation of interacting drug.
	Aminoglycosides (oral), colestipol, rifampin, St. John's wort, sulfasalazine	Decreases digitalis serum levels	Avoid concomitant use
	Benzodiazepines, clarithromycin, diphenoxylate, erythromycin, indomethasone, itraconazole, tetracycline, verapamil	Increases serum levels of digitalis and risk of toxicity	Avoid concurrent use or monitor serum levels 5–7 d after adding one of these drugs. Consider reducing digitalis dose by half if patient has signs of toxicity or a high normal digitalis level at initiation of interacting drug.
	Calcium channel blockers	Additive effects on AV node may result in complete heart block	Monitor patient carefully if both are chosen with HF
Food Interactions	High-bran meal	Taking with this meal results in reduced absorption of digitalis	Take 30 min prior to meal

Clinical Use and Dosing

Atrial Fibrillation, Paroxysmal Supraventricular Tachycardia

Asymptomatic or mildly symptomatic patients with a rapid ventricular response can be treated with a CG. Treatment is aimed at slowing the rate and converting to sinus rhythm if possible. The goal is a resting ventricular rate between 70 and 80 bpm (Table 16-10). Digoxin is preferred because it slows AV nodal conduction, resulting in a slower ventricular rate. It does not convert the rhythm directly. Slowing heart rate yields greater diastolic filling time, permitting improved myocardial oxygenation. Cardiac muscle with an improved supply-demand ratio may then return to sinus rhythm. Digoxin is less effective at slowing heart rate when vagal tone is low and adrenergic stimulation is high, such as during exercise, and in maintaining sinus rhythm or reducing the incidence of PSVT. Additional antiarrhythmic drugs may be needed.

Table 16–10 ⊗ Dosage Schedule: Cardiac Glycosides

Drug Form	Indication	Patient Status	Digitalizing or Loading Dose	Maintenance
Digoxin (G)	Atrial fibrillation with ventricular response <120 bpm or stable CHF	Young adult or normal renal function	None	0.25–0.5 mg/d for atrial fibrillation; 0.25 mg/d for CHF
		Older adult or impaired renal function	None	0.125 mg/d
	Atrial fibrillation with ventricular response 120–150 bpm or less stable CHF	Young adult or normal renal function	1–1.5 mg/d in 4 divided doses 6 h apart	0.25–0.5 mg/d for atrial fibrillation; 0.25 mg/d for CHF
		Older adult or impaired renal function	If creatinine clearance <20 mL/min, give half the loading dose in 4 divided doses 6 h apart	0.125 mg/d
	Atrial fibrillation with rapid ventricular response or heart failure	Adult with normal renal function	0.75–1.25 mg (10–15 mcg/kg) given as 50% of dose initially and additional fractions at 4–8 h intervals	0.063–0.5 mg/d as tablets or 0.035–0.5 mg/d as gelatin capsules. Dose is based on lean body mass and Ccr.* Usual dose is 0.25 mg/d in morning.

Table 16–10 🔀 **Dosage Schedule: Cardiac Glycosides—cont'd**

Drug Form	Indication	Patient Status	Digitalizing or Loading Dose	Maintenance
		Older adult or impaired renal function	Same as adult	Same calculation. Usual dose is 0.125 mg in morning.
		Children with normal renal function based on lean body weight: 2–5 yr	25–35 mcg/kg given as 50% of dose initially and additional fractions at 4–8 h intervals	25%–35% of digitalizing dose given daily in 2 divided doses
		5–10 yr	15–30 mcg/kg given as above	Same as above
		>10 yr	8–12 mcg/kg given as above	Same as above except in single dose
Digoxin (elixir50 mcg/mL)	Heart failure	Children with normal renal function based on lean body weight: Premature infant Full-term 1–24 mo 2–5 yr 5–10 yr >10 yr	20–30 mcg/kg given as 50% of dose initially and additional fractions at 4–8 h intervals 25–35 mcg/kg given as above 35–60 mcg/kg given as above 30–40 mcg/kg given as above 20–35 mcg/kg given as above 10–15 mcg/kg given as above	20%–30% of oral digitalizing dose given daily in 2 divided doses 25%–35% of oral digitalizing dose for full term to >10 yr All in 2 divided doses except for >10 yr

Oral tablet forms: 0.125 mcg = 125 mg; 0.25 mcg = 250 mg; capsules: 0.05 mg, 0.1 mg, 0.2 mg. Also available tablets of 0.625 mg and 0.1875mg.
*Maintenance dose = loading dose × (14 + Ccr/5). Ccr should be corrected to 70 kg body weight.
Therapeutic serum level of digoxin: atrial fibrillation, 1.5–2 ng/mL; CHF, 0.8–1.2 ng/mL.

Digoxin is classically presented as a medication requiring loading dose schedules. For elders and mildly symptomatic patients, a loading dose is rarely required. Treatment is started with a maintenance dose if the ventricular response is less than 120 bpm. For young patients and those with normal renal function, the maintenance dose is 0.25 mg to 0.5 mg daily. For older adults and those with renal impairment, the maintenance dose is 0.125 mg daily. Drug levels may be drawn at steady state (5 to 7 days), but the best indication of appropriate dosing is an acceptable heart rate.

If the ventricular rate is 120 to 150 bpm and still well tolerated, outpatient digitalization with an oral loading dose is reasonable. The dose is 10 to 15 mcg/kg in divided doses over 24 hours. The usual pattern is 50% of the total digitalizing dose and the remainder in divided doses over 4 to 8 hours. If creatinine clearance is less than 20 mL/min, give one-half the loading dose and start with 0.125 mg daily for maintenance. Patients who are not hemodynamically stable require rapid digitalization in a hospital.

Heart Failure

Although no longer the first-line drug for treatment of HF, digoxin is still central to treatment for patients with severe systolic dysfunction (ejection fractions less than 40% and with an audible S_3 heart sound). In fact, the resolution of S_3 is a potent predictor of response to CG therapy. The primary mechanism of action in HF is through its positive inotropic action, increasing ejection fraction at a given preload and afterload. Digoxin is also beneficial in HF resulting from uncontrolled HTN or severe aortic stenosis, although BP reduction and valve surgery are the mainstays of therapy in these disorders. CGs are less beneficial with ejection fractions more than 40% or in HF secondary to hypertrophic cardiomyopathies. They have no benefit in HF due to recurrent transient ischemia. An adequately digitalized HF patient has a serum level of 0.8 to 1.2 ng/mL, lower than that needed to treat atrial fibrillation, because it is only add-on therapy.

The American College of Cardiology/American Heart Association (ACCF/AHA, 2009) and ICSI (2011b) guidelines suggest that patients with mild-to-moderate HF often become asymptomatic on optimal doses of ACEIs and diuretics and usually do not require digoxin. It is added only after ACE/ARB and diruetics are already on board. For less stable patients, the treatment regimen includes a digoxin loading dose similar to that used to treat atrial fibrillation and a usual maintenance dose of 0.25 to 0.5 mg/d. (See Chap. 36 for further discussion.)

Rational Drug Selection

Formulation

Digoxin is well absorbed orally, with a bioavailability of 60% to 80% for tablets. Digoxin elixir in capsules and encapsulated gel form (Lanoxicaps) has a 90% to 100% bioavailability and may be useful when careful titration of the dose is important. Pediatric elixir has a bioavailability of 70% to 85%. Tablets are not generally used for children, but children's digitalizing and maintenance doses are provided for both the capsule and the elixir (see Table 16-10).

Brand and Cost

The best choice of CG is the purified glycoside, digoxin. It is well absorbed, can be used parenterally if needed, and has an intermediate duration of action, with a half-life of 36 to 48 hours. Even in the presence of renal failure, it can be used

if the dose is adjusted. Digoxin is available in a generic form that reduces the cost. Using the same generic manufacturer will reduce the impact of FDA allowable variance in bioavailability for generics.

Monitoring

Routine monitoring of digoxin levels is generally overdone. Monitoring should occur in addition to clinical judgment, rather than as a substitute for it. In general, testing should be done when any of the following occurs:

1. The patient is taking other drugs that may alter the pharmacokinetics of digoxin.
2. Steady state has been achieved (4 to 5 half-lives or 1 to 2 weeks) after starting a new dose.
3. Toxicity is suspected.
4. Confirmation of adequacy of maintenance dose is needed in situations of poor therapeutic response or patient adherence.
5. A reference point is needed in adjusting a dose.
6. The patient has progressive renal function decline.

To avoid sampling during the distribution phase of the drug response curve, levels should be drawn at least 6 hours after the last dose. Because of their critical role in sensitivity to toxicity, serum electrolytes (potassium, calcium, magnesium) and renal status should be monitored concurrently, especially for patients who are also taking diuretics. Levels should be evaluated periodically and prior to any dosage change.

Patient Education

Administration

The patient should take the drug exactly as prescribed, at the same time each day. The long half-life means that taking it at different times each day would be permissible, but the narrow therapeutic range means that missing a dose or doubling a dose could result in toxicity. Taking the drug at the same time each day lessens the likelihood of nonadherence to the appropriate regimen. When the drug is prescribed on an eccentric schedule (e.g., 0.25 mg Monday, Wednesday, Friday and 0.125 mg Tuesday, Thursday, Saturday, Sunday), taking a dose at the same time each day reduces the complexity of the schedule. Placing the appropriate dose in a pill container with compartments for each day of the week also reduces the chance of nonadherence and dosing mishap. If one dose is missed but remembered within 12 hours, it should be taken. If two doses are missed, the health-care provider should be contacted for instructions. The drug should not be stopped or the dosage altered without first contacting the health-care provider.

Although the presence of food in the gut does not alter absorption of CGs, the ingestion of a high-fiber meal may decrease absorption. Tablets can be crushed and administered with food for patients who have difficulty swallowing. Patients should eat a diet high in potassium (bananas, orange juice, tomato juice, spinach, melons, dates, raisins, soybeans, prunes, potatoes, and molasses), unless also taking a potassium-sparing diuretic or an ACEI, and eat moderate amounts of calcium (800 to 1,000 mg/d). Milk may have some effect on absorption, so doses should be separated by 1 hour.

> ### CLINICAL PEARL
>
> **Heart failure treatment**
> 1. CGs should not be used unless there is clear evidence of severe chronic systolic dysfunction or atrial fibrillation. In older adults, ankle edema is more often due to venous insufficiency than to heart failure. Even if it is related to heart failure, it is more often caused by diastolic dysfunction and better treated with diuretics or ACEIs.
> 2. Digoxin should not be discontinued unless a reversible cause of the heart failure has been completely corrected or there was no basis for the drug in the first place.
> 3. ST-T wave changes on the ECG do not correlate directly with serum drug levels and should not be used as an indication of toxicity. Serum drug levels are needed.

Do not alternate between dosage forms (see Table 16-10) such as liquids and capsules. Each form has a different bioavailability, and changing forms may result in toxicity. Store the drug in its original, tightly covered, light-resistant container. The patient who uses a pillbox for weekly dosing should not mix the digoxin with other drugs in the same compartment. Drugs often look alike and can be mistaken for one another. This allows for easier withholding of a dose if the HR is too low. Patients should also avoid concurrent use of OTC drugs and should not take antacids or antidiarrheal drugs within 1 hour of taking the CG.

Adverse Reactions

Patients should learn to take their own carotid pulse and then contact the health-care provider before taking the drug if the pulse rate is less than 60 or more than 100 bpm. Relying on a peripheral pulse counter may not accurately identify a pulse deficit. This may trigger an inaccurate withholding of a dose due to a low reading when dosing was still indicated.

Patients are also typically educated on signs and symptoms of toxicity, including nausea, vomiting, diarrhea, confusion, irregular pulse, yellow vision, and green halos around lights. Pulse changes and these symptoms should be reported to the health-care provider immediately. Some patients can tolerate pulses as low as 50 bpm without other symptoms and can be taught mainly to report symptoms of worsening HF. These signs and symptoms include persistent cough; shortness of breath; weight gain of more than 2 lb in 1 day or 5 lb in one week; swelling of ankles, legs, or hands; and a sensation of fullness in the abdomen. Follow-up appointments are also critical to evaluate the effectiveness of these drugs and to monitor for toxicity.

Lifestyle Management

A cardiac-healthy lifestyle is discussed in the drug class sections above. At all times, patients should carry identification or wear a medical information bracelet or necklace that describes the disease process and drug regimen.

ANTIARRHYTHMICS

Cardiac rhythm disturbances can range from benign and asymptomatic to malignant and life-threatening. For some arrhythmias, definitive drug therapy has research support; for others, selection of a specific drug is largely based on expert opinion, adverse responses, potential interactions with other drugs being taken, and concurrent clinical problems. Antiarrhythmic drugs are understood to be pro-arrhythmic; they can paradoxically correct one issue, but then cause another lethal arrhythmia. Deciding not to treat may be a better choice, especially in asymptomatic or minimally symptomatic patients.

Debate continues about the relative merits of invasive versus noninvasive testing to assist in the selection of a specific antiarrhythmic. Given these variables, it is best to refer to a cardiologist any patients with new rhythm disturbances or for whom rhythm control is difficult. When the drug is chosen by the specialist, management in the primary care setting requires understanding both the beneficial effects and the adverse effects of these drugs, the monitoring required, and appropriate patient education. The six classes of antiarrhythmics are discussed here with that management approach in mind. To be practical in a primary care setting, the drug must be available in oral form and have an effective half-life of at least 6 hours. Drugs that do not meet these criteria are not discussed.

Pharmacodynamics

Arrhythmias are caused either by abnormal pacemaker activity or by abnormal impulse conduction. The goal of therapy with an antiarrhythmic is to reduce ectopic pacemaker activity or alter abnormal conduction. The major mechanisms by which antiarrhythmics act to do this are (1) sodium channel blockade, (2) blockade of sympathetic nervous system (SNS) effects on the heart, (3) prolongation of the effective refractory period, and (4) blockade of the calcium channel. Different classes of antiarrhythmics act in one or more of these ways. Drugs in one class may have significant actions more commonly associated with a different class. Placement in a given class is based on predominant action.

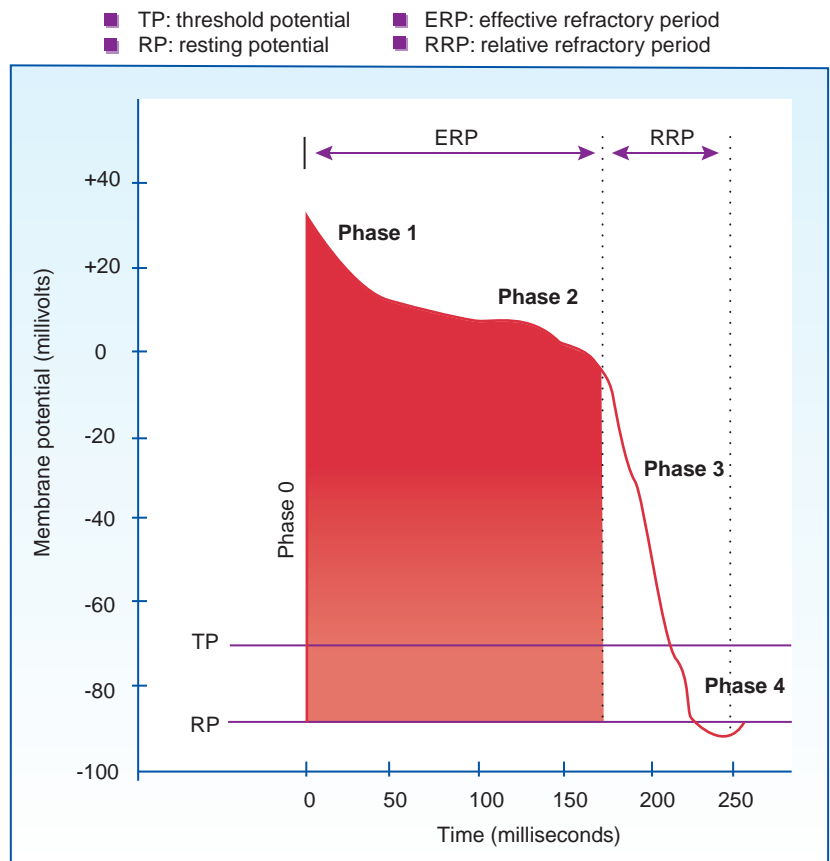
All pacemakers in the heart, normal and ectopic, depend on appropriate phase 4 diastolic depolarization. Increasing the phase 4 slope may result in accelerated pacemaker discharge. Figure 16-4 depicts the cardiac action potential with slope phases. Potential causes of this increased slope include hypokalemia, beta-adrenergic stimulation, fiber stretch, acidosis, and partial depolarization by currents of injury. Blockade of sodium channels (class I drugs) or calcium channels (class IV) reduces the permeability ratio of these ions to potassium, making the threshold more negative and reducing the phase 4 slope. BBs (class II) indirectly reduce the slope by blocking the chronotropic impact of


Figure 16–4. Cardiac action potential: ventricles.

norepinephrine. Hyperkalemia raises the membrane potential, which reduces the rate of pacemaker firing. Vagal discharge also reduces phase 4 slope and makes the potential more negative (CG activity).

Disturbances in impulse conduction are either (1) simple blocks related to depressed conduction that may be relieved by the parasympathetic action of atropine or (2) reentry conduction, in which one impulse excites areas of the heart more than once. Reentry requires (1) an obstacle to normal conduction, (2) a unidirectional block in the circuit, and (3) conduction flow around the circuit timed so that the impulse does not enter refractory tissue. Too slow an impulse results in bidirectional block or the impulse colliding with the next normal impulse; too fast results in bidirectional conduction or the impulse reaching tissue that is still refractory. Slowing conduction by depressing the sodium current (class I) or calcium current (class IV) abolishes reentry arrhythmias. Lengthening or shortening the refractory period also makes reentry less likely. Converting unidirectional block to bidirectional block (class III) also decreases reentry. See Table 16-11 for the mechanism of action.

Safer antiarrhythmics act more on cardiac tissue being abnormally stimulated than on normal cardiac tissue. These drugs decrease the automaticity of ectopic pacemakers more than the SA node, and they reduce conduction or increase the refractory period more in depolarized tissue than in normally polarized tissue.

Class I

Class I antiarrhythmic drugs are sodium channel blockers. Class IA lengthens the duration of the action potential, class IB shortens it, and class IC has no effect or may minimally increase the duration of the action potential. Class IB interacts rapidly with sodium channels, class IC acts slowly, and class IA is intermediate.

Class IA drugs reduce the rate of firing of ectopic foci, increase the effective refractory period (ERP), and reduce the speed of conduction. They also block parasympathetic nervous discharge, resulting in an increased conduction rate at the AV node. This anticholinergic activity can produce serious increases in ventricular rate in the presence of rapid atrial activity, such as that found in atrial fibrillation. Class IB drugs block both activated and inactivated sodium channels. The effect is extremely limited in normally polarized tissue but highly effective in depolarized and injured tissue. Class IB drugs do not affect the automaticity of the SA node or conductivity through the AV node. Their shortening effect on the ERP eliminates unidirectional block and may trigger reentry arrhythmias. Class IC drugs primarily block the sodium fast channel during phase 0 of the action potential. Because of their propensity for severe exacerbation of arrhythmias, even in normal doses with post-MI patients, they are reserved for patients with severe ventricular tachycardias for whom other drugs have not worked.

Class II

Class II drugs (BBs) reduce adrenergic activity in the heart. Blockade by these drugs increases threshold potential and prolongs ERP, thereby decreasing heart rate and conduction velocity. These effects probably convert unidirectional block to bidirectional. They also exert a significant negative inotropic effect, reducing force of contraction. This class includes beta$_1$ selective drugs that act mainly on cardiac muscle and nonselective beta$_1$ and beta$_2$ drugs that also act on lung, arteriole, pancreatic, kidney, adipose, and liver tissues, resulting in a range of adverse responses. BBs are also discussed in Chapters 14 and 40.

Class III

Class III drugs prolong the ERP by some mechanism other than sodium channel blockade, often by blocking potassium

Table 16–11 Mechanism of Action of Selected Antiarrhythmics

Drug	Effect on Sinoatrial Rate	Effect on Atrioventricular Node Refractory Period	Effect on PR Interval	Effect on QRS Duration	Effect on QT Interval	Sinoatrial Node Automaticity
Amiodarone	−	+	+	+	++	−
Disopyramide	± (2)	± (2)	± (2)	+	++	±
Flecainide	0	0	+	++	0	−
Mexiletine	0 (1)	±	0	0	0	−
Procainamide	±	± (2)	± (2)	+	+	±
Propafenone	0	+	+	+	0	0
Quinidine	± (2)	± (2)	± (2)	+	+	±
Sotalol	−	++	++	0	++	−
Tocainide	0 (1)	−	0	0	0	0/−

− = suppresses or slows; + = stimulates or increases speed or duration; (1) = may suppress diseased sinus nodes; (2) = anticholinergic effect and direct depressant action.

channels, which results in a decreased rate of automaticity of ventricular ectopic beats. They may also convert unidirectional block to bidirectional block in reentry arrhythmias but have little effect on depolarization. Most of the drugs in this class have significant actions associated with other classes.

Class IV

CCBs constitute class IV. They were discussed in more detail, including their role in arrhythmia management, earlier in this chapter. They are good for rate control, increasing O₂ supply via vasodilation and afterload reduction. The reduced workload helps depress abnormal function.

Pharmacokinetics

Absorption and Distribution

All classes of antiarrhythmics are well absorbed orally, with sustained-release forms and amiodarone (Cordarone) having slower absorption times (Table 16-12). Bioavailabilities vary greatly depending on protein binding, with propafenone (Rhythmol) having the lowest at 3% bioavailability, with 97% protein binding, and sotalol (Betapace) having the highest (90%), with no protein binding. The presence of food in the gut does not negatively affect bioavailability except for sotalol; food may reduce its absorption by as much as 20%. Fatty food increases dronedarone availability.

Distribution is to most body tissues. Amiodarone exhibits high levels of drug in fat, muscle, lung, and spleen tissues. Cardiac tissue concentration is about 30 times higher than plasma concentration. Amiodarone and quinidine easily cross the placenta. Quinidine and sotalol are found in breast milk, and mexiletine (Mexitil) is found in breast milk in concentrations similar to those found in plasma.

Metabolism and Excretion

All antiarrhythmics are metabolized by the liver. Half-lives of these drugs vary from 3 to 4 hours for procainamide to 26 or more days for amiodarone. As the only short-acting

Table 16–12 ✂ **Pharmacokinetics: Selected Antiarrhythmics**

Drug	Onset	Peak	Duration	Bioavailability	Protein Binding	Half-Life	Active Metabolite	Elimination
Amiodarone	1–3 wk	UK	wk–mo	35%–65%	95%	26–107 d	Yes (DEA)	99% in bile
Dronedarone	UK	3–6 h	UK	98%	4% w food; 15% high-fat	13–19 h	Yes (1/10th) potency	Feces 84%; urine 6%
Flecainide	Days	d–wk	12 h	>80%	40%	20 h	No	30% unchanged in urine
Mexiletine	0.5–2 h	2–3 h	8–12 h	>80%	60%–75%	12 h	No	10% unchanged in urine
Propafenone	UK	4–5 d	UK	3%–11%	97%	7 h (90% of patients); 10–32 h in slow metabolizers (10%)	Yes	<1% excreted unchanged
Quinidine PO (sulfate)	0.5 h	1–1.5 h	6–8 h		80%	6–8 h; increased in CHF and severe liver impairment	Yes	20% unchanged in urine; urinary excretion enhanced in acid urine
Quinidine PO (sulfate-ER)	0.5 h	4 h	8–12 h		80%	6–8 h; increased in CHF and severe liver impairment	Yes	20% unchanged in urine; urinary excretion enhanced in acid urine
Quinidine PO (gluconate)	0.5 h	3–5 h	6–8 h		80%	6–8 h; increased in CHF and severe liver impairment	Yes	20%% unchanged in urine; urinary excretion enhanced in acid urine
Sotalol	Hours	2–3 d	UK	90%	Not bound	7–12 h	No	90% unchanged in urine

UK = unknown; CHF = congestive heart failure.
   Class II (beta blockers) are covered in Chapter 14; class IV (CCBs) are covered earlier in this chapter.

antiarrhythmic, procainamide requires frequent dosing administration, with steady state achieved in 2 to 3 days. Other antiarrhythmics have longer half-lives and require more time to achieve steady state. Hepatic impairment increases half-life in those drugs eliminated totally or partially in feces. Renal impairment significantly increases half-life in those drugs eliminated all or largely in the urine. Reduced dosages of procainamide and quinidine are required for patients with CHF or renal impairment that decreases volumes of distribution of these drugs. Many cardiac patients who need antiarrythmics have either decreased systolic function or renal impairment. Because of these concerns, quinidine and procainamide are infrequently used for such patients. Approximately 10% of patients are slow metabolizers of propafenone, resulting in an increase in half-life from 7 hours to 10 to 32 hours. Because this drug has been associated with proarrhythmia and increased mortality post-MI, the trend is away from its use.

Pharmacotherapeutics

Precautions and Contraindications

Because their mechanisms of action differ, the various classes also have different precautions and contraindications.

Class IA

Antimuscarinic actions in the heart common to this class inhibit vagal effects and may lead to increased sinus rate and AV conduction. Use cautiously for patients with cardiac problems for whom increased heart rate might worsen the condition. Quinidine comes in a gluconate and sulfate form that has different dosing regimens.

Class IB

Use cautiously for patients with HF related to the potential for hypotension secondary to decreased myocardial contractility. This occurs mainly with large doses and in fewer than 10% of patients. The major extra cardiac adverse effects of these drugs are neurological and occur most frequently in older adults, so patients with neurological conditions and older adults should be carefully monitored for these adverse responses.

Class IC

No muscarinic effects are present with this class, but severe exacerbations of arrhythmia have occurred in patients with preexisting ventricular tachyarrhythmias and previous MI, even with normal doses of the drugs. These drugs should be reserved for patients unresponsive to less toxic drugs, especially if these patients have CHF, sinus nodal dysfunction, or heart block.

Class II

BBs are generally contraindicated for patients with unstable bronchospastic disorders such as asthma. They are used with caution for patients with diabetes who have major sugar variation ranges because they decrease insulin secretion and may mask many of the signs of hypoglycemia. BBs are the gold standard to help reduce the second cardiac event post-MI.

This recommendation is based on older data collected prior to the advent of stents and "clot busters" (Bangalore et al, 2014). More recent data puts this indoubt following modern intervention. DM is considered a cardiac risk equivalent. The protective impact of a BB holds greater import in most DM patients than the fear of hypoglycemia. Because of their peripheral vasoconstrictive effects, they are a poor choice for patients with PVD and Raynaud's syndrome. Chronic use is linked with age-related macular degeneration (Klein, Myers, & Klein, 2014) and psoriasis (Wu, Han, Li, & Quershi, 2014).

Abrupt withdrawal of BBs may result in rebound beta stimulation resulting in tachycardia; therefore, they should be tapered by half every 4 hours. Patients at high risk for serious exacerbation of their disease related to abrupt withdrawal include those with angina, CAD with ventricular arrhythmias, and migraines. Hypertensive patients are at lower risk.

Asian patients have a higher probability of lacking an enzyme to handle propranolol, causing toxic profiles that surface early in therapy. BBs are also discussed in Chapters 14 and 40.

Class III

Sotalol is the major class III drug used in primary care. It is a nonselective BB that also prolongs action potential. Its precautions are similar to those for class II. Amiodarone, also a class III drug, has significant properties of several other classes as well. The muscarinic effects associated with sodium channel blockade suggest cautious use for patients with SA or AV nodal dysfunction, bradycardia, or HF. Amiodarone inhibits the enzyme that converts T4 to T3, and iodine is a major component of this drug; therefore, about 5% of patients with underlying predisposition to thyroid disease may develop thyrotoxicosis or hypothyroidism. If this drug must be used to treat the rhythm disturbance, careful monitoring and treatment of the thyroid disorder must be undertaken. Potentially fatal pulmonary fibrosis occurs in 5% to 15% of patients, but preexisting pulmonary disorders do not make the risk more likely. Patients with known risk at baseline should have thyroid and pulmonary function studies done before amiodarone therapy is initiated.

Class III drugs are potassium channel blockers, but they also have effects found in other classes. Amiodarone, quinidine, and sotalol also have effects on sodium channels or beta receptors. "Pure" potassium channel-blocking drugs are currently entering clinical trials. Potassium channel blockade would result in increased action potential duration, increased refractoriness, and reduced automaticity. They should be effective in treating reentry problems, in inhibiting ventricular fibrillation that is due to myocardial ischemia, and in improving contractility.

CLINICAL PEARL

For patients with diabetes who must take a beta blocker, the diaphoresis associated with hypoglycemia is not masked by these drugs, and diabetics should be taught to recognize this indication of hypoglycemia.

Class IV

CCBs have been discussed earlier in this chapter. Worsening HF can trigger more rhythm issues. Only diltiazem and verapamil have FDA-approved rhythm indications.

Adverse Drug Reactions

The more common adverse reactions of antiarrhythmics are extensions of their actions. Reduction in BP may result in dizziness, hypotension, fatigue, and syncope. Decreased myocardial contractility may result in HF. Each class has the potential to produce rhythm disturbances, often exaggerations of or the reverse of the one being treated. Class IC drugs are especially pro-arrhythmic. GI symptoms that are especially disturbing to patients include nausea, vomiting, diarrhea, and constipation and can trigger nonadherence. GI symptoms are especially prevalent in class IA drugs, occurring in 33% to 50% of patients. Although not common, sexual dysfunction and urinary retention may occur in classes I and III. The atropine-like activity of disopyramide (urinary retention, dry mouth, and constipation) may require discontinuance of the drug. Adverse neurological reactions of antiarrhythmics include tremor, blurred vision, and nervousness. Amiodarone has several adverse drug effects not common to other antiarrhythmics, including extrapyramidal syndrome (EPS) effects, hepatitis, epididymitis, corneal deposits, peripheral neuropathy, and extreme burning photosensitivity that can result in a blue-grey skin tone (Drucker & Rosen, 2011). These effects increase with cumulative doses and limit its utility for long-term therapy. Adverse effects associated with beta blockade in class II drugs and sotalol are discussed in Chapter 14. Those relevant to CCBs have been discussed earlier in this chapter. All antiarrhythmics are Pregnancy Category C, except amiodarone, which is Pregnancy Category D.

Drug Interactions

Cross-class and intraclass increases in cardiac effects are common between antiarrhythmics, increasing serum levels and toxicity risks. Several drugs increase or decrease the metabolism of antiarrhythmics: cimetidine (Tagamet), phenobarbital, and rifampin (Rifadin). Phenytoin (Dilantin), which also has class IB antiarrhythmic activity, results in alterations in effectiveness and increases toxicity risk. The anticoagulation effects of warfarin (Coumadin) are increased by many antiarrhythmics, particularly amiodarone.

Additive anticholinergic effects occur as an interaction between several antiarrhythmics and other drugs that have anticholinergic properties. The metabolism and excretions of several class I drugs are significantly affected by urine pH, resulting in altered serum levels and toxicity risk. The CYP 3A4 system is involved in the metabolism of quinidine. Drugs that inhibit this system, including grapefruit juice, may increase free drug levels. CYP 2D6 is involved in flecainide (Tambocor) and propafenone metabolism. Drugs that inhibit this system may similarly increase free drug levels. Selected antiarrhythmics may potentiate the hypotensive effects of antihypertensives, nitrates, and alcohol. BBs may alter the effectiveness of insulin and oral hypoglycemics. Specific drug interactions and the appropriate actions to prevent them are given in Table 16-13.

Table 16–13 ⊞ Drug and Food Interactions: Selected Antiarrhythmics

Drug	Interacting Drug/Food	Possible Effect	Implications
Amiodarone*	Digoxin	Increases blood levels and toxicity risk	Decrease dose of digoxin by 50%. Monitor for toxicity.
	Class I antiarrhythmics	Increase blood levels and toxicity risk	Decrease these drugs by 30%–50%.
	Phenytoin	Increases blood levels of phenytoin; may decrease amiodarone blood levels	Avoid concurrent use. If they must be given together, monitor serum levels of both drugs.
	BBs, CCBs	Increases risk for bradyrhythms, sinus arrest, and AV block	Monitor for dizziness and orthostatic and mental status change. Safety issues.
	Cholestyramine	May decrease amiodarone blood levels	Separate doses by 1 h and give amiodarone first.
	Lovastatin		Limit statin to 40 mg/d (simvastatin 20 mg/d).
	Antihypertensives	May produce profound hypotension	Monitor BP. Safety issues.
Dronedarone	CCB, digoxin, BB, ciprofloxacin, CYP 3A4 inhibitors like grapefruit juice, topical lidocaine, other QT-prolonging agents	Increase dronedarone levels	Toxicity, cardiac suppression Decrease dose or avoid use altogether.
	CYP3A inducers (carbamazipine, phenobar, phenytoin, rifampin	Decrease dronedarone levels	

Continued

Table 16–13 ▦ **Drug and Food Interactions: Selected Antiarrhythmics—cont'd**

Drug	Interacting Drug/Food	Possible Effect	Implications
	Some statins, BB, CCB (non-dyp), colchicine, dabigatran, tamoxifen	May increase the levels of these drugs	Toxicity of the interacting drugs
	P-glycoproteins (digoxin)	Increase dronedarone	Decrease digoxin dose by 50%
	Phenothiazines, TCA	Both drugs are increased in levels	Contraindicated
	SSRI, midazolam tacrolimus	Increase dronedarone levels	Adjust doses of each
Flecainide[†]	CCBs, disopyramide	Increase arrhythmia risk	
	BBs, verapamil	Additive myocardial depression	Combination should be avoided or given cautiously
	Amiodarone	Doubles serum flecainide levels	Decrease flecainide dose by 50%
	Digoxin	Increases serum digoxin levels by small amount	Monitor serum digoxin level and indications of toxicity
	Alkalinizing agents, foods that increase urine pH to >7,[§] strict vegetarian diet	Promote reabsorption, increase blood levels, increase toxicity risk	Monitor serum levels
	Acidifying agents, foods that decrease urine pH to <5,[§] acidic juices	Increase renal elimination, decrease effectiveness	Monitor serum levels and clinical indicators of effectiveness
Mexiletine	Opioid analgesics, atropine, antacids	Slows absorption of mexiletine	Separate administration of antacids by at least 1 h
	Metoclopramide	Speeds absorption	
	Phenytoin; phenobarbital, cigarette smoking	Increase metabolism and decrease effectiveness of mexiletine	Avoid concurrent use
	Alkalinizing and acidifying agents[§]	Same as with flecainide	Same as with flecainide
Quinidine [†, ‡]	Digoxin	Increases serum levels and toxicity risk	Dosage reduction recommended
	Amiodarone	See amiodarone	See amiodarone
	Phenytoin, phenobarbital	Increase metabolism and decrease effectiveness of quinidine	Monitor therapeutic effects
	Verapamil	Decreases metabolism and increases serum levels of quinidine	Monitor for toxicity
	Antihypertensives, nitrates, alcohol	Additive hypotension	
	Procainamide, propafenone, tricyclic antidepressants (TCAs)	Increase serum levels and risk for toxicity for each of these drugs	
	Drugs with anticholinergic properties	Additive anticholinergic effects	Monitor for dry mouth, wheezing, urinary retention, orthostatic hypotension
	Alkalinizing and acidifying foods and drugs[§]	See flecainide	
Sotalol	General anesthetics, IV phenytoin, CCBs	Additive myocardial depression	
	Digoxin	Additive bradycardia	
	Antihypertensives, nitrates, alcohol	Additive hypotension	
	Amphetamines, ephedrine, epinephrine, norepinephrine, phenylephrine, pseudoephedrine	Unopposed alpha-adrenergic stimulation, leading to excessive HTN and bradycardia	Avoid concurrent use. Teach patient not to use OTCs without contacting health-care provider.
	Amiodarone, disopyramide, procainamide, quinidine	Increase pro-arrhythmia risk	Avoid concurrent use

Table 16–13 ▦ **Drug and Food Interactions: Selected Antiarrhythmics—cont'd**

Drug	Interacting Drug/Food	Possible Effect	Implications
	Clonidine	Potentiates rebound HTN when clonidine discontinued	Use caution and monitor BP closely when discontinuing clonidine
	Insulin, oral hypoglycemics	May alter effectiveness of diabetic drugs	Dosage adjustment of diabetic drugs may be required
	Monoamine oxidase inhibitors (MAOIs)	May result in increased HTN	Use cautiously within 14 d of MAOI

*Interacts with warfarin to increase anticoagulation. Monitor prothrombin time. Dosage of warfarin may need to be decreased. For amiodarone, the decrease may be 33%–50%.

†Interacts with cimetidine to increase serum levels of the antiarrhythmic. Choose different histamine₂ blocker. Monitor for toxicity if cimetidine must be used.

‡Interacts with rifampin to decrease serum levels and effectiveness of antiarrhythmic. If they must be used together, monitor for decreased therapeutic effect of antiarrhythmic, and adjust dosage as needed.

§Foods that alkalinize urine: all fruits except cranberries, prunes, plums; all vegetables; milk. Foods that acidify urine: cheeses, cranberries, eggs, fish, grains, meats, plums, poultry, prunes.

Clinical Use and Dosing

Atrial Arrhythmias (Atrial Fibrillation/Flutter, Atrioventricular Nodal Reentrant Tachycardia, Wolff–Parkinson–White Tachycardias)

All antiarrhythmics have some use in these disorders. Class IA drugs (quinidine, procainamide) are especially useful. Quinidine has a short-acting form that is given every 4 to 6 hours, a long-acting form for every 8-hour administration, and Quinidex Extentabs, which can be given twice daily (see Table 16-2). It has been combined with mexiletine to enhance effectiveness and reduce adverse effects.

Procainamide can be used in a hemodynamically stable patient for the acute treatment of focal atrial tachycardia and the acute management of stable atrial flutter (American College of Cardiology/American Heart Association/European Society of Cardiology [ACC/AHA/ESC], 2003; ACCF/AHA 2011). It can also be used in the long-term management of recurrent, well-tolerated atrial flutter if combined with an AV node-blocking agent and if no significant structural cardiac disease is present.

Amirodarone is very effective against supraventricular arrhythmias, especially in children, in whom it appears to be quite safe. The wide range of adverse reactions seen in adults and its many drug interactions make it a second-line drug choice. Dronedarone is possibly better for acute atrial fib (AF) conversion but should not be used for persistent AF suppression, because over 65% of patients return to the rhythm in less than 1 year (Connolly et al, 2011).

Reentrant supraventricular tachycardia is a major indication for verapamil; however, it can increase the risk for ventricular fibrillation in patients with reexcitation. It can also be used to decrease the rate in atrial fibrillation/flutter with rapid ventricular response. The long-acting form has the advantage of once-daily administration. The high risk for clot formation associated with atrial fibrillation requires concurrent anticoagulation therapy with warfarin.

Ventricular Arrhythmias (Ventricular Ectopic Beats, Ventricular Tachycardia, Ventricular Fibrillation)

Simple ventricular rhythm disturbances such as occasional PVCs are rarely treated in primary care. Complex ventricular irritability demonstrated with ventricular rhythm disturbances is associated with increased risk for MI and sudden death. Despite this fact, only symptomatic patients with underlying heart disease, malignant forms of arrhythmia such as recurrent ventricular tachycardia, and poor LV function seem to benefit from prophylactic antiarrhythmic therapy. Controlled trials of antiarrhythmic therapy in minimally symptomatic post-MI patients with reduced ejection fractions actually showed increased rates of arrhythmia-associated death in those treated.

Class IA agents have moderate efficacy in treating ventricular arrhythmias and are sometimes prescribed. Disopyramide has a pronounced negative inotropic effect, however, which limits its usefulness. For patients with HF, discontinuation of most antiarrythmics, CCBs, and NSAIDs is recommended (ACCF/AHA, 2009). Class IA agents in patients with reduced left ventricular ejection fraction especially increase the risk of serious arrhythmias. This is also true for class IC flecainide and propafenone and class III sotalol (ACC/AHA, 2003). These drugs are both cardiodepressant and pro-arrhythmic in HF patients. Class IB drugs are fairly weak antiarrhythmics for these problems and are either second-line drugs or used with class IA drugs. Their relatively long half-lives allow two doses daily or three times daily dosing. They are well tolerated in HF, having little negative inotropic effect, with mexiletine more negatively inotropic than tocainide. Class IC drugs are moderately effective but are reserved for very refractory cases because of their pro-arrhythmic qualities.

Class II drugs are useful in exercise-induced ventricular tachycardia but should be monitored with serial exercise testing to check efficacy. They are safe and especially useful in arrhythmias caused by ischemic heart disease because

they are among the few drugs proven to reduce CAD mortality. Selection for beta$_1$ receptors reduces many of their adverse reactions. Atenolol (Tenormin) has strong beta$_1$ selectivity, resulting in a low adverse-effect profile, and is used for post-MI arrhythmia prophylaxis. Propranolol (Inderal), a nonselective BB, is used for several arrhythmias. Class III drugs are the best choice for monomorphic ventricular tachycardia.

A common noncardiac cause of tachyarrhythmias is hyperthyroidism. Propranolol, a class II drug, slows the heart rate by its beta-blocking action and has the added effect of preventing peripheral conversion of T4 to T3, thereby reducing the serum levels of the more active form of thyroid hormone. (See hyperthyroid indication in Chap. 41)

Rational Drug Selection

Risk Versus Benefit

The choice of antiarrhythmic drugs is usually based not only on benefit (correction or prevention of the rhythm) but also on risks (adverse effects and toxicity). Benefits may be assessed and drugs chosen by electrophysiological studies. When no agent meets electrophysiological study criteria for choice, empiric amiodarone may be prescribed because of its effects in all classes and because it has been shown to reduce mortality in cardiac arrest survivors from 50% to 20% at 2 years' post-cardiac arrest. The more potentially lethal the arrhythmia is, the more acceptable the risks become. In terms of prevention, only BBs have been definitively shown by research to reduce mortality in relatively asymptomatic patients. Risks related to adverse reactions are present in all antiarrhythmics and increase with higher doses and longer times of administration.

Concurrent Diseases

The presence of diseases in other organ systems may dictate the choice of drug, based on the effects of the antiarrhythmic on that system (bronchospasm in asthma, urinary retention in benign prostatic hyperplasia).

Cost

Many antiarrhythmics are expensive. Those medications requiring frequent monitoring by diagnostic tests need to have the cost of this monitoring factored into final price. For example, amiodarone may require a chest x-ray every 3 to 6 months, pulmonary function tests, and ophthalmic examinations, as well as thyroid-stimulating hormone (TSH) and free thyroxine (T4) levels. This significantly raises the cost of this drug. Generic procainamide requires dosing every 6 to 8 hours; its cost is increased when switched to the sustained-release form, but adherence is improved.

Decision Steps

Because the margin between therapeutic efficacy and toxicity is narrow and the knowledge needed to prescribe these drugs is extensive, it is best to refer patients to a cardiologist for initiation of therapy. Phone consultation may also be required during therapy unless the provider has extensive experience with antiarrhythmic therapy. Several important steps are used in deciding on therapy:

1. Any factor that might be precipitating the arrhythmia should be determined and eliminated. Especially relevant are adverse drug reactions, underlying disease states such as thyroid disorders, and electrolyte disturbances.
2. A firm arrhythmia diagnosis should be established. Use of inappropriate drugs because of a misdiagnosis of the arrhythmia can be catastrophic in some cases.
3. Establish a reliable baseline on which to judge the efficacy of any subsequent dose change or new antiarrhythmic therapy. Methods include ambulatory monitoring, electrophysiological studies, and treadmill exercises.
4. The mere identification of an arrhythmia does not necessarily require its treatment. Evaluation of risk, symptomatology, and a risk/benefit analysis is imperative.

Monitoring

Laboratory Data

Potassium concentration in the extracellular space is the major determinant of resting membrane potential and membrane stability. Levels should always be checked and kept midrange (more than 4 mEq/L) for patients with rhythm disturbances. Renal and hepatic functions (blood urea nitrogen [BUN], creatinine, transaminases) are watched because they are the principal routes of excretion for antiarrhythmic drugs. Antiarrhythmics tend to have narrow therapeutic ranges and are often given to patients who are taking other drugs with which they may interact, increasing the risk of toxicity or lack of efficacy. Serum drug levels should be monitored at regular intervals after steady state is achieved. Timing of the blood draw is critical. The sample is usually drawn 4 to 6 hours after the last oral dose so that a peak serum level is not mistaken for a steady-state level. Anticoagulation studies (prothrombin time [PT], international normalized ratio [INR], activated partial thromboplastin time [apt]) are discussed in Chapter 18. Laboratory studies related to the underlying disease that may be causing the arrhythmia are not discussed here.

Electrocardiogram

Monitoring 12-lead electrocardiograms (ECGs) for indications of efficacy and toxicity is essential, especially concerning drugs for which ECG changes are the primary indicators of such problems. The frequency of monitoring depends on the stability of the patient's drug regimen and the presence of symptoms; however, potential asymptomatic issues with QT changes and development of conduction defects suggest at least yearly recordings.

Other Studies

Electrophysiological studies, echocardiography, and exercise stress testing are best done in consultation with a cardiologist. Monitoring for BBs is discussed in Chapter 14 and for CCBs earlier in this chapter. Monitoring parameters are further delineated in Table 16-14.

Table 16–14 Monitoring Parameters for Selected Antiarrhythmics

Drug	Parameters	Timing	Comments
Amiodarone	Chest x-ray, pulmonary function studies	Every 3–6 mo	High risk for pulmonary fibrosis. Risk of sudden cardiac death may outweigh risk associated with pulmonary dysfunction. Every effort should be made to rule out other treatable cause of pulmonary problem. Some providers schedule tests based on symptoms after 1 yr without problems.
	Thyroid-stimulating hormone (TSH), free T_4	Every 6 mo	Monitor closely for other indications of thyroid dysfunction as well
	Ophthalmic exam (slit lamp and fundoscopy)	Every 6 mo	Although rare, visual impairment may progress to permanent blindness. Any symptoms of impairment should result in prompt ophthalmic exam. Corneal microdeposits are reversible with reduction in dose and no reason to stop treatment.
Flecainide*	ECG Liver function studies Serum drug levels		Watch for sinus node problems and AV block. Highly metabolized in liver. Liver disease may significantly increase free drug level. Keep trough <1 mcg/mL.
Mexiletine*	Liver function studies		Aspartate aminotransferase (AST) elevations >3 times upper limit of normal (ULN) have been observed. Assess for other treatable causes such as CHF or acute Ml before stopping drug.
Procainamide†	Complete blood count (CBC) Antinuclear antibody (ANA) titer		At initiation of therapy to assess for blood dyscrasias At initiation of therapy and at any indication of lupus-like syndrome
Propafenone	Liver function studies		Highly metabolized by liver. Liver disease may increase bioavailability to 70%.
Quinidine†	CBC, renal and liver function studies		Discontinue drug if blood dyscrasias or hepatic or renal dysfunction occurs.
Sotalol	Fasting blood glucose		May affect insulin secretion and glucose metabolism. May mask indications of hypoglycemia in patients with diabetes.

All require monitoring of potassium level and 12-lead ECG. Most require serum drug levels. Monitoring of renal function is prudent in all.

*Changes in urine pH can alter drug excretion. Monitor urinalysis on annual visits.

†ECG changes are the primary indicators of toxicity in these drugs. QRS >25% above normal or prolonged QT intervals suggest reduction in dose by as much as 50%.

Patient Education

Cardiac rhythm disturbances tend to engender fear. A thin line exists between enough information to have the patient appreciate the seriousness of the disorder (or the lack of seriousness in benign forms of arrhythmia) and, therefore, adhere to the treatment regimen, and so much information that fear or denial takes over and adherence suffers. Most patients and their families appreciate an honest discussion of the disorder and the requirements for frequent monitoring that allow safer and effective treatment. Most antiarrhythmics have annoying side effects that patients are more likely to tolerate when the importance of the drug is explained.

Administration

The patient should take the drug exactly as prescribed. For doses taken more than once daily, the doses should be evenly spaced. Abrupt withdrawal of these drugs may result in life-threatening arrhythmias, HTN, or myocardial ischemia. The patient should keep enough medication on hand for weekends, holidays, and vacations. For amiodarone, if a dose is missed at its usual time, it should not be taken at all that day; the patient should simply take the next day's dose. Its very long half-life maintains a stable level. For disopyramide, mexiletine, procainamide sustained-release, propafenone, and tocainide, a dose that is missed should be taken as soon as it is remembered, unless the next dose is due in 4 hours or less. For flecainide, the missed dose should be taken unless the next dose is due in 6 hours, and for sotalol, 8 hours. For quinidine and standard formulations of procainamide, the separation is 2 hours.

Several drugs come in more than one formulation, from standard to sustained-release (Table 16-15). The patient should read the label carefully and follow the appropriate dosing schedule, especially if the drug is changed to a different form or a different drug. For sustained-release formulations, the tablets should not be crushed or chewed but must be swallowed whole. Patients who have difficulty in swallowing should be placed on standard formulations that can be crushed.

Food intake is a concern with some of the antiarrhythmics. Sotalol absorption is significantly decreased when it is taken with food, so it should always be taken on an empty stomach. Mexiletine, tocainide, and quinidine, however, have uncomfortable GI adverse effects unless they are taken

Table 16–15 ⊗ Dosage Schedule for Selected Outpatient Labeled Uses: Selected Antiarrhythmics

Drug	Indication/Plasma Concentration	Dosage Forms	Starting Dose	Maintenance Dose
Amiodarone (Cordarone, Pacerone) (G)	Ventricular arrhythmias Level: 1–2 mcg/mL	Tablets: 100 mg (Pacerone only); 200, 400 mg	800–1,600 mg/d in 1–2 divided doses for 1–3 wk; then 600–800 mg in divided doses for a month	Maint: 400 mg/d
Atenolol (Tenormin) (G)	Prevent primary arrhythmic event post-MI	Tablets: 25, 50, 100 mg	100 mg daily or 50 mg 2 doses daily	100 mg daily or 50 mg 2 doses daily for at least 9 d: post-MI
	Insufficient control of atrial fibrillation with digoxin		25–50 mg/d added to digoxin dose	100 mg/d; 50 mg/d if severe renal impairment
Flecainide* (Tambocor) (G)	Sustained ventricular tachycardia, PSVT	Tablets: 50, 100, 150 mg	100 mg q12 h for ventricular tachycardia; 50 mg q12h for PSVT	100–150 mg q12h for ventricular tachycardia; 50–100 q12h for PSVT *MAX Adjusted Dose:* Ventricular tachycardia: 400 mg/d; PSVT: 300 mg/d; adjust doses by 50 mg increments; minimum 4 d between adjustments
Mexiletine (Mexitil) (G)	Ventricular arrhythmias Level: 0.5–2 mcg/mL	Capsules: 150, 200, 250 mg	200 mg q8h (if rapid control of arrhythmia is essential, load with 400 mg)	200–300 mg q8h *MAX Adjusted Dose:* 1, 200 mg/d: adjust doses by 50–100 mg increments; minimum 2–3 d between adjustments.
Propafenone* Rythmol (G)	Ventricular arrhythmias (unlabeled use in PSVT associated with WPW) Level: 0.2–1.5 mcg/mL (nonlinear change in plasma level related to dose increase)	Tablet: 150, 225, 300 mg	150 mg q8h	225–300 mg q8h *MAX Adjusted Dose:* 300 mg per dose Increases doses at minimum of 34 d intervals:
Propafenone SR (Rhythmol SR)		Capsule SR	225 mg every 12 hours	325 mg *Max:* 425 mg Increase dose in 5 d intervals
Propranolol (Inderal, (G)	PSVT: atrial fibrillation; tachycardias associated with digitalis toxicity, excessive catecholamines; thyroid disorders	Tablets: 10, 20, 40, 60, 80 mg Solution (500 mL): 4 mg/mL, 8 mg/mL	10–30 mg 3 times daily–4 doses daily given ac and hs; for atrial fibrillation uncontrolled by digoxin, add 40–80 mg of propranolol to digoxin dose	*Max Adjusted Dose:* 240 mg/d
Quinidine Sulfate (G) Quinidine Gluconate (G)	Conversion/prevention atrial fibrillation, atrial flutter, atrioventricular nodal reentry; suppress ventricular rhythms not associated with complete heart block	Tablets: 200, 300 mg; Tablet XR: 300, 324 mg Dose of 267 gluconate = to 200 mg sulfate	Single-dose 200 mg to assess for idiosyncratic reaction. Then 300 mg of gluconate or 324 mg sulfate every 8–12 h.	200–300 mg 3 times daily or 4 doses daily immed. release; 300 mg–600 mg q8h for sustained release[†*]
Sotalol (Betapace)(G)	Ventricular arrhythmias	Tablets: 80, 120, 160, 240 mg	80 mg 2 doses daily	240–320 mg/d in 2 divided doses; *Max Adjusted Dose:* 640 mg; adjust doses at minimum 3 d interval
(Betapacce AF) (G)	Suppression AF	Tablets: 80, 120, 160 mg. Cannot substitute regular Betapace	80 mg 2 doses daily	120 mg twice daily *Max:* 160 mg twice daily

PSVT = paroxysmal supraventricular tachycardia; MI = myocardial infarction; WPW = Wolff–Parkinson–White syndrome.

*Because of pro-arrhythmic effects, use with lesser arrhythmias is not recommended.

†Because the rate of absorption from various sustained-release formulations may be markedly different, they are not interchangeable.

with food. Foods that alter urine pH affect the excretion of flecainide, mexiletine, and quinidine and should be avoided or taken in consistent amounts. (See Table 16-13 for a list of such foods.)

Drug interactions are frequent with both prescription and OTC drugs. The patient should consult a health-care provider before taking any other drugs, including OTC cold remedies.

Adverse Reactions

Dizziness is the most common adverse response. Changing position slowly, especially when arising from a lying position, decreases this reaction. Caution should be taken in driving or other activities that require alertness until any sedating response is known. Monitoring of pulse rate and rhythm and BP provides early indications of efficacy and toxicity. Patients should learn to take their own pulse and BP and check them whenever symptoms occur. Hypotension and slow, rapid, or irregular heart rates should be reported promptly. Bone marrow is affected in some classes. Patients should report fever, chills, sore throat, or unusual bruising. Photosensitivity may occur through window glass, thin clothing, and low-value sunscreens for patients who are taking amiodarone, diso - pyramide, or quinidine. Protective clothing and high SPF sunblock are recommended during therapy and for 4 months following it. Some find wearing dark glasses helpful for photosensitivity in the eyes. With amiodarone, a bluish discoloration of the skin in areas exposed to sunlight may occur. It is usually reversible and fades over several months. This drug is also associated with epididymitis and pulmonary fibrosis. Patients should report scrotal pain or swelling and decreased exercise tolerance. Procainamide occasionally is associated with a lupus-like syndrome. Joint swelling and rashes should be reported. Frequently using mouthwashes, practicing good oral hygiene, chewing sugarless gum, or sucking on hard candy may relieve the dry mouth commonly found with disopyramide. The patient should notify the health-care provider if dry mouth, constipation, difficulty in urinating, or blurred vision persist with this drug. Tremors are an early indication of excessive doses of mexiletine and should be reported promptly.

For all of these drugs, the importance of keeping follow-up appointments to monitor efficacy and adverse reactions cannot be overstated. Failure to discover problems early can result in permanent adverse changes and include life-threatening events.

Because these drugs are Pregnancy Category C or D, female patients capable of childbearing should be made aware of the risks of these drugs, and contraception should be instituted before prescribing them.

Lifestyle Management

Lifestyle management is similar to that discussed for ACEIs and general cardiovascular health. The patient should carry a medical identification card that states the name of the drug and the disorder for which it is being taken. Patient education related to BBs is discussed in Chapter 14. CG and CCB issues were covered earlier.

NITRATES

Nitrates were first introduced for the treatment of angina in the 19th century. Their ability to affect both oxygen supply and demand and their effectiveness in rapid relief of acute angina has made them one important part of the treatment for this disorder. They are joined by other drug groups to control this pain syndrome. A newer drug not part of the nitrate, CCB, or ACE/ARB drug classes is ranolazine (Renexa). This medication is not indicated in acute angina. It is covered in more detail in Chapter 28 on angina management, not in the section below.

Pharmacodynamics

Nitroglycerin (NTG) and its analogues act largely by providing more nitric oxide (NO) to vascular endothelium and arterial smooth muscle, resulting in vasodilation (Fig. 16-5). All parts of the vascular system, from larger arteries to large veins, relax in response to nitrates. Nitrates affect the supply–demand equation on both sides. Dilation of venous capacitance vessels results in decreased systemic vascular resistance (afterload), venous pooling, and decreased venous return to the heart, which leads to decreased preload. Arterial dilation, which occurs more commonly with higher doses, decreases systemic arterial pressure, resulting in decreased afterload. MOD is reduced by the reduced cardiac workload.

The decreased venous return decreases LV end-diastolic pressure (preload), resulting in decreased wall tension and an increased transmyocardial gradient. This increased gradient improves perfusion between the coronary arteries and the subendocardium and increases oxygen supply to the myo - cardium. Their coronary artery vasodilating effect—originally thought to be their primary role in improving MOD—is now thought to play a limited role because of atherosclerotic changes in the coronary arteries. They have little effect on angina associated with longer-duration atherosclerotic CAD.

Indirect actions include reflex responses of baroreceptors and hormonal mechanisms to decreased arterial pressure. The primary mechanism is sympathetic discharge, resulting in tachycardia and increased myocardial contractility. Another action of clinical significance is on platelet aggregation. NO released from NTG increases cyclic guanosine monophosphate (cGMP), resulting in decreased platelet aggregation. This action is believed to play a role in reduction of infarct size and mortality post-MI for patients given IV NTG and may also exist for other forms of NTG. Relaxation of smooth muscle of the bronchi, GI tract, and genitourinary tract also occurs but so briefly that this action is not considered clinically significant.

Pharmacokinetics

Absorption and Distribution

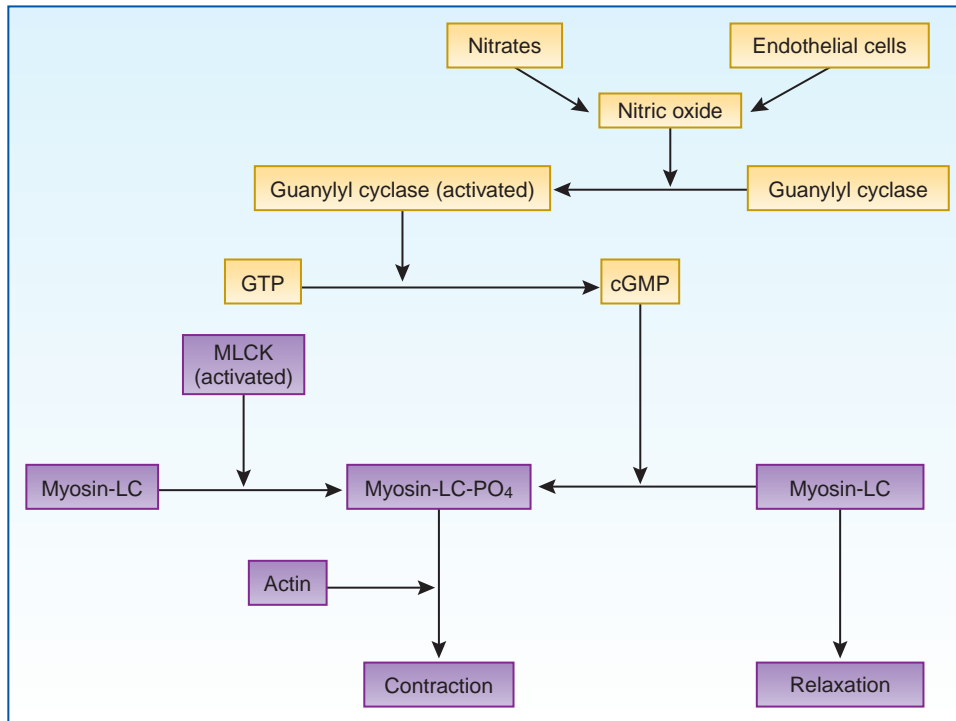
Nitrates are well absorbed by oral, buccal, sublingual, and transdermal routes (Table 16-16). Sublingual absorption is dependent on salivary secretion. Dry mouth (including drug-induced) decreases absorption. Amyl nitrite is available


Figure 16–5. Action of substances that increase nitric oxide concentration in smooth muscle cells. Nitrates, nitrites, and other substances that increase nitric oxide concentration in smooth muscle cells potentiate the activation of guanylyl cyclase. Activated guanylyl cyclase then facilitates the production of cyclic guanosine monophosphate (cGMP). Through a series of not clearly known intermediate steps, the cGMP facilitates the dephosphorylation of the myosin light chain, resulting in muscle relaxation.

Table 16–16 Pharmacokinetics: Selected Nitrates

Drug	Onset	Peak	Duration	Metabolite	Half-Life	Excretion
Amyl nitrate inhalant	0.5 min		3–5 min	None	UK	1/3 in urine
Isosorbide dinitrate, sublingual	2–5 min	6 min	1–3 h	Mononitrate	Drug 45 min Metabolite: 2–5 h	In urine
Isosorbide dinitrate, Oral	20–40 min	6 min	4–6 h	Isosorbide mononitrate	Drug: 45 min Metabolite: 2–5 h	In urine
Isosorbide dinitrate, oral (SR)	Up to 4 h	6 min	6–8 h	Isosorbide mononitrate	Drug: 45 min Metabolite: 2–5 h	In urine
Isosorbide mononitrate, oral	30–60 min	UK	7 h	Metabolized to glycerol and CO_2	UK	In urine and lung
Isosorbide mononitrate, oral (SR)	Slow	3–4 h	>12 h	Metabolized to glycerol and CO_2	UK	In urine and lung
NTG, sublingual	1–3 min	4 min	30–60 min	1,2-dinitroglycerol and 1,3-dinitroglycerol	Drug: 1–3 min Metabolites: approx. 40 min	In urine
NTG, translingual spray	2 min	4 min	30–69 min	1,2-dinitroglycerol and 1,3-dinitroglycerol	Drug: 1–3 min Metabolites: approx. 40 min	In urine
NTG oral (SR)	20–45 min	UK	3–8 h	1,2-dinitroglycerol and 1,3-dinitroglycerol	Drug: 1–3 min Metabolites: approx. 40 min	In urine
NTG transdermal patch	30–60 min	UK	Up to 24 h	1,2-dinitroglycerol and 1,3-dinitroglycerol	Drug: 1–3 min Metabolites: approx. 40 min	In urine

UK = unknown. All have approximately 60% protein binding. Half-life of NTG is 1–4 min; others have longer half-lives, with SR preparations up to 12 h.

in an inhaled form ("popper"), providing for very rapid absorption, but its use is not common clinically.

Metabolism and Excretion

Oral nitrates have a significant hepatic first-pass effect. Hepatic organic nitrate reductase removes nitrate groups from the parent molecule, yielding less potent vasodilators than the parent drug and resulting in low bioavailability for most products. Oral nitrates must be given in sufficiently high doses to sustain blood levels despite the first-pass effect. NTG has a short half-life (1 to 4 min), but the two major metabolites (1,2 and 1,3 dinitrates) have longer half-lives and appear in substantial concentrations, making them responsible for some of the pharmacological activity. The dinitrates are further metabolized to mononitrates. Isosorbide dinitrate is metabolized to active metabolites that accumulate more than the parent drug with long-term therapy. Because isosorbide mononitrate is the major active metabolite of isosorbide dinitrate and most of the clinical activity is attributed to this metabolite, it is now available as a single-entity product with a bioavailability of nearly 100%.

The sublingual route avoids hepatic first-pass effect and is preferred for achieving a rapid blood level. The buccal and transdermal routes also avoid the first-pass problems but have slower onsets of action. Total duration of effect by these routes is brief. When longer duration of action is needed, oral or topical preparations are given.

Metabolism of nitrates leads to glucuronide derivatives and carbon dioxide excreted by the kidneys and the lungs. Table 16-16 includes the pharmacokinetics of all formulations.

Pharmacotherapeutics

Precautions and Contraindications

Precautions and contraindications are largely related to the actions of these drugs. Vasodilation can result in increased intracranial pressure, so nitrates are contraindicated in head trauma or cerebral hemorrhage. Vasodilation can also result in postural hypotension. Patients with volume depletion and anemia should avoid using nitrates. *Drug Facts and Comparisons* (Wolters Kluwer Health, 2011) states that closed-angle glaucoma is also a contraindication because intraocular pressure (IOP) may be increased. Some individuals have hypersensitivity or idiosyncratic responses to nitrates and must avoid them. For the transdermal patches, allergy to their adhesive may limit their use.

Because the activity of these drugs may compromise maternal-to-fetal circulation, they are Pregnancy Category C. Amyl nitrite is Pregnancy Category X because it markedly reduces system BP and blood flow on the maternal side of the placenta. It is not known if nitrates are excreted in breast milk. The importance of the drug for the mother and possible risks to the infant should be taken into consideration when deciding on nitrate use in nursing mothers. Safety and efficacy in children have not been established.

Adverse Drug Reactions

The major adverse reactions are direct extensions of therapeutic vasodilation: orthostatic hypotension with potential for syncope, tachycardia, and throbbing headache. Hypotension may result in decreased diastolic filling pressure, and the tachycardia may result in decreased diastolic filling time, leading to myocardial ischemia, arrhythmias, and rebound HTN. Headache may be severe and persists in up to 50% of patients. For patients with severe, persistent headache, it may be necessary to use a different drug group to treat the disease process.

Less common adverse reactions include nausea, vomiting, incontinence of urine and feces, dysuria, impotence, and urinary frequency. Nonallergic rash and cutaneous vasodilation with flushing may occur with transdermal applications. This can be reduced by rotating sites. The vasodilating effect is linked with an increased risk of age-related macular degeneration (Klein et al, 2014).

Tolerance

With continuous exposure, smooth muscle develops clinically significant tolerance (tachyphylaxis). In well-controlled clinical trials, nitrates were no more effective than placebo after 18 to 24 hours of continuous therapy, particularly for long-acting/sustained-release preparations. The mechanisms by which this occurs are not fully understood. One mechanism proposed is that, over time, decreased substrate (sulfhydryl) results in decreased cGMP, leading to decreased vasodilation. Orally bioavailable compounds containing sulfhydryl groups, such as *N*-acetylcysteine, may also diminish tolerance to the hemodynamic effects of nitrates in HF. Attempts to overcome nitrate tolerance by increasing dosage have failed. Only after nitrates have been absent from the body for 10 to 12 hours does their effectiveness return. See the section "Clinical Use and Dosing" for recommendations to overcome this problem.

Drug Interactions

Additive hypotension is possible with other drug classes that have actions or adverse effects of hypotension (i.e., antihypertensives, BBs, CCBs, haloperidol, or phenothiazines). Drugs with anticholinergic effects may decrease absorption of sublingual or buccal NTG. Aspirin increases nitrate serum concentrations and may potentiate their action. Nitrates may decrease the pharmacological effects of heparin. Specific drug interactions and the appropriate actions to prevent them are given in Table 16-17.

Clinical Use and Dosing

Angina

Oxygen extracted from the coronary arteries is at maximum efficiency at all times, so there is no oxygen reserve during periods of increased oxygen demand. Ischemia occurs when demand exceeds supply. Increased oxygen supply is created by dilating the arteries to bring more blood flow to the myocardium. Unfortunately, atherosclerosis and plaque formation makes dilation of these arteries difficult, if not impossible. Although they have some ability to dilate the coronary arteries, nitrates are also able to facilitate movement of oxygen across the arterial–myocardial membrane. Their use in CAD relates as much to this action as it does to vasodilation. Ischemia caused by the imbalance between MOS and MOD produces pain (angina).

Table 16–17 Drug Interactions: Nitrates

Drug	Interacting Drug	Possible Effect	Implications
Isosorbide dinitrate	Antihypertensives, alcohol, BBs, phenothiazines	Additive hypotension	Monitor BP closely. Isosorbide mononitrate Teach home BP monitoring.
NTG	Antihypertensives, alcohol, BBs, CCBs, haloperidol, phenothiazines	Additive hypotension	Monitor BP closely. Teach home BP monitoring.
	Agents with anticholinergic properties	May decrease absorption of SL and buccal formulations	Use other formulation if possible

There are three types of angina: chronic stable angina, unstable angina, and Prinzmetal's angina. Chronic stable angina (exertional angina) is caused by narrowing of the arterial lumen and hardening of the arterial walls so that the affected vessels cannot dilate in response to the increased MOD associated with physical exertion or emotional stress. For many patients with stable, predictable angina, nitrates are sufficient to control symptoms. Dosage depends on formulation, with sublingual doses used to treat acute attacks and long-acting forms used for chronic prevention (Table 16-18). In exertional angina, short-acting forms taken within 5 or 10 minutes of exercise may prevent the anginal episode. For an angina episode, sublingual dosing is 0.4 to 0.6 mg every 5 minutes for up to three doses. If the angina is not relieved by the second dose, the recommendation is to take the third dose and call 911. Dosing for isosorbide dinitrate, a long-acting form, is 10 to 40 mg orally twice or three times daily; the sustained-release form is 40 to 80 mg daily. Isosorbide mononitrate dosing is 20 mg twice daily. For both long-acting forms, twice-daily dosing on an eccentric schedule, with doses separated by 7 hours, is preferred to reduce problems with tolerance.

For variant (Prinzmetal's) angina, in which the mechanism may be largely related to vasospasm, long-acting nitrates

Table 16–18 Dosage Schedule: Selected Nitrates

Clinical Use	Dosage Form	Starting Dose	Maintenance Dose
Treatment of acute angina (if NTG not effective)	Tablets SL: 2.5, 5, 10 mg	2.5–5 mg SL every 5–10 min	Titrate upward until angina relieved or adverse reactions limit. *Max* of 3 doses in 15–30 min
Treatment and prevention of angina; not for acute attack	Tablets: 5, 10, 20, 30, 40 mg (B) SR Caps (B): 40 mg	Tablets: 5–20 mg 2–3 times/d; SR Caps: 40–160 mg/d or 40 mg twice daily	10–40 mg bid (eccentric schedule 8 a.m. and 2 p.m.)
Treatment and prevention of angina; not for acute attack	Tablets: 10, 20 mg	5–10 mg 2 doses daily (eccentric schedule)	20 mg 2 doses daily (eccentric schedule)
Same as above	Tablets ER: 30, 60, 120 mg	30–60 mg daily	120 mg daily after several days on initial dose *Max*: 240 mg/d
Prophylaxis	Tablets: 0.3, 0.4, 0.6 mg	5–10 min prior to activities that might precipitate attack	N/A
Treatment of acute anginal attacks		0.4–0.6 mg tab under tongue every 5 min 3 times	Max: 3 tabs in 15 min
Prophylaxis	Spray: 0.4 mg/spray in 4.9 or 12 g	5–10 min prior to activities that might precipitate attack. Do not inhale spray.	
Treatment of acute anginal attacks		1–2 metered sprays onto or under tongue	3 metered sprays in 15 min
Prophylaxis or treatment of angina	Capsule: 2.5, 6.5, 9 mg	2.5–2.6 mg 3 times daily or 4 doses daily	Increase by 2.6/2.6 mg increments over a period of days or weeks until adverse reactions limit or reach 2.6 mg 4 doses/d
Prevention of angina	0.1., 0.2, 0.4, 0.6, 0.8 mg/h	0.2–0.4 mg/h on 12–14 h, then off 10–12 h	0.4–0.8 mg/h on 12–14 h, then off 10–12 h

(I) = Isordil brand; (S) = Sorbitrate brand; (M) = IMSO; (Mo) = Monoket; (Im) = Imdur. Patches: (M) = Minitran; (N) = NitroDur; (T) = Transderm-Nitro. Patch.

are occasionally sufficient to control symptoms, although CCBs are often added to the treatment regimen. Dosing is similar. For unstable angina, the prophylactic value of long-acting nitrates is uncertain, depending on the underlying pathology.

Angina nonresponding to initial therapy suggests serious progression of illness and the need for immediate assessment in a monitored area of an emergency room. Early therapy for such patients includes aspirin, nitroglycerine, and morphine. Long-acting nitrates appear to reduce mortality in trials that did not include thrombolysis. Optimal therapy for post-infarction angina is with BBs and long-acting nitrates. Isosorbide dinitrate is effective for this indication.

Heart Failure

With the advent of ACEIs and ARBs and the redefined role of BBs in HF, the newer guidelines no longer present an early role for nitrates in the management of HF (see Chap. 36). Their role in reducing ventricular filling pressure and pulmonary and system vascular resistance is sometimes useful. Isosorbide dinitrate administered chronically has been shown to be effective in improving exercise capacity and in reducing symptoms. Its limited effect on systemic vascular resistance and the problem of tolerance means that it is rarely single-drug therapy. Combining this drug with hydralazine has produced a more sustained improvement than either drug alone.

Initiation of Therapy

Start low and go slow are the appropriate steps if chronic therapy is indicated. Advancing low doses slowly over a period of 1 to 2 weeks usually results in the desired effects without the headaches or severe orthostasis. Headache or its absence is not a reliable variable by which to judge therapy because tachyphylaxis for this adverse effect is common within 1 to 4 weeks. Dosage increases should be made against the following parameters:

1. Reduced angina or lack of angina occurs with usual activity.
2. Heart rate at rest increases by no more than 15 bpm.
3. BP does not fall to the point of causing orthostatic hypotension.

Prevention of Tolerance

To prevent or reduce the development of tolerance, a nitrate-free interval of 10 to 12 hours/day is required. This is why nitro patches are applied and removed within a set period of time. Sustained-release preparations are more likely to lead to tolerance and should be avoided unless used daily. Short-acting products with two or three doses daily are less likely to lead to tolerance. For twice-daily dosing, use an eccentric dosing schedule separated by 7 hours (e.g., 7 a.m., 2 p.m.). Patients whose anginal symptoms occur at night may do best with a daytime nitrate-free interval, and the reverse holds for those whose symptoms occur during the daytime. If around-the-clock coverage is necessary for anginal symptoms, using a BB or CCB during the nitrate-free interval may be needed.

CLINICAL PEARL

Patients with migraine headaches are especially at risk for **nitrate headaches**. Start them first on a beta blocker for migraine prophylaxis, and then add the nitrate to prevent the problem with chronic use.

Rational Drug Selection

Formulation and Cost

Sublingual NTG has rapid action, long-established efficacy, easy use, and low cost. A disadvantage is its short duration of action. It is also volatile and must be kept in a tightly capped, amber container and stored in a cool place. Once a bottle is opened, it is generally effective for only about 6 months. Onset and duration of action of a single metered dose of translingual spray is about the same as for sublingual NTG. Each canister contains 200 doses and retains efficacy for up to 3 years. Some skill is required to use it; however, patients with advanced arthritis may prefer it to opening tightly closed bottles. Cost per dose is substantially higher than for the sublingual form, but the prolonged shelf-life helps reduce total cost for those patients who rarely need a dose. It is also a good alternative for patients who wear dentures or have dry mucosa.

Transdermal delivery systems offer easy use and release NTG at a constant rate to maintain steady-state plasma levels. Bioavailability varies significantly from patient to patient. Physical exercise and ambient temperatures may increase absorption.

Oral NTG has questionable efficacy and is available only in sustained release, a form associated with increased incidence of tolerance. Among the oral nitrates, isosorbide dinitrate provides sustained nitrate activity and better anginal prophylaxis. Single doses significantly improve hemodynamic parameters and exercise tolerance for up to 4 hours. Its action is not as rapid as sublingual NTG but does occur in 15 to 30 minutes, which is appropriate for angina prevention but not emergency intervention.

In generic form, the cost of NTG is low. Chewable forms provide more rapid onset of action, but the duration of action falls to about 2 hours. Because there appears to be no clear benefit over sublingual NTG, the higher cost may not justify chewable forms. Isosorbide dinitrate is also available in a sustained-release form that requires only one to two doses daily, but it has highly variable intestinal absorption, and the risk of nitrate tolerance is higher unless it is used only once daily.

Isosorbide mononitrate offers 100% bioavailability and the convenience of once-daily dosing, but otherwise appears to have no significant clinical advantage over isosorbide dinitrate. Nitrate tolerance occurs less often for the regular formulation. The sustained-release form has the same problems with tolerance as other sustained-release formulations, and the cost is higher.

Monitoring

No specific laboratory monitoring parameters exist for nitrates. Taking the history of efficacy and the number of tablets

to get pain relief is key. Trends of increased use can be tolerance, use of expired meds, or progression of the disease state.

Patient Education

Administration

Patients should take the drug exactly as prescribed. For oral doses taken more than once daily, a nitrate-free interval of 10 to 12 hours is necessary to prevent nitrate tolerance. An eccentric dosing schedule separated by 7 hours (e.g., 7 a.m., 2 p.m.) must be explained to help adherence.

Several drugs come in more than one formulation, from standard to sustained release (see Table 16-18). The patient should read the label if the drug is changed to a different form or a different drug. For sustained-release formulations, the tablets should not be crushed or chewed but must be swallowed whole, and they should be stored in tightly closed amber glass containers. Tablets lose potency when exposed to air, heat, or moisture or when mixed with other tablets. The bottle should not be opened frequently or kept next to the body (e.g., in a shirt pocket) or in an automobile glove compartment. A burning sensation under the tongue is not a reliable method of testing potency. When first opened, the bottle should be dated. It should be replaced within 6 months.

At the first sign of an angina attack, the patient should sit down and place one sublingual tablet under the tongue and allow it to dissolve. It should not be swallowed. If the pain is not relieved, repeat every 5 minutes for up to three doses. If the angina is not relieved by the second dose, the patient should take the third dose and call 911. Dry mouth may reduce the effectiveness of sublingual NTG. Dry-mouth problems should be discussed with the health-care provider. Sublingual spray, which is useful even with dry mouth, may be used in the same manner as the tablet. Lift the tongue and spray the dose under the tongue.

Transdermal patches also require a nitrate-free interval of 10 to 12 hours. The site of application should be changed each time, with the best sites being the anterior chest and the upper arms in areas not covered with hair. Before applying, the clear plastic cover over the medication side of the patch should be removed. A firm pressure should be applied over the patch to ensure contact with the skin. Physical exercise and ambient temperatures may increase absorption by this route. Caregivers should avoid touching the active portion of the patch to avoid getting a HA. Gloves are recommended.

For all forms, doses should not be doubled and should not be discontinued abruptly, which may result in rebound angina. Concurrent use of alcohol should be avoided with these drugs. Because some OTC drugs interact with nitrates or contain alcohol, no new OTC drugs should be taken, including cold remedies, without first discussing this with the health-care provider.

Adverse Reactions

The major adverse reactions are throbbing headaches, rapid heart rates, and decreased BP when arising from a sitting or lying position, with the potential for fainting. Headache may be severe; it is best treated with acetaminophen (Tylenol).

Unremitting headaches should be reported to the health-care provider. Rapid heart rate reactions post-dose should also be reported right away. They may worsen the condition for which the nitrate is prescribed. The chronic background headaches with newly prescribed daily dose formulations abate over a few weeks.

Incontinence of urine and bowel movements, pain on urination, frequent urination, and impotence are rare adverse responses. They should be reported so that a potential cause other than the nitrate can be ruled out or alterations in the drug regimen can be undertaken.

Lifestyle Management

See the previous drug class sections for general information. Orthostatic changes should be anticipated. Slowly making position changes minimizes the BP changes. When arising from lying down, the patient should sit on the edge of the bed for a few minutes before standing to allow the body to adjust to this different position.

PERIPHERAL VASODILATORS (PADs)

Peripheral vasodilators (PADs) are used to treat resistant HTN and PVD, although significant clinical improvement of PVD rarely occurs with these drugs alone. Peripheral alpha$_1$ antagonists and central alpha$_2$ agonists can be used for these purposes. They are discussed in Chapter 14. The focus of the discussion here is on the two remaining PAD drugs, hydralazine (Apresoline) and minoxidil (Loniten). Both are seldom-used add-on therapies, not first-line HTN medications.

Pharmacodynamics

Peripheral vasodilators useful in the treatment of HTN act by direct relaxation and dilation of arteriolar smooth muscle, thereby decreasing PVR. They do not dilate the epicardial coronary arteries and do not relax venous smooth muscle. Minoxidil is considered the more potent.

Pharmacokinetics

Absorption and Distribution

Hydralazine is well absorbed orally. Taking it with food increases absorption. It is widely distributed and crosses the placenta but enters breast milk in minimal amounts. It is compatible with breastfeeding, according to the American Academy of Pediatrics. Minoxidil is also well absorbed orally and widely distributed. It enters breast milk in larger amounts and should not be used while breastfeeding (see Table 16-19).

Metabolism and Excretion

With hydralazine, bioavailability is low and variable among patients, based on their genetics. Rapid acetylators have greater hepatic first-pass metabolism, lower bioavailability, and less antihypertensive benefit than do slow acetylators. Although hydralazine's half-life is short, vascular effects persist longer than blood concentrations would suggest, based on

Table 16–19 ⚏ **Pharmacokinetics: Selected Peripheral Vasodilators**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Hydralazine PO	45 min	1–2 h	6–12 h	87%	30%–50%	3–7 h	12%–14% in urine
Minoxidil	30 min	2–3 h	24+ h	None	UK	4.2 h	20% in urine

UK = unknown.

the avid binding of this drug to vascular tissue. Minoxidil is not protein bound and has a higher bioavailability. Its half-life is also short, but it also has a longer antihypertensive effect because of the persistence of its active metabolite, minoxidil sulfate.

Pharmacotherapeutics

Precautions and Contraindications

Use cautiously in patients with cardiovascular disease. Myo -cardial ischemia may result from the increased oxygen demand associated with SNS stimulation. Because these drugs do not dilate the epicardial coronary arteries, the peripheral arterial vasodilation may "steal" blood flow from any ischemic region of the heart. If used alone, sodium and water retention may precipitate high-output HF, especially in elders. Cautious use is also recommended for patients with pulmonary HTN related to the potential for severe hypotension in the pulmonary circuit.

Adverse Drug Reactions

Decreased peripheral resistance secondary to peripheral vasodilation triggers compensatory responses in the SNS and in the RAA system. These responses prevent the orthostatic hypotension and sexual dysfunction caused by many other antihypertensives, but they precipitate added tachycardia, increased cardiac contractility and output, sodium and water retention, headache, and tachyphylaxis to the antihypertensive effects. Hydralazine sometimes induces a lupus-like syndrome. It appears to be dose-related in that it occurs almost exclusively with doses above 50 mg. The incidence is highest in white women. A positive antinuclear antibody (ANA) test is found

in these patients, but no renal impairment is seen. Discontinuing the drug reverses the syndrome, but the ANA does not return to normal until 6 to 8 months after the drug is stopped. Minoxidil has been associated with elongation, thickening, and enhanced pigmentation of fine body hair. This effect has resulted in its use in treating male pattern baldness.

Both drugs are Pregnancy Category C and should be used only when benefits clearly outweigh risks. Hydralazine is acceptable with breastfeeding, but minoxidil is not. The safety and efficacy of both drugs have not been established by clinical trials with children, but children's doses are listed in the drug literature.

Drug Interactions

Additive effects may occur with other antihypertensives. NSAIDs may decrease their antihypertensive effects. Interactions with BBs and loop diuretics are positive in that they prevent the adverse effects common to the PADs. Specific drug interactions and the appropriate actions to prevent them are given in Table 16-20.

Clinical Use and Dosing

Hypertension

The usual oral dose of hydralazine is four doses daily of 25 to 100 mg, which provides smooth control of BP regardless of acetylator type. The maximum dose recommended is 200 mg/day to minimize the risk of the lupus-like syndrome. Minoxidil is usually started at 5 mg daily and increased at 3-day intervals to 10 mg, then 20 mg, and then 40 mg, each in two divided doses. Effective control of BP may occur at any of these doses. Adult's and children's doses are provided in Table 16-21.

Table 16–20 ⚏ **Drug Interactions: Peripheral Vasodilators**

Drug	Interacting Drug	Possible Effect	Implications
Hydralazine	Antihypertensives, alcohol, nitrates*	Additive hypotension	Avoid concurrent use or monitor BP closely
	MAOIs	Severe hypotension	Avoid concurrent use
	NSAIDs	Reduced antihypertensive effects	Choose different analgesic or anti-inflammatory
	Beta blockers	Increased blood levels of hydralazine	Used concurrently to treat adverse reactions. May require reduction of hydralazine dose.
Minoxidil	Antihypertensives, alcohol, nitrates, guanethidine	Additive hypotension	Avoid concurrent use or monitor BP closely
	NSAIDs	Reduced antihypertensive effects	Choose different analgesic or anti-inflammatory

*Hydralazine may be prescribed with isosorbide dinitrate to treat CHF.

Table 16–21 ⚗ **Dosage Schedule and Available Dosage Forms: Peripheral Vasodilators**

Drug	Indication	Available Dosage Form	Starting Dose	Maintenance Dose
Hydralazine (Apresoline) (G)	Add on for HTN or primary in pregnancy	Tablets: 10, 25, 50, 100 mg	10 mg 4 doses daily. After 2–4 d, may increase to 25 mg 4 doses daily for the rest of the first week, then increase to 50 mg 4 doses daily.	25–100 mg 4 doses daily. Once maintenance dose is achieved, may go to 2 doses daily dosing *Max*: 400 mg/d; to min risk of lupus syndrome 200 mg/d
	Children:		*Children:* 0.75 mg/kg/d in four divided doses	Increase over next 3–4 wk to BP control (see adult dose for protocol).
Minoxidil (G)	Add-on for severe HTN	Tablets: 2.5, 10 mg	5 mg/d increased at 3 d intervals to 10 mg/d then 20 mg/d then 40 mg/d; each in 2 divided doses	5–40 mg/d in two divided doses
			Children <12 yr: 0.2 mg/kg/d in single dose	Increase dose in 50%–100% increments in 3 d intervals until BP control. Usual dose: 0.25–1 mg/kg/d

The SNS stimulation and sodium and water retention problems associated with both of these drugs require the concurrent administration of a BB and a loop diuretic. BBs prevent tachycardia, increased cardiac output, and increased renin release; diuretics prevent the salt and water retention caused by decreased renal sodium excretion.

Heart Failure

Hydralazine with concurrent administration of isosorbide dinitrate has been used to treat HF. This combination has been demonstrated to reduce mortality in HF but is not a primary recommendation in current guidelines. The dosage is up to 800 mg three times daily to reduce afterload. This is not usually a long-term management solution unless the effects of an ACEI are desired in a patient with renal dysfunction. ACEIs, ARBs, BBs, CGs (digoxin), and diuretics are the drugs generally used to treat HF, not PAD drugs.

Rational Drug Selection

These drugs are third-line therapy for moderate to severe HTN. If the individual cannot tolerate the addition of a BB to counter the SNS stimulation of these PAD medications, a nondihydropride CCB (diltiazem, verapamil) might adequately substitute.

Monitoring

These drugs have no specific monitoring requirements beyond those used for patients with HTN. HTN is discussed in Chapter 40 and HF in Chapter 36.

Patient Education

Administration

Patients should take the drug exactly as prescribed at the same time each day. A missed dose should be taken as soon as it is remembered; doses should not be doubled. If more than two doses in a row are missed, the patient should consult the health-care provider. The patient should not stop or alter the dose without first contacting the health-care provider. Hydralazine should be taken with meals to enhance absorption. Minoxidil may be taken without regard to meals.

Adverse Reactions

Hypotensive reactions are the most common. Changing position slowly and avoiding exercise in hot weather can decrease these reactions. The patient should learn home BP and pulse monitoring and report decreases in BP by more than 20 mm Hg or increases in pulse of more than 20 bpm above baseline. Dyspnea, pronounced dizziness, or nausea should be reported. Because fluid retention may occur, patients should weigh themselves daily and report weight gain of more than 5 lb in 1 week or more than 1 lb in 1 day, as well as swelling of hands, feet, or ankles or decreased urine output.

Drug interactions occur with NSAIDs and some OTC drugs, especially cough, cold, and allergy remedies. Because these drugs are Pregnancy Category C, female patients capable of childbearing should be made aware of the risks of these drugs, and contraception should be instituted before they are prescribed.

Lifestyle Management

Adherence with other interventions for HTN, such as weight reduction, low-sodium diet, smoking cessation, moderation of alcohol intake, regular exercise, and stress management, is as important as in the other drug classes.

ANTILIPIDEMICS

Atherosclerosis is the major cause of CVD. It is characterized by deposits of cholesterol and other lipoproteins on the walls of arteries. Four major classes of lipoproteins are found in the serum of fasting individuals: low-density lipoproteins (LDLs), high-density lipoproteins (HDLs), very-low-density lipoproteins

(VLDLs), and triglycerides. The risk for CVD is associated with serum cholesterol levels greater than 200 mg/dL, fasting triglyceride levels greater than 150 mg/dL, LDL levels greater than 100 mg/dL, and HDL levels less than 45 for men and 55 for women. Lifestyle and pharmacological therapies are directed toward bringing elevated levels of these lipoproteins down to specific levels associated with reduced cardiovascular disease risk. The "lower the better" mantra has stronger evidence as the decades extend past the first use of statins (Boekholdt et al, 2014). Raising HDL levels is also theorized as important, but not yet a major part of the treatment protocol because evidence that raising this level has a real impact does not yet exist. Drugs differentially affect LDLs, HDLs, VLDLs, and triglyceride levels. The choice of drug is based on how that drug affects each of these.

This section focuses on the drugs used to lower plasma lipoprotein levels. The pathophysiology of atherosclerosis, the relationship of hyperlipidemia to atherosclerosis development, and the management of hyperlipidemia based on the National Cholesterol Education Program guidelines are discussed in Chapter 39.

> ### On The Horizon — CEPTS
>
> Cholesterol ester transfer proteins (CEPTs) facilitate turning good HDL cholesterol into atherogenic VLDL/LDL particles. Drugs in the pipeline inhibit this protein and it is hoped that they will increase HDL levels. The REVEAL and ACELERATE clinical trials will not publish until 2016.

Pharmacodynamics

Two pathways are involved in the metabolism of lipoproteins. The *exogenous pathway* is central to the lifestyle modifications that are the core of hyperlipidemia therapy. Drugs that affect absorption of fat and cholesterol in the intestine (bile-acid sequestrants and ezetimibe) and drugs that increase lipolysis of triglycerides via lipoprotein lipase (fibric-acid derivatives) also have some of their mechanism of action through this pathway. VLDLs are synthesized and secreted by the liver into the circulation in the endogenous pathway. They are triglyceride-rich, with some cholesterol present. VLDL interacts with lipoprotein lipase in the capillary endothelium to hydrolyze triglycerides into free fatty acids and glycerol, which are then absorbed by fat and muscle cells. About 50% of the VLDL remnants stay in the circulation and become intermediate-density lipoproteins (IDLs). IDLs are then enriched with cholesterol by hepatic triglyceride lipase to become LDLs, which carry about 75% of the circulating cholesterol.

LDL receptors in the liver are down-regulated by the presence of LDL; therefore, one mechanism for lowering LDL is drug therapy that increases the number of LDL receptors in the liver (bile-acid–binding resins, 3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitors). Drugs that inhibit VLDL synthesis in the liver (niacin, fibric-acid derivatives) also reduce LDL via the endogenous pathway.

Elevated lipoproteins, especially LDLs, have been associated with serious and potentially lethal cardiovascular disorders associated with atherosclerosis. HDLs, by contrast, exert antiatherogenic effects. Lowering LDL levels and raising HDL levels through diet, exercise, and drugs have been shown to decrease the progression of atherosclerosis.

Drugs differentially affect LDL, HDL, and triglyceride levels. Their clinical application is based on how they affect each of these. There are four general classes of lipid-lowering drugs: niacin, fibric-acid derivatives, bile-acid sequestrants, and competitive inhibitors of HMG-CoA reductase (Fig. 16-6). Each is discussed separately.

Niacin decreases VLDL and LDL levels. The primary mechanism of action is probably inhibition of VLDL secretion, which, in turn, decreases production of LDL levels by 10% to 15%. Clearance of VLDL via the lipoprotein lipase pathway also results in lowering of triglyceride levels by 20% to 80%. HDL catabolism is concurrently decreased, resulting in elevations of HDL levels by 20 to 30 mg/dL. The drug has no effect on bile-acid production. Reduction in circulating fibrinogen levels and increases in tissue plasminogen levels also decrease the risk for thrombogenesis. In theory, adding it to a statin should bolster the CV risk reduction, but evidence is not there; in fact CV events and strokes increase (Boden et al, 2011). It has fallen out of favor (The HPS2-THRIVE Collaborative Group, 2014).

Fibric acid derivatives (gemfibrozil [Lopid] and fenofibrate [Tricor]) increase lipolysis of triglycerides via lipoprotein lipase, resulting in a decrease of 50% or more in triglyceride
Figure 16–6. Sites of action of antihyperlipidemics.

levels. A decrease in VLDL is also related to decreased secretion by the liver. Only modest reductions in LDL levels (15% to 20%) occur in most patients. Patients with combined hyperlipidemia may actually increase their LDL levels. HDL levels increase by 15% to 25% as a direct consequence of decreasing triglycerides, not by direct action. The reduction of triglycerides (TG) by fenofibric acid does not independently benefit the CV outcomes of the patient but dramatically reduces the risk for pancreatitis that occurs with TG levels over 400 to 500 (Preiss et al, 2012).

A new omega 3 carboxylic acid drug group has added another alternative for high trigylcerdies. Eiscosapentaneoic acid (EPA) + docosahexcienoic acid (DHA) (Epanova) is indicated for triglyceride levels greater than 500mg/dL. The impact on pancreatitis and CV events is not yet known. Icosapentethyl (Vascepa) was marketed in 2012 for the same indication.

Bile acid sequestrants (colestipol [Colestid] and cholestyramine [Questran]) exchange chloride ions for negatively charged bile acids, promoting a 10-fold increase in bile-acid excretion. The increased clearance results in enhanced conversion of cholesterol to bile acids by the liver. Increased uptake of LDL from plasma results from the upregulation of high-affinity LDL receptors on cell membranes, especially in the liver. The net result is decreased LDL levels by 10% to 35%. HDL levels increase about 5%. Triglycerides may also rise initially, but they return to baseline within a few weeks.

Ezetimbe (Zetia) blocks the absorption of cholesterol across the intestinal border. This results in a 12% reduction in LDL; however, it is not considered a first-line therapy. In combination with a statin (e.g., Vytorin), it should increase LDL reduction, but this boosting benefit was not originally reported in a study that used an atypical endpoint not used in other studies for efficacy. This dramatically dropped the use of ezetimbe. It remains an alternative for patients who are statin intolerant and in high CV risk patients. The 2015 release of the IMPROVE—IT data (Improved Reduction of Outcomes: Vytorin Efficacy International Trial) will regenerate discussion of this combination therapy.

Reductase inhibitors (atorvastatin [Lipitor], fluvastatin [Lescol], lovastatin [Mevacor], pitivastatin [Livalo], pravastatin [Pravachol], rosuvastatin [Crestor], and simvastatin [Zocor]) block synthesis of cholesterol in the liver by competitively inhibiting HMG-CoA reductase activity. They induce an increase in high-affinity LDL receptors, resulting in an increased catabolism of LDL and an increase in the liver's extraction of LDL precursors. The net result is LDL levels decreased by 25% to 63%. Modest decreases in triglycerides of 12% to 43% and increases in HDL of 8% to 17% also occur that are independent of the LDL drop, but this response is less vigorous in the diabetic population. The anti-inflammatory properties of these medications are probably more important in CV risk reduction than just the impact on the lipids themselves. Some are associated with reversing the size of atheromas (Nicholls, 2011). This anti-inflammatory property is also being investigated as a potential renal protective agent from radio-contrast dyes (Toso, 2013; Leoncini et al, 2014)).

On The Horizon — PROPROTEIN CONVERTASE SUBTILISIN/KESIN TYPE 9 INHIBITORS

A new biological drug class called proprotein convertase subtilisin/kesin type 9 inhibitors helps clear LDL. Studies done on statin-intolerant patients demonstrated over 50% of LDL reduction in just 12 weeks. These monoclonal antibodies do appear to have a neurological adverse side effect profile. Because they are just coming to market, they are not further covered in this chapter.

Pharmacokinetics

Absorption and Distribution

Absorption and distribution vary greatly among antilipidemics (Table 16-22). Atorvastatin, niacin, fenofibrate, fluvastatin, gemfibrozil, and simvastatin are all well absorbed. Lovastatin, pravastatin, and rosuvastatin are poorly absorbed. The latter are dosed to enable them to have efficacy. Food decreases the rate of absorption of most reductase inhibitors. Food intake increases the rate of absorption of lovastatin and fenofibrate. It does not affect absorption of the other antilipidemics.

Most are widely distributed and enter breast milk in variable amounts. Cholestyramine and colestipol are not absorbed at all and have no distribution. Their action is entirely related to binding bile acids in the gut. Ezetimbe is also not absorbed.

On The Horizon — PHARMACOMETABOLICS

The new field of pharmacometabolics uses genetic and environmental data to inform treatment choices. The microbiome of the gut is being studied as the reason why some patients respond to statins and others do not. Bacteria modify the drug into its active metabolites. Poor responders do not have good levels of bile acids mediated by gut flora (Kaddurah-Daouk et al, 2011).

Metabolism and Excretion

Niacin, fenofibrate, and gemfibrozil have some metabolism by the liver but are excreted mostly unchanged in the urine. These drugs are affected by impaired renal function (Bonds et al, 2012). The reductase inhibitors are extensively metabolized by the liver, often employing CYP 2C6 and 3A4 enzyme systems, and usually on first pass. This explains the universally low bioavailabilities for the immediate-release formulations from less than 5% for simvastatin to 24% for fluvastatin. The extended-release formulation of lovastatin, however, has a bioavailability of 190%. Because reductase inhibitors are largely excreted in bile and feces, with only small amounts excreted unchanged in the urine, plasma levels are not significantly affected by renal function but may increase markedly with hepatic failure and chronic alcoholic cirrhosis. Plasma half-lives are generally short (45 min to 3 h), with

Table 16–22 ⊞ **Pharmacokinetics: Selected Antilipidemics**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Atorvastatin	Rapid	1–2 h	20–30 h	>98%	14%. First pass (CYP3A4)	14 h	<2% in urine
Cholestyramine	24–48 h	1–3 wk	2–4 wk	NA	0%	UK	Insoluble complex in feces
Colestipol	24–48 h	1 mo	1 mo	NA	0%	UK	Insoluble complex in feces
Fluvastatin	1–2 wk*	4–6 wk*	UK	>98%	24% (IR); 29% (XR). Saturable first pass (CYP2C9)	<1 h	5% in urine, 90% in feces
Gemfibrozil	2–5 d*	4 wk*	Months	95%	UK	1.5 h	70% in urine; 6% in feces
Lovastatin	2 wk*	4–6 wk	6 wk	>95%	<5% (IR); 190% (XR). Extensive first pass (CYP3A4)	3–4 h	10% in urine; 83% in feces
Niacin		45 min	UK	UK	UK	45 min	88% unchanged in urine
Pitivastin	UK	1 hour	UK	>99%	51%	12 h	79% feces; 20% urine
Pravastatin	1–2 wk*	4–6 wk*	UK	50%	17%. Extensive first pass	1.8 h	20% in urine; 70% in feces
Rosuvastatin	UK	2–4 wk	UK	88%	20%. 10% metabolized by CYP2C9	19 h	90% in feces
Simvastatin	1–2 wk*	4–6 wk*	UK	95%	<5%. Extensive first pass (CYP3A4)	3 h	13% in urine; 60% in feces

NA = not applicable; UK = unknown.
*Effect on plasma lipids.

the exception of atorvastatin, whose half-life is 14 hours. Bile-acid sequestrants and ezetimibe bind with cholesterol in the intestine and are not metabolized by the liver. They are excreted in bound form in the feces.

Pharmacotherapeutics

Precautions and Contraindications

Active liver disease is a contraindication for all antilipidemics except the bile-acid sequestrants. Marked persistent increases in serum transaminases and drug-induced hepatitis have occurred with reductase inhibitors, and they should be used with caution in any patient who consumes substantial quantities of alcohol or who has a history of liver disease. Routine monitoring of liver function is no longer recommended by the FDA after an intial baseline assessment is normal. Cautious use of the bile-acid sequestrants is suggested for patients with a history of constipation. Phenylketonuria (PKU) is a contraindication for cholestyramine. Severe renal impairment warrants cautious use of those drugs excreted largely unchanged in the urine (niacin, fenofibrate, and gemfibrozil). Some niacin products contain tartrazine (FDC yellow dye #5) and should be avoided for patients with an aspirin allergy. Because of its tendency to GI irritation, niacin should also be

used cautiously for patients with a history of peptic ulcer disease. The extended-release form is linked with hepatitis.

Niacin, fenofibrate, and gemfibrozil are Pregnancy Category C. Risks and benefits should be weighed. All the reductase inhibitors are Pregnancy Category X and should not be given to women who have the potential to become pregnant. No pregnancy category has been assigned to the bile-acid sequestrants because they are not absorbed systemically. All antilipidemics should be avoided during breastfeeding.

The FDA has required that all reductase inhibitors carry a warning about possible blood sugar increases along with concentration and memory issues (FDA, 2012). The JUPITER trial uncovered a 27% increase in new diabetic diagnoses for otherwise "healthy" participants using rosuvastatin, but the warning applies to the entire drug class. There is a small risk of developing more than glucose intolerance (OR, 1.09) (Naci, Brugts, & Ades, 2013). The risk of a major CV event is far greater, so the use of statins should continue.

The low cost of lovastatin has made it a popular generic medication. In 2012, the FDA placed new labeling changes on this statin restricting its use with many classes of medications. These issues did not come to light until its broad use with individuals with polypharmacy resulted in adverse events (Table 16-23).

Table 16–23 ▦ Drug Interactions: Selected Antilipidemics

Drug	Interacting Drug	Possible Effect	Implications
All reductase inhibitors	Digoxin	Slight elevation in digoxin levels. Concurrent administration with atorvastatin may increase steady-state levels by 20%.	If unable to choose alternative drug, monitor for digoxin toxicity. Avoid concurrent use of atorvastatin.
	Warfarin	Increased anticoagulant effect	Monitor PT/INR closely
	Itraconazole and other azole antifungals	Coadministration increases reductase inhibitor levels 20-fold	Temporarily interrupt reductase inhibitor if systemic azole antifungals needed or reduce dose
	Propranolol	Decreases antilipidemic activity	Choose alternative beta blocker
	Erythromycin, HIV protease inhibitors, nefazodone	Potent inhibitors of CYP3A4; may increase risk of myopathy	If must coadminister, monitor closely for myopathy
Atorvastatin*	Maalox TC	Coadministration decreases atorvastatin level by 35%; LDL reduction is not altered	Separate doses by at least 1 h
	Norethindrone, ethinyl estradiol	Increases contraceptive levels by 30% and 20%, respectively	Choose alternative contraceptive or antilipidemic
	Colestipol	Coadministration decreases atorvastatin levels by 25%; LDL reduction greater than either alone	May be therapeutic choice
	Erythromycin	Atorvastatin levels increased by 40%; increased myopathy risk	Choose alternative antibiotic (not clarithromycin)
	Cyclosporine, gemfibrozil, niacin	Increased myopathy and rhabdomyolysis risk	Avoid concurrent use
Cholestyramine	Mycophenolate	Decreases area under curve (AUC) by 40%	Monitor for indications of rejection
	Piroxicam	Elimination enhanced	Choose alternative NSAID
	Thyroid hormones	Possible loss of efficacy with potential hypothyroidism	Choose alternative antilipidemic
	Vitamins A, D, E, K, and folic acid	May interfere with vitamin absorption, with resultant bleeding tendencies	With long-term therapy vitamins A and D may be given in water-miscible form; vitamin K can be supplemented parenterally or orally
	Warfarin	Decreased anticoagulant effect	Choose alternative antilipidemic, or monitor PT/INR more closely
Fluvastatin	Alcohol	Daily intake of 20 g more than 2 h after evening meal or within 1 h of fluvastatin dose increases AUC by 30%	Avoid daily alcohol intake
	Niacin, propranolol, digoxin	Decreases fluvastatin bioavailability	Avoid concurrent administration
	Rifampin	May cause decrease in fluvastatin AUC and plasma clearance	Choose alternative antilipidemic
Gemfibrozil	Warfarin	Enhances anticoagulant effect	Choose alternative antilipidemic or monitor PT/INR closely
	Colestipol	Bioavailability of gemfibrozil reduced	Avoid concurrent use
	Lovastatin, Fluvastatin, Pitavastin, Rosuvastatin	Severe myopathy or rhabdomyolysis	Avoid concurrent use
	Pravastatin	Urinary excretion and protein binding reduced	Avoid concurrent use
Lovastatin	Isradipine	Increased lovastatin clearance with reduced effect	Choose alternative CCB
	Food	Taking on empty stomach decreases absorption by 30%	Take consistently with food
	Grapefruit	Large quantities may increase risk of myopathy	

Table 16–23 ⬛ Drug Interactions: Selected Antilipidemics—cont'd

Drug	Interacting Drug	Possible Effect	Implications
	Itraconazole, ketoconazole, posaconazole		
	Erythromycin, clarithromycin, teliothromycin		
	HIV protease inhibitors, boceprevir, telaprevir		
	Nefazodone		
Pravastatin†	Cholestyramine, colestipol	Decreases pravastatin levels by 40%–50%	Take pravastatin 1 h before or 4 h after bile-acid–binding resins
	Cyclosporine	Coadministration increases pravastatin level 7-fold	Separate doses as above

*Atorvastatin, lovastatin, simvastatin: avoid potent CYP 3A4 inhibitors and do dose reduction with CYP3A4.
†In seniors on clarithromycin avoid rosuvastatin, atorvastatin and fluvastatin.

Adverse Drug Reactions

Cutaneous flushing, especially of the face and upper body, has been associated with niacin. Gradually increasing initial low doses over a few weeks helps to reduce this adverse reaction. Niaspan, an extended-release form of niacin, can be administered at bedtime, with the smaller amount of cutaneous flushing occurring while the patient is sleeping to make the drug more easily tolerated. Taking an ASA 30 minutes prior to niacin, is touted as reducing the hot flashing; however, research does not support this claim. Combining niacin with the antiflushing agent laropiprant generated more adverse outcomes in the HPS2-THRIVE study (2014). Debate exists whether it was the previously untested laropiprant or the niacin at fault. Therefore more research is required.

Fenofibrate and gemfibrozil have a few GI symptoms, including dyspepsia, abdominal pain, and diarrhea. They may also produce cholelithiasis secondary to their increased cholesterol excretion into the bile. They are discontinued if gallstones are found. Both of these drugs have also been associated with mild to moderate decreases in hemoglobin, hematocrit, and WBCs. These levels tend to stabilize, however, with long-term use.

The bile-acid sequestrants' major problems are GI effects, including constipation that may be severe and result in impaction. Constipation is more common in older adults. A laxative or stool softener may be helpful. Other GI symptoms include flatulence, nausea, vomiting, and abdominal pain. Headache is also common. Reduced folate levels have been reported with long-term use, so supplementation with folic acid is suggested. A fairly rare symptom is a burnt odor to the urine.

The reductase inhibitors all have mild headache as a common adverse reaction. A recent concern of increases in intracerebral hemorrhage (ICH) has not been substantiated, but appears to be more common in those with the very lowest of LDL values (Boekholdt et al, 2014). Even patients already with ICH should benefit from statin use. Only those with a lobular bleed appear to have higher risk; however, those types of bleeds have a high re-bleed rate with or without statins (Bustamonte & Montaner, 2013).

Atorvastatin and simvastatin have the lowest adverse reaction profiles, with myalgia reported more at higher doses and more frequently with simvastatin. The water-soluble forms (rosuvastin, pravastin, and pitivastatin [Lovalo]) are reputed to have fewer myalgias than the other lipid-soluble forms (Parker et al, 2012). Fluvastatin, lovastatin, and pravastatin all have GI-associated adverse reactions (dyspepsia, abdominal pain, flatulence, constipation, or diarrhea). Generally, these reactions are mild and transient.

Rhabdomyolysis with renal dysfunction secondary to myoglobinuria has occurred with reductase inhibitors and fibric-acid derivatives. Although it occurs in only 0.1% to 0.5% of patients, when it does occur, it is serious with a fatality rate of 10%. The mechanism for the muscle disruption may be mediated by coenzyme Q10 depletion, among other things (Scordo, 2012). Studies to co-treat with CoQ10 supplementation are mixed. Generally 100 mg twice a day appears to reduce muscle issues (Parker et al, 2012). Pitivastatin does not change CQ10 levels (Parker et al, 2012). Myopathy should be considered in any patient with diffuse myalgias, muscle tenderness and weakness, and elevations in creatine kinase (CK) values more than 10 times the upper limit of normal. Consider temporarily withholding or discontinuing drug therapy in patients with a risk factor predisposing them to the development of renal failure secondary to rhabdomyolysis, including hypotension; major surgery or trauma; severe metabolic, endocrine, or electrolyte disorder; or uncontrolled seizures. Reactions tend to run in families. There are no tests to predetermine who is at risk. Myalgias with one drug might be alleviated by switching to another reductase inhibitor. Interestingly, myalgias are not linked with true muscle weakness (Parker et al, 2012). In 2012, a maximum dose reduction of simvastatin was required owing to higher levels of muscle problems related to its dosing above 40 mg.

Long-term, higher doses of reductase inhibitors were once theorized as being linked with cancer. The 11-year Heart Protection Study did not find any significant differences in cancer rates or incidence (Nicholls, 2011). This finding was repeated in the Cholesteral Treatment Trialist's (CTT) Collaboration meta-analysis of 2015.

Drug Interactions

All antilipidemics except niacin affect warfarin activity: bile acid sequestrants decrease its effect, and the other classes increase its effect. Gemfibrozil and fenofibrate interact with several other antilipidemics. All reductase inhibitors—atorvastatin most of all—increase digoxin levels. Systemic imidazole and triazole therapies increase reductase inhibitor levels by 20-fold. Propranolol decreases the antilipidemic activity of reductase inhibitors. Niacin, erythromycin, and cyclosporine all increase the risk of rhabdomyolysis when given with reductase inhibitors. Combining reductase inhibitors and fibric-acid derivatives also increases the risk for rhabdomyolysis. Taking lovastatin with food enhances its blood levels. Grapefruit ingestion should be avoided with simvastatin, lovastatin and atorvastatin. Specific drug interactions and the appropriate actions to prevent them are given in Table 16-23.

Clinical Use and Dosing

Increased Low-Density Lipoproteins

Niacin, bile-acid sequestrants, and reductase inhibitors all reduce LDL. Reductase inhibitors are first-line drugs in monotherapy and in combinations. Because of the diurnal pattern of cholesterol synthesis, reductase inhibitors are traditionally given in the evening in a single daily dose.

Rosuvastatin is considered the most potent drug in the class with an adverse reactions profile similar to that of atorvastatin, but considered higher risk. The usual starting dose is 5 to 20 mg/d with a maximum of 40 mg/d. Atorvastatin is the next most potent and has the best adverse reaction profile. The usual dose is 10 mg/d initially, increased at 2 to 4 week intervals to up to 80 mg/d.

If costs or other issues prevent using the new lipid drugs for heterozygous familial hyperlipidemia (FH) in children 10 to 17 year olds, reductase inhibitors can be used with the same starting dose, but the maximum dose recommended is 20 mg/d. Simvastatin also has an excellent research profile. It is twice as potent on a weight basis as lovastatin and pravastatin, but less so than atorvastatin. The initial dose is 20 to 40 mg/d, with a maximum of 40 mg/d. For adolescents (10 to 17 yr) with FH, the starting dose is 10 mg/d, with a maximum of 40 mg/d. Lovastatin has a midrange adverse reactions profile. It must be taken with food. The initial dose is 20 mg/d in immediate-release (IR) form or 20, 40, or 60 mg daily of the extended-release form (XR), with dosage increases at 6 to 8 week intervals to a maximum dose of 80 mg/d. For adolescents with FH, the starting dose is 10 mg/d, with a maximum dose of 40 mg.

Pravastatin is similar in potency and its adverse effects profile to lovastatin. The initial dose is 40 mg/d, with a maximum of 80 mg. Pediatric doses for this drug are available for children as young as 8 years of age. For 8- to 13-year-olds, the dose is 20 mg/d, for both initial and maximum doses. For 14- to 18-year-olds, the starting and maximum dose is 40 mg/d. Fluvastatin is about one-half as potent as lovastatin and has a midrange adverse reactions profile. The initial dose is 40 mg/d, with a maximum dose of 80 mg/d. Splitting the dose into two daily doses slightly improves its LDL-lowering ability (Table 16-24).

Table 16–24 ⊗ Dosage Schedule: Selected Antilipidemics Labeled Uses

Drug	Indication	Dosage Form	Starting Dose	Maintenance Dose
Atorvastatin (Lipitor) (G)	Hypercholesterolemia	Tablets: 10, 20, 40, 80 mg	10–20 mg daily. If >45% LDL reduction needed, 40 mg daily	10–80 mg daily. Dosage adjust 2–4 wk intervals *Max:* 80 mg/day
	Intensive LDL reduction post-MI		80 mg	Taper only if LDL levels reached
	Elevated TG		10 mg	10–40 mg/d
			Children: 10 mg	10–20 mg *Max:* 20 mg/d
Cholestryamine (Questran or Questran Light) (G)	Hyperlipidemia	Powder for suspension: 4 g/5 g; 4 g/5.7 g; 4 g/9 g	1 pkt (4 g) mixed in 6–8 oz juice slurry taken 30 min before, during, or 30 min after breakfast and dinner	2–4 pkt (8–16 g) mixed and taken as before *Max:* 24 g/d
			Children: Same as adults	Same as adults
Colesevelam (WelChol) (B)	Hyperlipidemia	Packet for suspension 3.75 mg Tablet: 625 mg	3.75 mg or 6 ts daily with meals and divided doses	3.75 mg/d
Colestipol (Colestid) (G)	Hyperlipidemia	Tablet: 1 g Granules: 5 g per scoop	Granules: 5 g/d in 1–2 divided doses. ts: 2 g/d in 1–2 divided doses	5–30 g/d. Dosage adjust at 1–2 mo intervals

Table 16–24 ⊗ **Dosage Schedule: Selected Antilipidemics Labeled Uses—cont'd**

Drug	Indication	Dosage Form	Starting Dose	Maintenance Dose
Fenofibrate (Antara micronized), Fenoglide, Lipofen, Lofibra Tricor; Triglide) (G)	Hyperlipidemia	Tablet: by market brand (F): 40, 120mg (G): 54, 160 mg (Lo): 54, 160 mg (T) 48, 145 mg (Tg): 50, 160 mg Capsules (A): 43, 130 mg (G): 67, 134, 200 mg (L) 50, 150 mg (Lo) 67, 134, 200 mg	(A): 130 mg/d; (F) 120 mg/d; (Li) 150 mg/d (Lo) 200 mg/d cap or 150 mg tab (T) 145 mg/d (Tgd) 160 mg/d If renal <30 mL/min contraindicated. If mild impairment, refer to package insert by brand.	If started at lowest levels increase dose at 4–8 wk intervals to target lipid levels
	Triglycerides		(A) 43–130 mg/d (F) 40–120 mg/d (Li) 50–150 mg/d (Lo) 54–160 mg/d (Lo micronized) 67–200 mg/d (T) 48–145 mg/d (Tg) 50–160 mg/d	*Max:* 130 mg/d *Max:* 120 mg/d *Max:* 150 mg/d *Max:* 160 mg/d *Max:* 200 mg/d *Max:* 145 mg/d *Max:* 160 mg/d
Fenofibric acid (Trilipix, Fibricor) (G)	Dyslipidemia	Tablet; 35, 105 mg Capsule delayed release: 45, 135 mg	Tablet: 105 mg daily or capsule: 135 mg daily Renal 30–80 mL/min; 35 or 45 mg daily	*Max:* 105 mg or 135 mg daily
	Triglycerides		Tablet: 35–105 mg daily Capsule: 45–135 mg daily	*Max:* Tablet 105 mg or capsule 135 mg daily
Fluvastain (Lescol and Lescol XL) (G)	Hyperlipidemia	Capsules: 20, 40 mg Tablets XL: 80 mg	40 mg/d	40 mg/d or 40 mg 2 doses daily or 80 mg XR/d *Max:* 80 mg/d
	10–16 yr and at 1 yr post-menarche		*Children:* 20 mg/d	Increase as tolerated
Gemfibrozil (Lopid) (G)	Hypertriglyceridemia, adjunct	Tablets: 600 mg	1,200 mg/d in 2 divided doses, 30 min before morning and evening meals	600–1,200 mg 2 doses daily *Max*: 2,400 mg/d
Lovastatin (Mevacor) (G) Extended release (Brand Altoprev)	Hyperlipidemia and primary prevention from CHD	Tablets: 10, 20, 40 mg ER 20 mg (B) 40 mg (B); 60 mg (B)	Adults: (IR) 20 mg/d with evening meal (XR) 20, 40, or 60 mg at bedtime	20–40 mg/d. Dosage adjustments at 4-wk intervals 10–40 mg/d *New Max:* 40 mg/day
	10–17 yr	(IR only) 10–20 mg/d	*Children:* 10 mg/d with evening meal	
			Renal: < 30 mL/min caution	
Niacin (IR = Nicor; XR = Niaspan) (G)	Hyperlipidemia, adjunct for high triglycerides or low HDL	Tablets: 500 mg (Nicor) Tablets (XR): 500, 750, 1,000 mg (Niaspan) Time-release OTC forms are not equal substitute for XL	(IR): 250 mg following the evening meal (XR): 500 mg at bedtime for 1–4 wk	1.5–2 g/d in 2–3 divided doses. Adjust at 4–7 d intervals; may increase to 3 g/d *Max:* 6 g/d Increase to 1 g at bedtime during wk 5–8. If target not met, increase to 1,500 mg at bedtime. *Max:* 2 g/d
Pitivastatin (Livalo brand only)	Hyperlipidemia	Tablets: 1, 2, 4 mg	2 mg daily	2–4 mg day *Max:* 4 mg/day Renal start 1 mg and *max* 2 mg
Pravastatin (Pravachol) (G)	Hyperlipidemia and primary prevention of CHD	Tablets: 10, 20, 40, 80 mg	40 mg once daily	40–80 mg once daily *Max:* 80 mg/d Signf. renal: 10 mg/d

Continued

Table 16–24 ⊗ **Dosage Schedule: Selected Antilipidemics Labeled Uses—cont'd**

Drug	Indication	Dosage Form	Starting Dose	Maintenance Dose
			Children: 8–13 yr: 20 mg once daily. *Children: 14–18 yr:* 40 mg once daily	20 mg once daily *Max:* 20 mg/d 40 mg once daily *Max:* 40 mg/d
Rosuvastatin (Crestor brand only)	Hypercholesterolemia	Tablets: 5, 10, 20, 40 mg	5–10 mg once daily Renal: < 30 mL/min 5 mg max	5–40 mg once daily. Dosage adjustments at 2–4 wk intervals *Max:* 40 mg/d
		10–17 yrs	*Children:* individualized per LDL need	*Max:* 20 mg/d
Simvastatin (Zocor) (G)	Hypercholesterolemia	Tablets: 5, 10, 20, 40 mg	20–40 mg daily in the evening. 10 mg/d for older adults or renal impairment (Ccr <30 mL/min)	20–40 mg/d. 20 mg/d for older adults and renal impairment *New Max:* 40 mg unless on 80 mg prior to 2010 without myalgias
		Girls 10–17 yr at least 1 yr post-menarche	*Children:* 10 mg/d	10–40 mg once daily or in 3 divided doses: *Max:* 40 mg

FH = familial hyperlipidemia; TG = triglycerides; BAS = bile-acid sequestrants; (IR) immediate release; (XR) = extended release.

Chapter 39 presents further discussion on the use of statins. Recent clinical trials have shown that LDL lipid-lowering therapy can now be used in persons in categories near but below the level required for the diagnosis of hyperlipidemia. In general, these new trials strongly reinforce prior recommendations and add a newer imperative of reducing C-reactive protein levels. The emphasis on diet and exercise remains the key, with patients on statins who do active exercise having up to 70% reduction in mortality events. The statin and the lifestyle changes were independent in their impact on outcomes (Kokkinos, Faselis, Myers, Pangiotakos, & Doumas, 2012).

Niacin is touted as lowering LDL cholesterol (20%) and triglyceride levels (30% to 40%) and raising HDL levels (30%); these claims are now suspect. As a B-complex vitamin, it is available OTC, but OTC doses are not sufficient to lower LDL. In prescription strength, niacin has been shown to reduce all-cause mortality for patients with CVD, when given as monotherapy. It failed to positively increase any CV outcomes when mixed with statins in both the AIM-HIGH (Boden, et al, 2011) and HPS2-THRIVE studies (2014). Because of its many adverse reactions, if used at all, it is most frequently given as adjunctive therapy with a bile acid sequestrant or a reductase inhibitor for patients with very high triglyceride and/or low HDL levels. For hyperlipidemia, a dose of 1.5 to 2 g/d is usually enough. The daily dose should be divided and given with meals, starting at 250 mg at bedtime and gradually increased at 4 to 7 day intervals (see Table 16-24).

Bile-acid sequestrants are best for patients with a low CV risk profile and moderately elevated LDL levels but who are unable to reduce their LDL by diet alone. Their biggest drawback is their GI adverse effect profile. Cholestyramine and colestipol come in powdered form. The initial dose is one packet mixed with juice in a slurry. They are never swallowed in dry form. Colestipol and colesevelam come in tablet form and require a large glass of water to follow. The dose is taken one-half hour before or during a meal or one-half hour after a meal for several days. Doses are increased gradually, based largely on GI adverse reactions. A common dose is 2 to 4 packets or 3 tablets at breakfast and supper.

Elevated Very-Low-Density Lipoproteins and Elevated Triglycerides

Fenofibrate and gemfibrozil are the most potent triglyceride-lowering agents because of their effect on VLDL. To prevent pancreatitis in patients with marked hypertriglyceridemia, niacin in large doses may be used for patients who do not respond to fibric-acid derivatives. Doses vary not only by drug but also by brand of fenofibrate. Data from the Helsinki Heart Study resulted in the recommendation that this drug not be used for patients with combined hyperlipidemia who have CVD symptoms. Bile-acid sequestrants and reductase inhibitors also produce marked reduction in triglyceride levels.

Omega-3 fatty acids can also be used for triglyceride care. EPA and DHA are found in fish and ALA is found in plants and flax seed oil; only the first two lower TG (American Academy of Nurse Practitioners [AANP], 2012). Prescription strength (Lovanza) and OTC omega-3 are also available. The prescription drug can drop TG by 14% to 30% and increase HDL by 15%. The highly reported "fish burp" side effect is actually only documented in 6% of research subjects. Evidence has not yet been established that fish oils impact mortality and the hope that they will reduce atrial arrthymias has been discounted (Mozffarian et al, 2012). They have also lost luster as good lipid therapy alternatives.

Decreased High-Density Lipoproteins

Niacin is an effective agent in increasing levels of HDL, with the percentage of increase near 30%. Gemfibrozil and fenofibrate are the next best at increasing HDL, followed by some reductase inhibitors. Rosuvastatin, atorvastatin, and simvastatin also have an ability to raise HDL 15%. Now recognized as a risk factor in heart disease, isolated low HDL levels are now addressed. Any increase in HDL is a bonus effect when choosing a drug to treat elevated LDL or VLDL levels. Currently there are no specific HDL-raising agents that reflect the same success as found in the statin impact on LDL (Parker et al, 2012).

Rational Drug Selection

In addition to the nature of the lipoprotein abnormality and the mechanism of action and adverse reaction profile of the drug, as discussed previously, factors taken into account in selecting the appropriate drug or drug combination include degree of CVD risk, age of the patient, and cost.

Degree of Coronary Vascular Disease Risk

For all risk groups, dietary reduction in saturated fat and cholesterol along with increased fiber intake is first-line therapy. For the highest-risk patient, these lifestyle changes are concurrently initiated with medications. For low-risk patients, diet might be adequate to control LDL levels.

For high-risk patients, reductase inhibitors are the most cost-effective and should be tried first. Absolute cut points of LDL values are no longer used with the new guidelines. However, the old ATP III values help new providers quantify what is a high or low benchmark for consideration when drawing up individualized therapeutic plans. When baseline LDL is greater than 130 mg/dL, relatively high doses or combination with other antilipidemics may be needed to achieve desired outcomes (Gibson et al, 2009; Nicholls et al, 2011). Commonly, achieving a individualized LDL goal is difficult with only one drug class. If patient response is inadequate after 4 months, switching to a more potent drug or trying a combination of drugs is standard step therapy. Combinations of reductase inhibitors with bile-acid sequestrants or niacin logically should increase impact, but the AIM-HIGH and HPS-THRIVE studies have dampened this expectation. The combination of a reductase inhibitor with fibric-acid derivatives is risky because of the increased risk for rhabdomyolysis. Patients whose response is still inadequate should be referred to a lipid disorder specialist. Aiming for the lowest LDL is indicated for the highest risk patients (Boekholdt et al, 2014).

For moderate-risk patients, drug therapy is based on 10-year CV risk. If that risk is greater than 7% to 10 %, reductase inhibitors are appropriate per the 2013 guidelines. Now, almost 1 of 3 Americans possibly qualify for statin therapy. For lower levels of risk, drugs generally are not needed if dietary modifications are followed. For isolated low-HDL patients, aerobic exercise, smoking cessation, and weight loss if they are obese are added to the dietary therapy. There is to date no evidence that drug treatment to increase HDL levels reduces CVD risk or mortality. Further discussion occurs in Chapter 40.

Elevated triglycerides are recognized as an independent risk factor for CVD, especially in women. Fibric-acid derivatives are the drugs of choice when treatment is chosen. It is also the drug of choice for patients with very high triglyceride levels (greater than 800 mg/dL) who are at risk for pancreatitis because of this high level. Attention to LDL reduction remains paramount, because TG reduction typically comes with LDL reduction.

Age

The prevalence of hypercholesterolemia and CVD risk is greatest among people older than age 65 years. Because dietary therapy alone often fails to achieve the LDL goal in older adults, drug therapy is used as an adjunct. Reductase inhibitors are the first-line choice. These drugs are well tolerated in the older adult, with minor diarrhea and occasional sleep disturbances being the most common problems. Monitoring of LFTs is no longer required for the general population. Because of the polypharmacy of elders and the fact these drugs are processed in the liver, it is prudent to monitor LFTs in selected older patients. Seniors on the antibiotic clarithromycin have a slight increased risk of acute renal injury and potassium levels with rosuvastatin, pravastatin, and fluvastatin (Li et al, 2014).

Niacin is not suggested in elders because it triggers hypotension and arrhythmias. Multiple daily dosing is also required, which may increase the complexity of a drug regimen often already complex. Bile-acid sequestrants are safe for older adults, but their GI problems, especially the risk of constipation and impaction, and their effect on the absorption of many of the drugs that older adults are often also taking make them less desirable than reductase inhibitors. Fibrates are known to increase creatinine levels in elders with DM but paradoxically may also slow down renal functional loss over time (Bonds et al, 2012).

Some reductase inhibitors (see current dosing circulars) have been approved for children with heterozygous or homozygous familial hypercholesterolemias with some residual receptor activity. The safety of most other antilipidemics has not been established for those under age 18.

Cost

Brand-name drugs are always more expensive than generic. Currently rosuvastin does not come in generic form; nor do the fibrates.

Monotherapy Versus Multiple Drugs

Few patients can achieve lipid targets on one drug class alone. The high doses required to do so result in unacceptable adverse responses. Combinations of drugs are the rule to achieve target levels. Specific combinations are discussed in Chapter 39.

Monitoring

Reduction of the LDL cholesterol level is the top priority, but the other lipid levels are gaining in importance. Labs should be measured beginning about 4 to 6 weeks after initiation of therapy and then every 3 to 4 months until control is established. After that, every 6 to 12 months is usually enough.

Monitoring protocols for specific drugs in addition to the standard lipid levels are as follows. For niacin, LFTs, uric-acid levels, and blood glucose levels are done initially at 4 to 6 week intervals until a stable dose is determined, and thereafter at 3 to 4 month intervals. For reductase inhibitors, LFTs are done prior to initiating therapy, after the first 3 months of therapy, and then only as indicated. If aspartate aminotransferase (AST) or alanine aminotransferase (ALT) levels increase to 3 times normal, reduce the dose or discontinue therapy. CK levels are monitored if muscle tenderness is exhibited. Statins may raise fasting blood sugars; however, the low glucose levels drawn in fasting patients can give a false sense of security. Longer-term glucose monitoring (i.e., HgA1C) will give a clearer picture of the impact of glucose metabolism for individual patients. For fibric-acid derivatives, LFTs should be assessed prior to initiating therapy and with the same protocol as reductase inhibitors.

Patient Education

The importance of patient education in the treatment of hyperlipidemia cannot be overemphasized because lifestyle management is the key to success (Kokkinos et al, 2012). This is also discussed in Chapter 39.

Administration

The patient should take the drug exactly as prescribed and not skip doses or double up on missed doses. Bile-acid sequestrants are taken before meals, mixed and vigorously shaken with 4 to 6 oz water, milk, fruit juice, or other noncarbonated beverage. Rinsing the glass with a small amount of additional liquid ensures that the entire dose is taken. For patients who require thick liquids, these drugs can also be mixed with cereals or pulpy fruits such as applesauce. The powder cannot be taken dry. If other drugs are to be taken, administer them 1 hour before or 4 hours after the bile-acid sequestrant. Reductase inhibitors are traditionally taken in the evening because of their action on cholesterol synthesis; however, this is not clinically significant except for lovastatin. Lovastatin is the only reductase inhibitor that should be taken with the evening meal to improve its absorption. Atorvastatin can be taken at any time of the day and without regard to food.

Adverse Reactions

Cutaneous flushing, especially of the face and upper body, has been associated with niacin. Hot fluids taken near the time of the dose make the flushing worse. Taking niacin with meals reduces the incidence of this reaction. A high-fiber diet or psyllium supplement just before a meal usually ameliorates the flatulence, constipation, or abdominal pain associated with bile-acid sequestrants. Natural laxatives such as prunes or stool softeners can also be helpful. For these drugs and for fibric-acid derivatives, the provider should be notified of persistent constipation. For all reductase inhibitors, muscle tenderness or pain may indicate a serious problem that may require discontinuance of the drug. Fluvastatin, lovastatin, and pravastatin all have GI-associated adverse reactions (dyspepsia, abdominal pain, flatulence, constipation, or diarrhea) and headache. Generally, these effects are mild and transient.

Suggestions to try a CQ10 supplement may be helpful, but the evidence on its usefulness is not well established (Scordo, 2012).Because the reductase inhibitors are Pregnancy Category D or X, female patients capable of childbearing should not take these drugs, or contraception should be instituted before prescribing them. The health-care provider should be notified if pregnancy is planned or suspected.

A meta-anlysis has put to rest the idea that women do not benefit as much as men from statin therapy. The positive effect is the same for each gender with a proportional reduction in major CV events no matter the level of risk (CTT, 2015).

Lifestyle Management

For a cardiac-healthy lifestyle, it is important to stress the need for regular aerobic exercise and smoking cessation. Medication helps to control hyperlipidemia, but it does not cure it. Lifestyle management is discussed in more detail in Chapter 39.

DIURETICS

Diuretics are first-line therapy in the treatment of HF and HTN through their reduction in ECF volume. Of the several classes of diuretics, the ones most commonly used in primary care are the distal tubular (thiazides and aldosterone antagonists) and loop diuretics. These drugs are the focus of this discussion. Amiloride (Midamor) is not an aldosterone antagonist, but is also a potassium sparing diuretic. It is covered tangentially as an adjunct medication.

Pharmacodynamics

Disease processes that increase renal sodium and water retention result in increased ECF volume. This increased volume increases capillary hydrostatic pressure. Taken together, the result is increased afterload, which leads to increased myocardial workload. Increased ECF volume also contributes to HTN. Diuretics act to reduce this volume in different ways (Fig. 16-7). The loop diuretics inhibit sodium reabsorption in the ascending loop of Henle. These drugs are short-acting and cause a large natriuresis. The thiazide-type diuretics act on the distal renal tubule to inhibit sodium reabsorption. Their effect is generally longer-lasting, and they cause less brisk diuresis. Both of these classes increase potassium excretion. The potassium-sparing diuretics include aldosterone antagonists and agents like amiloride that inhibit excretion of potassium distally. These agents are weak diuretics, often used in combination with thiazides to reduce potassium loss.

Initially, diuretics promote natriuresis, decrease plasma volume, and reduce cardiac output. With time, these effects return to baseline, but total peripheral resistance remains decreased. The mechanism behind this additional long-term effect of diuretics is not clearly known but may be related to the amount of sodium in the vessel walls themselves. Theoretically, sodium in vessel walls contributes to the ability of the vessels to constrict, and loss of sodium from the vessel walls may contribute to vasodilation, leading to decreased
Figure 16–7. Sites of action of diuretics.

PVR. Decreased PVR reduces afterload to improve cardiac functioning and reduce BP.

Diuretics may also be used as adjunct therapy for disease processes in which the treatment itself may contribute to fluid retention—for example, use of some CCBs and antiarrhythmics. Spironolactone blocks the mineral corticosteroid receptor that aldosterone binds to. This could be a useful action for aldosteronism. It is also useful in ventricular remodeling and decreasing the inflammatory cascade that can occur in the days following an MI; however, evidence is not yet there to demonstrate any long-term outcomes of HF symptoms or QOL measures (Edelmann et al, 2013). Amiloride's potassium-sparing characteristics are used to counter any chronic potassium losses that cannot be reliably corrected with diet or supplements.

Pharmacokinetics

Absorption and Distribution

Absorption and distribution vary among the diuretics (Table 16-25). Thiazide and loop diuretics are all well absorbed orally. Among the potassium-sparing diuretics, spironolactone (Aldactone) is well absorbed, amiloride (Midamor) is poorly absorbed, and triamterene (Dyrenium) has an absorption rate somewhere between the two. Food enhances the absorption of metolazone (Zaroxolyn). All are widely distributed, cross the placenta, and enter breast milk. The thiazides enter intracellular spaces as well, which may explain their preferential use in refractory edema.

Metabolism and Excretion

The liver is the primary site of metabolism for most diuretics. Furosemide (Lasix) has nonhepatic and hepatic metabolism. Amiloride is not metabolized by the liver. All diuretics are excreted mostly unchanged in the urine. Metolazone, amiloride, bumetanide (Bumex), and spironolactone have some excretion in feces and bile. Plasma half-lives vary from 30 to 60 minutes for furosemide to 35 to 50 hours for chlorthalidone. Impaired renal or hepatic function increases the half-life of furosemide.

The Kidney Disease Outcomes Quality Initiative (KDO-QI) guidelines encourage replacing thiazide diuretics with loop medications when GFR drops to 30 mL/min. Amiloride

Table 16–25 ⬛ **Pharmacokinetics: Selected Diuretics**

Drug	Onset (h)	Peak (h)	Duration (h)	Protein Binding	Bioavailability	Half-Life (h)	Elimination
Thiazide and Related Diuretics							
Chlorthalidone	2–3	2–6	24–72	UK	64%	35–50	Unchanged in urine
Hydrochlorothiazide	2	4–6	6–12	20%–80%	65%–75%	5.6–14.8	Unchanged in urine
Indapamide	1–2	2	up to 36	71%–79%	93%	14	–7%; unchanged in urine
Metolazone	1	2	12–24	<20%	65%	No data	6%–15% in feces, partially excreted; unchanged in urine
Loop Diuretics							
Bumetanide	0.5–1	1–2	4–6	94%–96%	72%–96%	1–1.5	50% in urine; 20% in feces
Furosemide	1	1–2	6–8	91%–97%	60%–64%	0.5–1 (increased in renal and hepatic impairment and in neonates)	Unchanged in urine
Potassium-Sparing Diuretics							
Amiloride	2	6–10	24	23%	15%–25%	6–9	50% in urine
Eplerenone	UK	1.5 hr	UK	50%	69%	4–6	Urine 67%; feces 32%; 5% unchanged
Spironolactone	24–48	48–72	48–72	>98%	>90%	13–24	In urine and bile
Triamterene	2–4	6–8	12–16	50%–67%	30%–70%	3	21% in urine

UK = unknown.

is contraindicated in diabetic nephropathy patients, and others with BUN levels over 30 mg/100 mL or creatinine levels over 1.5 mg. Metolazone is the only thiazide effective in stage 3 or 4 CKD (Zuber & Davis, 2012).

Pharmacotherapeutics

Precautions and Contradictions

All diuretics affect electrolytes. They should be used cautiously for patients with preexisting electrolyte abnormalities. Potassium-sparing diuretics have an absolute contraindication for patients with severely impaired renal function because they can produce hyperkalemia. Creatinine clearances less than 25 to 30 mL/min suggest careful monitoring of electrolytes and cautious use with all diuretic classes. Hepatic dysfunction suggests cautious use with all diuretics, especially those with some excretion in feces or bile.

For patients with a history of gout or renal calculi, cautious use of diuretics is suggested because of the potential for hyperuricemia. Diuretics should be used cautiously for patients with diabetes, who may require alterations in their hypoglycemic regimen related to glucose intolerance. The glucose issues with thiazides may turn out to be transient and not

clinically significant in the long term. There are fewer issues with metolazone and indapamide.

Older adults are at increased risk for hypotension with these drugs. They require careful BP monitoring and patient teaching about mobility with the background of possible orthostasis. The use of thiazide and loop diuretics has been associated with increased risk of falls in older adults. Any tinnitus or hearing loss should not be dismissed as age-related but be considered significant side effects.

Diuretics decrease plasma volume and may decrease placental perfusion. Several thiazide and loop diuretics are Pregnancy Category C and should be used only when benefits clearly outweigh risks. Jaundice and thrombocytopenia may be seen in neonates. Spironolactone, amiloride, hydrochlorothiazide, and chlorthalidone are Pregnancy Category B. Spironolactone appears to be the best choice for pregnant women when a diuretic must be used. Safety has been established in children only for furosemide, hydrochlorothiazide, and spironolactone.

Adverse Drug Reactions

Electrolyte imbalances are common in all diuretic classes. Thiazide and loop diuretics cause hypokalemia and may cause hypercalcemia, hyponatremia, and hypomagnesemia. When it

occurs, the hypomagnesemia must be corrected first to permit successful treatment of the hypokalemia. The average potassium loss is 0.6 mEq/L and is dose-related. High sodium intake as is found in many American diets exacerbates the potassium loss. Metabolic alkalosis may be associated with the hypokalemia. Potassium-sparing diuretics cause hyperkalemia especially when combined with ACE or ARB medications. High levels of uric acid may occur with all diuretics; thiazide and loop diuretics and spironolactone are the most likely to cause it, and indapamide (Lozol) is the least likely. The hyperuricemia itself is usually not treated unless gout or renal calculi develop.

Glucose intolerance can be a problem with all diuretic groups; thiazide and loop diuretics cause the most difficulty. This intolerance is directly linked to the serum potassium level. Correcting hypokalemia often relieves the problem. Hyperlipidemia with increases in cholesterol, LDL, and triglycerides has been seen with thiazide diuretics. The elevations are transient and tend to return to baseline in about 6 months. It is unknown what, if any, CV implications this transient rise has for diabetics who are already considered high-CV risk.

Hypotension secondary to fluid volume deficits can also occur with all diuretics. Starting with a low dose and increasing the dose gradually can reduce this problem. Instructing patients that oral fluid reduction is not indicated with these medications can help in this regard.

Gynecomastia occurs in 50% of patients receiving spironolactone. Impotence occurs in a smaller number. This can be distressing to men and their significant other. The next generation of this drug class, eplerenone (Inspra), has more affinity for the mineral corticoid receptor, but the reputed decrease in menstrual irregularity, acne, and gynecomastia is not considered significant enough to replace the older, generic spironolactone with this costly alternative (Chatterjee et al, 2012). The positive impact of eplerenone on HF outcomes during ACS is due to the reduction in BNP, a fact not previously researched with this drug class (Montalescot, 2013). Thiazide is known to have photosensitive reactions that can last years after discontinuation (Drucker & Rosen, 2011).

Drug Interactions

All diuretics have potential additive hypotensive effects with other drugs that lower BP. Synergistic hypokalemia is probable between thiazide and loop diuretics, and additive hypokalemia may occur between these classes and mezlocillin, piperacillin, ticarcillin, amphotericin B, and glucocorticoids. Hypokalemia may increase the risk of CG toxicity. Concurrent administration of potassium-sparing diuretics and ACEIs may lead to significant hyperkalemia. Potassium preparations, including nonsodium salt substitutes, may also result in significant hyperkalemia.

Thiazide and loop diuretics decrease the renal excretion of lithium and may induce lithium toxicity. These two classes may decrease the action of sulfonylureas and insulin. Thiazide diuretics and spironolactone diminish the anticoagulant effects of warfarin, whereas loop diuretics enhance its anticoagulant effects. Additive ototoxicity occurs between loop diuretics and aminoglycosides and cisplatin. NSAIDs and salicylates may decrease the diuretic effectiveness of all classes. Specific drug interactions and the appropriate actions to prevent them are given in Table 16-26.

Table 16–26 ▦ **Drug Interactions: Selected Diuretics**

Drug	Interacting Drug	Possible Effect	Implications
Thiazide diuretics	Allopurinol	Concurrent use may increase incidence of hypersensitivity reactions	Avoid concurrent use
	Anticholinergics	Increased diuretic absorption	Monitor diuretic effect
	Anticoagulants	Diminished anticoagulant effect	Monitor PT/INR. Adjust anticoagulant dose prn.
	Antigout agents	Diuretic may increase uric acid levels	Choose different diuretic or adjust antigout agent dose
	Antineoplastics	Diuretic may prolong antineoplastic-induced leukopenia	Monitor WBC. Choose alternative diuretic.
	Bile-acid–binding resins	Resins bind thiazides and reduce absorption by up to 85%	Give thiazide 2 h before or 4 h after bile-acid–binding resin
	Calcium salts	Hypercalcemia may be worsened	Avoid concurrent use
	Diazoxide	Hyperglycemia, often with symptoms of frank diabetes	Choose alternative antihypertensive
	Digitalis glycosides	Digitalis toxicity and toxicity-induced arrhythmias	Monitor potassium level and administer supplement as needed
	Lithium	Decreased renal excretion of lithium, resulting in toxicity	Monitor lithium level closely, or choose alternative diuretic
	Loop diuretics	Synergistic diuresis and hypokalemic effects	Reduce doses of both or one of these unless planned for therapeutic reasons. Monitor electrolytes closely.

Continued

Table 16–26 ⁂ **Drug Interactions: Selected Diuretics—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
	NSAIDs	Some may reduce diuretic effect; concurrent administration of indomethacin has been associated with renal failure	Monitor diuresis. Avoid concurrent administration of indomethacin.
	Sulfonylureas, insulin	Diuretics induce hyperglycemia and may decrease hypoglycemic effects	Monitor serum glucose. Adjust dose of hypoglycemic.
	Vitamin D	Biologic actions of vitamin D enhanced, resulting in hypercalcemia	Monitor serum calcium levels
Loop diuretics	Aminoglycosides, cisplatin	Increased risk for ototoxicity	Avoid concurrent use. If you must use aminoglycoside, use different diuretic during time it is administered.
	Anticoagulants	Enhanced anticoagulant activity	Monitor PT/INR. Adjust dose prn.
	Digitalis glycosides	Digitalis toxicity and toxicity-induced arrhythmias	Monitor potassium levels and administer potassium supplement prn
	Hydantoins	Reduces diuretic effect of furosemide	Monitor diuretic effect and adjust dose prn
	Lithium	Decreased renal excretion of lithium, resulting in toxicity	Monitor lithium levels closely or choose different diuretic
	NSAIDs, salicylates	Reduces effects of diuretic	Monitor diuretic effect and adjust dose
	Sulfonylureas	Diuretic-induced hyperglycemia may reduce hypoglycemic effect	Monitor serum glucose and adjust dose of sulfonylurea, or choose different diuretic
	Theophylline	Actions of theophylline may be enhanced or inhibited	Monitor theophylline levels closely, or choose different bronchodilator
Potassium-sparing diuretics	ACE inhibitors, potassium preparations	Concurrent use may result in hyperkalemia	Avoid concurrent use. Choose different diuretic.
	Anticoagulants	Decreased anticoagulant effects	Monitor PT/INR and adjust dose prn
	Cimetidine	May increase bioavailability and decrease renal clearance of triamterene only	Choose alternative histamine$_2$ blocker
	Digitalis glycosides	Interaction complex and difficult to predict risk of toxicity	Monitor digitalis level closely or avoid concurrent use
	NSAIDs salicylates	Decreased diuretic effect; interaction with indomethacin has resulted in renal failure	Monitor diuretic effect. Avoid concurrent use with indomethacin.

Clinical Use and Dosing

Regardless of the clinical use, start with the lowest effective dose, increase the dose gradually to reduce the likelihood of adverse reactions, consider reducing doses where appropriate, and consider potassium supplementation or combination with a potassium-sparing diuretic when laboratory studies indicate it is appropriate. Supplementation with potassium chloride of 20 mEq daily is sufficient for prevention of hypokalemia in most patients. Those with additional potassium losses will need 40 mEq/daily or more (Cohn, Kowey, Whelton, & Prisant, 2000).

Hypertension

Initial drug therapy for HTN is monotherapy, although rarely is one drug sufficient to achieve target BP. When the decision is made to begin drug therapy and there are no clear indications for another type of drug, a thiazide-type diuretic should be chosen because, in randomized controlled trials (RCTs) comparing diuretics with other classes of antihypertensive drugs, diuretics have been unsurpassed in preventing cardiovascular complications of HTN (Wright et al, 2009). The choice of diuretic should be based on level of kidney function and possibly weight. For estimated GFR rates higher than the mid-40 mL/min range, a thiazide diuretic should be used because loop diuretics are not as effective as thiazides in this setting. For GFRs less than the mid-40 mL/min range, loop diuretics, sometimes in combination with metolazone, are more appropriate. They are most effective when dosed twice daily.

Diuretics are preferred as initial therapy for sodium-sensitive patients such as blacks, older adults, the obese, and those with renal insufficiency. Thiazide diuretics are generally not the first drugs of choice for patients with hyperlipidemia because of their potential for worsening the hyperlipidemia; however, lipid disorders do not contraindicate the use of thiazide diuretics. Newer interpretation of the evidence implies nonobese patients are not good candidates for diuretics as first-line drugs. The ACCOMPLISH trial

demonstrated a 30+% difference in therapeutic impact based on weight with a recommendation that nonobese patients without another compelling reason for volume control be started on a different class of medications (Weber et al, 2012).

All classes of diuretics have been used to treat HTN, but the best results are with thiazide-type diuretics. The dose–response curve of diuretics is fairly flat. Increasing the dose produces more adverse reactions with little change in therapeutic benefit. Dosage should be increased no sooner than 4 weeks, which is the length of time usually required to achieve optimal therapeutic effect. When a thiazide diuretic is added to an existing antihypertensive regimen, reduce the dosage of the other antihypertensives to prevent excessive hypotension and orthostasis.

Edema Associated With Congestive Heart Failure, Hepatic Cirrhosis, and Renal Disease

First-line therapy in treating HF is with ACEIs, depending on the stage of failure. Chapter 36 discusses the most appropriate drug for initiation of therapy based on stage. Drugs are often introduced in combinations. The role of diuretics is supplemental and only part of a treatment regimen. The most effective class for this indication is the loop diuretics. Torsemide is a very good long-acting loop diuretic that is especially useful in HF management.

Loop diuretics are effective in moderate to severe disease and can be used when Ccr is less than 25 mL/min. Indapamide is also indicated for edema associated with HF and is effective with these low Ccr levels. Thiazide diuretics may be used to treat the edema associated with mild HF, corticosteroid and estrogen therapy, premenstrual syndrome, and limited renal dysfunction. They are not useful if the Ccr is less than 25 mL/min. Among the thiazides, hydrochlorothiazide and chlorthalidone are the first choices for this indication. Intermittent dosing may be advantageous and reduce the incidence of adverse reactions. With premenstrual syndrome, the drug should be taken 3 to 5 days before menstruation and discontinued when menstruation begins. Frequent dosage adjustments may be necessary in edematous patients. Dosages for both indications for each drug are indicated in Table 16-27.

Table 16–27 ⊗ Dosage Schedule: Selected Diuretics Labeled Use

Drug	Indication	Dosage Forms	Starting Dose	Maintenance Dose
Amiloride (Midamore) (G)	K+ sparing. Adjunct Rx edema of CHF and HTN	Tablets: 5 mg	5 mg daily	10 mg daily or 5 mg 2 doses daily *Max:* 20 mg/d
Bumetanide (Bumex) (G)	Edema of CHF, hepatic and renal disease; alt for Lasix allergy	Tablets: 0.5, 1, 2 mg	0.5 mg daily	2 mg/d; or dosing every other day or 3–4 d with 1–2 d between is safe and most effective *Max:* 20 mg/d
			Children: 0.015– 0.1 mg/kg/d every 6–24 h *Max:* 10 mg	
Chlorthalidone (Hygroten and Thalitone) (G)	Edema	Tablets: 15 mg (T only) 25, 50, 100 mg	50–100 mg/d	150–200 mg/d *Max:* 200 mg/d *Renal:* 40 mL/min probably ineffective
	Edema from HF		12.5 mg	12.5–25 mg/d *Max:* 100 mg/d
	HTN	<None>	25 mg/d	25–50 mg/d *Max:* 100 mg/d
Eplerenone (Inspra) (G)	HTN	Tablets: 25, 50 mg	50 mg/d (make take 4 wk for full effect)	Up to 50 mg twice daily
	HF post-MI		25 mg/d	Titrate to 50 mg in 4 wk
	High K+ dosing in HF		5.5–5.9 mEq/L decrease from 50 mg to 25 mg/d or every other day 6.0+ withhold	
Furosemide (Lasix) (G)	Refractory edema of CHF, hepatic and renal disease	Solution: 40 mg/5 mL; 10 mg/mL Tablets: 20, 40, 80 mg	20–80 mg daily or 2 doses daily	Titrate in increments of 20–40 mg q6–8h until desired diuresis; give 2 doses daily 8 a.m. and 2 p.m. *Max:* 600 mg/d in divided doses

Table 16–27 ⊗ **Dosage Schedule: Selected Diuretics Labeled Use—cont'd**

Drug	Indication	Dosage Forms	Starting Dose	Maintenance Dose
	HTN		40 mg 2 doses daily	Titrate up or down to control HTN
	Edema in infants and children		*Children:* 2 mg/kg/d	Titrate in increments of 1 mg/kg q6–8h until desired diuresis *Max*: 6 mg/kg/d
Hydrochlorothiazide (HydroDiurilMicrozide)	HTN	Capsules: 12.5 mg Tablets: 12.5, 25, 50 mg Micronized capsules: 12.5 mg (Minzide only)	12.5 mg/d	12.5–50 mg daily or in two divided doses Rarely need more than 50 mg/d *Max*: 100 mg/d
	Edema		25–100 mg/d in 1–2 divided doses	*Max*: 200 mg/d
	Edema or HTN: Infants <6 mo Infants 6 mo–2 yr Children 2–17 yr		1–3 mg/kg/d in 2 divided doses Same 3 mg/kg/d	*Max*: 37.5 mg age 6 mo–2 yr *Max*: 50 mg/d until age 17
Indapamide (Lozol) (G)	HTN	Tablets: 1.25 mg (B) 2.5 mg (B) 2.5 mg (G)	1.25 mg daily	2.5–5 mg d; increase at 4-wk intervals *Max*: 5 mg/d
	Edema of CHF		2.5 mg daily	If inadequate in 1 wk, up to *max* 5 mg/d
Metolazone (Zaroxolyn) (G)	Adjunct therapy for HTN	Tablets: 2.5, 5, 10 mg (G only)	2.5 mg daily	2–5 mg daily *Max*: 20 mg daily
	Edema		5 mg daily	10 mg daily *Max*: 20 mg daily
Spironolactone (Aldactone) (G)	HTN	Tablets: 25, 50, 100 mg	25–50 mg/d in divided dose	50–100 mg in 1–2 doses daily *Max*: 100 mg/d
	Edema of CHF (not severe), hepatic and nephrotic syndrome		25–100 mg/d; 3 times loading dose for fast effect	25–200 mg/d in divided doses; if inadequate after 5 d, change diuretics *Max*: >100 mg/d;
Triamterene/HCTZ (Dyazide, Maxzide) (G)	HTN add on RX and/or edema	HCTZ/Triamterne Capsules: 25 mg/37.5 mg Tablets: 25 mg/37.5 mg; 50 mg/75mg	25 mg/37.5 mg daily	Titrate to 50/75 mg in 2 doses daily *Max*: 300 mg/d

CHF = congestive heart failure; HTN = hypertension.

(G) = generic (*Note*: HCTZ is the generic hydrochlorothiazide); (B) = brand. Where more than one brand exists, the initial of the brand is used to differentiate them.

Rational Drug Selection

Indications

When HTN is mild, diuretic therapy can be initiated with 12.5 mg hydrochlorothiazide and increased to 25 mg. Due to the flat dosing impact, greater than 25 to 50 mg is generally unnecessary. Chlorthalidone (Thalitone) initiated at 15 mg and increased as needed to a maximum of 50 mg, was superior to all other drugs in the ALLHAT trial in treating hypertension with no change in subsequent trials and meta-analysis even 10 years later (Wright et al, 2009). For patients with renal impairment, the addition of 2.5 to 5 mg of metolazone is helpful. When these conditions are moderate to severe, 20 to 40 mg of furosemide is necessary. Potassium-sparing diuretics are relatively weak agents and are used mainly in conjunction with thiazide or loop diuretics to prevent hypokalemia. Some experts believe the hypertension guidelines will soon recommend more use of chlorthalidone in lieu of the thiazides.

Concurrent Disease Processes

Increasing glucose levels can be a problem for patients with diabetes, and hyperuricemia can be a problem for patients with gout. In the order of most likely to least likely to have these adverse effects, the drugs are thiazides, loop diuretics, potassium-sparing diuretics, metolazone, and indapamide. Drug choices for patients with diabetes or gout are in the

reverse order of this list. Low doses of thiazide diuretics can be used for patients with these disorders.

Hypokalemia can be a significant problem for patients with cardiac disorders. Drugs likely to have this adverse reaction are mostly the loop and then the thiazide diuretics. These drugs are still often chosen for their effects on the edema associated with HF. Careful monitoring of potassium levels must accompany their use with these patients. Hyperkalemia can be lethal for patients with renal failure and problematic for those with reduced renal function. Potassium-sparing diuretics are contraindicated in the former and rarely chosen in the latter. Both potassium-sparing diuretics and thiazides should be avoided for patients with Ccr less than 25 to 30 mL/min. Loop diuretics, metolazone, and indapamide are safe alternatives for these patients.

Hyperlipidemia is usually a transient phenomenon, and there is no consensus on the restriction of a drug class because of it. Indapamide effectively controls mild to moderate HTN, with no adverse reaction of lipids and minimum impact on potassium, glucose, and uric acid. It appears to address most concerns.

Combinations

Metolazone by itself is not a strong diuretic, but as an adjunct to loop diuretics its synergistic effect frequently overcomes refractory cases or enables dosage reduction of the loop diuretic, resulting in fewer adverse reactions. Combining a potassium-wasting diuretic with a potassium-sparing diuretic can prevent hypokalemia. Some drugs come in this combination (triamterene and hydrochlorothiazide [Maxzide], spironolactone and hydrochlorothiazide [Aldactazide]), making it possible to take only one tablet. Thiazides are typically the diuretic combined with other antihypertensives for dual therapy. (See Table 16-4.)

Cost

The generic form of each of these drugs is less expensive than the brand name and the combination tablets. The value of generic diuretics is quite clear.

Monitoring

In addition to monitoring the clinical indicators (BP, heart rate, edema, weight gain, dyspnea, cough, urine output), it is also critical to monitor renal function, glucose level, and electrolytes. Prior to initiating therapy, BUN, creatinine, electrolytes (sodium, potassium, calcium, and magnesium), uric acid, and glucose levels should be drawn. The patient should return to the clinic 4 weeks after initial prescription for a follow-up visit to check the clinical indicators and their electrolytes. Potassium levels of 3.5 to 4 mEq/L are usually not an indication for prescription supplementation in a noncardiac patient. Patients with cardiac disorders should have their potassium levels maintained at 4 to 4.5 mEq/L. Supplements need to be started even on asymptomatic patients with levels less than 3.5 mEq/L (Cohn et al, 2000). Spacing of monitoring after the first visit depends on labiality of symptoms and dosage adjustments. Specific indicators to monitor depend on the common adverse effects of the specific drug(s) being used. This topic is discussed further in Chapters 36 and 40.

Patient Education

Administration

Patients should take the drug exactly as prescribed and not skip or double doses. For drugs given twice daily, the morning dose should be taken at breakfast and the evening dose no later in the day than 4 p.m. These drugs increase urine output, and taking the drug later may make the patient get up at night to urinate. Some of these drugs come alone or in combination. Check with the pharmacist with each refill to make certain the drug is in the correct form. For patients experiencing extreme diarrheal illness and dehydration, a call to the provider is indicated to help manage a temporary change in dosing.

Patients needing potassium supplements typically find the liquid forms unpalatable. They need precautions about tooth staining and the need for oral care after taking them. The medications can create gastric distress. Adherence is best with microencapsulated formulas due to no taste and fewer GI issues (Cohn et al, 2000).

Adverse Reactions

Hypotensive reactions are the most common. Changing position slowly, not using alcohol, not standing for long periods, and avoiding exercise in hot weather can decrease these reactions. These drugs are used to reduce fluid volume in the body in HF patients. Weighing daily helps to monitor that fluid. The patient should notify the health-care provider if weight loss of more than 1 lb per day or 5 lb per week, excessive thirst, dry skin or mucous membranes, dizziness, muscle pain, weakness or cramps, nausea, vomiting, increased heart rate, or diarrhea occurs. These may indicate an abnormal potassium level.

Potassium-wasting diuretics may cause potassium loss from the body. The health-care provider monitors this loss with laboratory work. If instructed by the health-care provider, a diet high in potassium may be needed. Foods high in potassium include bananas, dates, figs, fish, citrus juices, melons, molasses, baked potatoes, prunes, soybeans, and tomatoes. If an oral potassium supplement is prescribed, powders or liquids can be diluted in at least 4 oz fruit juice to improve the taste. Tablets taken with meals reduce GI irritation.

Potassium-sparing diuretics cause the body to hold potassium. The health-care provider monitors this gain with laboratory work. Patients should not take potassium supplements or use salt substitutes that have potassium in them.

Occasionally, these drugs cause GI upset, which may be reduced by taking them with meals. Use of a sunscreen prevents photosensitivity reactions, although these are rare. Changes in blood sugar and other body chemicals may occur. Follow-up appointments that allow the health-care provider to assess levels of these chemicals and progression of the disease process are important.

Lifestyle Management

If diuretics are taken for HTN, it is important to continue with the other therapies for HTN, including weight loss, sensible sodium intake, stress reduction, regular aerobic exercise, not using tobacco products, and moderation in alcohol intake. These drugs help to control HTN but do not cure it. Patients should not use OTC preparations without first checking with the health-care provider. They may interact with these drugs or make the disease process worse.

Lifestyle management for the specific disorders managed in whole or part with diuretics is covered in Chapters 36 and 40.

DRUGS AFFECTING THE RESPIRATORY SYSTEM

Teri Moser Woo

Numerous medications are available to treat disorders of the respiratory system. Those discussed in this chapter include bronchodilators, which act on the bronchial smooth muscle to reverse bronchospasm, and leukotriene-receptor agents, which act to decrease the inflammation in the lungs of patients with asthma. Included in this chapter are antihistamines, decongestants, expectorants, and antitussive over-the-counter (OTC) medications. Inhaled anti-inflammatory medications used for asthma and intranasal steroids used for the treatment of seasonal or perennial rhinitis are also discussed. Prescribing recommendations for the multiple medications used in the treatment of asthma or chronic obstructive pulmonary disease (COPD) are provided in Chapter 31; prescribing recommendations for decongestants for upper respiratory infections are also found in Chapter 47. IV forms of respiratory medications, which are rarely used in primary care, are not discussed here.

BRONCHODILATORS

BETA$_2$-RECEPTOR AGONISTS

Beta$_2$-receptor-agonist (B2RA) bronchodilator agents are widely used in caring for all ages of patients to treat reversible bronchoconstriction caused by asthma, reactive airway disease

(RAD), or COPD. A variety of beta-agonist bronchodilators are available, and the medications come in multiple forms and delivery systems. Albuterol (ProAir, Ventolin, Proventil) is the most commonly prescribed drug in this class. Other sympathomimetic bronchodilator medications used in primary care are the short-acting B2RAs metaproterenol (Alupent), terbutaline (Brethine, Brethaire), bitolterol (Tornalate), pirbuterol (Maxair), and levalbuterol (Xopenex). The long-acting B2RAs include arformoterol (Brovana), formoterol (Foradil), indacaterol (Arcapta), and salmeterol (Serevent).

Pharmacodynamics

Bronchodilators act on the smooth muscle of the bronchial tree to reverse bronchospasm, thereby decreasing airway resistance and residual volume and increasing vital capacity and airflow. Beta agonists stimulate beta$_2$ adrenergic receptors in the lungs to increase production of cyclic adenosine monophosphate (cAMP) by activation of adenyl cyclase, the enzyme that catalyzes the conversion of adenosine triphosphate (ATP) to cAMP. Increased cAMP concentrations relax bronchial smooth muscle and inhibit release of mediators of immediate hypersensitivity from cells, especially from the mast cells.

The perfect bronchodilator would work only on the beta$_2$ receptors in the lungs and have no other actions or systemic

effects. Unfortunately, all of the currently available preparations have some effects on other body systems, such as the cardiovascular system, skeletal muscles, and the central nervous system (CNS).

Albuterol is a selective $beta_2$ agonist with some minor $beta_1$ activity. Albuterol's International Nonproprietary Name is salbutamol. It can increase heart rate by directly stimulating $beta_2$ receptors in the heart and by stimulating $beta_2$ receptors in vascular smooth muscle. The effect on cardiac $beta_2$ receptors is of consequence only at high serum levels of albuterol because it has a low affinity for these receptors and there are fewer $beta_2$ receptors than $beta_1$ receptors in the heart. Stimulation of the $beta_2$ receptors in the vascular smooth muscle leads to vasodilation, a decrease in diastolic blood pressure, and therefore a reflex increase in heart rate. Albuterol causes $beta_2$-receptor stimulation of skeletal muscle that leads to tremors. Albuterol has fewer cardiac and CNS effects than some of the other beta agonists and is, therefore, often the drug of choice for first-line therapy. Levalbuterol is similar to albuterol, where the (S)-isomer from racemic albuterol is removed, leaving the (R)-isomer, which has less adverse effects. Pirbuterol is a selective $beta_2$ agonist that is structurally identical to albuterol, except for the substitution of a pyridine ring for the benzene ring in its chemical makeup.

Terbutaline has a pharmacodynamic profile similar to that of albuterol, in that it is a selective $beta_2$ agonist with minor $beta_1$ activity. Terbutaline is also known to inhibit uterine contractions via its beta receptor–mediated action on uterine smooth muscle. Metaproterenol is also a selective $beta_2$ agonist with some $beta_1$ activity, although it is less selective than albuterol or terbutaline. Bitolterol is hydrolyzed by the esterases in the lung to colterol, or terbutylnorepinephrine, which is a selective $beta_2$ agonist.

Salmeterol, formoterol, indacaterol, and aformoterol are long-acting inhaled bronchodilators with a half-life ranging from 10 hours (formoterol) to more than 40 hours (indacaterol). Salmeterol is more selective for $beta_2$ receptors than is albuterol and has minor $beta_1$ activity. Formoterol has a 200-fold greater agonist activity at $beta_2$ receptors than at $beta_1$ receptors. Aformoterol is the (R, R)-enantiomer of formoterol and has twice the potency of formoterol. Indacaterol has a 24-fold greater agonist activity at $beta_2$ receptors than to $beta_1$ receptors. Salmeterol and formoterol exert long-lasting bronchoprotection effects against allergen-, exercise-, histamine-, and methacholine-caused bronchospasm.

Pharmacokinetics

Absorption and Distribution

Albuterol is most commonly inhaled and gradually absorbed from the bronchi. The overall systemic concentration remains low following recommended doses. The low systemic concentration is because of the need to use only 5% of the dose required orally to achieve the desired effects. Oral forms of albuterol are well absorbed from the gastrointestinal (GI) tract, rapidly enter the bloodstream, and are widely distributed in the body fluids and tissues. Extended-release oral albuterol is formulated to be absorbed from the stomach more slowly. Breast milk excretion is not known.

Levalbuterol is minimally absorbed from the respiratory tract and its distribution is unknown.

Pirbuterol is minimally absorbed from the respiratory tract, with amounts below the limits of serum assay detected after administration via inhalation. Its distribution is unknown.

Terbutaline is available in inhaled, oral, and subcutaneous (SC) forms. The inhaled form of terbutaline is minimally absorbed from the respiratory tract. Approximately 33% to 50% of the oral form is absorbed from the GI tract and is widely distributed. If administered SC, terbutaline is almost completely absorbed and is widely distributed. It crosses the placenta and is excreted in breast milk.

Metaproterenol may be administered via the inhaled route or orally. Approximately 3% of the inhaled metaproterenol dose is absorbed intact through the lungs. Oral dosing results in approximately 10% of the dose being absorbed intact. Distribution of metaproterenol is unknown.

Bitolterol absorption is too low to be measured by serum assay; distribution is unknown.

Salmeterol administered via inhaler is absorbed via the lungs in small amounts; undetectable amounts are found in the serum with recommended doses. With chronic administration, salmeterol is detected in the serum at very low levels. Salmeterol is excreted in breast milk in small amounts, approximately equal to plasma levels.

Formoterol is an inhaled dry powder capsule administered via a unique Aerolizer Inhaler. The powdered medication is quickly absorbed in the lungs, with an onset of 1 to 3 minutes. There are no human studies of distribution of formoterol into breast milk; in rat studies, the drug could be measured in milk.

Aformoterol inhalation solution is administered via standard jet nebulizer. Approximately 75% of an aformoterol dose is absorbed via the lungs and reaches peak levels in 30 minutes. Aformoterol has been measured in rat milk, but it is not known whether it is excreted in human milk.

Indacaterol is a dry powder packaged in gelatin capsules and is administered via the Arcapta Neohaler. Indacaterol reaches peak levels 15 minutes after inhalation. It is not known whether indacaterol is distributed in human breast milk.

Metabolism and Excretion

Most of the common bronchodilators are metabolized in the liver and excreted primarily in the urine.

Albuterol is metabolized into albuterol 49-O-sulfate, which has little or no beta adrenergic–stimulating effect and no beta adrenergic–blocking effect. Approximately 72% of inhaled albuterol is excreted in the urine within 24 hours of inhalation, 28% of this as unchanged drug and 44% as the metabolite. Another 10% of the inhaled albuterol is excreted in the feces. Oral administration of albuterol results in 65% to 90% of the dose being excreted in the urine over 3 days, the majority in the first 24 hours. About 4% of the oral albuterol dose is excreted in feces.

Levalbuterol is metabolized and excreted in the same fashion as albuterol.

Pirbuterol is not metabolized extensively, with 51% of the dose excreted in the urine as pirbuterol plus its sulfate conjugate. Terbutaline is partially metabolized in the liver, primarily to inactive sulfate conjugate, and is excreted in the urine. Metaproterenol is metabolized by the liver into its sulfate conjugate and excreted in the urine. Bitolterol is a prodrug that is hydrolyzed by esterases in tissue and blood to the active moiety colterol. Within 24 hours, 83% of the dose is excreted in the urine. After 72 hours, 85.6% of the dose has been excreted in the urine and 8% in the feces, as conjugated colterol.

Salmeterol xinafoate, an ionic salt, dissociates so that the salmeterol and 1-hydroxy-2-naphthoic acid (xinafoate) are metabolized and excreted independently. Salmeterol base is extensively metabolized by hydroxylation in the liver. Urinary elimination accounts for 25% of the drug, and 60% is eliminated in the feces over a period of 7 days. The xinafoate moiety has no apparent pharmacological activity, is extensively protein bound, and has a long elimination half-life of 11 days.

Formoterol fumarate is metabolized by glucuronidation in the liver. Renal elimination accounts for 59% to 62% of elimination; 32% to 34% is eliminated in the feces.

Aformoterol is almost completely metabolized in the liver, primarily by CYP2D6 and CYP2C19. Aformoterol is primarily excreted by the kidneys, with 67% excreted in the urine and 22% excreted in the feces.

Indacaterol is metabolized predominantly by CYP3A4 and is eliminated in the feces (54% unchanged, 23% hydroxylated metabolite) and urine (less than 2% unchanged).

Table 17-1 shows the pharmacokinetic properties of selected bronchodilators.

Pharmacotherapeutics

Precautions and Contraindications

Sympathomimetic bronchodilators have relatively few contraindications to use. Cardiac arrhythmias associated with tachycardia or heart block caused by digitalis intoxication, angina, narrow-angle glaucoma, organic brain damage (epinephrine only), and shock during general anesthesia with halogenated agents are all contraindications to beta $_2$ agonists. Because of these drugs' effects on the cardiovascular system, patients with hypertension, ischemic heart disease, coronary insufficiency, congestive heart failure, and a history of stroke and/or cardiac arrhythmias should be monitored closely for adverse effects during administration of any of the sympathomimetic bronchodilators. For patients with diabetes mellitus, there is a potential drug-induced hyperglycemia that may result in loss of diabetic control when using any of the beta$_2$ agonists, and their insulin dosage may need to be increased. For patients with hyperthyroidism, adverse reactions are more likely to occur with the use of bronchodilators. Patients taking digoxin require close monitoring when albuterol is started because albuterol increases the volume of distribution of digoxin and can cause up to a 30% decrease in blood digoxin levels. Patients with diagnosed or suspected pheochromocytoma should avoid the beta-adrenergic antagonists because severe hypertension may occur.

Table 17–1 Pharmacokinetics: Selected Bronchodilators

Drug	Onset	Peak	Duration	Half-Life	Metabolism	Elimination
Beta$_2$ Agonists						
Aformeterol Inhalation	5 min	30 min		10 h	Hepatic	Renal 67%; fecal 22%
Albuterol					Hepatic	Renal 90%; fecal 10%
Inhalation	5–15 min	0.5–2 h	2–6 h	3.8 h		
Oral short-acting	15–30 min	2–3 h	4–6 h	2.7–5 h		
Oral extended-release			8–12 h			
Bitolterol				UK	Hydrolyzed by esterases in tissues and blood to colterol	Renal
Inhalation	3–4 min	0.5–1	5–8 h			
Indacaterol		15 min		~40–56 hours	Hydroxylation predominantly by CYP3A4	Feces (54% unchanged, 23% hydroxylated metabolite); urine (<2% unchange)
Formoterol	1–3 min	15 min	12 h	10–14 h	Hepatic	Renal
Levalbuterol	10–17 min	1.5 h	5–6 h	3.3–4.0 h	Hepatic	Renal

UK = unknown.

Lower doses of bronchodilators may be necessary in older adults because of increased sympathomimetic sensitivity.

In the Salmeterol Multicenter Asthma Research Trial (SMART), there was a small but statistically significant increase in respiratory-related and asthma-related deaths in the study population receiving salmeterol versus placebo (Nelson et al, 2006). The study was terminated early owing to these findings. Further analysis indicates that the risk may be greater for African Americans than for white subjects (Nelson et al, 2006). The U.S. Food and Drug Administration (FDA) subsequently issued a Black-Box Warning for salmeterol and formoterol in 2005, and in December 2008 a follow-up FDA advisory was issued stating that the risks of salmeterol (Serevent) and formoterol (Foradil) outweighed the benefits and that they should not be used singly in asthma for all ages. Aformoterol and indacaterol were subsequently issued Black-Box Warnings when they became FDA-approved.

The safety and risks of the long-acting beta agonists (LABAs) continued to be studied with an emphasis on examining the risk for intubation and death in patients who use LABAs. Salpeter, Wall, and Buckley (2010) conducted a meta-analysis of pooled data of randomized controlled trials (RCTs) totaling 36,588 patients and found a 2-fold increase in catastrophic events (asthma-related intubations and death) in patients who were treated with LABAs. In February 2010, the FDA released a safety announcement regarding LABAs:

To ensure the safe use of these products:

• The use of LABAs is contraindicated without the use of an asthma controller medication such as an inhaled corticosteroid. Single-ingredient LABAs should only be

used in combination with an asthma controller medication; they should not be used alone.

- LABAs should only be used long-term in patients whose asthma cannot be adequately controlled on asthma controller medications.
- LABAs should be used for the shortest duration of time required to achieve control of asthma symptoms and discontinued, if possible, once asthma control is achieved. Patients should then be maintained on an asthma controller medication.
- Pediatric and adolescent patients who require the addition of a LABA to an inhaled corticosteroid should use a combination product containing both an inhaled corticosteroid and a LABA, to ensure compliance with both medications (http://www. fda.gov/Safety/MedWatch/ SafetyInformation/SafetyAlertsforHumanMedical Products/ucm201003.htm).

Providers should use caution when prescribing LABAs and provide close follow-up to ensure patient safety.

Terbutaline is Pregnancy Category B; the rest of the beta-agonist bronchodilators are Pregnancy Category C. No reports linking the use of albuterol with human congenital anomalies have been published. Terbutaline is used during pregnancy to prevent contractions related to preterm labor. This is not an FDA-approved use; therefore, oral forms of the beta agonists should be used selectively in patients in labor. Inhaled forms of the beta agonists are less likely to affect uterine contractions.

Small amounts of terbutaline and salmeterol can be measured in breast milk. The other inhaled beta-agonist bronchodilators cannot be measured in breast milk, probably because of the small amount of drug that is used and absorbed. The use of inhaled bronchodilators during lactation is most likely safe, with careful monitoring of the infant.

Albuterol is used extensively in infants and children with minimal adverse effects. Metaproterenol may also be used in young children, although albuterol is generally the first-choice medication. Dosing guidelines are provided on the label by the manufacturer of levalbuterol for children down to age 6, although a study of safety and efficacy in 2- to 5-year-olds indicated that the drug was effective and well tolerated by younger children (Skoner et al, 2005). Terbutaline may be safely prescribed to children, although it is not a first-line beta agonist for asthma. The safety of pirbuterol and bitolterol for use in children aged 12 years and under has not been established.

As previously mentioned, the FDA has issued a warning that LABA should not be prescribed as monotherapy to children or adolescents. Salmeterol should not be prescribed to children younger than age 4 and formoterol is not recommended for children age 5 years or younger. Indacaterol and aformeterol are indicated for chronic obstructive pulmonary disease (COPD), which is an adult disease and are not indicated for use in children or adolescents.

Adverse Drug Reactions

Adverse reactions to the beta-agonist bronchodilators are usually transient, and discontinuing the medication is not usually necessary, but a temporary reduction in the dose may alleviate some of the side effects. Slowly increase the dose after the reaction to the optimal dosing has subsided.

Supraventricular and ventricular ectopic beats have occurred with beta-agonist inhalation, but the incidence is low (bitolterol 0.5%, terbutaline about 4%, pirbuterol less than 1%). Tachycardia and palpitations are reported in 14% of patients who use these sympathomimetic bronchodilators.

The beta-agonist bronchodilators exhibit some CNS excitation effects, with tremors, dizziness, shakiness, nervousness, and restlessness reported in some patients. Headaches may occur with bronchodilator use in 2% to 28% of patients. Insomnia is rare, reported in 1% to 3% of patients. Patients (up to 26%) may exhibit a post-inhalation cough after using indacaterol.

Salmeterol has a documented increased risk of exacerbation of severe asthma symptoms if the patient is deteriorating. To avoid this risk, none of the LABAs should be started in patients with acutely deteriorating asthma and are best used in combination with an inhaled steroid.

Drug Interactions

Because of the cardiovascular effects of the bronchodilators, careful monitoring for drug interactions is necessary. If any of the beta agonists are prescribed with digitalis glycosides, caution and careful monitoring of the patient's electrocardiogram (ECG) is necessary because there is an increased risk of cardiac arrhythmia.

Beta agonists used with beta-adrenergic blocking agents (including ophthalmic preparations) may result in mutual inhibition of therapeutic effects. Tricyclic antidepressants and monoamine oxidase inhibitors (MAOIs) used with albuterol, metaproterenol, or terbutaline may potentiate the effects of the bronchodilator on the vascular system.

Hypokalemia or electrocardiogram changes may be seen with coadministration of the beta agonists with drugs that lower the potassium level, such as diuretics.

Table 17-2 shows drug interaction information.

Clinical Use and Dosing

Bronchospasm

The bronchodilators are used primarily in the treatment of bronchospasm associated with asthma, bronchitis (acute or chronic), and COPD.

The dose of albuterol metered-dose inhaler (MDI) in children over age 4 years and adults is two puffs every 4 to 6 hours. The dose of albuterol (Ventolin, Proventil) delivered via nebulizer for children over age 12 years as well as for adults is 2.5 mg (0.5 mL) in 2 mL normal saline; for younger children up to 15 kg, the dose is 0.1 to 0.15 mg/kg per dose. For children over 15 kg, the dose is the same as it is for adults, 2.5 mg/dose. Inhaled forms of albuterol may be repeated once after 5 to 10 minutes, up to 2 times (three doses total) during exacerbations. The oral albuterol dose in adults is 2 to 4 mg 3 or 4 times a day, up to a maximum of 32 mg/day. For children aged 6 to 12, 2 mg albuterol 3 or 4 times a day may be prescribed, although oral albuterol is rarely used in children.

Table 17–2 ▦ Drug Interactions: Selected Bronchodilators

Drug	Interacting Drug	Possible Effect	Implications
Beta₂ Agonists			
Aformoterol	Adrenergics	Sympathetic effects of aformoterol may be potentiated	Monitor HR and BP, use with caution in patients with cardiovascular disorders
	Beta blockers (including ophthalmic agents)	Mutual inhibition of therapeutic effects	Should not be used together
	Xanthine derivatives	May potentiate hypokalemia	Monitor potassium levels
	Steroids	May potentiate hypokalemic effect	Monitor potassium levels
	Diuretics	May potentiate hypokalemic effects ECG changes	Monitor potassium
	MAOIs	Potentiates adrenergic effects of aformoterol	Severe hypertension, headache, hyperpyrexia, and possible hypertensive crisis; do not use concurrently
	Tricyclic antidepressants	Potentiate andrenergic effects	Monitor HR and BP
	QTc prolonging drugs	Prolong QTc interval	Avoid concurrent use
Albuterol	Digoxin	Digoxin serum levels may be decreased	Decreased dose of albuterol may be needed
	Other sympathomimetics	Additive effects	Serious adverse cardiac effects; do not use concurrently
	MAOIs	Potentiates albuterol	Severe hypertension, headache, hyperpyrexia, and possible hypertensive crisis; do not use concurrently
	Tricyclic antidepressants	Potentiates the pressor response of sympathomimetics	Arrhythmias if used concurrently
	Beta blockers (including ophthalmic agents)	Mutual inhibition of therapeutic effects	Should not be used together
	Cocaine	Increased CNS stimulation	Observe patients for cardiac and CNS effects
	Thyroid hormones	Cardiac effects of both drugs enhanced	Increased risk of coronary insufficiency from combined use of these drugs; avoid this combination in patients with preexisting cardiac disease
	Ritodrine	Increased CNS stimulation	Avoid concurrent use
Bitolterol	Other sympathomimetics	Additive effects	Serious adverse cardiac effects; avoid concurrent use of sympathomimetics
	MAOIs	Potentiates bitolterol	Severe hypertension, headache, hyperpyrexia, and possible hypertensive crisis; do not use together
	Tricyclic antidepressants	Potentiates the pressor response of sympathomimetics	May cause arrhythmias; do not use together
	Beta blockers (including ophthalmic agents)	Mutual inhibition of therapeutic effects	Should not be used together
Indacaterol	Adrenergic drugs	↑ sympathetic effects	Monitor
	Xanthine derivatives	May potentiate hypokalemia	Monitor potassium levels
	Steroids	May potentiate hypokalemic effect	Monitor potassium levels
	Diuretics	May potentiate hypokalemic effects ECG changes	Monitor potassium

Table 17–2 ⚏ **Drug Interactions: Selected Bronchodilators—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
	MAOIs	Potentiates adrenergic effects of aformoterol	Severe hypertension, headache, hyperpyrexia, and possible hypertensive crisis; do not use concurrently
	Tricyclic andidepressants	Potentiate andrenergic effects	Monitor HR and BP
	QTc prolonging drugs	Prolong QTc interval	Avoid concurrent use
	Beta blockers (including ophthalmic agents)	Mutual inhibition of therapeutic effects	Should not be used together
Levalbuterol	Beta blockers	Mutual inhibition of therapeutic effects	Should not be used together
	MAOIs	Potentiates albuterol	Severe hypertension, headache, hyperpyrexia, and possible hypertensive crisis; do not use concurrently
	Tricyclic antidepressants	Potentiates the pressor response of sympathomimetics	Arrhythmias if used concurrently
	Digoxin	Digoxin serum levels may be decreased	Decreased dose of albuterol may be needed
	Other sympathomimetics	Additive effects	Serious adverse cardiac effects; do not use concurrently
Metaproterenol	Other sympathomimetics	Additive effects	Serious adverse cardiac effects; avoid concurrent use
	MAOIs	Potentiates metaproterenol	Severe hypertension, headache, hyperpyrexia, and possible hypertensive crisis; do not use together
	Tricyclic antidepressants	Potentiates the pressor response of sympathomimetics	May cause arrhythmias; do not use together
	Beta blockers (including ophthalmic agents)	Mutual inhibition of therapeutic effects	Should not be used together
	Inhalation anesthetics	Sensitizes the myocardium to the effects of metaproterenol	May cause arrhythmias; use with caution and, if possible, avoid concurrent use
	Theophylline or caffeine	Additive toxic effects	CNS stimulation or toxicity a concern; use with caution and close monitoring
	Thyroid hormones	Cardiac effects of both drugs enhanced	Increased risk of coronary insufficiency from the combined use of these drugs; use with caution in patients with preexisting cardiac disease
Pirbuterol	Other beta agonists	Additive effects	Increased adverse effects; avoid concurrent use
	MAOIs, tricyclic antidepressants	Potentiates pirbuterol	Severe hypertension, headache, hyperpyrexia, and possible hypertensive crisis; do not use within 14 d of each other
Salmeterol	Beta blockers (including ophthalmic agents)	Mutual inhibition	Avoid concurrent use
	MAOIs, tricyclic antidepressants	Potentiates vascular effects of salmeterol	Severe hypertension, headache, hyperpyrexia, and possible hypertensive crisis; do not use concurrently

Continued

Table 17–2 ▦ Drug Interactions: Selected Bronchodilators—cont'd

Drug	Interacting Drug	Possible Effect	Implications
Terbutaline	Halogenated anesthetics	Sensitizes the myocardium to the effects of terbutaline	Ventricular arrhythmias; do not use concurrently
	MAOIs, tricyclic antidepressants, maprotiline	Potentiates vascular effects of terbutaline	Severe hypertension, headache, hyperpyrexia, and possible hypertensive crisis; do not use concurrently Decreased antihypertensive effect; should not be used together
	Beta blockers and other antihypertensive agents	Mutual inhibition	Do not use together
	Cocaine	Increased CNS and cardiac stimulation	Observe patients for arrhythmias
	Cardiac glycosides, levodopa	Increased potential for cardiac arrhythmias	Dosage of cardiac glycoside or levodopa should be decreased and the patient closely monitored
Anticholinergics			
Aclidinium	Anticholinergics	Additive anticholinergic effects	Avoid concurrent use
Ipratropium	Cromolyn inhalation solution	Forms a precipitate when mixed together	Do not mix
Tiotropium	Anticholinergics	Additive anticholinergic effects	Avoid concurrent use
Xanthine Derivatives			
Theophylline	Allopurinol, beta blockers, calcium channel blockers, cimetidine, ciprofloxacin oral contraceptives, corticosteroids, disulfiram, ephedrine, influenza virus vaccine, interferon, macrolides, mexiletine, quinolones, thiabendazole, thyroid hormones, carbamazepine, isoniazid, loop diuretics, fluvoxamine, ticlopidine, propafenone	Increased serum theophylline levels if taken concurrently	Lower doses of theophylline may be necessary; monitor theophylline level closely when starting, stopping, or changing the dose of these medications; doses of theophylline may need to be temporarily decreased after administration of influenza vaccine
	Aminoglutethimide, barbiturates, charcoal, hydantoins, ketoconazole, rifampin, smoking (cigarettes, marijuana), sulfinpyrazone, beta agonists, thioamines, carbamazepine, isoniazid, loop diuretics, lansoprazole, primidone, ritonavir	Decreased serum theophylline levels if taken concurrently	Increased doses of theophylline may be necessary; monitor theophylline level closely when starting, stopping, or changing the dose of these medications; theophylline toxicity may occur if these medications are stopped suddenly
	Inhalation anesthetics	Increased risk of cardiac arrhythmias	Avoid or use with caution
	Sympathomimetics	May cause excessive stimulation, nervousness, irritability, and insomnia	Avoid concurrent use or use with caution
	Lithium	Theophylline may increase renal clearance of lithium	Monitor lithium clinical effectiveness if theophylline is prescribed
	Zafirlukast	May increase theophylline levels if added to an existing theophylline regimen	Monitor theophylline levels closely after adding zafirlukast to the treatment regimen

If prescribing to children under age 6, albuterol syrup is dosed at 0.1 mg/kg 3 times a day. Albuterol syrup is rarely used because the inhaled form is more effective and has less adverse effects.

Aformoterol (Brovana) is administered via nebulizer, dosed at 15 mcg by inhalation twice a day. Aformoterol is not approved for use in children and should not be used for acute asthma exacerbation.

Indacaterol (Arcapta Neohaler) is available as an inhalation powder that is administered by the Neohaler device. Indacaterol (Acarpta) dosing for adults with COPD is one capsule administered once a day using the Neohaler device. Capsules are not to be swallowed and should be used immediately after removing from the blister pack.

The recommended dose of levalbuterol (Xopenex) inhalation solution in adolescents over age 12 years and adults is 0.63 mg 3 times a day, every 6 to 8 hours. Dosing for children aged 6 to 11 is 0.31 mg 3 times a day per the manufacturer's label, with routine dosing not to exceed 0.63 mg 3 times a day. In the Skoner and colleagues (2005) study, children aged 2 to 5 years were dosed at both 0.31 mg and 0.63 mg 3 times a day without regard to weight; both doses were tolerated by the children, although they had less variation in heart rate when dosed at 0.31 mg. The authors recommend dosing young children at 0.31 mg 3 times a day, but note that 0.63 mg may be indicated for some patients. *Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma* (National Asthma Education and Prevention Program [NAEPP], 2007) recommends dosing levalbuterol via nebulizer, administering 0.31 to 1.25 mg in 3 mL of normal saline every 4 to 6 hours to children 4 years of age or younger, although the NAEPP notes that levalbuterol is not FDA-approved for children younger than 6 years. Levalbuterol (Xopenex HFA) inhaler is FDA-approved for use in adults and children age 4 and older; with a dose of one to two puffs repeated every 4 to 6 hours for wheezing appropriate for all patients.

Metaproterenol (Alupent) comes in MDI, inhalation solution, and syrup forms. The dose of metaproterenol MDI in children over age 12 and adults is two to three inhalations every 3 to 4 hours, not to exceed 12 inhalations per day. The dose of metaproterenol delivered via nebulizer in children age 12 and older and adults is 0.1 to 0.2 mL of 5% solution diluted in 2.5 mL normal saline up to every 4 hours. Metaproterenol is also available in nebulizer solution. The dose for infants and children of metaproterenol nebulizer solution is 5 to 15 mg diluted in 2 to 3 mL of normal saline every 4 to 6 hours. For adolescents and adults, the dose of metaproterenol nebulizer solution is 10 to 15 mg every 4 to 6 hours. Metaproterenol MDI is not recommended for children under age 12 years; oral syrup or nebulizer solution is the suggested therapy in this age group. Metaproterenol syrup dose in children over age 9 years is 20 mg (10 mL) 3 or 4 times a day. For children aged 6 to 9, the dose of metaproterenol syrup is 10 mg (5 mL) 3 or 4 times a day. The dose of metaproterenol in children aged 2 to 6 is 1.3 to 2.6 mg/kg per day in doses divided to take 3 or 4 times a day. Children under age 2 are dosed at 0.4 mg/kg per dose given 3 to 4 times a day; infants should be dosed every 8 to 12 hours.

Terbutaline is available in MDI (Brethaire), oral tablets (Brethine), or parenteral form for SC injection. The dose of terbutaline MDI in children age 12 and older and adults is two puffs every 4 to 6 hours. The dose of oral terbutaline for bronchospasm in adolescents age 15 or older and adults is 5 mg 3 times a day, with a maximum of 15 mg in 24 hours. For children aged 12 to 15 years, the dose of terbutaline is 2.5 mg 3 times a day, with a maximum dose of 7.5 mg in 24 hours. Children less than age 12 are dosed at 0.5 mg/kg every 8 hours, which may be gradually increased up to 0.15 mg/kg per dose, with a maximum daily dose of 5 mg. The dose of parenteral terbutaline (Brethine injection) in adults is 0.25 mg SC in the lateral deltoid. The dose may be repeated in 15 to 30 minutes. The maximum dose is 0.75 mg in 4 hours.

Pirbuterol is available only in MDI form (Maxair Autohaler). The dose of pirbuterol in children over age 12 and adults is one to two inhalations every 4 to 6 hours for a maximum of 12 inhalations in 24 hours. Younger children are dosed at 4 to 8 inhalations every 20 minutes for a total of three doses, then every 1 to 4 hours. Maintenance therapy for children and adults is two inhalations 3 to 4 times a day.

Bitolterol (Tornalate) is available in MDI form. The adult dose to treat acute bronchospasm is two puffs, 1 to 3 minutes apart, followed by a third puff if needed. For prevention of bronchospasm, the adult dose is two puffs every 8 hours. Bitolterol is not recommended for use in children younger than 12 years.

Salmeterol (Serevent DISKUS) is a long-acting bronchodilator available in powder for oral inhalation, packaged in a specially designed plastic delivery device that delivers 50 mcg per inhalation. The dose for children aged 4 and older and adults to control asthma and to prevent bronchospasm is one actuation/puff twice a day. Salmeterol is not to be used for short-term bronchospasm relief. If prescribing salmeterol for persistent asthma, the drug must be prescribed in conjunction with an inhaled corticosteroid or other asthma controller medication. LABAs should be prescribed for as short a time as possible to get the asthma under control, and then patients are maintained on their controller medication. To prevent exercise-induced bronchospasm, the dose of one actuation/puff (50 mcg) is inhaled 30 minutes before exercise. Patients who are using salmeterol twice a day for asthma control should not use an additional dose before exercise. Frequent use of LABAs for exercise-induced asthma is discouraged by the *Expert Panel 3* guidelines because it may be masking persistent asthma. Patients also need to have a short-acting bronchodilator prescribed for them to use for short-term relief, and they need to be educated not to use salmeterol for acute exacerbations. Salmeterol is packaged in combination with fluticasone (Advair DISKUS) with differing dosages of fluticasone (100 mcg, 250 mcg, 500 mcg per actuation) combined with 50 mcg of salmeterol (Advair DISKUS 100/50, Advair DISKUS 250/50, Advair DISKUS 500/50). The FDA recommends pediatric and adolescent patients who require the addition of a LABA to an inhaled corticosteroid be prescribed a combination product to increase compliance and ensure patient safety (U.S. Food

and Drug Administration, 2010). Dosing is covered in the "Inhaled Corticosteroid" section of this chapter.

Formoterol is packaged as a 12 mcg, single-use dry powder capsule. Dosing for children older than age 5 or adults is one capsule every 12 hours. Children younger than age 4 cannot generate enough inspiratory flow to administer the dry powder capsules.

Ipratropium is an inhaled anticholinergic that may be used in combination with albuterol to treat asthma exacerbation in the emergency department (NAEPP, 2007). Hospital admission may be avoided by the addition of ipratropium to the treatment regimen in cases of exacerbation seen in the clinic or emergency department. Ipratropium is the bronchodilator of choice in patients who are taking beta blockers or who do not tolerate beta$_2$ agonists.

Exercise-Induced Bronchospasm

Bronchodilators used just before exercise can prevent exercise-induced bronchospasm (EIB). The medications recommended by the *Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma* (NAEPP, 2007) are inhaled albuterol or other short-acting beta$_2$ agonist and salmeterol. The dose of albuterol MDI to prevent EIB is two puffs 15 minutes prior to exercise, which should prevent EIB for 2 to 3 hours. The dose of salmeterol is two puffs 30 to 60 minutes prior to exercise. Salmeterol should prevent EIB for 10 to 12 hours. Salmeterol and other long-acting beta$_2$ agonists have a shortened duration of action if used on a daily basis (NAEPP, 2007). Cromolyn or nedocromyl may be used before exercise, but they are not as effective as short-acting beta$_2$ agonists. Leukotriene modifiers may improve EIB in up to 50% of patients (NAEPP, 2007). Table 17-3 presents dosage recommendations.

Rational Drug Selection

The *Expert Panel Report 3* (NAEPP, 2007) does not differentiate or recommend a specific short-acting beta$_2$ agonist for use in asthma. Therefore, the practitioner who is prescribing

Table 17–3 � Dosage Schedule: Selected Bronchodilators

Drug	Indication	Dosage Form	Dose	Comments
Beta$_2$ Agonists				
Aformoterol Brovana	Long-term management of bronchoconstriction associated with COPD	Inhalation solution 15 mcg/2 mL	15 mcg/2 mL vial q 12 hr	
Albuterol **INHALER** ProAir HFA Proventil HFA Ventolin HFA Generic **INHALATION SOLUTION** Accuneb Generic **ORAL** Vospire ER tablets Generic	Bronchospasm associated with asthma or COPD	*Inhaler* 17 g (about 200 inhalations) *Accuneb inhalation solution* 0.63 mg/3 mL 1.25 mg/3 mL *Albuterol generic* Solution for nebulizer: 0.5% (5 mg/mL) Solution for nebulizer: 0.083% in unit-dose vial *Vospire ER Tablets* Extended-release tablets: 4 mg, 8 mg *Oral generic* Tablets: 2 mg, 4 mg Syrup: 2 mg/5 mL	*Inhaled:* 2 puffs q 4–6 h *Nebulizer* (run over 10–15 min) *Adults:* dilute 0.5 mL of 0.5% solution in 3 mL normal saline OR give 1 unit dose *Children:* 0.01–0.05 mL/kg of 0.5% solution diluted in 2 mL normal saline *Oral* *Adults:* 2–4 mg tid or qid up to a max of 32 mg/day *Children 6–12 yr:* 2 mg tid or qid *Children <6 yr:* 0.1 mg/kg divided tid	May repeat dose in 20 min × 3 during exacerbations; check proper inhaler technique with every clinic visit *Min:* 0.25 mL *Max:* 1.0 mL
	Exercise-induced asthma		*Inhaled:* 2 puffs 5 min prior to exercise	
Bitolterol Tornalate	Acute bronchospasm	Inhaler: 15 mL (about 300 inhalations)	*Inhaled* *Children >12 yr and adults:* 2 puffs 1–3 min apart, followed by a third puff if needed	Not recommended for children <12 yr
	Bronchospasm prevention		*Inhaled:* 2 puffs every 8 h	
Formoterol Foradil Aerolizer Oxeze Turbuhaler (Canada)	Long-acting bronchodilator for preventing bronchospasm	*Inhalation powder* 12 mcg capsule for inhalation	*Children >5 yr and adults:* 12 mg (contents of one capsule) q 12h	Should not be used as monotherapy for asthma

Table 17–3 ⊗ **Dosage Schedule: Selected Bronchodilators—cont'd**

Drug	Indication	Dosage Form	Dose	Comments
Perforomist Inhalation solution		*Inhalation solution* 20 mcg twice daily (morning and evening) by nebulization (max: 40 mcg/day)		
	Prevention of exercise-induced asthma		*Children >5 yr and adults:* 12 mg (contents of one capsule) 15 min before exercise	Should not use a second dose within 12 h
Indacaterol Arcapta Neohaler	Long-term mainte-nance of patients with COPD	75 mcg dry powder capsule for use in Neohaler device	75 mcg once daily via Neohaler	Not approved for use in children
Levalbuterol Xopenex	Bronchospasm in patients with reversible obstructive airway disease	HFA inhaler 45 mcg/inhalation Unit dose solution for nebulizer: 0.31 mg/3 mL 0.63 mg/3 mL 1.25 mg/3 mL Concentrated solu-tion for inhalation: 1.25 mg/0.5 mL	HFA MDI: ≥4 yr: 1–2 puffs every 4–6 h *Nebulizer* *Children ≥4 yr and adults:* 0.63 mg 3 times a day every 6–8 h; may be increased to 1.25 mg 3 times a day *Children 6–11 yr:* 0.31 mg 3 times a day every 6–8 h; not to exceed 0.63 mg 3 times a day *Children 2–6 yr:* Not labeled for use in this age. See comments.	*Children 2–5 yr:* 0.31–0.63 mg every 6–8 h; 0.31 mg well tolerated (Skoner et al, 2005)
Metaproterenol Alupent Metaprel Generic	Bronchospasm associated with asthma or COPD	Tablets: 10 mg, 20 mg Syrup: 10 mg/5 mL Metered-dose inhaler: 0.65 mg/puff Solution for inhala-tion: 0.4%, 0.6% Solution for inhalation: 5%	*Inhaler* *Children >12 yr and adults:* 2–3 inhalations every 3–4 h; do not exceed 12 inhalations/d *Nebulizer* *Children >6 yr and adults:* 0.1–0.2 mL of 5% solution diluted in 2.5 mL normal saline up to every 4 h *Hand bulb nebulizer* *Children >12 yr and adults:* 5–15 (usually 10) inhalations every 4 h or 3–4 times/d (chronic use) *Syrup* *Children >9 yr or who weigh >60 lb:* 20 mg (10 mL) tid or qid *Children 6–9 yr who weigh <60 lb:* 10 mg (5 mL) tid or qid *Children <6 yr:* 1.3–2.6 mg/kg/d in doses divided tid or qid	Metaproterenol MDI not recommended in children <12 yr Nebulizer solution not recommended in children <6 yr; oral syrup is the suggested therapy in this age group
Pirbuterol Maxair Autoinhaler	Bronchospasm associated with asthma	14 g MDI (about 400 inhalations; 0.2 mg/puff)	*Inhaled* *Children >4 yr and adults:* 2 puffs every 6–8 h (NIH guidelines)	Not recommended for children <4 yr
Salmeterol Serevent Diskus	Long-acting bronchodilator for preventing bronchospasm	Diskus Inhaler: (60 inhalations, 50 mcg/inhalation)	*Inhaled DISKUS* *Children >4 yr and adults:* 1 actuation/puff bid, 12 h apart	Not to be used for short-term relief or acute exacerba-tions; patients need to have a short-acting bronchodila-tor also prescribed for them. If using salmeterol for asthma control, patients should not use another dose for exercise-induced asthma; a short-acting bronchodilator or cromolyn should be used
	Exercise-induced asthma		*Inhaled Diskus* 1 puff/actuation 30–60 min before exercise	

Continued

Table 17–3 ⚬ Dosage Schedule: Selected Bronchodilators—cont'd

Drug	Indication	Dosage Form	Dose	Comments
Terbutaline Generic Brethine Bricanyl	Bronchospasm associated with asthma or COPD	10.5 g MDI (about 300 inhalations, 0.2 mcg/puff) Tablets: 2.5 mg, 5 mg Parenteral: 1 mg/mL	*Inhaled* 2 puffs every 4–6 h; do not repeat more often than every 4–6 h *Oral* *Children >15 yr and adults:* 5 mg tid; max 15 mg/24 h *Children 12–15 yr:* 2.5 mg tid; max 7.5 mg/24 h *Parenteral* *Adults:* 0.5 mg SC in the lateral deltoid; may repeat in 15–30 min; maximum dose is 0.5 mg in 4 h *Children <12 yr:* 0.05 mg/kg every 8 hr. May increase to 0.15 mg/kg dose. Maximum 5 mg/d.	Not recommended in children <12 yr Terbutaline is used to control premature contractions in pregnant women, so use with care in the patient in the third trimester nearing due date because it may affect labor
Anticholinergics				
Ipratropium Atrovent	Bronchospasm associated with asthma or COPD	12.9 g MDI (200 inhalations, 17 mcg/puff) 25 unit-dose vials (2.5 mL each, 500 mcg per unit-dose vial) per foil pouch	*Acute Exacerbation of Asthma* (NIH guidelines) *Children:* Nebulization: 250 mcg of 20 min × 3 doses then every 2–4 h MDI: 4–8 puffs as needed *Children >12 yr and adults:* Nebulization 500 mcg of 30 min × 3 then every 2–4 h MDI: 4–8 puffs as needed *Asthma Maintenance* (NIH Guidelines) *Children:* Nebulization: 250–500 mcg of 6 h MDI: 1–2 inhalations of 6 h; max 12 puffs/day *Children >12 yr and adults:* Nebulization: 250 mcg of 6 h MDI: 2–3 inhalations of 6 h; max 12 puffs/day *COPD* MDI: *Adults:* 2 puffs qid, may increase to 12 puffs/day Nebulizer: One unit-dose vial 500 mcg 3–4 times a day via nebulizer	Contraindicated in patients with soybean or peanut allergy. Ipratropium can be mixed with albuterol 0.5% solution for nebulizer use if used within 1 h.
Aclidinium bromide Tudorza	brochospasm associated with COPD	Inhalation powder (400 mcg/ inhalation) 30 dose, 60 dose	*Inhaled* *Adults:* 400 mcg bid	Not approved in children.
Tiotropium Spiriva	brochospasm associated with COPD	Handi Haler Inhalation: 18 mcg/inhalation	*Inhaled* *Adults:* 18 mcg qid	Not approved in children.
Combination Medications				
Albuterol/ ipratropium (Combivent)	Bronchospasm associated with COPD, not controlled with one bronchodilator alone	14.7 g MDI (200 inhalations, ipratropium 18 mcg/ puff combined with albuterol 90 mcg/puff)	*Inhaled* *Adults:* 2 puffs qid *Children <12 yr:* 1–2 puffs qid *Nebulizer* *Adults:* 3 mL q4–6h *Children:* 1.5 to 3 mL q 8h	Primarily used for COPD patients; simplifies medication regimen by combining two commonly prescribed medications
Xanthine Derivatives				
Theophylline IMMEDIATE-RELEASE Slo-Phyllin Theolair Generic	Bronchospasm associated with asthma, COPD, and bronchitis	Tablets: 100, 200 mg Syrup: 80 mg/5 mL Tablets: 125, 250 mg Solution: 80 mg/15 mL Tablets: 100, 200, 300 mg	The dose for asthma and COPD is variable with the patient's weight and serum theophylline levels *Adults* (>16): Initially: 6 mg/kg/24 h or 400 mg/ 24 h tid or qid; the dose is increased	Dosing adjustments are made based on the serum theophylline level: If the level is 5–10 mcg/mL, the dose is increased by 25% every 3 d until desired serum concentrations of theophylline

			every 3 d in 25% increments until
			  desired serum theophylline levels
			  are achieved (ideally between
			  10 and 20 mcg/mL); max dose:
			  13 mg/kg/d
			Children 1–9 yr:
			Initially: 16 mg/kg/24 h; max
			  400 mg/d; dosage may be increased
			  by 25% every 3 d to a maximum
			  based on age (1–9 yr, max 24 mg/
			  kg/d; 9–12 yr, max 20 mg/kg/d;
			  12–16 yr, max daily dose is
			  18 mg/kg)
			Monitoring for serum theophylline
			  levels is the same in children as
			  for adults, with a steady-state
			  theophylline level of 5–15 mcg/mL
			  the goal
				are reached; if the serum
				  concentration is between
				  10 and 15 mcg/mL,
				  maintain dosage if toler-
				  ated and recheck at 6 to
				  12 mo intervals; if level is
				  15–19.9 mcg/mL, consider
				  decreasing dose by 10% to
				  provide a greater margin
				  of safety; if the level is
				  20–25 mcg/mL, then
				  decrease dose by 10% and
				  recheck level in 3 d; if
				  serum level is 25–30 mcg/
				  mL, then decrease subse-
				  quent doses by 25%, and
				  redraw level in 3 d; if
				  theophylline level is >
				  30 mcg/mL, then skip next
				  2 doses, decrease dose by
				  50%, and recheck in 3 d

Caffeine citrate
Cafcit
	Apnea of prematurity	Oral solution:
		  20 mg/mL
			Loading dose: 10–20 mg/kg
			Maintenance: 5 mg/kg/d
				If theophylline has been given
				  in last 3 d, decrease loading
				  dose by 50%–75%

for adults may choose any of the short-acting bronchodilators. Choosing an appropriate bronchodilator is a matter of the age of the patient and the cost.

Patient Age

The only short-acting bronchodilators that can be prescribed for children under age 4 are albuterol and metaproterenol. Levalbuterol is labeled to be used in children older than age 4, and the *Expert Panel 3* (NAEPP, 2007) guidelines indicate that it should not be used in children younger than age 4. Albuterol is by far the most often used medication in clinical practice and is safe to use even in infants.

Cost

Of the short-acting bronchodilators, albuterol is the least expensive, especially if a generic formula is prescribed.

Monitoring

There is no specific monitoring required for bronchodilators. As a part of overall asthma management, pulmonary function and response to bronchodilators should be monitored with a peak flowmeter. If a patient is on digitalis, an ECG should be done prior to starting a beta agonist and routinely during therapy to detect cardiac arrhythmias that may occur. Patients who are concurrently taking diuretics or anything that affects potassium levels should be monitored for dysrhythmias.

Patient Education

Administration

The bronchodilator should be used as prescribed. Overuse of bronchodilators will lead to increased adverse effects, and using the bronchodilator less than prescribed may lead to increased bronchospasm and decreased pulmonary function.

The administration of bronchodilators via MDI can be difficult for most adults and all children. Learning to coordinate the release of the medication from the inhaler with a deep breath is difficult. Written and pictorial instructions are available with the inhaler, but the provider must not assume that the patient understands the proper method of administering inhaled medications. It is recommended that a spacer device be used with MDIs (Aerochamber, InspirEase) to increase deposition of medication into the lungs, rather than just in the mouth. Use verbal instructions as well as actual demonstration with a placebo inhaler to reinforce the written instructions. These instructions and demonstrations should be repeated at follow-up visits.

To use an inhaler properly, the patient should first exhale and then tilt the head slightly back and place the inhaler mouthpiece either about 2 inches from the open mouth or between the open lips. While inhaling, the patient should press down on the canister, breathe in slowly and deeply, and hold his or her breath for 10 seconds (count of 10) or as long

as comfortable. If two puffs are prescribed, then the patient should wait at least 1 full minute between inhalations.

CLINICAL PEARL

Administering a medication via a nebulizer to an infant or toddler is, at times, a challenge. A pediatric mask may be used if the child tolerates it. One trick is to "blow" the nebulized medication into the patient's face near the nose and mouth. This is achieved by occluding the mouthpiece end of the unit and aiming the "tail" end toward the patient's nose and mouth. This is especially effective if the child is sleeping and needs the medication. Another suggestion to parents of young children is to read a book to the child during the treatment or play an appropriate short video to make the time pass more quickly.

To assist with the delivery of inhaled medications, a spacer can be prescribed. The Global Initiative for Asthma Web site has instructions with diagrams for using all the different types of spacers, inhalers, and asthma medication delivery systems (www.ginasthma.org/documents/11). The Aerochamber is a tube-like device that has pictures drawn on the outside to remind the patient of the proper technique for using the inhaler. For younger children and older adults, the InspirEase spacer gives a visual cue of the spacer bag deflating to help in taking a deep-enough breath, or an Aerochamber with the appropriate-size mask can be used. Both of these devices emit a whistling sound if the patient is taking too rapid a breath, giving a cue to breathe more slowly.

The use of a nebulizer should be demonstrated to the patient either in the clinic or by the home health agency that is providing the device. Specific instructions vary slightly with the manufacturer. The key points that should be covered with nebulizer use are accurate measurement of the medication (if using nebulizer solution) and appropriate cleaning of the equipment. Many nebulizer medications are available in unit-dose packaging, which, although more expensive, is helpful if patients have difficulty accurately measuring their medication.

Instructions for salmeterol dry powder DISKUS (Serevent DISKUS, Advair DISKUS) administration say that the patient should use the medication as prescribed and should not exceed the prescribed dose. Patients should not exhale or blow into the DISKUS. The DISKUS should not be washed or taken apart.

Formoterol (Foradil AEROLIZER) is a dry powder capsule administered via a patented aerolizer. The Foradil capsule is placed into the aerolizer, then the aerolizer is squeezed to break the capsule. The patient inhales the medication. Patients should receive clear instructions not to swallow the capsule.

Indacaterol (Arcapta Neohaler) is a dry powder capsule administered via a patented inhalation device (Neohaler). Patients inhale the dry powder from the Neohaler device. The capsule must be removed from a blister pack immediately before inserting into the Neohaler, and Arcapta capsules that are exposed to air for prolonged periods should be discarded. Capsules should not be swallowed.

Adverse Reactions

The patient should be instructed not to exceed the recommended dosage of the medication because excessive use may lead to increased adverse effects. Overuse of the $beta_2$-agonist bronchodilators can lead to seizures, hypokalemia, anginal pain, and hypertension. Patients should understand that they may have some stimulant-like effects (e.g., increased heart rate, tremors) when they initially begin the medication, but these effects should lessen if they use it correctly. Some patients may get a headache with the use of bronchodilators. Patients who experience GI upset when taking oral medications should take the medications with food. The patient should inform the provider if palpitations, tachycardia, chest pain, muscle tremors, dizziness, headache, or flushing occurs.

Lifestyle Management

Lifestyle management issues related to the disease process being treated should be discussed. They often include the following:

1. The patient needs to self-monitor respiratory status with a peak flowmeter to determine the effectiveness of the prescribed medication.
2. The patient should avoid or quit smoking.
3. The patient should avoid environmental triggers for asthma at home, work, and school.

XANTHINE DERIVATIVES

Methylxanthines have declined in importance in the treatment of asthma, but some patients may still benefit from the use of theophylline. The other methylxanthines include aminophylline and caffeine. Theophylline and caffeine are closely related chemically in that theophylline is 1,3-dimethylxanthine and caffeine is 1,3,7-triethylxanthine, and they share many of the same effects on the body. Because many patients throughout the world consume caffeine in tea, coffee, and cola beverages and because many OTC preparations for analgesia contain caffeine, caffeine pharmacodynamics is discussed briefly here.

Pharmacodynamics

Theophylline and the other methylxanthines work directly by an unknown mechanism believed to be mediated by selective inhibition of specific phosphodiesterases (PDEs). This, in turn, produces an increase in cAMP, which then leads to bronchial smooth muscle and pulmonary vessel relaxation.

Theophylline and caffeine have an impact on most of the major body systems. They are powerful CNS stimulants, often causing insomnia and excitability. Although both drugs have cardiovascular effects, theophylline has a greater effect on the cardiovascular system. Theophylline directly stimulates the myocardium and increases myocardial contractility and heart rate. By relaxing vascular smooth muscle, theophylline dilates the coronary, pulmonary, and systemic blood vessels. Both theophylline and caffeine increase gastric acid secretion and may produce nausea and vomiting, although this reaction is probably due to CNS effects. Both methylxanthines stimulate skeletal muscle, causing tremors. Theophylline acts

directly on the renal tubules to cause increased sodium and chloride excretion. By increasing renal blood flow (from increased heart rate) and the glomerular filtration rate, theophylline and caffeine also cause diuresis. Often, these effects occur even when theophylline is within the therapeutic range.

Pharmacokinetics

Absorption and Distribution

Methylxanthines, such as theophylline, are most commonly used in an oral form that is rapidly and completely absorbed from the GI tract. Delayed-release and extended-release tablets are also available, and their rate of absorption varies among the various formulations. The absorption of slow-release forms of theophylline can be significantly altered by gastric pH and food ingestion; therefore, patient education regarding the timing of these medications is important to the success of the medication. Theophylline distributes rapidly in nonadipose tissue and body water, including breast milk and cerebral spinal fluid. Theophylline crosses the placenta. The volume of distribution (V_D) for theophylline averages 0.45 L per kg of body weight (L/kg) and ranges from 0.3 to 0.7 L/kg from infants to adults. The volume of distribution may be altered in premature neonates, elderly patients, adults with cirrhosis, pregnant women during the third trimester, and critically ill patients, probably because of altered protein binding. Serum theophylline levels should be monitored closely in these patients. Theophylline distributes readily into breast milk with milk levels at 70% of maternal serum levels.

Metabolism and Excretion

Theophylline is metabolized primarily in the liver, with very little or no first-pass effect. Metabolism is believed to occur over multiple parallel pathways, mediated by cytochrome P450 (CYP450) isoenzyme. Medications that induce CYP 450 can significantly increase clearance of theophylline. In neonates, several of these pathways are undeveloped but mature slowly over the first year of life. Caffeine is a minor active metabolite of theophylline in older children and adults. In premature neonates and children younger than 6 months, caffeine has a long half-life because of their immature livers, which results in significant accumulation. As the liver matures, the half-life of caffeine shortens and, therefore, does not accumulate in older children and adults. Table 17-1 outlines the half-life of theophylline in various ages of patients with a variety of diseases. Patients with congestive heart failure, cor pulmonale, pulmonary edema, and prolonged fever can have decreased metabolism of theophylline and, therefore, need to be closely monitored. Smoking and high-protein diets can increase the theophylline excretion rate, and high-carbohydrate diets can decrease it.

Pharmacotherapeutics

Precautions and Contraindications

The only true contraindications to theophylline are hypersensitivity to any xanthine, peptic ulcer disease, and underlying seizure disorder. Contraindications to caffeine include hypersensitivity to caffeine and use of caffeine sodium benzoate formulation in neonates.

Because of its effects on the cardiovascular system, patients with hypertension, ischemic heart disease, coronary insufficiency, congestive heart failure, or a history of stroke and cardiac arrhythmias should be monitored closely for adverse effects while taking theophylline.

Excessive doses may lead to toxicity. Incidence of toxicity increases when serum theophylline levels are above 20 mcg/mL. Toxicity is found if serum theophylline levels reach 25 mcg/mL in 75% of patients. Toxicity should not occur at recommended dosages but may occur if theophylline clearance is decreased (hepatic impairment, chronic lung disease, cardiac failure, patients older than age 55, and infants under age 1 year). Theophylline clearance may be decreased in patients over age 55.

Caffeine has a prolonged half-life of 72 to 96 hours in the neonate, whereas in infants over 9 months, children, and adults, the half-life is 5 hours.

Theophylline is Pregnancy Category C. There are no published reports linking theophylline with congenital defects. Theophylline crosses the placenta, and newborn infants may have therapeutic serum levels if maternal serum theophylline levels are in the high-normal range. Transient tachycardia, irritability, and vomiting can be found in newborns of women consuming theophylline.

With close monitoring, theophylline may be used in children. Infants younger than 1 year have decreased theophylline clearance and should have close monitoring of serum theophylline levels. Theophylline is used to treat apnea in preterm infants, with a therapeutic serum theophylline range of 5 to 10 mcg/mL. If levels are kept in this range, the neonate should not have signs of toxicity. Caffeine citrate is also commonly used to treat apnea of prematurity.

Adverse Drug Reactions

Adverse drug reactions are uncommon with serum theophylline levels below 20 mcg/mL, although some patients may show toxic effects between 15 and 20 mcg/mL, especially during initiation of therapy. The CNS adverse effects that may be seen include irritability, restlessness, seizures, and insomnia. Gastroesophageal reflux may occur. The cardiovascular adverse effects that may occur include palpitations, tachycardia, hypotension, and life-threatening arrhythmias. Other adverse effects include rash, diuresis, and tachypnea.

At serum theophylline levels above 20 mcg/mL, patients may experience nausea, vomiting, diarrhea, headache, insomnia, and irritability. At levels above 35 mcg/mL, the patient may have hyperglycemia, hypotension, cardiac arrhythmias, tachycardia, seizures, brain damage, and death.

Adverse effects of caffeine include cardiac arrhythmias, tachycardia, insomnia, agitation, irritability, headache, nausea, vomiting, and gastric irritation.

Drug and Food Interactions

Many medications act to either increase or decrease theophylline clearance due to metabolism via CYP450 isoenzyme CYP1A2, CYP2E1, and CYP3A3/4 substrate. These medications

are shown in Table 17-2. Of significance is smoking tobacco, which increases theophylline clearance. Theophylline levels should be monitored closely if the patient begins or quits smoking while on theophylline. Nicotine replacement products (gum or patch) also affect theophylline clearance. The theophylline clearance may not return to normal for 3 months to 2 years after smoking cessation.

The sedative effects of benzodiazepines may be antagonized by theophylline. Concurrent use of theophylline with beta$_2$-agonist bronchodilators may result in additive toxicity. Lithium levels may be reduced by theophylline. The concurrent use of tetracyclines with theophylline may lead to an increased incidence of theophylline adverse reactions. See Table 17-2 for other drugs that affect theophylline levels or interact with theophylline.

Theophylline elimination may be influenced by the patient's diet. A diet that is low in carbohydrates and high in protein increases the elimination (shortens the half-life) of the theophylline. A diet high in carbohydrates and low in protein decreases the elimination (lengthens the half-life) of the theophylline. A diet that contains a lot of charcoal-broiled foods accelerates the hepatic metabolism of theophylline because of the high polycyclic hydrocarbon content.

Caffeine is metabolized via the CYP450 isoenzyme CYP1A2, CYP2E1, and CYP3A3/4 substrate; therefore, other drugs metabolized via these isoenzymes will possibly interact. Cimetidine, ketoconazole, fluconazole, mexiletine, and phenylpropanolamine may impair caffeine metabolism, leading to increased serum levels. Caffeine elimination may be increased by coadministration of phenobarbital and phenytoin (FDA, 2005).

Clinical Use and Dosing

Theophylline and Chronic Obstructive Pulmonary Disease

The National Heart, Lung, and Blood Institute (NHLBI) *Expert Panel Report 3* (NAEPP, 2007), which provides guidelines for the management of asthma, recommends reserving theophylline for long-term control of asthma and an "alternative, not preferred" therapy in step 2 of asthma care. The *Expert Panel Report 3* recommends using theophylline as an alternative treatment in combination with inhaled corticosteroids (NAEPP, 2007). The guidelines recommend that long-acting beta$_2$ agonists (in combination with inhaled corticosteroids) be tried before theophylline because of toxicity issues with theophylline. Theophylline is not recommended for first-line therapy in the COPD patient, although if the patient has been stable on theophylline, there is no reason to discontinue the medication as long as serum theophylline levels are monitored.

The dose of theophylline for asthma and COPD varies with the patient's weight and serum theophylline levels. The adult patient (older than age 16 years) is started on a dose of 6 mg/kg per 24 hours or 400 mg/24 hours, whichever is less, divided at 6 to 8 hour intervals. The dose is increased every 3 days in 25% increments until the desired serum theophylline levels are achieved (ideally between 10 and 20 mcg/mL). The maximum dose for patients age 12 to 16 years is 13 mg/kg per day, and 10 mg/kg/day in healthy adolescents older than age 16 and adults. Dosing adjustments are made based on the serum theophylline level. If the level is 5 to 10 mcg/mL, then the dose of theophylline is increased by 25% every 3 days until desired serum concentrations of theophylline are reached. If the serum concentration is between 10 and 15 mcg/mL, maintain dosage if tolerated and recheck at 6 to 12 month intervals. If the serum theophylline level is 15 to 19.9 mcg/mL, consider decreasing the dose by 10% to provide a greater margin of safety. If the serum theophylline level is 20 to 25 mcg/mL, then decrease the dose by 10% and recheck the level in 3 days. If the serum level is 25 to 30 mcg/mL, skip the next dose and decrease subsequent doses by 25%; redraw the theophylline level in 3 days. If the theophylline level is above 30 mcg/mL, then skip the next two doses and decrease the dose by 50%; recheck in 3 days. If the patient has a serum theophylline level above 20 mcg/mL, consultation with a physician is indicated to determine if hospitalization for theophylline toxicity is warranted, based on clinical status.

The *Expert Panel Report 3* (NAEPP, 2007) for the management of asthma in children indicates theophylline as alternative therapy in moderate persistent asthma, in combination with low-dose inhaled corticosteroid in children aged 5 years or older. The initial dose of theophylline in children is 16 mg/kg per 24 hours up to a maximum of 400 mg per day. The dosage may be increased by 25% every 3 days to a maximum that is based on age. For children aged 1 to 9 years, the maximum is 24 mg/kg per day; for 9 to 12 years, the maximum dose is 20 mg/kg per day; for 12- to 16-year-old patients, the maximum daily dose is 18 mg/kg. If the patient is over age 16, then the dosing is the same as it is for adults—maximum 13 mg/kg per day. Monitoring for serum theophylline levels is the same in children as for adults, with a steady-state theophylline level of 5 to 15 mcg/mL the goal. Theophylline is not recommended for use in children with asthma who are younger than age 5 because of altered metabolism during viral or febrile illnesses affecting serum concentration (NAEPP, 2007).

Apnea of Prematurity

A loading dose of caffeine citrate 10 to 20 mg/kg is given in the treatment of apnea of prematurity, with a maintenance dose of 5 mg/kg per day. If theophylline has been given to the patient in the previous 3 days, the loading dose is decreased by 50% to 70%. The maintenance dose is adjusted based on clinical response and serum caffeine levels (8 to 20 mcg/mL). If theophylline is used to treat apnea of prematurity, the patient is given a loading dose of 4 mg/kg per dose, with a maintenance dose of 4 mg/kg per day in the premature infant or newborn up to age 6 weeks. The total daily dose is divided and administered every 12 hours. A recent RCT comparing caffeine and theophylline for the treatment of apnea of prematurity found both drugs are equally effective in decreasing apnea spells in infants less than 33 weeks' gestation, but caffeine is significantly more effective as prophylaxis against apnea in infants at risk (Skouroliakou, Bacopoulou, & Markantonis, 2009). The Skouroliakau and colleagues study found no sustained benefit of one drug over the other after the first week of therapy.

Rational Drug Selection

Because theophylline is the only xanthine derivative that is commonly used in asthma and COPD, the selection process basically involves choosing between the different forms of theophylline that are available on the basis of their cost and convenience. There are immediate-release, timed-release, and liquid formulas. Capsules that can be opened and sprinkled on soft foods are convenient for some patients.

Immediate Release

When therapy is initiated, the daily dose may be changing frequently based on serum theophylline levels, and immediate-release tablets or capsules should be prescribed. The variety of dosage tablets available (100 mg, 125 mg, 200 mg, 250 mg, 300 mg) makes titrating the dose easier if incremental increases or decreases are required. Immediate-release theophylline requires dosing every 6 to 8 hours. Children younger than age 12 usually require every-6-hour dosing, whereas adolescents and adults usually require every-8-hour dosing, although this timing may vary by individual. The cost of immediate-release theophylline is slightly higher than that of most of the timed-release formulas because more doses are taken and, therefore, more tablets need to be dispensed in a month. Many patients are stabilized to a set dose per 24 hours and then switched to a timed-release formula.

Timed Release

The variety of available timed-release theophylline products are described in Table 17-3. The formulas range from 8 to 24 hour release. It is recommended that patients be stabilized on immediate-release formulas to determine the total 24-hour dose that is required and then switched to a timed-release formula of choice. With some timed-release theophylline formulas offering once-daily dosing, there is a definite improvement in convenience with the timed-release products. One caution for the patient is that the dose must be taken at the same time every day to have steady serum theophylline levels.

Liquid

The liquid forms of theophylline may be used for children or patients who have difficulty in swallowing pills or capsules. The liquid is available in 80 mg/15 mL.

Monitoring

The patient who is taking theophylline needs to be monitored closely for signs of toxicity. When therapy is initiated, theophylline levels should be drawn frequently as the dosage is titrated. If the patient is demonstrating any signs of toxicity, a serum theophylline level should be drawn. Once the patient is stabilized and has a steady theophylline level, then monitoring should be done every 6 to 12 months. More frequent levels may need to be done if a new medication is added to the patient's regimen (see Table 17-2) or if the patient has a change in overall health that may affect the ability to metabolize or excrete theophylline. Theophylline levels need to be timed to measure peak levels of the drug. A serum theophylline level should be drawn 1 to 2 hours after immediate-release formulas and 5 to 9 hours after the morning dose of sustained-release formulas. The patient should have a theophylline level drawn when changing brands of theophylline because the bioavailability varies among brands.

Patient Education

Administration

The patient should be instructed to take the medication exactly as prescribed. Missed doses or irregular timing of doses can cause wide variations in the serum theophylline level, resulting in either subtherapeutic or toxic levels. The patient may take the medication either with or without food, but consistency is important because food can alter the absorption of the medication. The patient should not chew or crush enteric-coated, sustained-release tablets or capsules.

Adverse Reactions

Toxicity should be discussed with any patient who is taking theophylline. Patients who are having signs of toxicity may mistakenly think they have a viral illness. Instead, patients with any unusual symptoms should contact their provider. The symptoms to report include nausea, vomiting, insomnia, jitteriness, headache, rash, severe GI pain, restlessness, convulsions, or irregular heartbeat.

The patient should avoid large amounts of caffeine-containing beverages, which can increase the adverse effects of theophylline. Explain that theophylline elimination may be influenced by the patient's diet. A diet that is low in carbohydrates and high in protein increases the elimination of theophylline, a diet that is high in carbohydrates and low in protein decreases the elimination of theophylline, and a diet that contains a lot of charcoal-broiled foods accelerates the hepatic metabolism of theophylline. Any drastic changes in patients' diets should be discussed with the provider and a plan for monitoring developed.

The impact on serum theophylline levels that different drugs may have should be discussed with the patient. Any change in the patient's overall medication regimen should warrant a status review and possibly the drawing of serum theophylline levels. The impact of smoking on theophylline levels should be discussed and patients advised to notify their provider if they start or stop smoking.

Lifestyle Management

Lifestyle management issues related to the disease process should be discussed. They often include the following:

1. The patient needs to self-monitor respiratory status with a peak flowmeter to determine the effectiveness of the medication prescribed.
2. The patient should avoid or quit smoking.
3. The patient should avoid environmental triggers for asthma at home, work, and school.

ANTICHOLINERGICS

Inhaled anticholinergics are used primarily to treat COPD, although ipratropium may be used in combination with albuterol as the emergent treatment of an asthma exacerbation or when a patient is intolerant to beta$_2$ agonists (NAEPP,

2007). Ipratropium bromide (Atrovent) is a quaternary amine anticholinergic that is structurally similar to atropine. It is available as a single medication (Atrovent) or combined with albuterol (Combivent). Tiotropium bromide (Spiriva) and aclidinium bromide (Tadorza Pressair) are inhaled anticholinergics available to treat COPD.

Pharmacodynamics

The action of each of the inhaled anticholinergics is similar. Ipratropium acts to block the muscarinic cholinergic receptors by antagonizing the action of acetylcholine. Blocking the cholinergic receptors decreases the formation of cyclic guanosine monophosphate (cGMP), which leads to decreased contractility of the smooth muscle of the lungs, probably because of the actions of cGMP on intracellular calcium. The amount of bronchodilation caused by ipratropium inhalation is thought to reflect the level of parasympathetic tone. When inhaled, ipratropium's actions are confined to the mouth and airways. Tiotropium and aclidinium bromide exhibit their pharmacological action by inhibiting the muscarinic M_3 receptors in the lungs, causing smooth muscle bronchodilation.

Pharmacokinetics

Absorption and Distribution

Ipratropium, when inhaled, is poorly absorbed from both the lungs and the GI tract. Only 1% to 2% of a dose is systemically absorbed. Ipratropium penetrates the CNS poorly. It is unknown whether ipratropium crosses the placenta. Ipratropium is excreted into breast milk in minimal amounts.

Tiotropium is administered via dry powder inhaler, has a bioavailability of 19.5%, and is 72% protein bound in human plasma. Similar to ipratropium, tiotropium demonstrates poor GI absorption when administered orally with an absolute bioavailability of 2% to 3%. Tiotropium does not cross the blood–brain barrier. Tiotropium is distributed in breast milk of rats; it is unknown whether it is excreted in human milk or whether it crosses the placenta.

Aclidinium bromide is a dry powder administered via inhalation. Aclidinium is absorbed via the lungs and has a bioavailability of 6%. Peak onset of aclindinium is 10 minutes after inhalation. Aclidinium bromide is excreted into the milk of lactating female rats; it is not known if it is excreted in human milk.

Metabolism and Excretion

Most of the dose (90%) of ipratropium is swallowed and excreted in the feces unchanged. The portion of the dose that is absorbed is partially metabolized by ester hydrolysis to inactive metabolites. Approximately 50% of the absorbed drug is excreted unchanged in the urine. Tiotropium that is absorbed is eliminated unchanged in the urine. Aclidinium bromide is rapidly and extensively metabolized by hydrolysis, with 54% to 65% excreted in the urine and 20% to 33% excreted in feces.

Pharmacotherapeutics

Precautions and Contraindications

Ipratropium is contraindicated in patients with hypersensitivity to atropine or atropine derivatives and for those with bromide sensitivity. Tiotropium is contraindicated in patients with hypersensitivity to ipratropium or tiotropium.

The inhaled anticholinergics (aclidinium, ipratropium, and tiotropium) should not be used for the treatment of acute bronchospasm. The exception is if ipratropium is combined with albuterol in emergency room treatment of acute bronchospasm (NAEPP, 2007).

Inhaled anticholinergics (aclidinium, ipratropium, and tiotropium), even though poorly absorbed systemically, should be avoided for patients with urinary retention, bladder neck obstruction, or prostatic hypertrophy because of the anticholinergic effects. A systematic review found an increased risk of acute urinary retention associated with the use of inhaled anticholinergics, with older patients with benign prostatic hyperplasia at the greatest risk, particularly at the beginning of therapy (Loke & Singh, 2013). All three inhaled anticholinergic drugs may increase intraocular pressure in patients with closed-angle glaucoma.

Ipratropium bromide is Pregnancy Category B; aclidinium and tiotropium are Pregnancy Category C. Their safety in pregnancy has had limited study; therefore, inhaled anticholinergics should be used in pregnancy only if clearly indicated. Ipratropium is excreted in breast milk in minimal amounts. Atropine, a chemically related drug, is considered safe during lactation. Because such small amounts of drug reach the breast milk, ipratropium is probably safe for use if needed during breastfeeding.

The safety and effectiveness of ipratropium have not been established in children under age 12. Providers may use ipratropium in younger children as an adjunct to beta-agonist (albuterol) therapy in acute exacerbations of asthma per the *NAEPP Expert Panel Report 3* (2007). Aclidinium and tiotropium are approved only for COPD, which does not normally occur in children. Safety and effectiveness of aclidinium and tiotropium in children have not been established.

Adverse Drug Reactions

The most common adverse drug reaction reported with ipratropium is cough. Also reported are the related symptoms of hoarseness, throat irritation, and dysgeusia. Nausea, vomiting, and dyspepsia are thought to be related to the local anticholinergic effects that ipratropium has on the GI system. Xerostomia (dry mouth) is reported in 2% of patients.

Dry mouth is the most commonly reported adverse reaction to inhaled tiotropium (Spiriva HandiHaler), reported in 16% of patients in the manufacturer's clinical trials. Mouth irritation, pharyngitis, nasal congestion, sinusitis, headache, and upper respiratory infections occurred at slightly higher rates in patients using Spiriva than in those using a placebo in the initial clinical trials (Boehringer-Ingelheim, 2009).

Headache was the most common adverse reaction reported in premarketing studies of aclidinium, with 6.6% of patients reporting headache compared to 5% who were using placebo (Forest Pharmaceuticals, 2012). Nasopharyngitis,

cough, and rhinitis were all reported more frequently in inhaled aclidinium users than in placebo users.

Other anticholinergic effects that are reported in premarketing trials (in less than 2% of patients) include urinary retention, dizziness, drowsiness, and constipation. Prostate disorders may also be noted (less than 2% reported) in patients using ipratropium. In a 4-year trial of tiotropium (Spiriva HandiHaler) constipation occurred at a slightly higher rate than it did in those using a placebo (5.1% versus 3.7% in placebo patients). Urinary retention is increased with the use of inhaled anticholinergics, particularly in patients with benign prostatic hyperplasia (Loke & Singh, 2013).

If ipratropium is accidentally sprayed in the eyes, the patient may experience temporary eye irritation, pain, mydriasis, blurred vision, cycloplegia (paralysis of the ciliary muscle), irritant conjunctivitis, and visual disturbances.

Rare allergic and anaphylactoid reactions may occur. Reactions include urticaria; maculopapular rash; bronchospasm; pruritus; laryngospasm; oropharyngeal edema; and angioedema of the tongue, lips, and face. The patient's history usually includes sensitivity to other drugs and foods. Patients with milk protein hypersensitivity should not be prescribed aclidinium bromide (Tudorza Pressair).

Drug Interactions

Ipratropium and tiotropium are minimally absorbed into the systemic circulation after inhalation; therefore, there are no major drug interactions. Patients who are concurrently using cromolyn sodium and ipratropium bromide via nebulizer should be cautioned not to mix the two, because a precipitate will form.

Clinical Use and Dosage

Chronic Obstructive Pulmonary Disease

The dose of ipratropium from an MDI is 18 mcg per spray. The dose of ipratropium for adults with COPD is two inhalations (36 mcg) 4 times a day, for a total of eight puffs per day. If needed, the patient may take up to 12 puffs per day (maximum of 216 mcg/24 h). If using a nebulizer, the dose of ipratropium is one unit-dose vial (500 mcg) 3 to 4 times a day via nebulizer, with doses 6 to 8 hours apart. Ipratropium may be mixed with albuterol if used within 1 hour.

Aclidinium bromide (Tudorza Pressair) is an inhalation powder administered via inhaler, with 400 mcg delivered via each actuation of the inhaler. Dosing for COPD is one inhalation twice a day.

Tiotropium (Spiriva) is a dry powder capsule administered via a patented HandiHaler device. The dosage for COPD is two inhalations of a single 18-mcg capsule once daily.

The ipratropium-albuterol combination (Combivent) is indicated for second-line use for patients with COPD. It should be prescribed for patients already on a bronchodilator who continue to have bronchospasms that may benefit from a second bronchodilator. Each inhalation of Combivent administers 103 mcg of albuterol sulfate and 18 mcg of ipra-tropium bromide. The dose of Combivent is two inhalations 4 times a day. The patient may take additional inhalations but must not exceed 12 inhalations per 24 hours.

Asthma

The adult dose of ipratropium for asthma maintenance is two to three inhalations 4 times a day. It should not be used for exercise-induced asthma. For children under age 12 years, the dose is one or two inhalations every 6 hours. The dose of ipratropium solution in adults is 250 mcg administered via a nebulizer 4 times a day. The dose for children under age 12 is 250 to 500 mcg every 8 hours. Infants are dosed at 125 to 250 mcg 3 times a day. Dosing for acute exacerbation of asthma per the National Institutes of Health (NIH) guidelines is found in Table 17-3. Ipratropium may be mixed with albuterol if the combination is used within 1 hour.

The ipratropium-albuterol combination (Combivent) is a second-line quick-relief medication in the treatment of asthma. Each inhalation of Combivent administers 103 mcg of albuterol sulfate and 18 mcg of ipratropium bromide. The dose of Combivent in adults is two to three inhalations 4 times a day, and in children under age 12, one to two inhalations every 6 hours. The dose of nebulizer solution of albuterol (2.5 mg/3 mL) and ipratropium (0.5 mg/3 mL) is 3 mL every 4 to 6 hours for adults and 1.5 to 3 mL every 8 hours in children under age 12.

Tiotropium is not indicated for the treatment of asthma. The dosing for the treatment of COPD is one 18-mcg capsule daily via HandiHaler.

Rational Drug Selection

Ipratropium is a second-line bronchodilator in the treatment of asthma and COPD. For the practitioner considering prescribing both ipratropium and albuterol, an appropriate choice would be the combination product Combivent. Tiotropium (Spiriva) is for use in COPD; cost and ease of use (dry powder versus inhaler) may be the deciding factor.

Cost

The cost of a month's supply of Atrovent HFA MDI is $237 at multiple retail pharmacies (Walmart, K-Mart, Kroger, Costco). Generic ipratropium inhaler is no longer available. The cost of Atrovent inhalation solution is more than $200 for 150 unit-dose vials, and generic ipratropium inhalation solution is $57 for 150 unit-dose vials. The cost of the combination product Combivent is $307 (Costco.com) or $76.19 for Duoneb (ipratropium and albuterol nebulizer solution) per 30 vials, a significant cost savings over prescribing the two products individually. The generic combination product is even less expensive at $13.97 for ipratropium/albuterol nebulizer solution (http://www.costco.com). The provider needs to be familiar with the cost to the patient for each medication when making decisions regarding prescribing. It may be less expensive to prescribe the combined medication for COPD, or, depending on the patient's prescription drug coverage, it may be less expensive to prescribe each product individually.

Tiotropium (Spriva) is available only as a dry powder capsule for use with the HandiHaler. The cost of 1 month's worth of capsules (30) is $223.07.

Aclidinium bromide (Tudorza Pressair) inhaler costs $234 for 60 doses, or 1 month's supply.

Monitoring

There is no specific laboratory monitoring necessary with the use of the inhaled anticholinergics, other than monitoring the disease process.

Patient Education

Administration

Ipratropium, aclidinium, and tiotropium should be used as prescribed. Overuse of bronchodilators leads to increased adverse effects, and using the bronchodilator less than prescribed may lead to increased bronchospasm and decreased pulmonary function.

The administration of medication via an MDI can be difficult for most adults and all children. Learning to coordinate the release of the medication from the inhaler with a deep breath is difficult. Written and pictorial instructions are available with the inhaler, but the provider must not assume that the patient understands the proper method of administering inhaled medications. Use verbal instructions as well as actual demonstration with a placebo inhaler to reinforce the written instructions. These instructions and demonstrations should be repeated at follow-up visits.

To use an inhaler properly, the patient should first exhale and then tilt the head slightly back and place the inhaler mouthpiece either about 2 inches from the open mouth or between the open lips. While inhaling, the patient should press down on the canister, breathe in slowly and deeply, and hold her or his breath for 10 seconds (count of 10) or as long as comfortable. If two puffs are prescribed, then the patient should wait at least 1 full minute between inhalations. If the patient is prescribed other inhalers, advise the patient to use the ipratropium first and wait 5 minutes before using the other inhalers as directed.

To assist with the delivery of inhaled medications, a spacer can be prescribed. The Aerochamber is a tube-like device that has pictures drawn on the outside to remind the patient of the proper technique to use in administering the inhaler. For younger children and older adults, the InspirEase spacer gives a visual cue of the spacer bag deflating to help in taking a deep-enough breath. If the patient is taking too rapid a breath, both of these devices emit a whistling sound as a cue to breathe more slowly.

Administration of ipratropium via nebulizer is per the manufacturer's directions. One unit dose of ipratropium is administered every 6 to 8 hours. Albuterol can be added to the ipratropium if the mixture is used within 1 hour. Cromolyn will precipitate if added to ipratropium solution; the patient should be advised of this if both medications are prescribed. The nebulizer medication cup should be rinsed well between drugs if these two medications are to be used concurrently via nebulizer. Regardless of administration method, patients should rinse their mouth with water after inhaling ipratropium or tiotropium to minimize dry mouth.

To prime the MDI, patients using Combivent are recommended to "test-spray" the oral inhalation aerosol 3 times into the air before using it the first time. The patient should also prime the MDI in this manner if the medication has not been used in more than 24 hours.

Spiriva should be administered via the patented Handi-Haler device only. Capsules of tiotropium (Spiriva) dry powder are inserted into the HandiHaler, and the medication is administered via breath actuation. The Spiriva package insert has step-by-step pictures and text explaining how to administer the medication.

Adverse Reactions

The patient should be advised that a cough may develop with either inhaled anticholinergic and that less common complaints of throat irritation, hoarseness, or dry mouth may occur. Using a spacer device and rinsing the mouth with water after administration will decrease the incidence of these adverse effects. Other adverse effects occur less often, but patients should be aware of the possible adverse effects and be instructed to notify their provider if they begin to have adverse effects from the inhaled anticholinergics, particularly urinary retention.

Lifestyle Management

Lifestyle management issues related to the disease process should be discussed. They often include the following:

1. Patients need to self-monitor their respiratory status with a peak flowmeter to determine the effectiveness of the medication prescribed.
2. The patient should avoid or quit smoking.
3. The patient should avoid environmental triggers for asthma at home, work, and school.
4. Patients with COPD should avoid unnecessary exposure to viral respiratory infections.

LEUKOTRIENE MODIFIERS

Leukotriene-receptor agonists (LTRAs) and 5-lipoxygenase pathway inhibitors were developed under the theory that cysteinyl leukotrienes play a significant role in the chronic inflammation associated with asthma and allergy. Leukotrienes are substances that induce numerous effects that contribute to the inflammatory process, including smooth muscle contractility; neutrophil aggregation, degranulation, and chemotaxis; vascular permeability; and on lymphocytes. There are two LTRAs available for use in asthma, zafirlukast (Accolate) and montelukast (Singulair), and one 5-lipoxygenase pathway inhibitor, zileuton (Zyflo).

Pharmacodynamics

Leukotriene-Receptor Agonists

Zafirlukast is a synthetic, selective, and competitive LTRA of leukotriene D4 and E4 (LTD4 and LTE4). These leukotrienes have been identified as components of slow-reacting substance of anaphylaxis. Montelukast is a selective LTRA that inhibits the cysteinyl leukotriene (CysLT1) receptor. It binds with high affinity and selectivity to the CysLT1 receptor. Montelukast inhibits the actions of LTD4 at the CysLT1 receptor. There is evidence that the cysteinyl leukotrienes contribute to the pathophysiology of asthma and allergy, including airway edema, smooth muscle constriction, and cellular changes

associated with the inflammatory process. In vitro studies demonstrated that zafirlukast antagonized the contractile activity of three leukotrienes (LTC4, LTD4, and LTE4) in the conducting airway smooth muscle. Montelukast may also inhibit symptoms of allergic rhinitis, as leukotrienes are also released from the nasal mucosa during allergen exposure.

5-Lipoxygenase Pathway Inhibitors

Zileuton is an inhibitor of 5-lipoxygenase, the enzyme that catalyzes the formation of leukotrienes from arachidonic acid. By inhibiting 5-lipoxygenase, zileuton inhibits the formation of leukotrienes LTB_4, LTC_4, and LTE_4, identified as components of slow-reacting substance of anaphylaxis.

Pharmacokinetics

Absorption and Distribution

Zafirlukast is rapidly absorbed from the GI tract following oral administration. Peak plasma concentrations are reached in 3 hours. The bioavailability of zafirlukast may be decreased when taken with food, and it should be taken on an empty stomach. Zafirlukast is greater than 99% protein bound, primarily to albumin. Zafirlukast is excreted in breast milk in measurable amounts (50 ng/mL) compared with 255 ng/mL in plasma, when administered in healthy women in 40 mg/day dosages.

Montelukast is rapidly absorbed following oral administration, with peak plasma concentration achieved in 3 to 4 hours for the film-coated tablet and in 2 to 2.5 hours after administration of the chewable tablet. Montelukast is more than 99% protein bound. There is minimal distribution across the blood–brain barrier in rats; no human studies are available. Montelukast crosses the placenta in rats and is excreted in rat milk; there are no human studies available.

Zileuton is rapidly absorbed after oral administration, with a peak time of 1.7 hours. Food increases the maximum concentration (C_{max}) of zileuton up to 27%. Zileuton is 93% protein bound. It crosses the placental barrier in rats and is excreted in rat's milk. There are no controlled studies in pregnant women.

Metabolism and Excretion

Zafirlukast is extensively metabolized. In vitro studies using human liver microsomes showed that the hydroxylated metabolites of zafirlukast are formed through the CYP450 2C9 (CYP2C9) enzyme pathway. Additional studies using human liver microsomes show that zafirlukast inhibits

CYP3A4 and CYP2C9 isoenzymes at concentrations close to the clinically achieved plasma concentrations. The metabolites of zafirlukast found in plasma are at least 90 times less potent LTD4 receptor antagonists than zafirlukast. Following oral administration of zafirlukast, urinary excretion accounts for approximately 10% of the dose, and the remainder is excreted in the feces. Unmetabolized zafirlukast is not found in the urine.

Montelukast is extensively metabolized by the liver, with no detectable amounts of metabolites found in the plasma. CYP3A4 and CYP2C9 are the liver enzymes involved with the metabolism of montelukast. Montelukast and its metabolites are excreted almost exclusively via the bile, with less than 0.2% excreted in the urine.

Zileuton is metabolized in the liver via CYP1A2, CYP2C9, and CYP3A4. Renal elimination is the primary method of elimination, with 94.5% eliminated in the urine.

Table 17-4 presents the pharmacokinetics of the leukotriene modifiers.

Pharmacotherapeutics

Precautions and Contraindications

The leukotriene modifiers are not to be used for primary treatment of an acute asthma attack. The only true contraindication to the leukotriene modifiers zafirlukast and montelukast is hypersensitivity to any of the components of the medication. Chewable montelukast tablets are contraindicated in patients with phenylketonuria because the product contains phenylalanine. Zileuton is contraindicated in patients with active liver disease.

Zafirlukast should be used with caution in patients with hepatic dysfunction because it is extensively metabolized by the liver. If a patient has alcoholic cirrhosis, the clearance of zafirlukast is reduced about 50% to 60%. There is no need to adjust the dose of montelukast in the patient with mild to moderate hepatic insufficiency because the elimination is only slightly prolonged, although use should be avoided in patients with severe liver disease.

Leukotriene modifiers should not be abruptly substituted for inhaled or oral steroids. Caution is advised as systemic corticosteroids are reduced. There have been reports that the reduction of oral steroid dose in some patients on zafirlukast has been followed by eosinophilia, vasculitic rash, worsening pulmonary symptoms, cardiac complications, and/or neuropathy sometimes presenting as Churg–Strauss syndrome, a systemic eosinophilic rash.

Table 17–4 ✛ Pharmacokinetics: Leukotriene Modifiers

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Metabolism	Elimination
Montelukast	—	3–4 h	—	>99%	64%	2.7–5.5 h	Extensive hepatic	Bile
Zafirlukast	3–14 d	2–4 h	—	>99%	Unknown	About 10 h	Extensive hepatic	Feces: 90%; urine: 10%
Zileutin		1.7 h		93%	UK	2.5 h	Hepatic	Urine: 95%

Neuropsychiatric events have been reported in post-marketing surveillance of adult, adolescent, and pediatric patients taking leukotriene modifiers. The reported neuropsychiatric events include agitation, aggression, anxiousness, dream abnormalities and hallucinations, depression, insomnia, irritability, restlessness, suicidal thinking and behavior (including suicide), and tremor (FDA, 2009). Sleep disorders were more frequent in all three products than in placebo in the original clinical trials (FDA, 2009). The FDA (2009) recommends that patients be informed of the potential for neuropsychiatric events with these medications and should consider discontinuing leukotriene modifiers if the patient develops neuropsychiatric problems.

Zafirlukast and montelukast are Pregnancy Category B. Zileuton is Pregnancy Category C.

The safety and efficacy of zafirlukast have been established in children aged 5 and older. Montelukast may be prescribed for children as young as age 12 months for chronic asthma. The safety and effectiveness of Zileuton in pediatric patients younger than age 12 years have not been established.

Caution should be used in prescribing any of the leukotriene modifiers to lactating women because the effects on infants are unknown.

Adverse Reactions

The most common adverse reaction reported with zafirlukast use is headache. GI upset, myalgias, and fever are reported in a small percentage of patients. There is a reported increase in respiratory infections in patients older than age 55 years who are taking zafirlukast. The respiratory infections were usually mild to moderate and associated with coadministration of inhaled corticosteroids.

The reported adverse reactions of those taking montelukast are similar to placebo.

Zileuton has similar effects to placebo in clinical trials, except for a significant increase in dyspepsia (8.2% versus 2.9%) in patients treated with zileuton. Hepatic injury, including hepatitis and death, is reported, with 1.9% of patients exhibiting elevated ALT in the clinical trials.

Drug Interactions

Zafirlukast should be used with caution with any drug that is metabolized by CYP2C9 and CYP3A3/4 isoenzymes. Coadministration of aspirin with zafirlukast results in about a 45% increase in plasma zafirlukast level. Erythromycin coadministered with zafirlukast results in a 40% decrease in plasma zafirlukast level. Concurrent terfenadine use leads to decreased plasma zafirlukast levels, and theophylline use has a similar profile. When warfarin is prescribed to the patient taking zafirlukast, there is a clinically significant increase in prothrombin time (PT).

Monitor closely the patient who is taking drugs that are metabolized by CYP450 isoenzymes CYP2A6, CYP2C9, and CYP3A3/4 (phenobarbital, rifampin) concurrently with montelukast. Coadministration with drugs metabolized by CYP3A4 and zileuton should be monitored closely as there is a theoretical interaction. Coadministration of zileuton and theophylline may elevate serum theophylline levels. A reduction of the -ophylline dose by 50% is recommended by the manufacturer of Zyflo. Terfenadine plasma levels are increased by up to 35% and clearance is reduced by 22% when administered with zileuton. Coadministration with warfarin may theoretically increase prothrombin time; monitoring closely is warranted.

Table 17-5 presents drug interactions between the leukotriene modifiers and other medications.

Table 17–5 ⦙⦙⦙ Drug Interactions: Leukotriene Modifiers

Drug	Interacting Drug	Possible Effect	Implications
Montelukast	Phenobarbital	Decreases area under curve (AUC) of dose by about 40%	Monitor patient closely
	Rifampin	Decreased metabolism of montelukast	Monitor
Zafirlukast	Aspirin	Increased plasma levels of zafirlukast	Monitor
	Erythromycin	Decreased plasma levels of zafirlukast	Use together with caution
	Theophylline	Decreased plasma levels of zafirlukast	Use cautiously
	Warfarin	Increased PT/INR	Closely monitor PT/INR
	Drugs metabolized by CYP2C9: amitriptyline, diclofenac, ibuprofen, imipramine, phenytoin, tolbutamide	Possible interactions	Until more data known, zafirlukast should be used cautiously in patients stabilized on these medications
	Drugs metabolized by CYP3A4: alprazolam, astemizole, carbamazepine, cisapride, some corticosteroids, cyclosporine, diazepam, calcium channel blockers (felodipine, isradipine, nicardipine, nifedipine, nimodipine), diltiazem, erythromycin, lidocaine, lovastatin, midazolam, quinidine, simvastatin, triazolam, verapamil	Possible interactions	Until more data known, zafirlukast should be used cautiously in patients stabilized on these medications

Table 17–5 ⚏ **Drug Interactions: Leukotriene Modifiers—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
Zileutin			
	Theophylline	Increased half-life of theophylline. More theophylline ADRs	Use cautiously
	Warfarin	Increased AUC of warfarin	Closely monitor PT/INR
	Proproanolol	Increased propranolol concentration	Monitor HR closely. Decrease dose of propranolol if needed.

Clinical Use and Dosing

Zafirlukast is indicated in the treatment of chronic asthma in children aged 5 years or older and adults. Montelukast is indicated for use in the treatment of persistent asthma for patients aged 12 months or older. Montelukast may be prescribed for the prevention of exercise-induced bronchoconstriction in adolescents age 15 years or older and adults. Montelukast may also be used to treat seasonal allergic rhinitis in patients 2 years or older and perennial allergic rhinitis in patients 6 months and older. Zileuton is indicated for the treatment of persistent asthma in children aged 12 years and older and adults.

The dose for zafirlukast is 20 mg twice daily in children aged 12 years or older and adults, and 10 mg twice a day for children aged 5 to 11 years. Because food reduces the bioavailability of zafirlukast, it must be taken on an empty stomach.

The adult dosage (patients aged 15 years or older) of montelukast is 10 mg once a day in the evening. The dose of montelukast in children aged 6 to 14 years is 5 mg once a day in the evening. Children aged 2 to 5 years are dosed with 4 mg of montelukast before bed; children aged 12 to 24 months are prescribed 4 mg of oral granules. Montelukast may be taken without regard to meals. Montelukast is dosed the same for allergy as for asthma.

The dose of zileuton is 600 mg 4 times a day or two 600 mg extended-release tablets twice a day, 1 hour after meals. Table 17-6 shows the dosage schedule.

Rational Drug Selection

Drug selection is based on the age of the patient and convenience in dosing. Children under age 5 years may be prescribed only montelukast. Montelukast offers once-a-day dosing without regard to meals, which may make it more convenient than zafirlukast. Zileuton is dosed 4 times a day or extended-release twice a day. Singulair (montelukast) costs $170 for a 30-day supply (30 tablets), generic montelukast costs $40 for a 30 day supply. Accolate (zafirlukast) costs $135 for 60 tablets, a 30-day supply and generic zafirlukast $63 for 60 tablets. A 30-day supply of zileuton (Zyflo) costs $525.

Monitoring

Monitoring of improving or worsening asthmatic symptoms, bronchodilator use, and pulmonary function is necessary to determine the efficacy of the leukotriene modifiers. Patients should be monitored for new onset of neuropsychiatric symptoms, including depression or behavior change.

Patient Education

Patient education focuses on proper dosing of the medication, adverse reactions, and the general asthma management plan. The incorporation of the leukotriene medications into the asthma treatment plan is covered in Chapter 31.

Administration

The patient must take the medication as prescribed, even if symptom-free. These medications are not for acute episodes

Table 17–6 ⚭ **Dosage Schedule: Leukotriene Modifiers**

Drug	Indication	Dosage Form	Dose	Comments
Montelukast Singulair Generic	Prophylaxis and treatment of chronic asthma	Tablets: 10 mg Chewable tablets: 5, 4 mg Granules: 4 mg/packet	*Adults:* 10 mg once daily in p.m. *Children 6–14 yr:* 5 mg at bedtime *Children 2–5 yr:* 4 mg at bedtime *Children 12–24 mo:* 4 mg granules at bedtime	Not recommended for children <12 mo
Zafirlukast Accolate Generic	Prophylaxis and treatment of chronic asthma	Tablets: 20 mg Tablets: 10 mg	*Adults:* 20 mg bid *Children 5–11 yr:* 10 mg bid	Not recommended for children <5 yr; must be taken on an empty stomach
Zileutin Zyflo Zyflo CR Generic	Prophylaxis and treatment of chronic asthma	600 mg tablet Zyflo CR: 600 mg extended-release tablet	Adults: 600 mg qid	Not recommended for children

of asthma. Patients must continue to use the bronchodilator inhaler for acute episodes of bronchospasm. They are not to decrease or discontinue any of their other asthma medications unless instructed to do so by their health-care provider.

Zafirlukast must be taken on an empty stomach, whereas montelukast may be taken without regard to meals. Zileuton may be taken with or without food.

Pregnant or nursing women should not take these medications.

Patients should be aware of significant drug interactions with leukotriene modifiers because of the way these drugs are metabolized by the liver. Patients should be advised to discuss with their health-care provider any new medications that are prescribed or discontinued.

Adverse Reactions

Patients and parents of pediatric patients should be informed of the potential for neuropsychiatric events, including agitation, aggression, anxiousness, dream abnormalities and hallucinations, depression, insomnia, irritability, restlessness, suicidal thinking and behavior (including suicide), and tremor. Any new neuropsychiatric symptoms should be reported to the provider.

Lifestyle Management

Lifestyle management issues related to the disease process should be discussed. They often include the following:

1. The patient needs to self-monitor respiratory status with a peak flowmeter to determine the effectiveness of the medication prescribed.
2. The patient should avoid or quit smoking.
3. The patient should avoid environmental triggers for asthma at home, work, and school.

Table 17-6 presents the available dosage forms.

RESPIRATORY INHALANTS

CORTICOSTEROIDS

The *Expert Panel Report 3* states that corticosteroids are the "most potent and effective anti-inflammatory medication currently available" (NAEPP, 2007, p 213). Their anti-inflammatory effects lead to reduction in the severity of asthma symptoms, increased peak flow readings, and decreased airway hyperresponsiveness. In general, inhaled steroids are safe and well tolerated at recommended dosages and can be used by both children and adults. Corticosteroids are also used intranasally for the treatment of allergic rhinitis.

The commonly prescribed inhaled corticosteroids for asthma are beclomethasone dipropionate (QVAR), triamcinolone acetonide (Azmacort), budesonide (Pulmicort), flunisolide (AeroBid), mometasone furoate (Asmanex Twisthaler), fluticasone (Flovent), and ciclesonide (Alvesco). There are significant differences among the different formulations in the amount of steroid delivered per inhalation, and they are not interchangeable without adjusting the inhalations per day.

The corticosteroids that are available for intranasal use are beclomethasone (Beconase), triamcinolone (Nasacort AQ), budesonide (Rhinocort Aqua), flunisolide (Nasalide, Nasarel), mometasone (Nasonex), fluticasone (Flonase), and ciclesonide (Omnaris).

Pharmacodynamics

In the treatment of asthma and allergic rhinitis, the primary actions of orally inhaled corticosteroids are anti-inflammatory. The inhaled adrenocorticosteroids inhibit the immunoglobulin E (IgE) and mast cell–mediated migration of inflammatory cells into the bronchial tissue (late-phase allergic reaction). The exact mechanism of action by which the inhaled corticosteroids inhibit bronchoconstrictor mechanisms and produce smooth muscle relaxation is unknown. The exact mechanism of action of corticosteroids on the nasal mucosa is unknown. Intranasal corticosteroids applied topically to the nasal tissues exert local anti-inflammatory effects without any systemic glucocorticoid effects.

Pharmacokinetics

Absorption and Distribution

Absorption of inhaled corticosteroids occurs from the lungs and from the GI tract. Approximately 10% to 30% of the dose from an MDI is delivered to the lungs. If a spacer device is not used, approximately 80% of the dose from an MDI is swallowed, with the oral bioavailability differing from drug to drug.

Beclomethasone is rapidly absorbed from the nasal and pulmonary tissues and GI tract. Upon inhalation, 10% to 25% of the drug is deposited in the tissues of the mouth, trachea, and lungs, where it is completely absorbed. The remainder of the dose is swallowed. The oral bioavailability of inhaled beclomethasone is 20%. Beclomethasone is highly protein bound. It and its metabolites do not appear to distribute into the tissues, but beclomethasone does cross the placenta. With systemic administration, steroids are excreted in breast milk; it is unknown whether inhaled beclomethasone is found in breast milk.

Triamcinolone (Azmacort) MDI is packaged with a built-in spacer to enhance the delivery of the medication to the lungs. Triamcinolone (Nasacort) for intranasal use is delivered via intranasal metered-dose pump. Triamcinolone is rapidly and completely absorbed from lung tissues and nasal mucosa. It is distributed throughout the hilar areas of the lungs. The oral bioavailability of the swallowed portion of the dose is 10.6%. Triamcinolone is weakly protein bound and crosses the placenta. It is unknown whether inhaled triamcinolone is excreted in breast milk.

Approximately 20% of the inhaled dose of budesonide reaches the systemic circulation. Once absorbed from the nasal tissues or lungs, the distribution of budesonide is extensive. Budesonide is 88% protein bound. It is unknown if budesonide is excreted in breast milk, but it passes through the placenta.

Flunisolide is rapidly absorbed from the bronchial tree, with 10% to 20% of the inhaled dose distributing into the

lungs. Fifty percent of an intranasal dose of flunisolide is absorbed into the systemic circulation. The oral bioavailability of the dose is 20% to 40%. Flunisolide crosses the placental barrier. Breast milk excretion is unknown.

Less than 1% of mometasone oral powder for inhalation is absorbed. With nasal administration, the medication that is swallowed is absorbed, although plasma concentrations are near or below the level of quantification. Breast milk excretion is unknown.

Fluticasone is primarily absorbed in the lungs, resulting in systemic bioavailability of 30% of the dose. Intranasal fluticasone has a systemic bioavailability of less than 2%. It is highly lipid-soluble, is rapidly distributed into the tissues, and is 91% protein bound. Fluticasone crosses the placenta. Breast milk excretion is unknown.

Ciclesonide is minimally absorbed and what is absorbed is 99% protein bound in distribution.

Metabolism and Excretion

Some portion of the dose of all inhaled corticosteroids is swallowed. After GI absorption, they all undergo high first-pass liver metabolism.

In the lung, beclomethasone is rapidly metabolized to beclomethasone 17-monopropionate and more slowly to free beclomethasone. Metabolites of beclomethasone are excreted mainly in the feces, with a small portion excreted in the urine.

Triamcinolone is metabolized into three less-active ingredients: 6-β-hydroxy triamcinolone acetonide, 21-carboxytriamcinolone, and 21-carboxy-6-β-hydroxytriamcinolone acetonide. All of the metabolites of triamcinolone are eliminated in the feces.

Budesonide undergoes extensive first-pass metabolism into two main metabolites: 16-α-hydroxyprednisolone (24%) and 6-β-hydroxybudesonide (5%). The metabolites are excreted in the urine (66%) and the feces.

The part of the flunisolide dose that is swallowed is absorbed and metabolized by the liver into several metabolites. One of the metabolites has minor glucocorticoid activity. The drug is further metabolized into inactive metabolites. Excretion of inhaled flunisolide is not described, but oral doses are excreted equally in the feces and the urine.

Mometasone is extensively metabolized in the liver via CYP3A4 isoenzyme. It is excreted primarily via the bile; 74% of metabolites is excreted in feces.

Fluticasone is metabolized in the liver primarily by CYP3A4. The only detectable metabolite is a 1-β-carboxylic acid derivative. Excretion is primarily in the feces; less than 5% is excreted in the urine.

Ciclesonide is metabolized by CYP3A4 into an active metabolite, des-ciclesonide. Sixty-six percent of ciclesonide is excreted in the feces and approximately 20% in the urine.

Pharmacokinetics is presented in Table 17-7.

Pharmacotherapeutics

Precautions and Contraindications

All of the inhaled corticosteroid preparations are contraindicated in acute status asthmaticus or when intensive, acute therapy is warranted. They should not be used for relief of acute bronchospasm.

Care should be used when substituting any of the inhaled corticosteroids for oral corticosteroid therapy. There have

Table 17–7 ⊞ Pharmacokinetics: Respiratory Inhalants

Drug	Onset	Peak	Protein Binding	Bioavailability	Half-Life	Metabolism	Elimination
Corticosteroids							
Beclomethasone	Few days to 3 wk	—	—	<5%	15 h	Hepatic	Feces
Budesonide	—	—	88%	10%	2 h	Hepatic	Renal
Flunisolide	Few days to 4 wk	10–30 min	—	20%	1.8–2 h	Hepatic	Renal, feces
Fluticasone	—	—	91%	30%	—	Hepatic	Feces
Mometasone	11 h	1–2 wk	98%	—	5.8 h	Hepatic	Bile, renal
Triamcinolone	—	—	Weak	10%	0.5–1 h	Hepatic	Feces
Inhaled Antihistamine							
Azelastine	30 min–1 h	2–3 h	88%	40%	22 h	Hepatic	Feces
Anti-Inflammatory Agents							
Cromolyn sodium	—	—	—	<1%	—	Not metabolized	Bile, renal
Nedocromil	—	20 min	—	6–9%	1.5–2.3 h	Not metabolized	Renal: 64%; feces: 36%

been deaths due to adrenal insufficiency in asthmatic patients who were switched from oral to inhaled corticosteroids.

The risk for hypothalamic-pituitary-adrenal (HPA) suppression is low with inhaled corticosteroids, but the risk increases when inhaled corticosteroids are administered while the patient is taking oral steroids.

Inhaled corticosteroids should be avoided in patients with Cushing's syndrome. They should be used with caution in patients with ocular herpes simplex infections, tuberculosis, oral or nasal surgery or trauma, healing nasal septal ulcers, and untreated respiratory infection (viral, fungal, or bacterial).

All of the inhaled corticosteroids are Pregnancy Category C. There have been no well-controlled studies of the effects of inhaled corticosteroids during pregnancy.

The use of high-dose inhaled steroids in children may inhibit growth, but so can poorly controlled asthma. A large ($N = 943$) long-term study of the effects of inhaled corticosteroids on children followed for more than 12 years, to an average age of 25 years, observed a 0.47 inch difference in average height for the subjects in the budesonide group (NHLBI, 2012). Doses higher than 400 mcg/day in younger children warrant close monitoring of growth. Triamcinolone inhalant therapy should not be prescribed to children under age 6 years because the safety and efficacy have not been established. Budesonide safety has been determined for children as young as 6 months. Inhibition of growth has been noted in children on high-dose inhaled fluticasone. Fluticasone must be prescribed with caution to children under age 4 years. Mometasone nasal spray may be prescribed for children as young as age 2 years, but the safety of mometasone oral inhalation powder for asthma management has not been established for children younger than age 12. The safety of inhaled flunisolide in children under age 6 has not been established. Studies were conducted in children aged 6 to 11 years regarding the safety of nasal ciclesonide; nasal ciclesonide (Omnaris) is considered safe and effective in children aged 6 or older. During clinical trials the safety and efficacy of inhaled ciclesonide (Alvesco) was studied in children aged 4 to 11 years with asthma. To control asthma symptoms, ciclesonide (Alvesco) was determined to be safe, but not effective, in children younger than 12.

Adverse Reactions

All of the inhaled corticosteroids have associated xerostomia, hoarseness (5% to 50% of patients), tongue and mouth irritation, flushing, and dysgeusia (altered taste sensation). Rash and urticaria have been reported with the use of flunisolide, beclomethasone, and fluticasone. Dysmenorrhea has been reported in 1% to 3% of patients using inhaled fluticasone and 4% to 9% using mometasone oral inhalation powder.

Local immunosuppression can lead to oral candidiasis with any of the inhaled corticosteroids. Cataracts can be induced with corticosteroid use, even with inhaled cortico - steroids. Bronchospasm may occur with any of the inhaled

corticosteroids. With high-dose inhaled corticosteroid use, HPA suppression is theoretically possible. Concurrent use of systemic corticosteroids with inhaled corticosteroids increases the likelihood of HPA suppression, compared with the use of either one alone.

Pulmonary infiltrates with eosinophilia may occur with inhaled flunisolide, usually when inhalation corticosteroid therapy replaces systemic corticosteroid therapy. The cause is unknown.

Intranasal corticosteroid use may cause nasal irritation, itching, sneezing, and nasal dryness. The patient may experience bloody nasal mucus or epistaxis.

Drug Interactions

There are no known drug interactions with inhaled triamcinolone, flunisolide, mometasone, beclomethasone, or ciclesonide.

Ritonavir significantly increases fluticasone serum concentrations and may lead to increased corticosteroid effects of fluticasone. Ketoconazole increases plasma concentration of fluticasone and budesonide when coadministered. The interaction is due to inhibition of CYP3A4 isoenzyme, the enzyme that metabolizes fluticasone and budesonide. There are no other known drug interactions, but close monitoring for corticosteroid-related side effects is advisable if coadministered with other drugs that are known to inhibit CYP3A4. Those drugs include anastrozole (Arimidex) in high doses, delavirdine (Rescriptor), erythromycin, fluconazole (Diflucan), fluoxetine (Prozac), itraconazole (Sporanox), mibefradil (Posicor), nefazodone (Serzone), nelfinavir (Viracept), ritonavir (Norvir), and zileuton (Zyflo). Drug interactions are presented in Table 17-8.

Clinical Use and Dosing

Asthma

The inhaled corticosteroids are the preferred long-term control medications for managing the inflammatory process associated with asthma (NAEPP, 2007). Dosages for the inhaled corticosteroids vary with the specific product and the delivery method. The patient with persistent asthma is started on inhaled corticosteroids according to the *Expert Panel Report 3* guidelines for the management of asthma discussed in detail in Chapter 30 (NAEPP, 2007). All patients with mild persistent asthma are started on a low dose of inhaled corticosteroids. Children older than age 12 and adults may be treated with cromolyn, nedocromil, leukotriene modifiers, or theophylline as alternative therapy. If the patient has moderate persistent asthma, then the patient is prescribed daily low- to medium-dose inhaled corticosteroids combined with a long-acting beta agonist. Alternatively, the patient can be prescribed medium-dose inhaled corticosteroids or a combination of low- to medium-dose inhaled cortico - steroids and a leukotriene modifier. Severe persistent asthma requires daily high-dose inhaled corticosteroids and long-acting beta agonists. See Table 17-9 for dosing inhaled corticosteroids for children over age 5 and adults.

Table 17–8 ⁙ Drug Interactions: Respiratory Inhalants

Drug	Interacting Drug	Possible Effect	Implications
Corticosteroids			
Beclomethasone	None known	—	—
Budesonide	Ketoconazole*	Increased budesonide concentrations and suppression of plasma cortisol levels	Observe the patient for increased corticosteroid-related side effects
Flunisolide	None known	—	—
Fluticasone	Ketoconazole* Ritonavir	Increased fluticasone concentrations and suppression of plasma cortisol levels	Observe the patient for increased corticosteroid-related side effects
Mometasone	None known	—	—
Triamcinolone	None known	—	—
Inhaled Antihistamines			
Azelastine	Cimetidine	The mean maximum concentration (C_{max}) and area under the curve (AUC) of azelastine is increased when coadministered with cimetidine	Monitor closely if coadministering
	Ethanol or other CNS depressants	Reduced mental alertness and impairment of CNS performance may occur	Use concurrently with caution
Anti-Inflammatory Agents			
Cromolyn	None known	—	—
Nedocromil	None known	—	—

*There are no other known drug interactions, but close monitoring is advisable if coadministered with other drugs that are known to inhibit CYP3A4. Those drugs include anastrozole in high doses, delavirdine, erythromycin, fluconazole, fluoxetine, itraconazole, mibefradil, nefazodone, nelfinavir, ritonavir, and zileuton.

Table 17–9 ⚕ Dosage Schedule: Respiratory Inhalants

Drug	Indication	Dosage Form	Dose	Comments
Corticosteroids				
Beclomethasone QVAR	Asthma	40 mcg/puff 80 mcg/puff	*Children >12 yrs and adults:* Low dose: 80–240 mcg daily in divided doses either bid, tid, or qid Medium dose: 240–480 mcg daily in divided doses High dose: >480 mcg daily in divided doses *Children 5 yrs to 11 yrs:* Low dose: 80–160 mcg daily in divided doses (2–4 puffs 40 mcg/puff; 1–2 puffs 80 mcg/puff) Medium dose: 160–320 mcg daily in divided doses (4–8 puffs 40 mcg/puff; 2–4 puffs 80 mcg/puff) High dose: >320 mcg daily in divided doses (>8 puffs 40 mcg/puff; >4 puffs 80 mcg/puff)	Patients should rinse their mouth with water after use; if needed, use inhaled bronchodilator first
Qnasl Beconase AQ	Allergic rhinitis	80 mcg/inhalation 42 mcg/inhalation	*Children >6 yr and adults:* 42 mcg/spray nasal inhaler: 1 spray each nostril bid times/d 80 mcg/spray aqueous nasal spray: 1–2 sprays each nostril once a day	Not recommended for use in children <6 yr
Budesonide Pulmicort Flexihaler Pulmicort Respules Generic	Asthma	Power inhalation: 90 mcg/inhalation 180 mg/inhalation Nebulizer suspension 0.25 mg/2mL	*NIH Asthma Guidelines (2007):* *>age 12 yr and adults:* Low dose: 180–600 mcg daily Medium dose: 600–1,200 mcg daily High dose: >1,200 mcg daily	Rinse mouth after use Has rapid onset for an inhaled steroid Improvement can occur within 24 h of beginning treatment,

Table 17–9 ⊗ Dosage Schedule: Respiratory Inhalants—cont'd

Drug	Indication	Dosage Form	Dose	Comments

			Children 5–11 yr:
			Low dose: 180–400 mcg/d
			Medium dose: 400–800 mcg/d
			High dose: > 800 mcg/d
			Children 12 mo–8 yr:
			Pulmicort respules or generic nebulizer solution:
			Previously treated with bronchodilators alone:
			  0.25 mg twice daily or 0.5 mg daily, max 0.5 mg/d
			Previously treated with inhaled corticosteroids:
			  0.25 mg bid or 0.5 mg daily, max 2 mg/d
			Previously treated with oral corticosteroids: 0.5 mg
			  or 1 mg daily, max 1 mg daily
			Children >6 yr previously treated with bronchodilators:
			Low dose: 200 mcg daily (1 inhalation daily)
			Medium dose: 200–400 mcg daily (2–3 inhalations
			  daily)
			High dose: >400 mcg/d (>2 inhalations daily)
			NIH Asthma Guidelines:
			Nebulization
			Children ≤ 4 yr:
			Low dose: 0.25–0.5 mg/d
			Medium dose: 0.5–1.0 mg/d
			High dose: > 1 mg/d
			Children 5–11 yr:
			Low dose: 0.5 mg/d
			Medium dose: 1 mg/d
			High dose: 2 mg/d
				although maximum benefit may not be achieved for 1–2 wk
				Dose should be titrated to the lowest effective dose once asthma is controlled

Rhinocort Tubohaler Rhinocort Aqua	Allergic rhinitis	100 mcg/inhalation 64 mcg/inhalation	*Children >6 yr and adults:* Initially 2 sprays in each nostril bid or 4 sprays once daily in the a.m. (max 4 sprays/nostril/d)	Blow nose prior to using For perennial rhinitis, gradually reduce over 2–4 wk to lowest effective dose

Flunisolide	Allergic rhinitis		*Adults:*
			Initially 2 sprays each nostril bid, maximum
			  8 sprays each nostril/d
			Children 6–14 yr:
			Initially 1 spray each nostril tid or 2 sprays each
			  nostril bid; maximum 4 sprays/nostril/d
				Blow nose prior to using
				Safety in children <6 yr has not been established

Fluticasone Flovent Diskus Flovent HFA	Asthma	Oral dry powder inhaler (60):
		50, 100, 260 mcg
		Inhaler (120 puffs):
		44, 110, 220 mcg/inhalation
			Dry powder inhaler:
			Children >12 yr and adults:
			Low dose: 100–300 mcg daily
			Medium dose: 300–500 mcg daily
			High dose: >500 mcg daily
			Children 5–11 yr:
			Low dose: 100–200 mcg daily
			Medium dose: 200–400 mcg daily
			High dose: >400 mcg daily
			Inhaler:
			Children >12 yr and adults:
			Low dose: 88–264 mcg daily (2–6 puffs
			  44 mcg/puff divided bid)
			Medium dose: 264–660 mcg daily (2–6 puffs
			  110 mcg/puff daily divided bid)
			High dose: >660 mcg (>6 puffs 110 mcg/puff or
			  >3 puffs 220 mcg/puff)
			Children 5–11 yr:
			Low dose: 88–176 mcg daily (2–4 puffs
			  44 mcg/puff divided bid)
			Medium dose: 176–352 mcg daily (2–4 puffs
			  110 mcg/puff divided bid)
			High dose: >264–440 mcg (>4 puffs 110 mcg/puff or
			  >2 puffs 220 mcg/puff)
				Safety in children <4 yr has not been established

Table 17–9 ✂ **Dosage Schedule: Respiratory Inhalants—cont'd**

Drug	Indication	Dosage Form	Dose	Comments
			Children 0–4 yrs: Low dose: 176 mcg Medium dose: >176–352 mcg High dose: >352	
Veramyst Flonase Generic	Allergic rhinitis	27.5 mcg/ inhalation 50 mcg/inhalation	*Children >11 yr and adults:* Initially 2 sprays each nostril once a day or 1 spray in each nostril bid; for maintenance, reduce dose to 1 spray each nostril daily *Children 4–11 yr:* Initially 1 spray in each nostril once daily; may increase to 2 sprays in each nostril once daily if needed; for maintenance: 1 spray in each nostril once daily	Safety in children <4 yr has not been established
Fluticasone and Salmeterol Advair HFA Advair Diskus	Persistent asthma	Inhaler: ADVAIR HFA 45/21 Inhalation Aerosol (fluticasone propionate 45 mcg and salmeterol 21 mcg) ADVAIR HFA 115/21 Inhalation Aerosol (fluticasone propionate 115 mcg and salmeterol 21 mcg), and ADVAIR HFA 230/21 Inhalation Aerosol (fluticasone propionate 230 mcg and salmeterol 21 mcg) Oral inhalation powder: ADVAIR DISKUS 100/50 (fluticasone propionate 100 mcg and salmeterol 50 mcg) Inhalation Powder ADVAIR DISKUS 250/50 (fluticasone propionate 250 mcg and salmeterol 50 mcg) Inhalation Powder ADVAIR DISKUS 500/50 (fluticasone propionate 500 mcg and salmeterol 50 mcg) Inhalation Powder	*No prior inhaled corticosteroid:* *Children 4–11 yr:* Fluticasone 100 mcg/salmeterol 50 mcg 1 inhalation bid *Children ≥12 yr and adults:* Fluticasone 100 mcg/salmeterol 50 mcg 1 inhalation bid *COPD: Adults:* Fluticasone 250 mcg/salmeterol 50 mcg 1 inhalation bid	Titrate dose to lowest effective strength that maintains control of asthma
Mometasone Nasonex	Allergic rhinitis	50 mcg/spray	*Children 2–11 yr:* 1 spray each nostril once a day *Children ≥12 yr and adults:* 2 sprays each nostril twice a day	

Drug	Indication	Dosage Form	Dose			Comments
Asmanex Twisthaler	Asthma	200 mcg, 400 mcg	*Children ≥12 yr and adults:*			Contains lactose. If administered once a day, dose should be taken in the p.m. Safety not established in children <12 yr.
			Previous therapy	Recommended starting dose	Highest recommended daily dose	
			Bronchodilators alone	220 mcg daily p.m.	440 mcg	
			Inhaled corticosteroids	220 mcg daily p.m.	440 mcg	
			Oral corticosteroids	440 mcg bid	880 mcg	

Table 17–9 ⊗ Dosage Schedule: Respiratory Inhalants—cont'd

Drug	Indication	Dosage Form	Dose	Comments
Mometasone and formoterol Dulera	Chronic asthma	**DULERA 100 mcg/ 5 mcg** (mometasone furoate 100 mcg and formoterol fumarate dihydrate 5 mcg) **DULERA 200 mcg/ 5 mcg** (mometasone furoate 200 mcg and formoterol fumarate dihydrate 5 mcg)	Previously on medium dose inhaled corticosteroids: DULERA 100 mcg/5 mcg, 2 inhalations twice daily, maximum 400 mcg daily Previously on high dose inhaled corticosteroids: DULERA 200 mcg/5 mcg, 2 inhalations twice daily, max 800 mcg/daily	Rinse mouth after use Safety in children <6 yr has not been established
Triamcinolone Nasacort AQ	Allergic rhinitis	55 mcg/inhalation	*Children >12 yr and adults:* 2 sprays in each nostril once daily; may increase if needed to a maximum of 8 sprays/d; reduce dose as condition improves *Children 6–12 yr:* 2 sprays each nostril once daily; may reduce as condition improves	Safety in children <6 yr has not been established
Inhaled Antihistamine				
Azelastine Astelin Astepro	Allergic rhinitis	0.1% solution: 137 mcg/ inhalation 0.15% solution: 205 mcg/ inhalation	*Children >12 yr and adults:* 2 sprays (137 mcg/spray) per nostril bid *Children 5–11 yr:* 1 spray per nostril bid	Safety in children <5 yr has not been established The unit must be primed before using for the first time by pumping the activator 4 times, until a fine mist occurs
Anti-Inflammatory Agents				
Cromolyn Generic	Asthma	20 mg/2 mL solution	*Nebulizer* *Children >2 yr and adults:* 1 unit dose qid, weaning down to bid	Cromolyn must be used continuously 3–4 wk before maximum effect is achieved Cromolyn is very safe to use in children, with fewer side effects than inhaled steroids
Cromolyn NasalCrom	Allergic rhinitis	40 mg/mL solution	*Children >6 yr and adults:* 1 spray in each nostril 3–4 times a day; may increase dosage to 6/d if needed	Begin therapy 1 wk before known exposure; for allergic rhinitis; 2–4 wk of therapy may be needed to produce relief; blow nose prior to administering Once control is established, the dose can be reduced to 3 times a day; after several weeks the dose can be further decreased to bid

Chapter 31 should be referred to for comprehensive asthma management.

Children with persistent asthma require daily anti-inflammatory therapy. Young children with mild persistent asthma are usually started on step 2 therapy, a low-dose inhaled corticosteroid (via nebulizer or MDI and mask), with an alternative therapy being cromolyn or montelukast. If the child has moderate persistent asthma, low-dose inhaled corticosteroids combined with montelukast or a long-acting inhaled beta agonist are begun. Because salmeterol is not approved for children younger than age 4, an alternative treatment would be medium-dose inhaled

corticosteroids, or low-dose inhaled corticosteroids combined with a leukotriene modifier (montelukast). High-dose inhaled steroids combined with a long-acting inhaled beta agonist or montelukast are prescribed for severe persistent asthma. The provider should be familiar with the differences in dosing young children and adults. The full *Expert Panel Report 3* guidelines for step-wise management of asthma are available in Chapter 31.

Allergic Rhinitis

Allergic rhinitis results when allergens come in contact with the nasal mucosa, causing a hypersensitivity reaction. Nasal corticosteroids are used to manage the inflammatory response associated with seasonal or perennial allergies. Intranasal corticosteroids may be used once or twice a day, depending on the drug chosen. Once clinical improvement occurs, usually in 3 to 7 days, the dose can be decreased. See Table 17-9 for dosing information.

Rational Drug Selection

The *Expert Panel Report 3* and update (NAEPP, 2007) do not recommend one inhaled corticosteroid over another; therefore, the choice is mostly based on ease of dosing and the adverse drug interactions and indications previously addressed. There are no generic equivalent formulas for the inhaled cortico - steroids but there is generic fluticasone nasal spray, which may make cost a factor as more generic formulas are available.

Dosing

If a patient requires a high dose of inhaled steroid, the bec - lomethasone 42 mcg/puff dose would be more than 20 puffs per day, whereas the dose of budesonide would be 8 or more puffs per day. High-dose triamcinolone would also be 20 puffs per day. Fluticasone and flunisolide have the highest steroid anti-inflammatory effect per puff, which makes dosing high-dose inhaled steroids more convenient (see Table 17-9   for dosing). If the patient requires a low dose or if trying to wean the dose, beclomethasone or triamcinolone would be the first choice.

Monitoring

The patient who is using inhaled corticosteroids needs to be monitored for adverse effects of the medication, effectiveness of the medication, and the asthma disease process. If high-dose inhaled corticosteroids are used for a long time, blood glucose and potassium should be monitored, as well as growth in young children.

Patient Education

Administration

Patients who are concurrently using an inhaled bronchodilator should administer the bronchodilator first and wait several minutes before using the inhaled corticosteroid. This procedure enhances the absorption of the steroid in the bronchial tree.

The administration of inhaled corticosteroids via an MDI can be difficult for most adults and all children. Learning to coordinate the release of the medication from the inhaler with a deep breath is difficult. Written and pictorial instructions

are available with the inhaler, but the provider must not assume that the patient understands the proper method of administering inhaled medications. Use verbal instructions as well as actual demonstration with a placebo inhaler to reinforce the written instructions. These instructions and demonstrations should be repeated at follow-up visits.

To use an inhaler properly, the patient should first exhale and then tilt the head slightly back and place the inhaler mouthpiece either about 2 inches from the open mouth or between the open lips. While inhaling, the patient should press down on the canister, breathe in slowly and deeply, and hold his or her breath for 10 seconds (count of 10) or as long as comfortable. If multiple puffs are prescribed, then the patient should wait at least 1 full minute between inhalations.

To assist with the delivery of inhaled medications, spacers can be prescribed to ensure the medication is deposited in the lungs, not the mouth. The Aerochamber is a tube-like device that has pictures drawn on the outside to remind the patient of the proper techniques. For younger children and older adults, the InspirEase spacer gives a visual cue of the spacer bag deflating to help in taking a deep-enough breath. Both of these devices cue the patient to breathe slowly by emitting a whistling sound if the patient is taking too rapid a breath. The Global Initiative for Asthma Web site has extensive information and diagrams on the use of the different types of spacers and inhalation delivery devices (www.ginasthma.org/documents/11).

Dry powder, breath-actuated inhalers require adequate inspiratory effort to deliver the medication into the bronchial tree. Patient self-administration should be observed to determine whether the medication is being used appropriately.

Patients should rinse their mouth with water after each use to help reduce dry mouth, hoarseness, and candidiasis infection.

The patient should clear the nasal passages of mucus prior to using intranasal corticosteroids. If the nasal passages are swollen and blocked, the patient should administer a topical decongestant prior to using intranasal corticosteroids. The medication is sprayed into the nasal passages. The patient does not need to inhale the medication. The patient should understand that the effects are not immediate and that clinical improvement may take 3 to 7 days. Rinsing the mouth with water after use will reduce the rare chance of candidiasis infection associated with intranasal corticosteroid use.

Inhaled steroids are not to be used as abortive asthma medications; they are for preventive therapy only. The provider should have patients bring in all their inhalers and review which are to be used for abortive therapy (short-acting beta agonists) and which are for preventive therapy. The patient should be advised to continue to use the inhaled corticosteroid even when not having asthma symptoms.

Adverse Reactions

The patient should be advised to notify the provider if sore mouth or throat occurs. Oral *Candida* infections are possible, and the patient should get prompt treatment. The patient should be aware of the possibility of dysphonia developing. Rinsing the mouth with water and using a spacer device will decrease its incidence. Other adverse effects occur less often, but the patient should be aware of them and be instructed to

notify the provider if adverse effects begin to develop from the inhaled medication.

Relatively few medications interact with the inhaled corticosteroids. Ketoconazole should be avoided for patients who are prescribed fluticasone, ciclesonide, and budesonide. Patients should be instructed to notify all providers that they are on inhaled corticosteroids to avoid possible interactions.

Lifestyle Management

Lifestyle management issues related to the disease process should be discussed. They often include the following:

1. Patients need to self-monitor their respiratory status with a peak flowmeter to determine the effectiveness of the medication prescribed.
2. The patient should avoid or quit smoking.
3. The patient should avoid environmental triggers for asthma at home, work, and school.

Available dosage forms are presented in Table 17-9.

INHALED ANTI-INFLAMMATORY AGENTS

Cromolyn sodium and nedocromil are synthetic compounds that inhibit antigen-induced bronchospasm. Cromolyn was originally produced to be used as a bronchodilator but was found to have no bronchodilator activity. Nevertheless, cromolyn inhibits antigen-induced bronchospasm, blocks the release of histamine, and is a mast cell stabilizer. Nedocromil is similar to cromolyn in many ways but is now only available in ophthalmic solution, which is discussed in Chapter 27. Cromolyn is used in the treatment of asthma; it (Nasalcrom) is also used in treating allergic rhinitis.

Pharmacodynamics

Cromolyn acts to inhibit mast cell degranulation, which prevents the release of histamine and slow-reacting substance of anaphylaxis (SRS-A). Neither drug prevents the binding of IgE to the mast cell or the binding of antigen to IgE. Cromolyn also prevents the release of leukotrienes, which induce numerous effects that contribute to the inflammatory process in the lungs. With continued use, cromolyn reduces bronchi hyperreactivity to stimuli such as cold air, allergens, and environmental irritants. Cromolyn does not have bronchodilator, antihistamine, or vasoconstrictor activity, and at therapeutic doses, does not have systemic activity.

Pharmacokinetics

Absorption and Distribution

Inhaled cromolyn is poorly absorbed systemically; only 8% of the dose is absorbed. Approximately 5% to 10% of the inhaled dose reaches the lungs, with the amount affected by the degree of bronchoconstriction present. Intranasal cromolyn is minimally absorbed. Distribution of the absorbed amount of the drug is unknown. Minimal amounts of cromolyn cross the placenta and distribute into breast milk.

Metabolism and Excretion

The portion of the dose of cromolyn that is absorbed from the lung is rapidly excreted unchanged in the urine and bile. The remaining portion of the dose is exhaled or swallowed and excreted unchanged in the feces.

Pharmacotherapeutics

Precautions and Contraindications

Cromolyn is not a bronchodilator, and it is contraindicated in the treatment of acute bronchospasm or status asthmaticus. Hypersensitivity to cromolyn is a contraindication to its use.

Cromolyn is Pregnancy Category B and should be used with caution in the lactating mother because safety has not been established. Cromolyn is safe for use in children as young as 2 years (nebulizer solution).

Adverse Reactions

Cromolyn is generally well tolerated. Inhaled cromolyn may cause bronchospasm, which can be avoided by preadministering a beta-agonist bronchodilator. Throat irritation and cough are also reported. Intranasal cromolyn may produce nasal irritation and cause sneezing.

Drug Interactions

There are no clinically significant drug interactions with cromolyn. Cromolyn solution for nebulizer use will form a precipitate if mixed with ipratropium solution.

Clinical Use and Dosing

Asthma

Cromolyn is considered an alternative long-term control drug for the treatment of mild persistent asthma. It is available in inhaled form and nebulizer solution. The dosage of cromolyn MDI for children older than 5 years and adults is two sprays (800 mcg/spray) inhaled 4 times a day at regular intervals. The dose of nebulizer solution of cromolyn is one ampule (20 mg) 4 times a day at regular intervals. The dose of cromolyn may be decreased after the patient is stabilized (usually after 4 weeks) to two or three doses a day. If used concurrently with bronchodilators, the bronchodilator should be administered first. Cromolyn may be mixed with albuterol in a nebulizer cup to simplify dosing. The patient should understand that the effectiveness of cromolyn depends on using it regularly.

Oral cromolyn is also used for systemic mast-cell disease (mastocytosis) and inflammatory bowel disease. Dosing for mastocytosis is 200 mg of Gastrocrom oral concentrate 4 times a day in adults and 100 mg 4 times a day in children aged 2 to 12 years. Initial adult dosing for inflammatory bowel disease is 200 mg 4 times a day of Gastrocrom oral concentrate, which may be doubled if not responding after 2 to 3 weeks to 400 mg 4 times a day. Children aged 2 to 12 with inflammatory bowel disease are dosed at 100 mg 4 times a day. The dose may be doubled but should not exceed 40 mg/kg/day (Takemoto et al, 2009).

Bronchospasm Prophylaxis

Cromolyn is indicated for patients with exercise-induced bronchospasm or individuals who have bronchospasm with known

precipitating factors (e.g., pet exposure). The dose of cromolyn MDI for children aged 5 years or older and adults is two inhalations 10 to 15 minutes before exercise. If exercise is prolonged, the dose may be repeated. Nebulizer dosing in children aged 2 years or older and adults is one ampule administered via nebulized solution not more than 1 hour prior to exercise. For maximum effectiveness, the time between the use of inhaled cromolyn sodium and exercise should be as brief as possible.

Allergic Rhinitis

The dosage of cromolyn sodium nasal inhalation spray in children aged 6 years and older and adults is one spray in each nostril 3 to 4 times a day. The dose may be increased to 6 times a day if needed. The dose is administered while the patient is inhaling, and the nostrils should first be cleared of mucus. Two to four weeks of therapy may be needed to produce relief from perennial rhinitis.

Rational Drug Selection

The decision regarding which inhaled anti-inflammatory to use is often based on cost, availability, and patient variables such as age or ease of dosing.

Patient Variables

Cromolyn has dosage forms available for use in children as young as 2 years.

Administration

Cromolyn comes in multiple formulations that allow the provider to match the patient's age and lifestyle with an administration form. Cromolyn MDI (Intal) has been discontinued in the United States, but generic inhalation solution for nebulizer use is available.

Cost

Cromolyn is available in generic nebulizer solution; the cost of 96 ampules is $212.

Monitoring

No specific monitoring is required other than monitoring associated with the disease process.

Patient Education

Administration

The administration of inhaled anti-inflammatory agents requires the patient to use the medication as prescribed. Cromolyn is not effective if not used at regular intervals. Clarification regarding the use of inhaled bronchodilators that can be used as needed and the inhaled anti-inflammatory agents will enable the patient to use the medication appropriately, as will a written plan.

The use of cromolyn via nebulizer must be demonstrated to the patient in the clinic or by the home health agency that is providing the nebulizer. Because the vials are premeasured, there is no concern about dosing error.

Adverse Reactions

At therapeutic dosages, minimal adverse reactions are reported. The patient should be instructed not to exceed the recommended dosage of the medication.

Lifestyle Management

Lifestyle management issues related to the disease process being treated should be discussed. They often include the following:

1. The patient needs to self-monitor respiratory status with a peak flowmeter to determine the effectiveness of the medication prescribed.
2. The patient should avoid or quit smoking.
3. The patient should avoid environmental triggers for the asthma at home, work, and school.

INHALED ANTIHISTAMINES

Azelastine (Astelin, Astepro) and olopatadine (Patanase) are the intranasal H_1 blockers currently available in the United States. They are used for the treatment of seasonal allergic rhinitis and vasomotor rhinitis.

Pharmacodynamics

Azelastine is an H_1 agonist and a potent inhibitor of histamine release from the mast cells. Azelastine and its metabolite desmethylazelastine inhibit the effects of histamine by competing with histamine for H_1 binding sites. Azelastine may also interfere with histamine- and leukotriene-induced bronchospasm. Olopatadine is a selective H_1 receptor antagonist.

Pharmacokinetics

Absorption and Distribution

Azelastine, administered intranasally, has a systemic oral bioavailability of 40%. Protein binding of azelastine is 88% and for the active metabolite desmethylazelastine, it is 97%. Peak serum concentrations are reached in 2 to 3 hours. Exact absorption information is unknown. Distribution is unknown, but because somnolence is a reported adverse effect, azelastine is assumed to enter the CNS. It is unknown whether azelastine crosses the placenta or is distributed in breast milk.

Olopatadine is absorbed from nasal mucosa and peaks in 15 minutes to 2 hours after administration. The portion of olopatadine absorbed is 55% protein bound.

Metabolism and Excretion

Azelastine is metabolized into the principal active metabolite desmethylazelastine. Following intranasal dosing of azelastine to steady state, plasma concentration of desmethylazelastine is 20% to 30% of azelastine. Excretion of azelastine and desmethylazelastine is via the feces. Olopatadine is not extensively metabolized and is eliminated in the urine.

Pharmacotherapeutics

Precautions and Contraindications

Some patients using intranasal azelastine may experience somnolence and should be cautioned not to drive or operate heavy equipment while using it. Patients should not use alcohol or other CNS depressants while using azelastine. Olopatadine is contraindicated only in patients with nasal diseases other than allergies. Spraying into the eyes should be avoided.

It is unknown whether azelastine is excreted in breast milk. Use during lactation with caution. Olopatadine has been measured in the milk of nursing rats; no studies of use in lactating women have been done. Because seasonal allergic rhinitis is not generally a life-threatening disease, the benefits do not outweigh the unknown risks to the infant.

Azelastine and olopatadine are Pregnancy Category C. It should be used in pregnancy only if the potential benefits outweigh the risks to the fetus. There are no adequate studies in pregnant women. In animals receiving more than 240 times the normal dose, external and skeletal abnormalities have been noted.

The safety of azelastine in children under age 5 years and of olopatadine in children younger than age 12 years has not been established.

Adverse Reactions

The most commonly reported adverse reaction to azelastine is bitter taste (19%). Other reported adverse reactions are somnolence (11%), headache, weight gain (2%), and myalgia (1.5%). Local effects such as nasal irritation, epistaxis, sneezing, and rhinitis are also reported. Bitter taste (12.8%), headache (4.4%), and epitaxis (3.2%) are also reported in patients using intranasal olopatadine.

Drug Interactions

There is an additive impairment of CNS function when azelastine is used with ethanol or other CNS depressants. When azelastine is coadministered orally with cimetidine, the area under the curve (AUC) and C_{max} are increased by 65%. Data regarding interactions with intranasal azelastine and cimetidine are not available. Azelastine should be used cautiously with other antihistamines. There is theoretical additive CNS depression when olopatadine is administered with other CNS depressants or alcohol.

Clinical Use and Dosing

Allergic Rhinitis

Azelastine is approved for use in seasonal allergic rhinitis. It is used to treat the specific symptoms of rhinorrhea, sneezing, and nasal pruritus. The dose for children older than age 12 years and adults is two sprays (137 mcg/spray) per nostril twice a day. Children age 5 to 12 years should use one spray in each nostril twice a day. Dosing for olopatadine is two sprays in each nostril twice a day in children older than age 12 years and in adults.

Rational Drug Selection

Oral Versus Intranasal Antihistamine

The provider may choose to use intranasal azelastine or olopatadine rather than a systemic antihistamine because of decreased adverse effects or fewer drug interactions noted with the intranasal product.

Cost

The cost of azelastine (Astelin) is $146 for a 30 mL bottle, with the generic costing $77 for a 30 mL bottle. Olopatadine (Patanase) costs $175 for a 30.5 g bottle.

Patient Variables

Azelastine should not be prescribed to children under age 5 years and olopatadine should not be prescribed to children younger than age 12. Both drugs should be used with caution in pregnant and lactating patients.

Monitoring

There is no specific monitoring required with the use of azelastine or olopatadine other than symptoms of allergic rhinitis to determine efficacy.

Patient Education

Administration

The patient should be instructed to prime the medication unit before use by pumping the activator 4 times, or until a fine mist appears. The patient should keep the sprayer pointed away from the face, other people, and pets when priming the medication. The patient should wipe the tip of the sprayer with a clean tissue after using and replace the cap between uses. To prevent the spread of infection, the sprayer should be used by only one person.

Adverse Reactions

The patient should be instructed about the most common adverse reactions. Caution regarding driving or operating heavy equipment while using azelastine should be stressed. The bitter taste that some patients experience may be decreased by drinking water or another fluid after administration. The patient should report any unusual adverse reactions to the provider.

The patient should be cautioned not to drink alcohol or take any other CNS depressants while using intranasal azelastine. The patient may not be aware that an intranasal medication can have an interaction with an orally administered medication, and therefore, the provider must give careful instructions before prescribing azelastine.

Lifestyle Management

Lifestyle management related to the disease process needs to be discussed with the patient. Points to discuss often include avoidance of known allergens and using environmental methods to control dust mites and other common allergens.

OXYGEN

Oxygen is a basic element essential for human life; oxygen deprivation leads to rapid death. Therapy with oxygen is necessary for life in several diseases that interfere with normal oxygenation of blood and tissues. Oxygen as a therapeutic gas is delivered from steel containers and is 99% pure.

Pharmacodynamics

Oxygen is prescribed to treat hypoxia, or tissue deprivation of oxygen. Hypoxia can be caused by an inadequate supply of oxygen to the lungs, which can be due to poor ventilation or inadequate partial pressure of inspired oxygen. Inadequate pulmonary function can lead to hypoxia, as in a mismatch

between ventilation and perfusion. Tissue hypoxia may occur with inadequate delivery of oxygen to the tissues, such as occurs in low cardiac output. Tissue hypoxia may also occur if the oxygen concentration of the blood is low, as occurs in anemia.

The effects of hypoxia can be observed in all major organ systems. The respiratory system increases the ventilatory rate and depth as a result of stimulation of carotid and aortic chemoreceptors. The heart increases cardiac output by increasing the heart rate. With severe hypoxia, bradycardia develops and ultimately leads to circulatory failure. The CNS is the most sensitive to hypoxia, with initial impaired judgment and psychomotor ability, leading to confusion; restlessness; and ultimately stupor, coma, and death.

Pharmacokinetics

The oxygen content of inhaled air is normally 20.9%, equivalent to a partial pressure of 159 mm Hg. As oxygen is inhaled, it enters the pulmonary airways and travels to the distal airways and alveoli. In the distal airways, the partial pressure of oxygen (PO_2) is decreased by dilution with carbon dioxide and water vapor and by uptake into the blood. The diffusion of oxygen into the pulmonary capillary blood is driven by the gradient between the PO_2 in mixed venous blood and that in the alveolar gas. The pressure gradient increases when 100% oxygen is administered, causing increased oxygen diffusion into the pulmonary capillary blood. Oxygen is delivered via the circulation to the tissue capillary beds, where it is diffused by its higher partial pressure out of the blood and into the cells.

Oxygen in the blood is carried by the hemoglobin, with a small amount in physical solution in the plasma. The amount of oxygen carried by the hemoglobin depends on the partial pressure of carbon dioxide ($PaCO_2$) and is usually illustrated with the oxyhemoglobin dissociation curve.

Pharmacotherapeutics

Precautions and Contraindications

The only contraindication to oxygen use is concurrent smoking while the oxygen is running. Oxygen is a flammable gas that will ignite if a flame is too near. This has implications for chronic smokers, who should turn off their oxygen to smoke.

Oxygen should be prescribed to patients with chronic carbon dioxide retention with extreme caution and close monitoring. Because hypoxemia may be the primary stimulus for respiration in these patients, the lowest possible concentration of oxygen to avoid serious tissue hypoxia should be used. In patients with hypercapnia, the sudden increases in $PaCO_2$ produced by oxygen may result in cessation of respiration.

Adverse Drug Reactions

Dry Nasal Passages

The most common adverse drug reaction reported in patients who are administered oxygen is dry nasal passages from the flow of gas through the nasal cannula (NC). This can be prevented by administering humidified oxygen by mask or by keeping the flow rate low (less than 5 to 6 L/min).

Toxicity

Oxygen toxicity occurs when inspired concentrations of oxygen exceed those of air for prolonged periods of time. Cell membrane damage and death are thought to be caused by increased production of reactive species such as superoxide anion, singlet oxygen, hydroxyl radical, and hydrogen peroxide. Some tissues, including the respiratory tract, the CNS, and the retina, are more sensitive to high oxygen concentration.

In the respiratory tract, inhalation of 100% oxygen for 6 to 8 hours can lead to decreased movement of tracheal mucus. In as little as 12 hours of 100% oxygen, the patient may experience tracheobronchial irritation and complain of chest tightness. After 17 hours, there is increased alveolar permeability and inflammation. Overall pulmonary function decreases after 18 to 24 hours of continuous 100% oxygen. After 24 hours of 100% oxygen, the patient usually has symptoms of nausea, vomiting, and anorexia. The patient may survive 1 week on toxic levels of oxygen. Death occurs from pulmonary edema. Oxygen toxicity of the CNS does not occur until the partial pressure of inspired oxygen (PIO_2) is greater than 2 atm, which usually occurs in a hyperbaric chamber.

The retina of a premature neonate can be damaged by exposure to high levels of oxygen for prolonged periods. The development of retrolental fibroplasia is thought to be related to high levels of partial pressure of oxygen in arterial blood (PaO_2) administered to the neonate. Adults rarely have oxygen-induced retinopathy, even with hyperbaric levels.

Drug Interactions

There are no drug interactions with oxygen.

Clinical Use and Dosing

Oxygen is administered to treat hypoxia as determined by pulse oximetry or arterial or mixed venous blood gases. Hypoxia is usually a symptom or manifestation of an underlying disease, and therefore, oxygen therapy is not curative, but it does provide symptomatic and temporary improvement in the patient's status. The underlying cause of hypoxia needs to be treated.

Correction of Hypoxia

To correct hypoxia, oxygen is administered to the patient via a variety of oxygen-delivery systems. The provider chooses a delivery system based on the fraction or percentage of oxygen (FIO_2) that is desired for treatment. The goal of treatment is to maintain oxygen saturation above 90%.

An NC will deliver an FIO_2 of 0.24 to 0.35 if the flow of oxygen is at 5 to 6 L/min. Higher flow rates via NC dry out the nasal mucosa and will not achieve higher FIO_2 because the oxygen is mixed with ambient air. Humidified oxygen can be delivered to decrease nasal passage dryness. The percentage of oxygen that can be delivered via NC is 22% to 44%.

Masks cover the mouth and nose and allow for a higher concentration of oxygen to be delivered. Oxygen delivery via mask requires a flow rate above 5 L/min to avoid accumulation of exhaled air in the mask. A flow rate of 8 to 10 L/min is recommended. A simple face mask, which allows room air

to dilute the oxygen, delivers 40% to 60% oxygen to the patient. A face mask with an oxygen reservoir provides a constant flow of oxygen at above 60% concentration. If the flow rate of oxygen is 6 L/min, then the oxygen concentration is 60%. The oxygen concentration increases by 10% for every liter per minute increase in flow. When 10 L/min of oxygen is delivered via a mask with an oxygen reservoir, the percentage of oxygen delivered reaches 100%. A Venturi mask allows for controlled percentages of oxygen to be delivered to patients. The mask can be adjusted to deliver 24%, 28%, 35%, and 40%. This type of mask is used on patients with chronic hypercapnia (e.g., COPD patients) to tightly control the amount of oxygen delivered and avoid respiratory depression associated with high oxygen concentrations in these patients.

Oxygen may also be delivered by hood or tent to provide a known concentration to the patient, with little cooperation required from the patient. Flow rates must be high enough to prevent accumulation of carbon dioxide.

Monitoring

Monitoring the patient on oxygen is necessary to treat hypoxia and to avoid toxicity. The most accurate yet invasive method to monitor blood oxygenation is by arterial or mixed venous blood gas sampling. This procedure can be painful for the patient and requires rapid transport of the specimen to the laboratory. Blood gases have the advantage of providing additional information, besides oxygenation, regarding the patient's status that may assist in the treatment of the underlying cause of hypoxemia. Pulse oximetry is a noninvasive method of monitoring the patient receiving oxygen therapy. It measures the difference in absorption of light by oxyhemoglobin and deoxyhemoglobin in an accessible location, such as the finger, toe (in children), or ear. Pulse oximetry measures the hemoglobin saturation and not PO_2.

The need for continuing oxygen therapy should be monitored by drawing arterial blood gases after 1, 3, and 6 months of therapy.

Patient Education

Administration

The patient who is receiving home oxygen therapy requires knowledge of the appropriate use of oxygen, as well as education about safe administration. The patient should use the oxygen as prescribed by the provider. Increasing or decreasing the flow rate of oxygen may have adverse effects. Using oxygen for fewer hours than prescribed will increase hypoxia and will have detrimental effects.

The patient should understand that oxygen is a flammable gas that should be kept away from open flame. Patients who smoke should be cautioned not to smoke while their oxygen is running.

Adverse Reactions

There are minimal adverse reactions with the use of oxygen. The patient should be advised of the potential of developing dry nasal passages. Increasing hydration and increasing the humidity of the home will help somewhat.

Oxygen toxicity should be discussed and the patient advised to use the oxygen only as directed. Patients who begin to exhibit symptoms that may be related to toxicity should contact their health-care provider.

Lifestyle Management

Lifestyle management issues related to the disease process being treated should be discussed. They often include the following:

1. The patient should avoid or quit smoking.
2. COPD patients should avoid unnecessary exposure to viral respiratory infections.
3. Patients with COPD or other chronic respiratory diseases should avoid high altitudes.
4. Before traveling by air, the patient should contact the provider to formulate a plan of care.

ALLERGY MEDICATIONS

ANTIHISTAMINES

Antihistamines are used in primary care to treat a variety of allergic conditions. This chapter addresses the antihistamines used to treat allergic symptoms specific to the respiratory tract. Antihistamines are also called H_1 receptor antagonists, which describes the action the medication has at the cellular level. This text uses *antihistamine*, the more commonly used name in clinical practice.

The first antihistamines became available in the 1940s, with the still widely used diphenhydramine first available in the 1950s. They are referred to as the first-generation antihistamines. The 1980s brought a new generation of nonsedating antihistamines that provided relief to allergy sufferers without causing the drowsiness of the earlier medications. They are referred to as second-generation antihistamines. New antihistamines that are longer acting and have better adverse-effect profiles continue to be developed.

Pharmacodynamics

Antihistamines are H_1 receptor antagonists that reduce or prevent most of the physiological effects of histamine at the H_1 receptor site. Antihistamines compete with histamine for H_1 receptor sites on the effector cells. They do not prevent histamine release or bind with histamine that has already been released. They prevent, but do not reverse, responses mediated by histamine. The effects of antihistamines include inhibition of respiratory, vascular, and GI smooth muscle constriction by antagonism of the constrictor action on smooth muscle. Antihistamines strongly block the action of histamine that results in increased capillary permeability and formation of edema and wheal. They also decrease the flare and itch responses of histamine on peripheral nerve endings. Histamine-activated exocrine secretions (salivary, lacrimal) are decreased with the use of systemic antihistamines. Antihistamines with strong anticholinergic (atropine-like) properties may have an increased drying effect by decreasing secretions from cholinergically innervated glands.

The first-generation antihistamines competitively antagonize the effects of histamine at the peripheral H_1 receptor sites in the GI tract, uterus, large blood vessels, and bronchial muscle. First-generation antihistamines bind nonselectively to the central H_1 receptors and can cause both CNS stimulation and depression. CNS depression is found even with therapeutic doses of the first-generation antihistamines. Some of them are more likely than others to depress the CNS, and patients vary in their sensitivity to the different preparations. Commonly prescribed first-generation antihistamines include the ethanolamine drugs diphenhydramine (Benadryl) and clemastine (Tavist), the alkylamines brompheniramine (Dimetane) and chlorpheniramine (Chlor-Trimeton), the piperazine hydroxyzine (Atarax, Vistaril), the piperidine cyproheptadine (Periactin), and carbinoxamine maleate (Arbinoxa).

Second-generation antihistamines are selective for peripheral H_1 receptors and therefore as a group are less sedating. They do not cross the blood–brain barrier in appreciable amounts; consequently, very little of the second-generation antihistamines gets into the brain. Their effects on performance and on objective measures of sedation vary little from those of a placebo. Second-generation antihistamines that are commonly prescribed include the piperazine drug cetirizine (Zyrtec) and the piperidines desloratadine (Clarinex), fexofenadine (Allegra), and loratadine (Claritin).

Antihistamines have other pharmacodynamic properties related to their central action rather than their histamine-receptor blockade action. Several first-generation antihistamines have significant antiemetic and antinausea properties owing to strong anticholinergic properties caused by the antihistamine's binding to the muscarinic receptors. Diphenhydramine can be used to reverse the extrapyramidal adverse effects caused by phenothiazines. Probably because of their anticholinergic actions, some of the antihistamines (diphenhydramine) have effects on Parkinson's symptoms and may be effective in the early stages of treatment.

Pharmacokinetics
Absorption and Distribution

The first-generation antihistamines are stable, lipid-soluble amines that are well absorbed from the GI tract. Diphenhydramine is widely distributed throughout the body tissues and fluids, including the CNS. It crosses the placenta and is found in breast milk. The distribution of clemastine is unknown, but the drug does cross the placenta and is distributed in breast milk. Chlorpheniramine is approximately 72% protein bound and is widely distributed in body tissue and fluids. Chlorpheniramine crosses the placenta and is found in breast milk. Distribution of hydroxyzine has not been fully described, and it is unknown whether it crosses the placenta or is distributed in breast milk. The distribution of cyproheptadine, dimenhydrinate, and brompheniramine is unknown.

The second-generation antihistamines are rapidly absorbed from the GI tract, although concurrent food ingestion can decrease or delay absorption. Fexofenadine is rapidly absorbed, and absorption is not affected by food intake. Administration of loratadine with food decreases absorption up to 40% for the syrup or tablet and 48% for the rapid-disintegrating tablet. Desloratadine is well absorbed, and food intake dose not affect absorption. Absorption of cetirizine is slightly reduced by food intake. Cetirizine is widely distributed, except in the CNS, where concentrations are less than 10% of the peak serum concentration. It is unknown whether cetirizine crosses the placenta, but it has been measured in breast milk. Fexofenadine distribution is unknown. Loratadine is 97% protein bound and is excreted in breast milk. It is not known if loratadine crosses the placenta. Desloratadine is highly (82% to 87%) protein bound, it is not known whether it crosses the placenta, and only minimal amounts are excreted in breast milk.

Metabolism and Excretion

The first-generation antihistamines are metabolized primarily in the liver. Diphenhydramine is metabolized in the liver, with the unchanged portion of the dose and metabolites excreted in the urine in 24 to 48 hours. Clemastine is extensively metabolized by an unknown mechanism. Clemastine and its metabolites are excreted primarily in the urine. Metabolism of chlorpheniramine is extensive, occurring first in the gastric mucosa and then on the first pass through the liver. Metabolites of chlorpheniramine are excreted in the urine, with the excretion rate dependent on the pH of the urine and urinary flow. Cyproheptadine is metabolized in the liver into several conjugated metabolites, with excretion in the urine and feces. Hydroxyzine is completely metabolized by the liver. Metabolism and excretion of brompheniramine and dimenhydrinate are unknown.

Most of the second-generation antihistamines are metabolized by the liver to active metabolites by the hepatic microsomal P450 system. Consequently, metabolism of these drugs can be affected by competition for the P450 enzymes by other drugs. Cetirizine is minimally metabolized by the P450 enzymes and is primarily excreted unchanged in the urine. Approximately 5% of the dose of fexofenadine is metabolized, with 80% excreted in the feces and 11% excreted in the urine. Loratadine has a high first-pass effect and is metabolized in the liver to the active metabolite descarboethoxyloratadine. Patients with chronic liver disease have higher peak plasma concentrations (double the normal levels) of loratadine than do healthy patients. Elimination of loratadine is through the urine and feces.

See Table 17-10 for the pharmacokinetics.

Pharmacotherapeutics
Precautions and Contraindications

The precautions and contraindications differ between the first-generation and second-generation antihistamines.

First-Generation Antihistamines

Although first-generation antihistamines are available without prescription and all antihistamines are widely prescribed, the provider must be aware of the precautions and absolute contraindications to the antihistamines.

Table 17–10 ⬛ Pharmacokinetics: Selected Antihistamines

Drug	Onset	Peak	Duration	Protein Binding	Half-Life	Metabolism	Elimination
First-Generation Antihistamines							
Brompheniramine	15–30 min	2–5 h	4–6 h	—	25 h	Hepatic	Renal
Clemastine	15–30 min	2–5 h	10–12 h (up to 24 h)	—	—	Probably hepatic	Renal
Chlorpheniramine	30–60 min	2–6 h	4–8 h	72%	*Adults:* 20–24 h *Children:* 10–13 h	Gastric mucosa and hepatic	Renal
Cyproheptadine	—	6–9 h	8 h	—	1–4 h	Hepatic	Primary renal; some in feces
Diphenhydramine	15–30 min	2–4 h	4–6 h	98%–99%	1–4 h	Hepatic	Renal
Hydroxyzine	15–60 min	—	4–6 h	—	3–20 h	Hepatic	Renal
Second-Generation Antihistamines							
Cetirizine	Rapid	1 h	—	93%	8.3 h	Minimal 60% excreted unchanged	Renal, feces (10%)
Desloratadine	1 h	3 h	24 h	82%–87%	27 h	Hepatic	Renal, fecal
Fexofenadine	1 h	2.6 h	12 h	60%–70%	14.4 h	95% excreted unchanged	Fecal (80%); renal (11%)
Loratadine	1–3 h	8–12 h	>24 h	97%	8.4 h	Hepatic CYP3A4 and CYP2D6	Fecal, renal

The first-generation antihistamines are generally safe and effective. Antihistamines are contraindicated in patients with narrow-angle glaucoma, lower respiratory tract symptoms (they thicken secretions and impair expectoration), stenosing peptic ulcer, symptomatic prostatic hypertrophy, bladder neck obstruction, pyloroduodenal obstruction, and MAOI use.

There are few but significant precautions to the first-generation antihistamines. Because of the anticholinergic effects, caution is required for patients with a predisposition to urinary retention, history of bronchial asthma, increased intraocular pressure, hyperthyroidism, cardiovascular disease, or hypertension. Antihistamines cause varying degrees of sedation and drowsiness and reduce mental alertness; therefore, patients should not drive or perform other tasks requiring mental alertness while taking the first-generation antihistamines. Children should be supervised when they are taking these medications and performing potentially unsafe activities such as swimming or bicycling.

The first-generation antihistamines—chlorpheniramine, brompheniramine, diphenhydramine, clemastine, and cyproheptadine—are Pregnancy Category B. Hydroxyzine and carbinoxamine are the only first-generation antihistamines classified as Pregnancy Category C.

First-generation antihistamines are contraindicated in newborns and premature infants, who may have severe reactions (convulsions). Breastfeeding is also a contraindication for the use of first-generation antihistamines because all of the medications are excreted in breast milk and they may decrease milk production.

Caution should be exercised with the use of first-generation antihistamines in young children because a paradoxical CNS stimulation can occur. Do not exceed recommended dosages for each age group of children. Chlorpheniramine, brompheniramine, cyproheptadine, dimenhydrinate, and diphenhydramine are all labeled to be used in children over the age of 2 years. Hydroxyzine syrup may be prescribed for infants and children for pruritus, although cetirizine may be a safer choice. Carbinoxamine is not recommended for children younger than 2 years of age.

The first-generation antihistamines—carbinoxamine, chlorpheniramine, diphenhydramine, clemastine, and cyproheptadine—are all on the Beers criteria list of medications that should be avoided in geriatric patients.

Second-Generation Antihistamines

The second-generation antihistamines have only a few contraindications. Two second-generation antihistamines, astemizole (Hismanal) and terfenadine (Seldane), have been voluntarily removed from the market because of potentially life-threatening drug interactions and increased prolonged QT interval associated with their use.

The second-generation antihistamines are generally not recommended during pregnancy, especially during the third trimester, because of a seizure risk to the fetus. Loratadine and cetirizine are classified Pregnancy Category B. The other second-generation antihistamines—loratadine, desloratadine, and fexofenadine—are Pregnancy Category C, and their use should be avoided.

Fexofenadine are not recommended for children under age 6. Loratadine may be prescribed to children as young as age 2. Cetirizine syrup and desloratadine syrup may be used in children as young as 6 months.

Adverse Drug Reactions

As described previously, the major adverse reaction to first-generation antihistamines is sedation, which can interfere with a patient's ability to function at work or school. Other central adverse effects include dizziness, tinnitus, lassitude, disturbed coordination, fatigue, headache, irritability, nervousness, blurred vision, diplopia, and tremors. The next most common adverse effects are GI and include increased or decreased appetite, nausea, epigastric distress, vomiting, constipation, and diarrhea. Dry mouth, urinary retention, and dysuria are also adverse effects reported in patients taking first-generation antihistamines. The concurrent ingestion of alcohol or other CNS depressants produces an additive effect that further impairs function.

The second-generation antihistamines have few central adverse effects. The major improvement in the second-generation antihistamines is that the incidence of drowsiness is greatly reduced. They are well tolerated by the GI system and have a minimal incidence of dry mouth (less than or equal to 5%). Overall, when patients have adverse reactions to the first-generation antihistamines, a change to a second-generation drug often alleviates the problem.

Drug Interactions

The first-generation antihistamines should be used with caution concurrently with any medication that has CNS depressant effects. All of the first-generation antihistamines exhibit additive CNS sedation effects if coadministered with ethanol, anxiolytics, sedatives, hypnotics, and barbiturates. The anticholinergic effects of antihistamines may be enhanced if coadministered with tricyclic antidepressants and phenothiazines. It is recommended that H_1 agonists not be used within 2 weeks of MAOIs because of increased anticholinergic effects. Cyproheptadine may reverse the antidepressant effects of selective serotonin reuptake inhibitors (SSRIs). Two antihistamines should not be prescribed at the same time to avoid additive anticholinergic and sedative effects.

The second-generation antihistamines, although not sedating when used singly, may have additive CNS sedation effects if used with other CNS depressants (barbiturates, anxiolytics, sedatives, hypnotics, ethanol, and benzodiazepines). Concurrent use with another H_1 blocker may cause sedation.

Desloratadine and loratadine are extensively metabolized by the CYP450 enzymes, and coadministration of other medications that are also metabolized by these enzymes should be avoided, such as are erythromycin, cimetidine, and ketoconazole.

Table 17-11 presents drug interactions.

Table 17–11 Drug Interactions: Selected Antihistamines

Drug	Interacting	Drug Possible Effect	Implications
First-Generation Antihistamines			
Brompheniramine	MAOIs	MAOIs can prolong and intensify the effects of antihistamines	Avoid concurrent use
	Ethanol and other CNS depressants	Additive CNS depression	Use with caution
Clemastine	MAOIs	Additive anticholinergic effects	Concurrent use contraindicated
	Antimuscarinics: Tricyclic antidepressants, phenothiazines, ethanolamine-derivative H_1 blockers (clemastine, carbinoxamine, promethazine, trimeprazine) clozapine, cyclobenzaprine, disopyramide	Additive anticholinergic effects	Avoid concurrent use
	CNS depressants: Ethanol, antipsychotics, sedatives, hypnotics, opiate agonists, barbiturates	Enhanced CNS-depressant effect	Avoid concurrent use
Chlorpheniramine	MAOIs	Additive anticholinergic effects	Avoid concurrent use
	Antimuscarinics: Tricyclic antidepressants, phenothiazines, benztropine	Enhanced anticholinergic effects of chlorpheniramine	Chlorpheniramine has moderate anticholinergic effects and is preferable to other H_1 blockers when an H_1 blocker must be used

Table 17–11 ▦ Drug Interactions: Selected Antihistamines—cont'd

Drug	Interacting	Drug Possible Effect	Implications
	CNS depressants	Enhanced CNS-depressant effect	Avoid concurrent use
Cyproheptadine	*Antimuscarinics:* Tricyclic antidepressants, phenothiazines, ethanolamine-derivative H$_1$ blockers (clemastine, diphenhydramine), benztropine	Increased anticholinergic effects of cyproheptadine	Avoid concurrent use
	CNS depressants: Barbiturates, ethanol, benzodiazepines, tricyclic antidepressants, opiate agonists	Enhanced CNS-depressant effect	Avoid concurrent use
	SSRIs	Reversal of antidepressant effects of SSRIs	Use cyproheptadine only if needed
Diphenhydramine	MAOIs	Additive anticholinergic effects	Do not use within 2 wk of each other
	Antimuscarinics: Tricyclic antidepressants, phenothiazines, ethanolamine-derivative H$_1$ blockers (clemastine, carbinoxamine, promethazine, trimeprazine) clozapine, cyclobenzaprine, disopyramide	Additive anticholinergic effects	Avoid or use with caution; monitor closely if coadministration is necessary
	CNS depressants: Ethanol, antipsychotics, sedatives, hypnotics, opiate agonists, barbiturates	Enhanced CNS-depressant effect	Avoid concurrent use
Hydroxyzine	MAOIs	May prolong and intensify the anticholinergic effects of antihistamines	Concurrent use contraindicated; avoid use within 2 wk of each other
	Antimuscarinics: Tricyclic antidepressants, phenothiazines, ethanolamine-derivative H$_1$ blockers (clemastine, carbinoxamine, promethazine, trimeprazine) atropine, benztropine	Additive anticholinergic effects	Avoid concurrent use
	CNS depressants: Ethanol, antipsychotics, sedatives, hypnotics, opiate agonists, barbiturates	Additive CNS-depressant effects	Avoid concurrent use
Second-Generation Antihistamines			
Cetirizine	Theophylline	May ↓ cetirizine clearance	Avoid concurrent use
	CNS depressants: Barbiturates, ethanol, benzodiazepines, tricyclic antidepressants, opiate agonists	Additive CNS-depressant effects and drowsiness	Use with caution
Desloratadine	Ketoconazole, erythromycin, CNS depressants	Increases plasma concentrations of desloratadine Additive CNS depression	Does not cause cardiac toxicity, but coadminister with caution Avoid or minimize concurrent use
Loratadine	Macrolide antibiotics (clarithromycin, erythromycin, troleandomycin)	Interferes with the metabolism of loratadine, resulting in increased serum concentrations of loratadine	Does not cause cardiac toxicity, but coadminister with caution
	CNS depressants: Barbiturates, ethanol, benzodiazepines, tricyclic antidepressants, opiate agonists	Additive CNS-depressant effects and drowsiness	Avoid or minimize concurrent use

Table 17–11 ⬤ **Drug Interactions: Selected Antihistamines—cont'd**

Drug	Interacting	Drug Possible Effect	Implications
Fexofenadine	Ketoconazole Erythromycin Aluminum- and magnesium-containing antacids Alcohol	↑ fexofenadine plasma levels ↑ fexofenadine levels ↓ fexofenadine absorption CNS depression	Avoid concurrent use Avoid concurrent use Administer fexofenadine 1 h before antacids Avoid concurrent use

Clinical Use and Dosing

Respiratory Allergies

Most of the antihistamines are effective in the treatment of seasonal allergic rhinitis and conjunctivitis. Antihistamines effectively treat the sneezing, rhinorrhea, watery eyes, and itching of eyes, nose, and throat associated with seasonal allergies or hay fever. The treatment decision is often made according to the adverse-effect profile and cost. Although the first-generation drugs diphenhydramine, chlorpheniramine, brompheniramine, and clemastine are effective, inexpensive, and available without prescription, their adverse effect of drowsiness often prevents patients from being able to continue their daily activities. The usual adult dose of diphenhydramine for respiratory allergies is 25 to 50 mg every 4 to 6 hours. The adult dose of chlorpheniramine is 4 mg every 4 to 6 hours or 8 to 12 mg of the extended-release form every 8 to 12 hours. Brompheniramine is dosed at 4 mg every 4 to 6 hours in adults with respiratory allergies. Carbinoxamine dosing for adults is 4 mg to 8 mg 3 to 4 times a day. Pediatric doses for these medications are given in Table 17-12.

If a patient cannot tolerate the first-generation antihistamines, a second-generation medication can be prescribed to treat respiratory allergies. The dose of cetirizine that should be prescribed for children over 12 years and adults is 5 to 10 mg/day given once a day. In children aged 6 to 11 years, the dose of cetirizine is 5 to 10 mg once daily. For cetirizine syrup prescribed to children aged 2 to 5 years, the dose is 2.5 mg (half tsp of 5 mg/5mL syrup) once daily. The dose of cetirizine may be increased to 5 mg/day, delivered as 5 mg once daily or 2.5 mg twice a day. Children aged 6 to 12 months are dosed at 2.5 mg once a day. Children aged 12 to 23 months are also prescribed 2.5 mg once a day, with an increase to 2.5 mg twice a day if needed. The dose of fexofenadine in healthy children aged 12 years or older and adults is 60 mg twice a day. Children aged 6 to 11 years should be prescribed 30 mg twice a day of fexofenadine. If a patient has renal impairment (creatinine clearance [CCr] less than 80 mL/min), the dose of fexofenadine is 60 mg once daily. The dose of loratadine in healthy children over age 6 years and adults is 10 mg once a day, with children aged 2 to 5 prescribed 5 mg once a day. If an adult has renal or liver disease, the dose of

Table 17–12 ⊗ **Dosage Schedule: Selected Antihistamines**

Drug	Indication	Dosage Form	Dose	Comments
First-Generation Antihistamines				
Brompheniramine Dimetapp Allergy Bromfed Children's Dimetapp Cold & Allergy	Allergic and vasomotor rhinitis, pruritus, conjunctivitis	Capsules: 4 mg Scored tablets: 4 mg Brompheniramine 4 mg Pseudoephedrine 60 mg Per 5 mL: Brompheniramine 1 mg; phenylephrine 2.5 mg	*Adults:* 4 mg PO q 4–6 h *or* 8–12 mg of sustained-release form 2 to 3 times/d; Maximum dose: 12 mg/24 h *Children 6–12 yr:* 2 mg q 4–6 h; max 12 mg/24 h *Children <6 yr:* 0.125 mg/kg/d in divided doses every 6–8 h	May be administered with or without food Cough and cold medications are not recommended for use in children younger than 4 years of age
Clemastine Tavist Generic	Allergic rhinitis	Scored tablets: 1.34 mg (1 mg clemastine) Scored tablets: 2.68 mg (2 mg clemastine) Syrup: 0.67 mg (0.5 mg clemastine)/5 mL	*Children >12 yr and adults:* 1 mg bid *Children 6–12 yr:* 0.5 mg bid	May be administered without regard to meals
	Pruritus, mild urticaria, angioedema		*Children >12 and adults:* 2 mg bid *Children 6–12 yr:* 1 mg bid	May be administered without regard to meals
Chlorpheniramine Chlor-Trimeton Allergy 4 hour	Allergic rhinitis, conjunctivitis, pruritus, urticaria	4 mg tablets 8 mg sustained-release tablet	*Children >12 yr and adults:* 4 mg every 4–6 h; max 24 mg/d	Administer with food or milk to minimize gastric irritation

Continued

Table 17–12 ⚕ Dosage Schedule: Selected Antihistamines—cont'd

Drug	Indication	Dosage Form	Dose	Comments
Chlor-Trimeton Allergy 8 hour Chlor-Trimeton Allergy 12 hour Chlor-Trimeton syrup Generic		12 mg sustained-release tablet Syrup: 2 mg/5 mL	*Children 6–12 yr:* 2 mg every 4–6 hr; max 12 mg/d *Children 2–5 yr:* 1 mg every 4–6 h; max 4 mg/d *Extended-release form:* *Children >12 yr and adults:* 8–12 mg bid or tid; max 24 mg/d *Children 6–12 yr:* 8 mg once daily; max 12 mg/d *Children 2–5 yr:* use other forms	Do not crush or chew extended-release tablets
Cyproheptadine Periactin Periactin syrup Generic	Allergic rhinitis, conjunctivitis, pruritus, urticaria	Tablets: 4 mg Syrup: 2 mg/5 mL	*Children >14 yr and adults:* 4 mg q 8–12 h; usual range 12–16 mg/d; max dose 0.5 mg/kg/d *Children 7–14 yr:* 4 mg q 8–12 h; max 16 mg/d *Children 2–6 yr:* 2 mg q 8–12 h; max 12 mg/d	Administered without regard to meals
Diphenhydramine Benadryl Allergy Benadryl Dye-Free Allergy Softgels Benadryl Allergy liquid Benadryl Allergy Dye-Free liquid Benadryl Allergy Chewables Generic	Upper respiratory allergies	25 mg capsules 25 mg tablets 12.5 mg/5 mL 6.25 mg/5 mL 12.5 mg chewable tablet	*Children >12 yr and adults:* 25–50 mg every 4–6 h; max 300 mg/d *Children 6–12 yr:* 12.5–25 mg q 4–6 h; max 150 mg/24 h *Children 2–6 yr:* 6.25 mg; max 37.5 mg/24 h	May cause drowsiness; may cause excitability in young children
Hydroxyzine Atarax Vistaril	Allergic and vasomotor rhinitis, pruritus Nausea/ vomiting	Tablets: 10, 25, 50, 100 mg Syrup: 10 mg/5 mL Tablets: 25, 50, 100 mg Suspension: 25 mg/5 mL	*Adults:* 25 mg 3–4 times/d *Children >6 yr:* 12.5–25 mg 3–4 times/d; max 50–100 mg/24 h *Children <6 yr:* 1–2 mg/kg every 6–8 h *Adults:* 25–100 mg 3–4 times/d *Children 6–12 yr:* 12.5 mg every 6 h or 1–2 mg /kg/d/ in divided doses *Children <6 yr:* 12.5 mg every 6 h or 1–2 mg/kg/d in divided doses	May cause drowsiness
	Insomnia		*Adults:* 50–100 mg PO 30–60 min before bedtime	May cause drowsiness
Second-Generation Antihistamines				
Cetirizine Zyrtec Generic	Seasonal or perennial rhinitis, chronic urticaria, pruritus	5 mg tablet 10 mg tablet Syrup: 1 mg/mL	*Children >12 yr and adults:* 5–10 mg once a day *Children >6–11 yr:* 5–10 mg once a day *Children 2–5 yr:* 2.5 mg initially; can increase dose to 5 mg/d (either as one 5 mg dose or 2.5 mg q 12 h) *Children 6–12 mo:* 2.5 mg once daily *Children 12–23 mo:* 2.5 mg once daily; may be increased to 2.5 mg twice daily	May be administered without regard to food, but food may delay absorption by up to 1 h; patients with renal impairment (CCr <31 mL/min) decrease dose to 5 mg once daily

Table 17–12 ⚗ **Dosage Schedule: Selected Antihistamines—cont'd**

Drug	Indication	Dosage Form	Dose	Comments
Desloratadine Clarinex	Allergic rhinitis, chronic urticaria	5 mg tablet 2.5 mg, 5 mg disininte- grating tablet Syrup: 0.5 mg/mL	*Children >12 yr and adults:* 5 mg once a day *Children 6–11 yr:* 2.5 mg once a day *Children 1–5 yr:* 1.25 mg once a day Children 6–12 mo: 1 mg once a day	
Fexofenadine Allegra Generic	Allergic rhinitis	Tablets: 180, 60, 30 mg 30 mg/mL suspension	*Children >12 yr and adults:* 60 mg PO bid *Children 6–11 yr:* 30 mg PO bid	Dose without regard to meals; not recom- mended in children <12; patients with renal im- pairment (CCr <80 mL/ min) reduce starting dose to 60 mg once daily
Loratadine Claritin Generic Allegra	Allergic rhinitis, chronic urticaria	Tablets: 10 mg Syrup: 1 mg/mL Rapidly disintegrating tablets: 10 mg (Claritin Reditabs) Rapidly disintegrating tablets: 10 mg	*Children >6 yr and adults:* 10 mg once daily *Children 2–5 yr:* 5 mg once daily	Dose without regard to meals; patients with renal impairment (CCr <30 mL/min) reduce starting dosage to 10 mg every other day

loratadine is 10 mg every other day. Desloratadine is dosed at 5 mg once daily in children 12 and older and adults. In patients with renal or hepatic impairment, desloratadine is given every other day. Pediatric dosing for the second-generation antihistamines is found in Table 17-12.

Hypersensitivity Reactions

The first-generation antihistamine diphenhydramine is usually the drug of choice for patients with acute hypersensitivity reactions. It is available in oral tablet, capsule, and liquid forms without prescription and in parenteral form for acute IM or IV use. The adult oral dose of diphenhydramine is 25 to 50 mg every 4 to 6 hours for hypersensitivity reactions. In children 6 to 12 years with hypersensitivity reactions, the dose of diphenhydramine is 12.5 to 25 mg every 4 hours. Children aged 2 to 6 are prescribed diphenhydramine syrup, at a dose of 6.25 mg every 4 hours. In an acute hypersensitivity reaction, IM administration of diphenhydramine may be necessary. The adult dose of diphenhydramine is 10 to 50 mg deep IM or IV, with a maximum of 400 mg/day. In children, the dose is 1.25 mg/kg per dose IV or given deep IM every 4 hours, or 5 mg/kg/day divided every 6 to 8 hours, with a maximum daily diphenhydramine dose of 300 mg. Cyproheptadine is also indicated for use in hypersensitivity reactions. The adult dose of cyproheptadine is 4 mg 3 times a day. No second-generation antihistamines are indicated for use in hypersensitivity reactions.

Urticaria and Angioedema

In urticaria, histamine is the primary mediator and therefore the antihistamines are the drugs of choice and quite effective. Clemastine, a very effective treatment for urticaria, is available in both tablet and liquid form for use with children (older than 6 years) and adults. Hydroxyzine is effective in the management of pruritus due to allergic conditions such as chronic urticaria and in histamine-mediated pruritus. It is also available

in tablet and liquid form. Hydroxyzine may be used safely in children younger than age 6 and therefore may be a better choice than clemastine in younger children with urticaria. Cetirizine, desloratadine, and loratadine may be prescribed for urticaria. See Table 17-12 for dosing information.

Nighttime Sleep Aid

Diphenhydramine is available without prescription as a sleep aid and is a safe treatment for occasional insomnia. The recommended dose for adults is 50 mg at bedtime. Table 17-12 presents dosing information.

Motion Sickness/Antiemetic

Dimenhydrinate (Dramamine) is used in the treatment and prevention of nausea, vertigo, and vomiting associated with motion sickness. Dosing for children aged 2 to 5 years is 12.4 to 25 mg every 6 to 8 hours, to a maximum of 75 mg/day. Children aged 6 to 12 are given 25 to 50 mg of dimenhydrinate every 6 to 8 hours, with a maximum of 150 mg/day. An alternative dose is 5 mg/kg per day divided into four doses. Children 12 years and older and adults are given 50 to 100 mg every 4 to 6 hours, not to exceed 400 mg/day. The onset of action of dimenhydrinate is 15 to 30 minutes, so predosing for motion sickness would require that the medication be taken with food or water at least 15 minutes before needed.

Rational Drug Selection

First- Versus Second-Generation Antihistamines

Although many of the first-generation antihistamines are readily available without prescription, the common adverse effect of sedation prevents their use during the day by patients who need to be alert for work or school. The second-generation antihistamines are well tolerated and do not impair daytime functioning. They are also longer acting, allowing for convenient once- or twice-a-day dosing.

Cost

The second-generation antihistamines used to be more expensive than the first-generation antihistamines, but with many second-generation drugs now available in generic form, cost has less impact on decision making. Most insurance companies will not pay for the cost of the more expensive, brand-name, second-generation antihistamines. For the patient, the cost is offset by the ability to perform daily functions more easily when taking the second-generation medications.

Monitoring

No specific laboratory monitoring is necessary with anti-histamines.

Patient Education

Patient education focuses on proper use of the medication, adverse reactions, and safety precautions while using the medications.

Administration

Patients should be instructed regarding the proper dosing of the drug. Especially if patients are switching from a shorter-acting first-generation to a longer-acting second-generation antihistamine, they need to be aware of the dosing schedule. Doses should not be doubled or increased unless prescribed by the health-care provider. The long-acting second-generation antihistamines should not be taken closer together than prescribed, so missed doses need to be held until the time of the next dose (every 12 or 24 hours).

Some antihistamines cause GI upset and need to be taken with food. Loratadine should be taken on an empty stomach because absorption may be decreased by as much as 60%.

Patients should be instructed not to crush or chew sustained-release tablets.

Adverse Reactions

Some antihistamines (first generation) may cause drowsiness, and patients should observe caution while driving or performing other tasks requiring alertness. Patients should avoid alcohol and other CNS depressants while taking antihistamines and should be instructed to report excessive drowsiness to their health-care provider to determine whether another medication would provide therapeutic effects without sedation.

Patients taking loratadine should be aware of the serious interaction between the antihistamines and macrolide antibiotics and the oral azol antifungals. Written instructions regarding the specific medications to avoid are the most effective and safest method of ensuring that patients do not accidentally get placed on any new medication that would cause a serious adverse reaction. The additive CNS depression that occurs with the antihistamine and other CNS depressants (e.g., alcohol) should be addressed and the patient cautioned regarding driving or operating heavy machinery.

Lifestyle Management

Lifestyle management related to the disease process needs to be discussed with the patient. Points to discuss often include avoidance of known allergens and using environmental methods to control dust mites and other common allergens. Available dosage forms are presented in Table 17-12.

COUGH AND COLD MEDICATIONS
DECONGESTANTS

Decongestants are widely used for congestion associated with the common cold and allergic rhinitis. Many preparations are available without a prescription, and they are available in many formulations. They come in liquid, tablet, capsule, nasal spray, or drops, providing a variety of methods of administration. Although patients may self-treat with decongestants and the health-care provider may rarely prescribe them, they are included here for the provider to learn about the proper dosing and potential adverse effects or drug interactions that may occur with these medications.

Pharmacodynamics

The decongestants are alpha-adrenergic–receptor agonists (sympathomimetic) that produce vasoconstriction by stimulating alpha receptors within the mucosa of the respiratory tract, which temporarily reduces the swelling associated with inflammation of the mucous membranes. These sympathomimetic amines act on the alpha receptors of the vascular smooth muscle, causing vasoconstriction, pressor effects, and nasal decongestion. Other alpha effects include constriction of the GI and urinary sphincters, mydriasis, and decreased pancreatic beta cell secretion. Pseudoephedrine (Sudafed), the most commonly used systemic decongestant, is noted to have mild CNS stimulant effects, especially in patients sensitive to sympathomimetic drugs. Phenylpropanolamine, which was often combined with an antihistamine in OTC cold medications, was removed from the market in 2005 after a public health advisory found an increased risk for hemorrhagic stroke in women. Other effects of the systemic decongestants are increased heart rate, force of contraction, and cardiac output. These effects are usually mild in healthy patients, and at appropriate dosages, decongestion occurs without dramatic blood pressure changes.

Pseudoephedrine is being replaced in some decongestant products with phenylephrine hydrochloride to deter the manufacture of methamphetamine, which uses pseudoephedrine as an ingredient. In 2006, the Combat Methamphetamine Epidemic Act was added to the USA Patriot Act. The Combat act applies to all cough and cold products (including combination products) that contain the methamphetamine precursor chemicals ephedrine, pseudoephedrine, or phenylpropanolamine. The law includes a daily and 30-day limit on purchases of known methamphetamine precursors whether at a retail store or via the Internet. All potential precursors are to be stored behind the counter in retail stores and retailers are required to ask for identification and keep a log of who is purchasing the drugs. Some states (Oregon) have made pseudoephedrine a Schedule III drug, requiring a prescription to be written by a provider who is licensed to prescribe controlled substances.

Topical decongestants are sympathomimetic amines that cause intense vasoconstriction when applied directly to swollen mucous membranes of the nasal passage. This shrinks the swollen membranes, causing almost immediate relief from nasal congestion. There are minimal systemic effects from topical use of nasal decongestants.

Pharmacokinetics

Absorption and Distribution

The oral decongestants are well absorbed from the GI tract and widely distributed. Pseudoephedrine is widely distributed and presumed to cross the blood–brain barrier and placenta. Small amounts of pseudoephedrine are excreted in breast milk. Absorption and distribution of the topical decongestants have not been described.

Metabolism and Excretion

Pseudoephedrine is partially metabolized in the liver into norpseudoephedrine, an active metabolite. Pseudoephedrine and its metabolite are excreted in the urine, with 50% to 75% of the dose excreted as unchanged drug. Excretion of pseudoephedrine is highly dependent on the pH of the urine. If the urine is acidic (pH near 5), the rate of urinary excretion is increased. If the urine is alkaline (pH of 8), the rate of excretion is slowed, as some of the drug is reabsorbed into the renal tubule.

Metabolism of phenylephrine is via the enzyme monoamine oxidase in the liver. Excretion of phenylephrine or its metabolites has not been described. Metabolism and excretion of the topical decongestants are not available.

Table 17-13 presents the pharmacokinetics of selected decongestant.

Pharmacotherapeutics

Precautions and Contraindications

There are only a few absolute contraindications to taking decongestants. The oral decongestants are absolutely contraindicated for patients on concurrent MAOI therapy. Concurrent use of these medications may result in severe headache, hypertension and hyperpyrexia, and possibly hypertensive crisis. Oral decongestants are also contraindicated for patients with severe hypertension or coronary artery disease.

Safety and efficacy of decongestant medications have been questioned after a number of reports of deaths of infants taking cold medications (Centers for Disease Control and Prevention, 2007). In October 2007, an FDA panel met and recommended all pediatric cough and cold medications be relabeled as not indicated for use in children under age 4 years. In October 2007, manufacturers voluntarily removed all infant drop formulas of cough and cold medications from the market. After decongestants were relabeled in 2007, the American Association of Poison Control Centers reported 54% fewer reports of therapeutic errors involving OTC cough and cold medications in children younger than 2 years of age (Klein-Schwartz, Sorkin, & Doyon, 2010).

Topical imidazolines (oxymetazoline) are to be used with caution in children under age 6 years. Topical naphazoline is contraindicated for patients with glaucoma.

Adverse Drug Reactions

Adverse effects are minimal at recommended doses, unless a patient is sensitive to sympathomimetics. CNS effects may include anxiety, tenseness, restlessness, headache, light-headedness, dizziness, drowsiness, tremor, insomnia, hallucinations, psychological disturbances, CNS depression, and weakness. Of these CNS effects, the most common adverse effects are restlessness and tremors. Cardiovascular adverse effects include transient hypertension, arrhythmia, and cardiovascular collapse, with hypotension, palpitations, tachycardia, and bradycardia. These adverse reactions are rare at recommended doses in healthy individuals. Other adverse effects are nausea, vomiting, pallor, and, rarely, shortness of breath or respiratory difficulty (at higher doses).

Topical decongestants have adverse reactions related to the intense vasoconstrictor effect of the nasal spray or sensitivity to additives such as sulfites. Transient stinging is the most common adverse effect reported. Burning, sneezing, dryness, and local irritation are all reported with topical

Table 17–13 Pharmacokinetics: Selected Decongestants

Drug	Onset	Peak	Duration	Protein Binding	Half-Life	Metabolism	Elimination
Systemic							
Pseudoephedrine	30 min	—	4–8 h 12 h (extended release)	—	9–16 h	Hepatic	Renal 55%–75% as unchanged drug; affected by urine pH
Phenylephrine	15–20 min	—	2–4 h	—	2.5 h	—	—
Topical							
Phenylephrine	—	—	0.5–4 h	—	—	Hepatic, intestinal	Unknown
Oxymetazoline	—	—	—	—	—	—	—
Tetrahydrozoline			3 h	—	—	—	—

drugs. The most significant adverse reaction with topical decongestants is rebound congestion (rhinitis medicamentosa) with prolonged or chronic use. This does not occur with short-term (3 to 5 day) use.

Drug Interactions

The MAOIs and beta-adrenergic blockers increase the effects of sympathomimetics; therefore, patients taking these medications should avoid decongestants. Phenothiazines and tricyclic antidepressants potentiate the pressor effects of pseudoephedrine. See Table 17-14 for further drug interactions.

Clinical Use and Dosing

Nasal Congestion

Oral decongestants are used for the temporary relief of nasal congestion due to the common cold, sinus infection, and allergic rhinitis. They may be used to promote nasal or sinus

drainage and are also indicated in the relief of eustachian tube congestion. The adult dose of pseudoephedrine for nasal congestion is 60 mg every 4 to 6 hours. In children aged 6 to 12 years, the dose is 30 mg every 4 to 6 hours, and in children aged 2 to 6, the dose of pseudoephedrine is 15 mg every 4 to 6 hours. Pseudoephedrine is no longer recommended for use in children younger than 4 years, but if prescribing, the dose of pseudoephedrine is 4 mg/kg per day divided in four-times-a-day doses. Phenylephrine (Sudafed PE) is dosed at 10 mg every 4 hours in children over age 12 and adults (maximum 60 mg in 24 hours). Dosing of phenylephrine for children aged 6 to 12 years is 7.5 mg every 4 to 6 hours up to 30 mg per day. In children aged 2 to 6 the dose of phenylephrine is 3.75 mg every 4 to 6 hours, up to 15 mg per day. Phenylephrine is not recommended for use in children younger than 2 years. Complete dosing of the different forms of the oral decongestants is found in Table 17-15.

Table 17–14 ▦ **Drug Interactions: Selected Decongestants**

Drug	Interacting Drug	Possible Effect	Implications
Systemic			
Phenylephrine	MAOIs	Hypertensive crisis	Do not use within 14 d of each other
Pseudoephedrine	Caffeine, cocaine, and other sympathomimetic drugs	Additive sympathomimetic activity	Use concurrently with caution
	MAOIs, furazolidone, procarbazine	Concurrent use can prolong and intensify the cardiac stimulation and vasopressor effects; may lead to severe cardiovascular and cerebrovascular response	Avoid use within 14 d of each other
	Ergot alkaloids	Peripheral vasoconstriction, additive vasoconstriction	Avoid concurrent use
	Methyldopa, reserpine	Decreased antihypertensive effects	Monitor BP closely if using concurrently
	Thyroid hormones	Increased effects of both agents on the cardiovascular system	Use concurrently with caution
	Urinary alkalinizers: Sodium bicarbonate, sodium citrate, potassium citrate, sodium lactate, sodium acetate	Increased alkalinization of the urine leads to tubular reabsorption of pseudoephedrine	Observe for increased adverse effects; use together with caution
Topical			
Phenylephrine	MAOIs, tricyclic antidepressants	Hypertensive crisis	Do not use within 14 d of each other
	Beta blockers	May increase vasopressor effects of sympathomimetics	Monitor closely for adverse reaction
Oxymetazoline	MAOIs, tricyclic antidepressants	Hypertensive crisis	Do not use within 14 d of each other
	Beta blockers *Anesthetics:* Cyclopropane, halothane	May increase vasopressor effects of sympathomimetics May sensitize the myocardium to sympathomimetics	Monitor closely for adverse reaction Discontinue oxymetazoline prior to use
Tetrahydrozoline	None reported	—	—

Table 17–15 ⊗ Dosage Schedule: Selected Decongestants

Drug	Indication	Dosage Form	Dose	Comments

Tetrahydrozoline Tyzine Tyzine Pediatric Drops Generic	Nasal congestion	Solution: 0.1% Solution: 0.05%	*Children >6 yr and adults:* 2–4 drops or 3–4 sprays of 0.1% solution in each nostril every 3–4 h prn *Children <6 yr:* 2–3 drops of 0.05% solution in each nostril every 3–4 h prn	Advise patients to use nasal decongestant spray for a maximum of 2–3 d in a row to avoid rebound congestion

Topical decongestants are indicated in the symptomatic relief of nasal congestion due to the common cold, sinus infection, and allergic rhinitis. As previously mentioned, topical decongestants are only for short-term (3 to 5 day) use because of the rebound congestion of long-term use. Nasal decongestants may also relieve ear block and pressure pain in air travel, especially if a patient is suffering from a common cold or sinus infection. The adult dose of oxymetazoline topical nasal spray is one or two drops or sprays of 0.05% solution in each nostril twice a day or up to every 6 hours if needed. Children aged 2 to 5 years should use two to three drops of the 0.025% solution in each nostril. The use of 0.05% oxymetazoline should be avoided in children. The dose of topical phenylephrine nasal solution in adults is one to two sprays or drops of 0.25% or 0.5% solution every 4 hours as needed for congestion. Adults with severe congestion can use phenylephrine 1% solution. Children aged 6 to 12 years should use 0.25% solution, two sprays in each nostril every 4 hours. If the child is between age 6 months and 6 years, the 0.16% solution should be prescribed. The dose of phenylephrine in young children (younger than age 6 years) and infants is 1 to 2 drops or sprays every 4 hours. Use topical nasal decongestants sparingly in young children.

Table 17-15 presents dosing information.

Rational Drug Selection

Topical Versus Systemic

Topical decongestants are effective and have few adverse effects. Many health-care providers recommend them for short-term use for the common cold and sinusitis. A concern is the significant rebound congestion that occurs if the topical decongestants are used long term. It can occur in as little as a week of constant use. Therefore, topical decongestants for allergic rhinitis, although safe, must be accompanied with strict patient education to prevent rebound congestion. In patients who are sensitive to the drying effects of the topical decongestants, the oral form may be better tolerated. The reverse is also true; in patients sensitive to sympathomimetics, the topical decongestants are usually tolerated.

Short- Versus Long-Acting

There are short- and long-acting forms of both oral and topical decongestants. In general, the short-acting forms are better tolerated and have fewer adverse effects. The longer-acting forms are useful for patients who require all-day or all-night relief, if the patients can tolerate them.

Cost

Cost is usually not a major factor in prescribing decongestants, which are available OTC, and generic forms of all the medications are available.

Monitoring

There is no specific monitoring required with the decongestants.

Patient Education

Administration

The first concern that the health-care provider should address is self-prescribing and dosing of the nonprescription decongestants. Whether a drug interaction is a concern or a patient may be taking an inappropriate dose, it is important for the health-care provider to be aware that the patient may be taking a decongestant. A thorough history should include any self-prescribed medications and the amount and timing of these medications. Patient teaching should include proper dosing, especially in pediatric patients. Patients with cardiovascular disease, hyperthyroidism, diabetes mellitus, or prostatic hypertrophy should use these products sparingly and only on the advice of their health-care provider.

When topical decongestants are recommended, it is imperative that the patient be warned about rebound congestion and cautioned to use the medication for only 3 to 5 days or, for chronic allergic rhinitis use, only 2 of every 7 days.

Parents should be cautioned not to use adult-formula nasal sprays in children. Children's strength oxymetazoline (0.025%) and phenylephrine HCl (0.125%) are available.

Adverse Reactions

Patients should notify their health-care provider if insomnia, dizziness, weakness, tremor, or irregular heartbeat occurs with topical decongestants. Patients should be cautioned not to exceed the recommended dosage because higher doses cause nervousness, dizziness, or sleeplessness.

Lifestyle Management

Patients should maintain adequate hydration while taking decongestants to keep mucus mobile. They should also refrain from smoking when they are congested. Caffeine-containing products may cause tachycardia if ingested with decongestants.

Table 17-15 presents available dosage forms.

ANTITUSSIVES

Antitussives are widely used by patients to self-treat coughs. It is essential for the health-care provider to educate the patient on the useful physiological mechanism a cough provides by clearing the airway of secretions and foreign material. Therefore, a cough should not be suppressed if it is protecting the airway. There are times when an antitussive is necessary to provide rest or sleep. The cough reflex is complicated, involving both the CNS and peripheral nervous system, as well as the smooth muscle of the bronchial tree. The drugs that can affect this complex mechanism are diverse, ranging from bronchodilators to drugs that act centrally or peripherally to suppress cough. This section discusses the nonprescription antitussives dextromethorphan and benzonatate. Codeine, which is also used as an antitussive, is covered in Chapter 16 with the other opioids. Dosing of codeine for antitussive use is included here.

Pharmacodynamics

Cough results when sensory stimuli or irritation in the bronchial tree stimulates cough receptors, probably located in the bronchial smooth muscle. A message is sent via the afferent nervous system to the cough centers in the medulla. Antitussives work either centrally or peripherally to affect the

cough. The exact mechanism of action of antitussives is poorly understood. Dextromethorphan, the d-isomer of the codeine analogue levorphanol, acts centrally in the cough center in the medulla to elevate the threshold for coughing. Codeine works as an antitussive through direct action on receptors in the cough center of the medulla, at lower doses than is required for analgesia. Benzonatate (Tessalon) is related to tetracaine and is thought to anesthetize the stretch receptors in the respiratory passages, thereby decreasing their activity and calming the cough peripherally at its source.

Pharmacokinetics

Absorption and Distribution

Dextromethorphan, codeine, and benzonatate are absorbed well from the GI tract. The distribution of dextromethorphan and benzonatate is unknown. Codeine is 7% protein bound and widely distributed, including in the CNS. Codeine freely crosses the placenta and is distributed into breast milk.

Metabolism and Excretion

Dextromethorphan is extensively metabolized by the liver and excreted in the urine, mostly as metabolites. Codeine is metabolized in the liver by glucuronidation into morphine and norcodeine. The metabolism of codeine into morphine is mediated by CYP450 2D6. Codeine is eliminated in the urine as unchanged drug, norcodeine, and free and conjugated morphine. The metabolism and excretion of benzonatate is unknown. See Table 17-16 for the pharmacokinetics of selected preparations.

Pharmacotherapeutics

Precautions and Contraindications

Antitussives are not to be used for persistent or chronic cough caused by smoking, asthma, or emphysema. In asthma, antitussives may impair expectoration and thus cause increased airway resistance. Expectorants must not be used by patients with excessive respiratory secretions for the same reason. Patients must be cautioned not to self-medicate their cough for long periods (more than 7 days) without seeking the care of their health-care provider. If high fever or rash accompanies a cough, patients must be seen by their health-care provider.

Benzonatate is contraindicated for patients allergic to tetracaine, procaine, or related compounds.

Dextromethorphan, codeine, and benzonatate can cause drowsiness, dizziness, nausea, and GI upset. In addition, patients taking benzonatate may experience headache, constipation, pruritus, skin eruptions, a sensation of burning eyes, a vague "chilly" sensation, chest numbness, and hypersensitivity. Patients with hepatic function impairment should be monitored if dextromethorphan is prescribed because metabolism of the drug may be impaired. The metabolism of codeine can be affected by deficiency of CYP450D or by medications that may inhibit CYP2D6.

Codeine may cause dependence and should be used with caution in a patient with a history of substance abuse. Although dextromethorphan is not addictive, there have been reports of abuse of dextromethorphan-containing products, especially among teenagers. The FDA issued a Talk Paper in 2005 to warn the public, providers, and law enforcement of the potential for dextromethorphan abuse and has begun exploring whether dextromethorphan should become a scheduled drug.

Codeine causes decreased gastric motility and therefore should be used cautiously by patients with GI obstruction, ileus, or preexisting constipation. Patients with acute ulcerative colitis may be more sensitive to the constipating effects of codeine.

Dextromethorphan and codeine are Pregnancy Category C, but no teratogenic effects have been demonstrated. Codeine should be used with caution near term in pregnancy. Benzonatate is Pregnancy Category C and is to be given to pregnant women only if clearly needed. There are better-studied choices for antitussives in pregnancy, such as dextromethorphan or short-term codeine.

Drug Interactions

Use of antitussives with any CNS depressant may cause increased CNS depression. Concurrent use of dextromethorphan and MAOIs is contraindicated.

Codeine should be used with caution concurrently with medications that are metabolized by CYP2D6 isoenzymes. Quinidine has been shown to interfere with the metabolism of codeine. Other medications that inhibit CYP2D6 are amiodarone (Cordarone), tricyclic antidepressants, metoclopramide (Reglan), selective serotonin reuptake inhibitors (SSRIs), cimetidine (Tagamet), thioridazine (Mellaril), propafenone (Rythmol), and haloperidol (Haldol).

Drugs interactions are shown in Table 17-17.

Table 17–16 ⬛ Pharmacokinetics: Selected Cough Preparations

Drug	Onset	Peak	Duration	Protein Binding	Half-Life	Metabolism	Elimination
Dextromethorphan	15–30 min	—	5–6 h	—	11 h	Extensive hepatic	Renal
Codeine (used as an antitussive)	30–60 min	1–2 h	4–6 h	7%	3–4 h	Primarily hepatic (CYP2D6)	Renal

Expectorants							
Guaifenesin	Rapid	—	—	—	1 h	—	Renal

Table 17–17 ▦ Drug Interactions: Selected Cough Preparations

Drug	Interacting Drug	Possible Effect	Implications
Antitussives			
Dextromethorphan	MAOIs	Dextromethorphan can block neuronal uptake of serotonin and can increase concentrations of serotonin if combined with MAOIs; hypertensive or hyperpyretic crisis is possible	Use concurrently with caution, if at all; avoid use within 14 d
	SSRIs	SSRIs interfere with dextromethorphan metabolism, leading to toxicity	Use lower doses of dextromethorphan
	CNS depressants	Additive CNS depression	Use with caution
	Amiodarone, quinidine	These drugs inhibit CYP2D6; dextromethorphan toxicity may occur	Monitor for toxicity if prescribed concurrently
Codeine (used as an antitussive)	CNS depressants, alcohol	Additive CNS depression	Use cautiously and reduce dose to avoid additive effects
	Antihypertensive agents	Antagonizes antihypertensives	Monitor patients closely
	Antidiarrheals	Can lead to severe constipation	Use with caution; monitor the patient
Benzonatate	None known	—	—
Expectorants			
Guaifenesin	None known	—	—

Clinical Use and Dosing

Cough

Dextromethorphan, codeine, and benzonatate are used to control nonproductive cough. Antitussives should be used only for the nonproductive, irritant-like cough, after other pathology has been ruled out, specifically asthma or pneumonia. Antitussives are not to be used for asthmatic cough or for coughs accompanied by excessive respiratory secretions.

Dextromethorphan is available in many forms and either singly or in combination with expectorants. As it is available without prescription, it is widely used by patients to self-medicate their cough, not always appropriately. The adult dose of dextromethorphan is 10 to 30 mg every 4 to 8 hours. Children aged 6 to 12 years are given a dose of 5 to 10 mg every 4 hours or 15 mg every 6 to 8 hours. The dose of dextromethorphan in children aged 2 to 6 years is 2.5 to 7.5 mg every 4 to 8 hours, although current guidelines recommend not using cough medication in children with cough (Chang & Glomb, 2006).

Benzonatate is available only by prescription and is effective in controlling dry, irritant-like coughs. The dose for children aged 10 years and older and adults is 100 mg 3 times a day. Benzonatate does not cause CNS sedation and may be preferred over dextromethorphan or codeine in patients who need to remain alert or who have a history of substance abuse and want to avoid opioids.

Codeine, a Schedule III, IV, or V medication (depending on combination with other medications), may be administered alone or in combination with another agent such as guaifenesin for cough suppression. The adult dose of codeine for cough suppression is 10 to 20 mg every 4 to 6 hours, with the maximum daily dose not exceeding 120 mg. Children aged 6 to 12 years can be prescribed 5 to 10 mg every 4 to 6 hours (maximum 60 mg/d). Guidelines recommend against the use of antitussives in children (Chang & Glomb, 2006). Table 17-18 presents dosing information.

Rational Drug Selection

Patients may self-medicate their cough with a nonprescription form of dextromethorphan, and the health-care provider has little to do with the choice of the medication. (Advertising has the largest impact.) The health-care provider becomes involved when the patient asks for a recommended formula or if nonprescription products are not effective.

Cost

Although nonprescription dextromethorphan is less expensive than benzonatate- or codeine-containing preparations, patients with good prescriptive coverage may actually pay less out of pocket for the prescription product. Cost must therefore be evaluated on an individual basis.

Effectiveness

Patients might feel that a prescription medication is more effective than nonprescription, but dextromethorphan has been found to be as effective as codeine in the treatment of cough.

Monitoring

There is no specific monitoring required when prescribing antitussive medications.

Table 17–18 ✂ **Dosage Schedule: Selected Cough Preparations**

Drug	Indication	Dosage Form	Dose	Comments

Patient Education

Patient education centers on proper administration, adverse reactions, and drug interactions with the antitussive agents.

Administration

Patients should be aware of the proper dosing of antitussive medication. When they are self-medicating, they are often not following the recommended dosing schedule. The health-care provider needs to determine if the patient is taking the proper amount, measured with a calibrated measuring spoon (not a flatware teaspoon or tablespoon), and spacing the dosage appropriately. The medications may be taken without regard to food but may be better tolerated if taken with food or milk.

Adverse Reactions

CNS depression is the major concern. Some of the antitussives are in alcohol-containing syrup form, and others may cause sedation. Driving or operating hazardous machinery should be undertaken with caution, and not at all if the patient is sensitive to the sedating effects of the antitussives.

Patients should also be aware that if they have long-term cough (occurring for more than 7 days) or cough accompanied by fever, they should be seen by their health-care provider.

Patients concurrently taking MAOIs should not take antitussives. Antitussives should be taken with caution if the patient is concurrently taking any other CNS-sedating medications.

Lifestyle Management

The patient with a cough should be encouraged to increase fluid intake to improve the viscosity of the respiratory secretions. The patient should refrain from smoking and, if possible, stop smoking. Avoidance of respiratory irritants and people with respiratory infections will decrease the incidence of cough.

Table 17-18 presents available dosage forms.

EXPECTORANTS

Guaifenesin is the only expectorant ingredient listed by the FDA panel as having scientific evidence of safety and efficacy.

Guaifenesin is indicated as an expectorant in the symptomatic treatment of cough due to the common cold and mild upper respiratory infections.

Pharmacodynamics

Guaifenesin's main mechanism of action is to increase the output of the respiratory tract by decreasing adhesiveness and surface tension. The increased flow of the thinned secretions promotes ciliary action and facilitates the removal of respiratory mucus. This changes a dry, nonproductive cough into a more productive cough.

Pharmacokinetics

Absorption and Distribution

Guaifenesin is rapidly absorbed from the GI tract after oral administration. Distribution is unknown. It is not known whether guaifenesin crosses the placenta or is distributed in breast milk.

Metabolism and Excretion

The exact mechanism of metabolism of guaifenesin is unknown. Its major metabolite, beta (2-methoxyphenoxy) lactic acid, is excreted in the urine.

Pharmacotherapeutics

Precautions and Contraindications

Guaifenesin is not to be used for persistent cough, such as that found with smoking, asthma, or emphysema. Cough related to heart failure or angiotensin-converting enzyme (ACE) inhibitor therapy should not be treated with guaifenesin. A cough accompanied by high fever or lasting longer than 7 days should be evaluated by a health-care provider.

Guaifenesin is Pregnancy Category C. There have been no problems documented in breastfeeding women taking this medication. Use in children as young as age 2 years is considered safe.

Adverse Drug Effects

GI upset, nausea, and vomiting are the most commonly reported adverse effects of guaifenesin. Drowsiness, diarrhea, dizziness, rash, and headache have also been reported. Guaifenesin is contraindicated only if the patient is hypersensitive to guaifenesin.

Drug Interactions

There are no drug interactions of significance with guaifenesin; however, guaifenesin may cause false readings in certain laboratory determinations of 5-hydroxyindoleacetic acid (5-HIAA) and vanillylmandelic acid (VMA).

Clinical Use and Dosing

Dry, Nonproductive Cough

Guaifenesin is indicated in the symptomatic relief of dry, nonproductive cough, with mucus in the respiratory tract.

The dose of guaifenesin for children over age 12 years and adults is 200 to 400 mg every 4 hours. The guaifenesin dose in children aged 6 to 11 years is 100 to 200 mg every 4 hours. Children aged 2 to 5 years should be dosed with 50 to 100 mg of guaifenesin every 4 hours.

Monitoring

There is no specific laboratory monitoring required with the use of guaifenesin.

Patient Education

Administration

The patient should be aware of the proper dose of guaifenesin. The patient should be using a calibrated medication spoon and taking the appropriate dose per age.

Guaifenesin is an OTC product, and patients may self-medicate, often without proper understanding of the medication. The provider may assist the patient in making the proper choice of cough medication by explaining the difference between the OTC products guaifenesin and dextromethorphan. An explanation of the many combination products that are available and some guidance about appropriate use will assist the patient in making an informed choice.

Adverse Reactions

Although the adverse drug reactions of guaifenesin are mild, patients should be instructed regarding the mild gastrointestinal upset that may occur.

Lifestyle Management

Patients should be instructed to remain well hydrated while taking guaifenesin, and they should refrain from smoking.

DRUGS AFFECTING THE HEMATOPOIETIC SYSTEM

Teri Moser Woo • Kristen Osborne

There are multiple classes of medications that affect the hematopoietic system, including anticoagulants and antiplatelet drugs that affect clotting, hematopoietic growth factors, and the supplements, iron, folic acid, and vitamin B$_{12}$.

ANTICOAGULANTS AND ANTIPLATELETS

Thromboemboli are a common cause of morbidity and mortality. Venous thromboembolism occurs in approximately 108 of every 100,000 persons in the United States each year (American Heart Association Writing Group Members et al, 2012). Pulmonary embolism is a common complication of deep vein thrombosis (DVT), with silent pulmonary embolism occurring in up to one-third of patients with DVT (Stein, Matta, Musani, & Diaczok, 2010). The morbidity and mortality associated with these emboli could be significantly reduced by timely use of anticoagulation therapy. Oral anticoagulation therapy has been used in primary care for over 50 years, and the number of indications for its use has steadily increased. The introduction of low-molecular-weight heparin (LMWH) with less bleeding risk has allowed the outpatient use of injectable anticoagulation therapy as well. With more selective and reliable laboratory tests to monitor blood levels, the management of anticoagulation therapy has become a major tool in the prevention of thrombus formation in primary care.

Thrombi tend to develop whenever intravascular conditions promote activation of the clotting cascade. These conditions include injury to the intimal lining of the artery; roughing of this surface such as occurs in atherosclerosis; inflammation, which is a cardinal part of atherogenesis; traumatic injury; infection; alteration in the normal laminar blood flow; low blood pressure; or obstructions that cause blood stasis and pooling within the vessels.

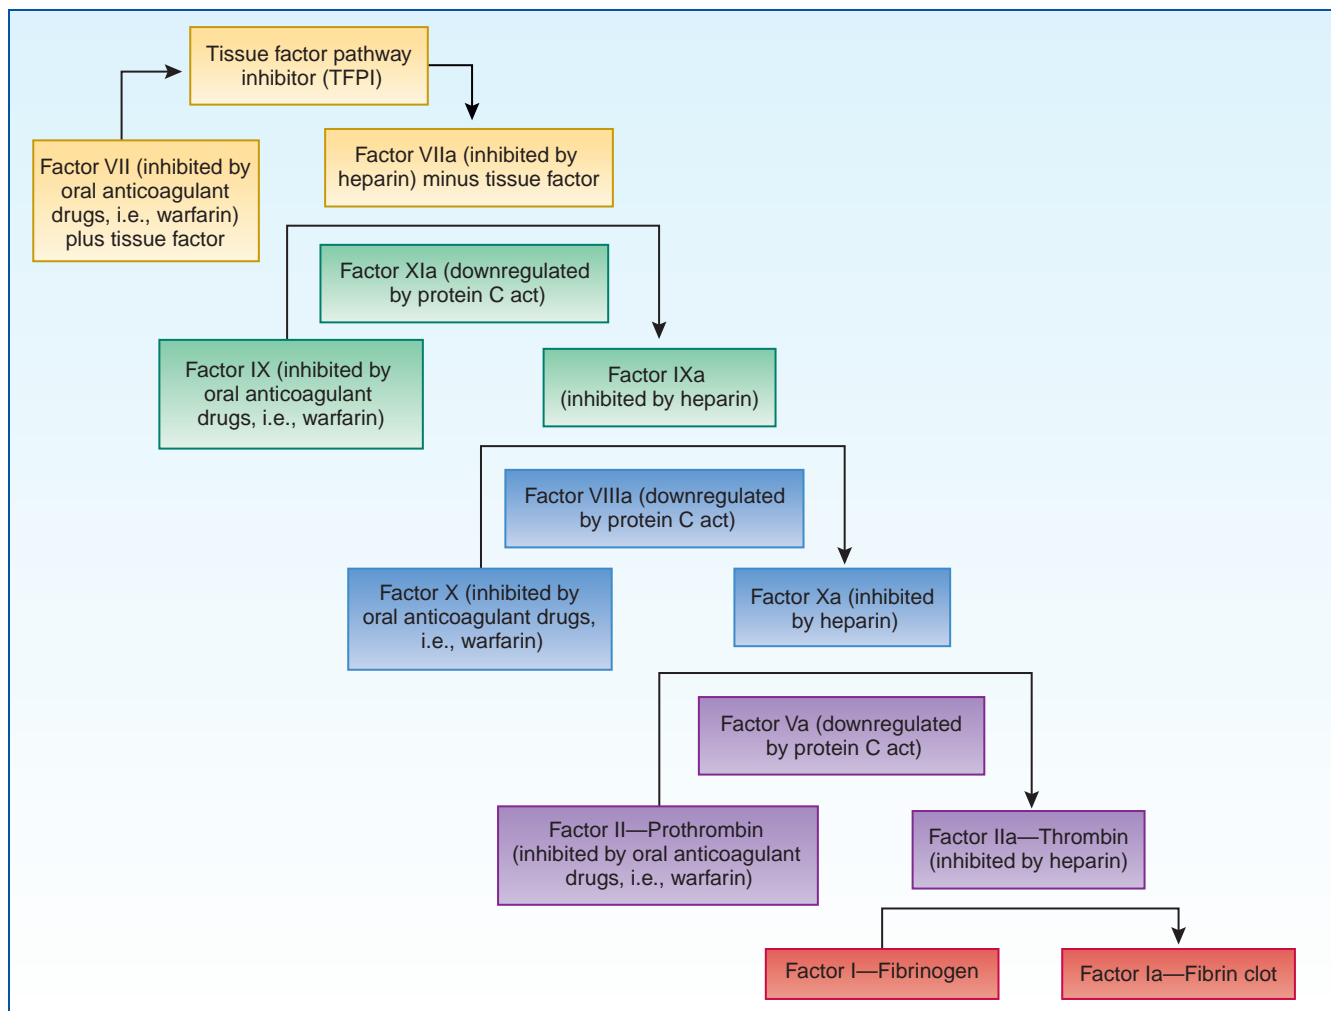
Although the exact details of the clotting mechanism are not fully understood, it is generally accepted that clotting occurs when several circulating proteins interact in a cascading series of limited proteolytic actions (Fig. 18-1). At each step, a precursor protein is converted to an active protease that activates the next clotting factor, and finally, a solid clot is formed. The key regulatory protein in this cascade that initiates blood coagulation is likely factor VII (McCance & Huether, 2010). The components involved at each stage are a protease from the preceding stage, a precursor protein, a protein activator, calcium, and an


Figure 18–1. The clotting cascade.

organizing surface provided by platelets. Fibrinogen is the substrate for the enzyme thrombin (factor IIa). This protease is formed by activation of its precursor protein, prothrombin. Prothrombin is bound by calcium to a platelet surface, where activated factor X (Xa), in the presence of factor V (Va), converts it to circulating thrombin. Thrombin then converts fibrinogen to fibrin to form the clot. Venous thrombi are mainly fibrin and red blood cells (RBCs) and occur when the balance of the clotting pathway is altered by thrombophilic abnormalities, vessel wall damage, or stasis (Weitz, Hirsh, & Samama, 2004). Arterial thrombosis occurs when an atherosclerotic plaque is disrupted and a thrombus forms at the site of disruption (Weitz et al, 2004).

Pharmacodynamics

Oral anticoagulants such as warfarin (Coumadin) inhibit the hepatic synthesis of several clotting factors, including factor X. The decline in clotting factors is a function of the half-life of each factor, which varies from 5 hours for factor VII to 72 hours for factor II. Plasma also contains protease inhibitors that inactivate coagulation proteins. One of these factors is antithrombin III. Heparin inhibits the activity of several activated clotting factors by accelerating the activity of antithrombin III. LMWH enoxaparin (Lovenox) potentiates the activity of antithrombin III and inactivates factors Xa and IIa (thrombin). Dabigatran (Pradaxa) is a direct thrombin inhibitor. Thrombin is required for the conversion of fibrinogen to fibrin in the clotting cascade, thus dabigatran's inhibition of thrombin prevents thrombi from forming. Fondaparinux (Arixtra) is a selective inhibitor of antithrombin III and a factor Xa inhibitor. An anticoagulant, rivaroxaban (Xarelto), is a highly selective factor Xa inhibitor that inhibits thrombin formation and the

On The Horizon **IDRABIOTAPARINUX**

Idraparinux is an analog of fondaparinux given once a week, but trials were discontinued due to excessive bleeding. Idrabiotaparinux is a biotinylated version of idraparinux that is currently being studied for treatment of pulmonary embolism and is as effective as warfarin with less bleeding (Büller et al. 2012). Idrabiotaparinux is also being studied for prophylaxis treatment of DVT (Equinox Investigators, 2011).

development of thrombi. Apixaban (Eliquis) is a selective inhibitor of factor Xa.

The formation of a clot also requires that platelets aggregate to form the organizing base for the clot. Platelets adhere to injured vessel walls, undergo granulate discharge, and aggregate into clumps, releasing biochemical mediators. Several factors affect platelet adherence, including sufficient concentrations of calcium in the platelet so that it can change shape, aggregate, degranulate, and activate arachidonic pathways. Adhesion occurs when the platelet receptor binds to von Willebrand factor, bridging the plate to the injury site. Two of the mediators released by platelets are serotonin and histamine, which affect smooth muscle in the vascular endothelium causing an immediate temporary vasoconstriction. Vasoconstriction reduces blood flow and diminishes bleeding. Vasodilation follows to permit the inflammatory process to occur.

The arachidonic pathway uses cyclooxygenase to produce thromboxane A_2 (TXA$_2$), a prostaglandin, and prostacyclin I$_2$ (PGI$_2$). TXA$_2$ causes vasoconstriction and promotes degranulation of other platelets, which then release more adenosine diphosphate (ADP) to promote adherence. PGI$_2$ inhibits the effect of TXA$_2$ by promoting vasodilation and inhibiting platelet degranulation. The net effect is to permit platelet aggregation at the injury site but to prevent adherence to normal vascular endothelium. Aspirin antagonizes the cyclooxygenase pathway and interferes with platelet aggregation. NSAIDs have this same action. NSAIDs are not used as antiplatelet drugs, but this explains why concurrent use with anticoagulants is contraindicated (Kniff-Dutmer, Schut, & van der Laar, 2003). Ticlopidine (Ticlid) and clopidogrel (Plavix) reduce platelet aggregation by inhibiting the ADP pathway of platelets. Unlike aspirin, they have no effect on prostaglandin metabolism. Ticagrelor (Brilinta) reversibly interacts with the platelet P2Y$_{12}$ ADP-receptor to prevent platelet activation. Vorapaxar (Zontivity) is a protease-activated receptor-1 (PAR-1) antagonist, inhibiting thrombin-induced and thrombin receptor agonist peptide-induced platelet aggregation.

Aspirin and ibuprofen also have analgesic, antipyretic, and anti-inflammatory actions related to their cyclooxygenase (COX) activity. These actions are discussed in Chapter 25.

Pharmacokinetics

Absorption and Distribution

Heparin, including the low-molecular-weight drugs dalteparin (Fragmin), enoxaparin (Lovenox), fondaparinux (Arixtra), and tinzaparin (Innohep), are not absorbed in the gastrointestinal (GI) tract and must be given IV or SC. The IV route is used in acute care. SC injection of heparin results in considerable individual variation in bioavailability. LMWHs have less variation, but bioavailability between drugs is not consistent, and these drugs are not interchangeable. Once absorbed, heparin is distributed in plasma and extensively protein bound. The LMWHs are distributed in plasma and have limited to no protein binding (Table 18-1). Volume of distribution (V$_d$) is different between the

LMWHs and may factor into choosing among them for specific populations.

The coumarin derivative most commonly used is warfarin (Coumadin). Warfarin is rapidly and completely absorbed orally. Although serum levels are found in 1 to 2 hours, the anticoagulation effect is dependent on depletion of clotting factors. Because factor II has a life of 72 hours, the full effect does not occur for 3 to 4 days. Warfarin is highly bound to plasma protein.

Rivaroxaban is rapidly absorbed when given orally, is 80% to 100% bioavailable, and is highly protein bound. Rivaroxaban effects protime (PT) in 2 to 4 hours after the first tablet is ingested.

Aspirin is rapidly and completely absorbed after oral administration. Bioavailability is dependent on the dosage form, the presence of food, gastric emptying time, gastric pH, presence of antacids or buffering agents, and particle size. Bioavailability of enteric-coated forms is erratic. Aspirin is partially hydrolyzed during absorption and distributed to all body tissues and fluids, including fetal tissues and breast milk. Protein binding is highest with low plasma concentrations and lower with high concentrations.

Ticlopidine is rapidly absorbed after oral administration. Administration after meals increases the area under the curve (AUC) by 20%.

Clopidogrel is rapidly absorbed after oral administration. Bioavailability is not affected by food.

Ticagrelor is absorbed from the GI tract with a bioavailability of 36% and with peak serum levels 1.5 hours after ingestion. Ticagrelor is extensively protein bound (greater than 99% bound).

Dabigatran is absorbed slowly from the GI tract with peak serum levels in 1 hour. High-fat foods delay peak to 2 hours. Food intake does not affect bioavailability. Dabigatran is 35% bound to plasma proteins.

Vorapaxar peaks 1 to 2 hours after a single oral dose and is 100% bioavailable. A high fat meal delays peak time by approximately 45 minutes. Vorapaxar is 99% protein bound.

Apixaban reaches maximum concentrations 3 to 4 hours after oral administration. Apixaban is 87% protein bound.

Metabolism and Excretion

Heparins are metabolized by the liver and the reticuloendothelial system. A secondary site of metabolism may be in the kidney. Clearance is nonlinear, and the half-life may be prolonged at higher doses and in liver disease.

In patients with severe renal insufficiency, the mean dalteparin terminal half-life of anti-factor Xa may be considerably longer, with greater accumulation than in other patients. The AUC for anti-factor Xa is marginally increased with enoxaparin for mild to moderate renal insufficiency but significantly increased with creatinine clearance (Ccr) less than 30 mL. Tinzaparin has a similar problem with a 24% reduction in clearance in severe renal insufficiency.

The risk of fondaparinux-associated major bleeding increases with age, from 1.8% for those under age 65 to 2.7% for those older than 75. This drug should be used cautiously

Table 18–1 **Pharmacokinetics: Selected Anticoagulants and Antiplatelets**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability/ Volume of Distribution	Half-Life	Elimination
Anticoagulants							
Dalteparin	—	4 h	Up to 24 h	—	87%/40–60 mL	3–5 h (increased in renal insufficiency)	In urine
Dabigatran		1 h		35%	50 to 70 L	12–17 h	In urine
Enoxaparin	—	3–5 h	12 h	—	100%/4.3 L	4.5 h	In urine
Heparin (SC only)	20–60 min	2–4 h	8–12 h	Extensive	—	1–3 h (nonlinear and dose-dependent; 30 min for doses of 25 mcg/ kg vs. 150 min for doses of 400 mcg/kg); half-life shorter for patients with deep vein thrombosis (DVT) than those with pulmonary embolism; half-life may be prolonged in liver disease	50% unchanged in urine; some urine degradation products have anticoagulant activity; also eliminated by reticuloendothelial system (lymph nodes and spleen)
Fondaparinux	—	2 h	—	None	100%/7–11 L	11–21 h	In urine
Tinzaparin	—	—	—	None	87%/3.1–5 L	3–4 h	In urine
Warfarin	—	3–5 d	2–5 d	99%	100%/0.14 L	40 h	92% in urine as metabolites
Antiplatelets							
Aspirin	5–30 min	1–3 h	3–6 h	Concentration-dependent low doses: (100 mcg/mL) = 90% high doses: (400 mcg/mL) = 76%	—	15–20 min	Renal excretion depends on urine pH; as pH increases from 5 to 8, renal clearance increases from 2%–3% to more than 80%
Clopidogrel	—	1 h	3–7 d	98%	50%	8 h	50% in urine; 46% in feces
Ticagrelor		1.5 h		99%		7 h	58% in feces, 26% in urine
Ticlopidine	2 h	8–11 d	2 wk	98%	—	12.6 h for single dose; 4–5 d with repeated dosing	60% in urine, 23% in feces; clearance decreases with age
Rivaroxaban		2–4 h		92%–95%		5–9 h	urine (30%), feces (21%)

in the elderly. It also has increased terminal half-life in renal impairment.

Warfarin is metabolized by hepatic microsomal enzymes cyproheptadine (CYP) 1A2 and 2C9 and is excreted primarily in the urine as inactive metabolites.

Rivaroxaban is metabolized by CYP 3A4 and 2J2 and is eliminated renally with a half-life of 7 to 11 hours.

Apixaban is primarily metabolized by CYP3A4 and excreted in the urine and feces.

Aspirin is extensively metabolized by the liver and excreted by the kidney. The amount excreted depends on urine pH. As pH increases, the amount excreted as unchanged drug increases from 2% or 3% to 80%.

Ticlopidine is extensively metabolized by the liver. Because of its nonlinear pharmacokinetics, clearance decreases markedly with repeated administration. In older adults, half-lives of 12.6 hours after the first dose increased to 4 to 5 days with repeated dosing. Steady-state levels occur in about 14 to

21 days. Trace amounts of intact drug are found in the urine, and one-third of the dose is excreted in feces and bile as intact drug. Clearance decreases with age. Renal impairment alters plasma levels but does not seem to affect platelet aggregation or bleeding times, except in moderately impaired patients.

Clopidogrel is a prodrug and the liver rapidly converts it to a metabolite that is the active antiplatelet compound. Plasma levels are significantly higher in the elderly but are not associated with differences in platelet aggregation and bleeding time, so no dosage adjustment is needed for this population. Steady state occurs in 3 to 7 days. It is excreted almost equally in urine and in feces, making it safer for patients with renal insufficiency.

Ticagrelor is metabolized in the liver by CYP3A4 into an active metabolite, which also has antiplatelet activity. Ticagrelor and its active metabolite are extensively metabolized into inactive metabolites and excreted in the bile.

After oral administration, dabigatran etexilate is converted to dabigatran via conjugation. Dabigatran is renally eliminated.

Vorapaxar is metabolized via CYP3A4 and CYP2J2, with metabolites excreted 58% in the feces and 25% in the feces. The half-life for vorapaxar is 8 days (range 5 to 13 days).

Pharmacotherapeutics
Precautions and Contraindications

All anticoagulants are contraindicated for patients who are hypersensitive to the drug or actively bleeding or who have hemophilia, thrombocytopenia, severe hypertension (HTN), intracranial hemorrhage, infective endocarditis, active tuberculosis, or ulcerative lesions of the GI tract.

Heparins are contraindicated in advanced hepatic or renal disease. They may be used in patients who are actively bleeding to treat disseminated intravascular coagulation (DIC). Heparin is Pregnancy Category C. Although it does not cross the placenta, its use during pregnancy has been associated with unfavorable outcomes, including stillbirth and prematurity. It should be used only when clearly indicated. Safety has not been established in neonates. Some heparin preparations contain benzyl alcohol, which is known to cause "gasping syndrome," a fatal toxicity in neonates. Hyperkalemia may develop, and use for patients with diabetes or renal insufficiency requires care and frequent monitoring of activated partial thromboplastin time (aPTT). Heparin has been associated with fatal medication errors because of the different strengths of preparations available, including a highly concentrated 10,000 units in 1 mL. The Joint Commission has listed anticoagulant therapy as a National Patient Safety Goal requiring each facility to have a plan in place to reduce patient harm (Joint Commission, 2015).

LMWHs are contraindicated for patients with allergies to pork, sulfites, or benzyl alcohol; uncontrolled bleeding; and in patients who have antiplatelet antibodies. Renal impairment requires cautious use and is discussed in the metabolism and excretion section. Body weight less than 50 kg is also associated with markedly increased risk for bleeding; however, it is possible to adjust the dose of enoxaparin for patients who weigh less than 45 kg. Cautious use is also indicated in untreated HTN, retinopathy (hypertensive or diabetic), severe liver disease, recent history of ulcer, or malignancy. LMWH should not be used for thromboprophylaxis in patients with mechanical prosthetic heart valves, especially pregnant women, as prosthetic heart valve thrombosis may occur.

Enoxaparin is Pregnancy Category B. Teratogenicity and fetal death have been reported as well for tinzaparin, although a clear cause-and-effect relationship was not established. Fondaparinux is also listed as Pregnancy Category B but without adequate or well-controlled studies in pregnancy. LMWHs do not cross the placenta and do not cause teratogenicity or fetal bleeding (Bates et al, 2012). The American College of Chest Physicians recommends LMWH as the first-line drug for women who require antithrombotic therapy during pregnancy (Guyatt et al, 2012). The pharmacokinetics of LMWHs are altered during pregnancy. LMWH passes in small amounts into breast milk but has low oral bioavailability and may be safely used during breastfeeding (Bates et al, 2012).

Hepatic dysfunction potentiates the response to warfarin through impaired synthesis of coagulation factors. Hypermetabolic states produced by fever or hyperthyroidism also increase responsiveness to warfarin, probably by increasing the catabolism of vitamin K–dependent coagulation factors. Warfarin should be used cautiously with these patients. Increased risk for bleeding is also an issue with older adults. Cautious use based on a balance between the potential for decreased risk of thromboembolism and the risk for bleeding is necessary for older adults with dementia or severe cognitive impairment; history of three falls within the previous year or recurrent, injurious falls; uncontrolled HTN; or who are nonadherent or unreliable (Sebastian & Tresch, 2000). Warfarin crosses the placenta and can cause hemorrhagic disorders in the fetus and serious birth defects. It is Pregnancy Category X and should not be administered during pregnancy. The Institute for Clinical Improvements ([ICSI], 2010) states that the amount of warfarin in breast milk is too small to affect the baby. Warfarin is considered safe during lactation, because a minimal amount is excreted in breast milk (LactMed, 2010).

Rivaroxaban (Xarelto) was given a Black-Box Warning in August 2013 indicating the premature discontinuation of anticoagulants including rivaroxaban may lead to thrombotic events. An increased risk of stroke is seen in patients with atrial fibrillation when transitioning to warfarin. Rivaroxaban is Pregnancy Category C and is not recommended for use in pregnant women. Apixaban (Eliquis) was given a similar Black Box warning regarding premature discontinuation leading to thrombotic events when it was approved. Although there are no well-controlled studies, apixaban is Pregnancy Category B.

Hypersensitivity to aspirin and cross-sensitivity with NSAIDs may occur, contraindicating the drug. Aspirin hypersensitivity is more prevalent in patients with asthma, nasal polyps, or chronic urticaria. Reye syndrome has been associated with its use in children and teenagers who have influenza or chickenpox. Reversible hepatotoxicity has occurred.

Use aspirin cautiously in patients who have liver damage, preexisting hypoprothrombinemia, or vitamin K deficiency. Aspirin is Pregnancy Category C and Pregnancy Category D in the third trimester. Aspirin should be avoided during lactation, especially in young infants (LactMed, 2010). If a woman is on chronic high-dose aspirin therapy, salicylates levels should be monitored in the infant (LactMed, 2010).

Patients with severe hepatic disease may have bleeding disorders; neither clopidogrel nor ticlopidine is recommended for these patients. They are also not recommended for patients with GI ulcers. Both drugs are Pregnancy Category B. Despite the lack of evidence of teratogenic potential with this drug, it should be used in pregnancy only when clearly indicated. Safety and efficacy in children under age 18 have not been established. Clearance of ticlopidine increases with age, and older adults' increased sensitivity to this drug requires close monitoring for adverse effects. Older adults have increased plasma levels of clopidogrel, but no dosage adjustments are needed. In older adults, clopidogrel is a safer drug. See the discussion in the Metabolism and Excretion sections for more detail. Ticlopidine causes elevations in serum cholesterol (8% to 10%) and triglycerides within 1 month of therapy, and the higher levels persist. The ratios of subfractions of cholesterol remain unchanged. This may be a factor in choosing a drug for patients with dyslipidemias.

Ticagrelor has a Black-Box Warning to not use in a patient with active pathological bleeding or history of intracranial hemorrhage. Ticagrelor should be discontinued 5 days prior to any surgery.

Dabigatran has a Black-Box Warning concerning discontinuation increasing risk of thrombotic events. There is no reversal agent available for dabigatron if excessive bleeding occurs.

Vorapaxar has a Black-Box Warning to not use in patients with a history of stroke, transient ischemic attack (TIA), intracranial hemorrhage, or active pathological bleeding. Vorapaxar is Pregnancy Category B, with no congenital malformations found in animal studies, but no studies conducted in pregnant women. Safety and effectiveness in children has not been established.

Adverse Drug Reactions

All anticoagulants can cause excessive bleeding. Several studies have shown that the incidence of bleeding severe enough to require hospitalization or transfusion is less than 5%. Risk of this complication is higher early in the initiation of therapy, with wide fluctuations in aPTT or international normalized ratio (INR) and in older adults, especially women above age 60. Patients with laboratory studies within the therapeutic range who exhibit this adverse reaction should be evaluated for underlying pathological processes that may be the source of the bleeding before implication of the anticoagulant.

Heparins can also cause thrombocytopenia and anemia. The incidence of thrombocytopenia is up to 30% and is more likely with bovine than with porcine heparin. Early thrombocytopenia occurs 2 to 3 days after initiating therapy, and a delayed form occurs 7 to 12 days after initiation. If the platelet count falls below 100,000/mm³, the heparin should be discontinued. The antidote for enoxaparin overdose is protamine sulfate 1 mg for each mg of enoxaparin; for dalteparin and tinzaparin, it is 1 mg for each 100 anti-Xa international units (IU) of dalteparin. Both are given by slow IV injection. There is no known antidote for fondaparinux. Because of heparin's short half-life, heparin overdose is usually treated by withdrawal of the drug. If treatment is required, protamine sulfate is also the antidote for heparin overdose.

Toxicity and overdose of warfarin are usually treated by withholding one or more doses. If it must be treated, 1 to 10 mg of vitamin K is the antidote for warfarin overdose with minor bleeding; 5 to 50 mg may be used for frank bleeding.

Hemorrhagic skin necrosis in women and cyanotic toes in men have been observed in patients taking warfarin with therapeutic INR levels (Maddali et al, 2013). The mechanism appears to be related to a transient inhibition in proteins S and C in patients in whom these clotting factors are congenitally absent and in patients with heparin-induced thrombocytopenia (Maddali et al, 2013).

Although rare, allergic reactions do occur with warfarin, they are characterized by symmetrical, maculopapular, erythematous lesions. Some are isolated and some confluent. They tend to occur on the face, neck, and torso. Because of the length of time to therapeutic dose for warfarin, the drug reaction does not occur until the patient has been on the drug for 8 to 10 days.

Bleeding is the major adverse effect of ribaroxaban, with 5.6% of patients experiencing major bleeding during clinical trials. There is no reversal agent for ribaroxaban. Other adverse effects seen more commonly in patients taking ribaroxaban than placebo include back pain (3.7%), upper abdominal pain (1.7%), osteoarthritis (1.7%), dyspepsia (1.3%), and fatigue (1.0%).

The major adverse effect seen with apixaban is bleeding with major bleeding occurring in 2.13% of patients who used it for a year. There is no reversal agent for apixaban.

Aspirin can produce gastric erosions that increase the risk of serious upper GI bleeding. This adverse effect is more likely when it is used in combination with other anticoagulants such as warfarin. Salicylism (tinnitus) associated with the use of aspirin occurs at serum levels above 200 mcg/mL. In addition to tinnitus, indications of aspirin toxicity are headache, hyperventilation, agitation, mental confusion, lethargy, diarrhea, and sweating. Severe toxic effects may occur at levels above 400 mcg/mL that occur with high doses. Such high doses are not used for antiplatelet therapy, so the management of severe toxicity is discussed in Chapter 25, which covers the use of aspirin for anti-inflammatory therapy.

The major adverse effect of ticagrelor is bleeding, with 4.5% of patients experiencing major bleeding in clinical trials and 2.1% experiencing life-threatening bleeding. Dyspnea is the major nonbleeding-related adverse effect seen with ticagrelor, with 13.8% of patients reporting symptoms. The dyspnea was mild to moderate in intensity and usually resolved with continued use but occasionally required discontinuation of therapy (0.9% of patients). Headache (6.5%), cough (4.9%), dizziness (4.5%), and nausea (4.3%) were other common adverse effects of ticagrelor.

Reversible neutropenia has occurred 3 weeks to 3 months after the initiation of therapy with ticlopidine. Severe neutropenia (less than 450 neutrophils/mm³) or thrombocytopenia (less than 80,000 platelets/mm ³) is an indication to discontinue the drug.

Clopidogrel has been evaluated for safety in a very large number of patients and its tolerability is similar to that of aspirin, with approximately the same number of patients withdrawing from treatment because of adverse reactions.

Adverse effects of dabigatran include bleeding, with 16.6% of patients experiencing any bleeding during clinical trials and 3.3% experiencing a major bleed. Gastrointestinal side effects of dabigatran include dyspepsia and gastritis-like symptoms. Angioedema and thrombocytopenia have been reported in post-marketing surveillance of dabigatran (Pradaxa).

Vorapaxar adverse effects measured during clinical trials include bleeding, with 27.5% experiencing any bleeding and 1.3% of study subjects experiencing severe bleeding. GI bleeding was experienced by 4.7% of subjects in clinical trials. Other adverse reactions observed during clinical trials include anemia (5%), depression (2.4% vs 2.1% for placebo) and rashes or eruptions (2.2%).

Drug Interactions

Cephalosporins and penicillins given parenterally have both been associated with coagulopathies, increasing the risk of bleeding when given with heparin. Although not reported for these drugs when they are given orally, there is a theoretical increased risk for bleeding. Second- and third-generation cephalosporins and high doses of penicillins, regardless of route of administration, have also been associated with an increased bleeding risk with warfarin because they inhibit the cyclic interconversion of vitamin K.

Drugs that affect platelet functioning or cause hypoprothrombinemia—including aspirin, NSAIDs, dipyridamole, quinidine, and valproic acid—increase the risk of bleeding when used with any anticoagulant. Others are listed in Table 18-2.

Table 18–2 ⁛ Drug Interactions: Selected Anticoagulants and Antiplatelets

Drug	Interacting Drug	Possible Effect	Implications
Anticoagulants			
Dalteparin, Enoxaparin	Salicylates, NSAIDs, dipyridamole sulfinpyrazone, ticlopidine	Increased risk of bleeding	
Fondaparinux, Tinzaparin	Thrombolytics, dextran, clopidogrel, some penicillins Natural products: anise, arnica, chamomile, clove, feverfew, garlic, ginger, ginkgo, and panax ginseng	Increased risk of bleeding Increased risk of bleeding	Avoid concurrent use Some are used as spices in cooking. Warn patients about this interaction and to avoid their concurrent use.
Heparin	Cephalosporins and penicillins	Altered platelet aggregation and other coagulopathies with increased risk of bleeding	Mainly related to parenteral administration of these drugs; close monitoring required regardless of route of administration if used concurrently
	Nitroglycerin	Effect of heparin may be decreased	Reports are conflicting; monitor drug effects closely
	Platelet inhibitors: aspirin, salicylates, NSAIDs, dipyridamole, hydroxychloroquine, phenylbutazone, ticlopidine	Increased risk of bleeding	Avoid concurrent use
	Digitalis, tetracycline, nicotine, antihistamines	May partially counteract anticoagulant action	Avoid concurrent use
Warfarin	Alcohol (if concomitant liver disease), amiodarone, anabolic steroids, cimetidine, clofibrate, cotrimoxazole, erythromycin, fluconazole, isoniazid, metronidazole, omeprazole, phenylbutazone, piroxicam, propafenone, propranolol, sulfinpyrazone, citalopram, entacapone, sertraline, zileuton,	Evidence indicates it is highly probable that these drugs potentiate action with increased risk of bleeding	Avoid concurrent use; if necessary, dosage adjustment of warfarin may be required. Draw INR within 4–7 d of starting concerning drug.
	Food/supplement: fish oil, mango		

Continued

Table 18–2 ▦ **Drug Interactions: Selected Anticoagulants and Antiplatelets—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
	Acetaminophen, chloral hydrate, ciprofloxacin, celecoxib, disulfiram, itraconazole, quinidine, phenytoin, tamoxifen, pachitaxel, tolterodine, tetracycline, amoxicillin/clavulanate, azithromycin, levofloxacin, ritonavir, simvastatin, ropinirole, interferon, tramadol Food: grapefruit	Evidence indicates these drugs probably potentiate action with increased risk of bleeding	Close monitoring of INR. Draw INR within 4–7 d of starting drug with possible interaction.
	Herbal supplements: dashen, dong quai, lycium barbarum, PC-SPES		
	Aspirin	Increases risk of bleeding with higher doses; even low doses of aspirin (100 mg/d) have been associated with increased risk of minor bleeding	Avoid concurrent use
	Oral contraceptives Barbiturates, carbamazepine, chlordiazepoxide, cholestyramine, dicloxacillin, griseofulvin, nafcillin, rifampin, flu vaccine Foods: foods high in vitamin K,* large amounts of avocado, soy milk Herbs: ginseng	May decrease the anticoagulant effect Inhibits anticoagulant action	Use other birth control method Avoid concurrent use of drugs. Maintain stable intake of foods high in vitamin K so that diet is balanced.
Dabigatran	Rifampin P-gp inhibitors ketoconazole, amiodarone, verapamil, and quinidine	Decreased dabigatran levels Increased dabigatran levels	Avoid concurrent use If renal function normal, no dosage adjustment needed. The concomitant use of P-gp inhibitors in patients with severe renal impairment (CrCl 15–30 mL/min) should be avoided.
	Platelet inhibitors: aspirin, salicylates, NSAIDs, dipyridamole, hydroxychloroquine, phenylbutazone, ticlopidine Heparin	Increased risk of bleeding Increased risk of bleeding	
Apixaban	Dual inhibitors of CYP3A4 and P-gp (ketoconazole, itraconazole, ritonavir, clarithromycin) Strong dual inducers of CYP3A4 and P-gp (rifampin, carbamazepine, pheyntoin, St. John's Wort)	Increased bleeding risk Decreased apixaban and increased risk of stroke and other thrombotic events	Decrease apixaban dose by 50% Avoid concomitant use
Antiplatelets Clopidogrel	Platelet inhibitors: aspirin, NSAIDs, dipyridamole, ticlopidine Anticoagulants: heparin and warfarin	Increased risk of bleeding	Avoid concurrent use except with aspirin in selected cases (see ACCP recommendations)
	Proton pump inhibitors Cimetidine, esomeprazole, fluoxetine, fluconazole, ketoconazole	Significant interaction that lowers antiplatelet effect of clopidogrel due to competitive inhibition of CYP2C19	The FDA recommends PPIs and other drugs that inhibit CYP2C19 be avoided in patients taking clopidogrel
	Phenytoin, tolbutamide, tamoxifen, torsemide, fluvastatin, and NSAIDs Natural products: see LMWHs above	May decrease metabolism and increase effects of interacting drugs	With high doses and based on data related to CYP450 2C9 inhibition. No data to predict level of interaction. Use with caution.
Ticagrelor	Strong CYP3A inhibitors (e.g., ketoconazole, itraconazole, and clarithromycin) CYP3A inducers (e.g., rifampin) P-gp inhibitors (e.g., cyclosporine)	Increased ticagrelor exposure Substantially reduces ticagrelor blood levels Increase ticagrelor exposure	

Table 18–2 ⁖ **Drug Interactions: Selected Anticoagulants and Antiplatelets—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
Ticlopidine	Platelet inhibitors: aspirin, NSAIDs, dipyridamole, clopidogrel Anticoagulants: heparin, LMWHs, and warfarin	Increased risk of bleeding	Avoid concurrent use
	Antacids	Concurrent administration results in 18% decrease in ticlopidine plasma levels	Separate drug administration; give ticlopidine first and antacids 1 h later
	Cimetidine	Chronic use of cimetidine reduced ticlopidine clearance by 50%	Use different histamine$_2$ blocker if reducing gastric acid is required
	Digoxin	Digoxin plasma levels decreased 15%	Avoid concurrent use
	Phenytoin	Elevated phenytoin plasma levels associated with somnolence and lethargy	Use with caution and remeasure phenytoin levels
	Theophylline	Significantly increased theophylline elimination half-life with comparable reduction in total plasma clearance	Avoid concurrent use
Rivaroxaban	Combined P-gp and strong CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, lopinavir/ritonavir, ritonavir, indinavir/ritonavir, and conivaptan)	Increases in rivaroxaban exposure and pharmacodynamic effects	Avoid concomitant use
	Combined P-gp and strong CYP3A4 inducers (e.g., carbamazepine, phenytoin, rifampin, St. John's wort)	Decreased rivaroxaban exposure by up to 50%	Avoid concomitant use

*Foods high in vitamin K: asparagus, beans, broccoli, Brussels sprouts, cabbage, cauliflower, cheese, collards, fish, milk, mustard greens, pork, rice, spinach, turnips, yogurt.

Heparin and LMWHs have similar drug interactions but also interact with antiplatelets (including NSAIDs) and dextran. Some natural products are also associated with increased risk for bleeding (see Table 18-2). Some of these are used as spices in cooking, and patients should be warned about their use. Clopidogrel has increased risk for bleeding from this same group of natural products.

Warfarin has many drug interactions and increased INR monitoring (within 4 to 7 days) is recommended when other drugs are started or stopped, even short-term drugs such as antibiotics. Vitamin K has an antagonistic interaction with warfarin, decreasing warfarin's effectiveness. Inhibitors of CYP 1A2, 2C9, or 3A4 isoenzymes increase the effect of warfarin. Inhibitors of CYP 1A2, 2C9, or 3A4 decrease the effectiveness of warfarin. Drugs inducing and inhibiting warfarin are shown in Table 18-2. Warfarin interacts with any other drug that increases bleeding, including anticoagulants, antiplatelets, NSAIDs, and SSRIs. Antibiotics and antifungals may affect INR levels in patients taking warfarin. Herbal products that may increase bleeding include ginkgo biloba, and garlic. Herbal therapies that may decrease effectiveness of warfarin include St. John's wort, ginseng, and coenzyme Q10. Herbal therapies and foods that may influence the metabolism of warfarin include St. John's wort, echinacea, ginkgo, goldenseal, and grapefruit juice.

Rifampin interacts with dabigatran, leading to decreased levels of dabigatran (66% of expected). Dronedarone increases dabigatran levels by 70% to 150%. The calcium channel blocker verapamil increases dabigatran levels with levels dependent on verapamil dose and time of administration. Amiodarone increases dabigatran levels by 50% and clopidogrel increases dibigatran levels by 40%.

Ticagrelor is metabolized by CYP3A4; therefore, use of strong inhibitors of CYP3A should be avoided, including ketoconazole, itraconazole, voriconazole, clarithromycin, nefazodone, ritonavir, saquinavir, nelfinavir, indinavir, atazinavir, and telithromycin. Inducers of CYP3A should be avoided, including rifampin, dexamethasone, phenytoin, carbamazepine, and phenobarbital.

Avoid use of vorapaxar with inhibitors of CYP3A, including ketoconazole, itraconazole, posconazole, clarithromycin, nefazodone, ritonavir, saquinavir, nelfinavir, indinavir, boceprevir, telaprevir, telithromycin and conivaptan. Use of strong inducers of CYP3A should also be avoided (rifampin, carbamazepine, St. John's Wort and phenytoin).

Clinical Use and Dosing

Prevention and Treatment of Thromboembolism

Warfarin is the drug of choice for the prevention of venous thrombosis, systemic thrombosis, and pulmonary embolism. For prevention, warfarin should be given in a dose sufficient to maintain an INR between 2 and 3 (Guyatt et al, 2012). The beginning dose is 10 mg daily for the first 2 days, with a recheck of INR in two to three doses (Guyatt et al, 2012).

The ICSI antithrombotic guidelines recommend starting warfarin at 5 mg per day with a range of 2.5 mg to 7.5 mg daily (Maddali et al, 2013). Further dosing is based on INR ICSI recommends lower initiation doses be considered for patients with any of the following (Maddali et al, 2013):

- Older than 75 years
- Multiple comorbid conditions
- Poor nutrition (low albumin)
- Elevated INR when off warfarin
- Elevated liver function tests
- Changing thyroid status

If the INR is greater than 2 after the first three doses, consider decreasing the dose by one-half. If INR rises rapidly, search for reasons, such as drug interactions, poor nutritional status, infection, or systemic disease process. Monitoring is discussed later.

Patients with acute pulmonary emboli (PE), DVT, or acute systemic embolization are admitted to the hospital for parenteral anticoagulation therapy with heparin, LMWH, or SC fondaparinux and then placed on oral anticoagulation. If PE is highly suspected, the American College of Chest Physicians (ACCP) recommends treatment with anticoagulants while awaiting diagnostic tests. In patients with acute PE, initial treatment is heparin, LMWH, or fondaparinux for at least 5 days and until INR is greater than or equal to 2.0 for at least 24 hours (Guyatt et al, 2012). The ACCP recommends starting warfarin on the first day of treatment in conjunction with heparin, LMWH, or fondaparinux, with LMWH and fondaparinux favored over IV or SX heparin (Guyatt et al, 2012). Treatment for PE due to a transient (reversible) risk factor is warfarin for 3 months (Guyatt et al, 2012).

Superficial Vein Thrombosis

The ACCP recommends 45 days of prophylaxis with fondaparinux or LMWH in patients with superficial vein thrombosis of the lower limb of at least 5 cm in length (Guyatt et al, 2012). The ACCP recommends fondaparinux 2.5 mg daily over prophylactic LMWH.

Deep Vein Thrombosis

The ACCP divides the treatment of acute DVT into acute treatment of DVT of the leg and treatment of upper extremity DVT. The initial treatment of acute DVT of the leg or upper extremity is short-term treatment with SC LMWHs, SC fondaparinux, or IV or SC heparin for at least 5 days and until the INR is 2.0 for at least 24 hours (Guyatt et al, 2012). LMWH and SC fondaparinux are preferred over heparin (Guyatt et al, 2012). Warfarin should be initiated on the first treatment day, as for PE. For a patient with an idiopathic DVT, the patient is maintained on warfarin with a target of 2.5 (range 2.0 to 3.0) for 3 months (Guyatt et al, 2012).

Patients with an indwelling central line catheter are at risk for developing a DVT. In most patients with an indwelling central venous catheter, the catheter is not removed if it is functional and is needed for therapy (i.e., chemotherapy). Treatment is the same as for leg DVT. If the catheter is removed, the patient should still receive at least 3 months of anticoagulant therapy (Guyatt et al, 2012).

All other patients requiring anticoagulant therapy can be safely started on warfarin as outpatients. Therapy is initiated with 10 mg daily (ACCP Guidelines) or 5 mg daily (ICHI Guidelines) unless the patient weighs less than 110 lb, is over age 75, or is at increased risk of bleeding. Patients with these weight, age, and risk parameters are started on 2.5 mg daily. Steady state is achieved in 5 to 7 days, at which time dosage adjustments are made, based on INR laboratory results. The goal of therapy is an INR of 2 to 3 for all treatment durations. Therapy is usually continued for 3 months for patients with a transient (reversible) DVT risk factor. Although not in the ACCP guidelines, the dose of apixaban to treat DVT and PE is 10 mg twice daily for 7 days then 5 mg twice daily. The maintenance dose of apixaban to reduce the risk of further DVT and PE is 2.5 mg twice daily.

For patients with DVT or PE and cancer, the ACCP guideline recommends LMWH for the first 3 to 6 months of long-term anticoagulant therapy (Guyatt et al, 2012). Patients who have coagulopathies should be referred for management.

Air travel time longer than 8 hours places patients at risk of developing a DVT. The ACCP (Guyatt et al, 2012) recommends the following measures to prevent thrombus formation: wearing loose clothing, avoiding tight clothing around the waistline or lower extremities, achieving good hydration, and performing frequent calf muscle exercises. If patients have a high risk of developing a DVT, the ACCP recommends that they wear compression stockings providing 15 to 30 mm Hg of pressure during air travel. For all patients, the ACCP stresses that immobility (bedrest) is counterproductive. They recommend ambulation as tolerated and the use of elastic compression stockings with a pressure of 30 to 40 mm Hg at the ankle for 2 years after an episode of DVT.

Dosage recommendations for anticoagulants are given in Table 18-3.

Prevention of Embolic Stroke in Atrial Fibrillation

Atrial fibrillation (AF) is a common cardiac arrhythmia, with up to 1 in 4 persons experiencing AF during their lifetime. The turbulence associated with AF places the patient at risk for stroke if not on antithrombotic therapy. For patients at low risk of stroke or with a $CHADS_2$ (congestive heart failure, hypertension, age equal to or greater than 75 years, diabetes mellitus, prior stroke or TIA or thromboembolism) score of 0, the ACCP guidelines recommend no therapy. If a patient chooses antithrombotic therapy, then aspirin dosed at 75 mg to 325 mg daily is prescribed (You et al, 2012). Patients with intermediate risk of stroke (a $CHADS_2$ score of 1) should be treated with oral anticoagulation therapy. If intermediate-risk patients refuse to take anticoagulants, a combination of aspirin (75 mg to 325 mg once daily) and clopidrogrel (You et al, 2012) may be prescribed. Patients at high risk of stroke ($CHADS_2$ score of 2 or greater) require oral anticoagulation therapy. The 2012 ACCP guidelines recommend 150 mg of dabigatran twice daily as the anticoagulant therapy of choice rather than warfarin (You et al, 2012). For patients with persistent or paroxysmal AF at high risk for stroke, the recommendation is warfarin with a target INR between 2 and 3. For patients with AF and mitral stenosis, the recommendations

Table 18–3 ⚕ Dosage Schedule: Selected Anticoagulants and Antiplatelets

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
Aspirin	MI and stroke prevention	81 mg chewable (orange flavor) 81 mg tablet 165 mg enteric-coated 325 mg tablet	75–325 mg daily	75–325 mg daily
Clopidogrel (Plavix)	Prevention of new ischemic event (CVA or MI) in patients with recent CVA, MI, or established PAD	75 mg tablets	75 mg once (may need 150 mg in some patients)	75 mg daily
	Acute coronary syndromes		300 mg once	75 mg daily. Aspirin 75–325 mg given concurrently
Dalteparin* (Fragmin)	Prevention of DVT after abdominal surgery	2,500, 5,000, 7,500, 10,000, 12,500, 15,000, or 18,000 anti-factor Xa international units (IU)	2,500–5,000 IU on day of surgery	2,500–5,000 IU daily for 5–10 d post-operatively
	Hip replacement		2,500 2 h pre-op	2,500 IU evening post-op, then 5,000 IU daily for 5–9 d
Enoxaparin* (Lovenox)	DVT and/or PE	Prefilled syringes: 30 mg/0.3 mL 40 mg/0.4 mL 60 mg/0.6 mL 80 mg/0.8 mL 100 mg/1 mL	1 mg/kg q 12 h	Transition to warfarin
	Hip replacement and knee replacement		30 mg 12–24 h post-op or 40 mg 12 h pre-op	or 40 mg daily for 3 weeks
	Abdominal surgery		40 mg 2 h pre-op	40 mg daily for 7–10 d
Fondaparinux† (Arixtra)	Hip-fracture surgery and hip or knee replacement	2.5 mg in 0.5 mL single-dose prefilled syringe with needle	2.5 mg 6–8 h after surgery	2.5 mg for 24 d following hip-fracture surgery or 5–9 d for hip or knee replacement
	Therapy for DVT		Patients <50 kg: 5.0 mg daily Patients 50–100 kg: 7.5 mg daily Patients >100 kg: 10 mg daily	Continue same dose
Heparin	Preventive of post-operative thromboembolism	In multidose vials: 1,000 U/mL 5,000 U/mL 10,000 U/mL	5,000 IU 2 h pre-op	5,000 U q 8–12 h for 7 d after surgery
Ticlopidine (Ticlid)	Preventive of stroke in patients intolerant of aspirin	250 mg tablets	250 mg bid with food	250 mg bid with food
Tinzaparin* (Innohep)	DVT and/or PE	20,000 U/mL in 2 mL multidose vials	175 anti-Xa IU/kg	175 anti-Xa IU/kg daily for 6 d with transition to warfarin
Warfarin (Coumadin)	Prevention and treatment of venous thrombosis, systemic embolism, and pulmonary embolism; prevention of embolic stroke in atrial fibrillation	Scored tablets: 1 mg pink 2 mg lavender 2.5 mg green 3 mg tan 4 mg blue 5 mg peach 6 mg teal 7.5 mg yellow 10 mg white	5 mg–10 mg daily; for patients <50 kg; >age 75, or at increased risk of bleeding: 2.5 mg daily	Measure INR at 5–7 d and adjust to INR of 2–3

Table 18–3 ⊗ **Dosage Schedule: Selected Anticoagulants and Antiplatelets—cont'd**

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
	Recurrent systemic embolism and mechanical heart valves			Measure INR at 5–7 d and adjust to INR of 3 (2.5–3.5)
	Total hip replacement or hip-fracture surgery*		5 mg daily for patients <110 lb; >age 75, or at increased risk of bleeding: 2.5 mg daily	Measure INR at 5–7 d and adjust to INR of 2–3
Dabigatran* (Pradaxa)	Reduce the risk of stroke and systemic embolism in patients with non-valvular atrial fibrillation	150 mg capsule	150 mg bid Severe renal impairment (CrCl 15–30 mL/min): 75 mg twice daily	
Ticagrelor (Brilinta)	Acute coronary syndrome	90 mg tablet	180 mg (two 90 mg tablets) loading dose	
Vorapaxar (Zontivity)	Reduction of thrombotic cardiovascular events in patients with a history of myocardial infarction or with peripheral arterial disease	Tablet: 2.08 mg	One tablet daily	
Apixaban (Eliquis)	Reduction of risk of stroke and systemic embolism in non-valvular atrial fibrillation.	2.5 mg, 5 mg tablet	5 mg bid	5 mg bid
	prophylaxis of DVT following knee replacement surgery		2.5 mg twice daily	
	Treatment of DVT and PE		10 mg bid for 7 days, followed by 5 mg bid	2.5 mg bid

*Doses reduced for severe renal impairment (Ccr <30 mL/min). Only outpatient indications are covered.
†Recommendation of the American College of Chest Physicians. The ACCP also states that low-molecular-weight heparin may be used for hip-fracture surgery, ischemic stroke with paralysis of lower extremities, and medical patients with clinical risk factors. Specific doses are not given for these indications, but fixed dose bid started post-operatively is recommended for surgical patients.

follow those for patients at high risk. If the valvular heart disease has resulted in valve replacement, the recommendations follow those for patients with heart valves, regardless of the presence or absence of AF.

Apixaban dose to reduce risk of stroke and systemic embolism in nonvalvular atrial fibrillation is 5 mg orally twice daily. Patients who are older than age 80 years, weigh less than 60 kg, or have serum creatinine greater than 1.5 mg/dL should be dosed at 2.5 mg twice daily.

Mitral Valve Disease

For patients with rheumatic mitral valve disease but no AF and a left atrial diameter of less than 55 mm, the ACCP recommends no antithrombotic therapy (Guyatt et al, 2012). Patients with rheumatic mitral valve disease with a left atrial diameter of greater than 55 mm or left atrial thrombus or atrial fibrillation or previous embolism are all managed with warfarin to a target INR of 2.5 (range 2.0 to 3.0). Therapy is continued indefinitely in all these cases.

Antithrombotic Therapy for Ischemic Stroke

The ACCP recommendation for patients with an acute ischemic stroke or transient ischemic attack (TIA) is early (within 48 hours) aspirin therapy at a dose of 160 to 325 mg; with aspirin preferred over parenteral anticoagulant therapy

(Guyatt et al, 2012). ACCP recommends three options for long-term therapy after a noncardioembolic ischemic stroke or TIA: 75 to 100 mg aspirin daily, the combination of aspirin (25 mg) and extended-release dipyridamole (200 mg bid), 75 mg clopidogrel daily, or 100 mg cilostazol twice daily (Guyatt et al, 2012). The ACCP guidelines recommend the combination of aspirin and extended-release dipyridamole or clopidrogrel over aspirin alone be used as preventive therapy for TIA or stroke. Patients with a history of ischemic stroke or TIA with AF should be prescribed anticoagulants with 150 mg dibigatron twice daily preferred over warfarin in these patients (Guyatt et al, 2012).

Recurrent Embolism or Prosthetic Heart Valves

Warfarin is the drug of choice for patients with recurrent embolism or a prosthetic heart valve. Therapy is initiated and maintained the same as for prevention of venous thrombosis, except that the target INR depends on the type of valve. The targets are shown in Table 18-4. Of note, for patients who have mechanical valves and additional risk factors such as AF, myocardial infarction (MI), left atrial enlargement, endocardial damage, and low ejection fraction, 75 to 100 mg/day of aspirin should be added to their warfarin protocol. The same is true for patients with caged ball or caged disc valves. Long-term management of patients with bioprosthetic valves who are in sinus

Table 18–4 Recommended INR Values Based on Reason for Warfarin Use

Reason for Use	INR range
Prevention of DVT, pulmonary embolism, or systemic embolism	2.0–3.0
Prevention of embolic stroke in patients with atrial fibrillation	2.0–3.0
Patients with St. Jude Medical bileaflet prosthetic heart valve	2.0–3.0
Patients with tilting disk valves and bileaflet prosthetic heart valves in aortic position	2.5–3.5
Patients with CarboMedics bileaflet valve or Medtronic Hall tilting disk prosthetic heart valve	2.0–3.0
Patients with mechanical valves and high risk (e.g., atrial thrombus, AF, hypercoagulable state, low ejection fraction)*	2.5–3.5
Patients with caged ball or caged disk prosthetic heart valves*	2.5–3.5
Patients with bioprosthetic valve in mitral position	2.0–3.0
Patients with bioprosthetic valve in aortic position	2.0–3.0

*In addition to warfarin, these patients should also receive aspirin 75–100 mg/d.

rhythm may be managed on 75 to 100 mg/day of aspirin alone (Guyatt et al, 2012). Therapy is continued indefinitely for mechanical heart valves. For systemic embolization that recurs after 6 months of therapy, therapy is usually continued for an additional 12 months.

Pregnant patients with a mechanical heart valve require anticoagulant therapy that places the fetus and mother at lowest risk of complications. The ACCP guidelines for use of anticoagulants in pregnancy recommend women with a mechanical heart valve be treated with one of three regimens: (1) LMWH twice daily during pregnancy; (2) SC heparin every 12 hours; or (3) SX heparin or LMWH until the 13th week of pregnancy, then warfarin until close to delivery when LMWH or heparin is resumed (Bates et al, 2013). Warfarin is a known teratogen and may cause fetal hemorrhage, whereas heparin and LMWH do not cross the placenta and therefore do not cause teratogenicity or fetal bleeding, though bleeding at the uteroplacental junction is possible (Maddali et al, 2013). Women with mechanical heart valves at high risk of thromboembolism should have low-dose aspirin (75 to 100 mg daily) added to the anticoagulant regimen (Bates et al, 2012). Women on warfarin who are planning a pregnancy should have frequent pregnancy tests and substitution of heparin or LMWH when pregnancy is achieved (Bates et al, 2012). Despite the ACCP presenting guidelines for the use of thrombotic agents during pregnancy, in general, pregnant patients with prosthetic heart valves should be managed by an anticoagulation specialist and perinatologist (Bates et al, 2012).

Prevention of Myocardial Infarction

Results of clinical trials have shown that several protocols are effective in prevention of MI in patients with and without chronic coronary artery disease. The ACCP presents a number of options for treatment in its guidelines (Guyatt et al, 2012). Patients over age 50 without symptomatic cardiovascular disease should be prescribed low-dose aspirin therapy (75 to 100 mg daily). Patients with established coronary artery disease, including those with 1-year post-acute coronary syndrome, with prior revascularization, coronary stenoses greater than 50% by coronary angiogram, and/or evidence for cardiac

ischemia on diagnostic testing, may be treated with aspirin (75 to 100 mg/day) or clopidogrel (75 mg/day) (Vandvik et al, 2012). Patients with acute coronary syndrome who have undergone percutaneous coronary intervention (PCI) with or without stent placement should be placed on dual antiplatelet therapy with 90 mg ticagrelor twice daily plus 75 to 100 mg aspirin daily (Vandvik et al, 2012). Clopidogrel 75 mg and low-dose aspirin may be used for patients who have undergone PCI, but the ACCP guidelines recommend the use of ticagrelor over clopidogrel (Vandvik et al, 2012).

Patients who have already experienced an acute MI (AMI) also need to be maintained on anticlot therapy. Patients who have AMI with ST-segment elevation (STEMI) are often treated acutely with fibrinolytics, then with ongoing therapy after hospital discharge. A number of options are available for post-AMI treatment. Patients with anterior AMI with risk for left ventricular thrombus (ejection fraction less than 40% or anteroapical wall motion abnormality) who do not get a stent are treated with warfarin (INR target 2.0 to 3.0) and 75 to 100 mg aspirin daily (Vandvik et al, 2012). Patients with an acute MI who have a bare-metal stent placed are treated with triple therapy consisting of warfarin (INR target 2.0 to 3.0), low-dose aspirin and 75 mg daily clopidogrel for a month after stent placement, then warfarin and one antiplatelet drug for months 2 and 3 after stent placement (Vandivik et al, 2012). After 3 months, warfarin can be discontinued and replaced with dual antiplatelet therapy (90 mg ticagrelor twice daily plus 75 to 100 mg aspirin daily or 75 mg clopidogrel daily plus low-dose aspirin) for up to 12 months. The appropriate dose of medication for prevention of cardiovascular disease in diabetic patients is not yet clearly determined by evidence. The increased prevalence of cardiovascular morbidity and mortality and disturbances in coagulation in diabetes patients leads to a recommendation of 75 to 162 mg/day aspirin in a joint statement by the American Heart Association, American Diabetes Association, and the American College of Cardiology (Pignone et al, 2010).

Vorapaxar received FDA approval in 2014, after the ACCP guidelines were published. Vorapaxar is approved for reduction of thrombotic cardiovascular events in patients

with a history of myocardial infarction or with peripheral arterial disease. The patient takes one 2.08 mg tablet daily in addition to aspirin or clopidogrel.

Prevention of Post-Operative Thromboembolism

All hospitals are required by the Joint Commission to have a formal, active strategy to prevent venous thrombosis. The ACCP recommends the use of LMWH, low-dose heparin, or fondaparinux as thromboprophylaxis in the following surgical procedures: moderate-risk major general surgery, higher-risk patients who are having a major procedure for cancer, major vascular surgery, major gynecological surgery, major urological procedures, bariatric surgery, thoracic surgery, and many orthopedic surgeries (Guyatt et al, 2012). The length of treatment is determined by the type of surgery, ranging from a single dose with minor procedures to 10 days for most orthopedic procedures, to 28 days in high-risk patients, patients undergoing major gynecological surgery, and patients having major surgery for cancer (Guyatt et al, 2012). Apixaban dose following hip or knee replacement surgery is 2.5 mg twice daily.

Perioperative Therapy of Patients on Warfarin or Antiplatelet Therapy

Patients who are having surgery should stop warfarin 5 days before surgery and resume 12 to 24 hours after surgery (Guyatt et al, 2012; Maddali et al, 2013). Patients on warfarin therapy for prevention of thromboembolism (mechanical heart valve, atrial fibrillation) who need an invasive procedure may require parenteral anticoagulation perioperatively. The decision to take a patient off warfarin and "bridge" with heparin is determined by balancing bleeding risk due to the surgical procedure and clotting risk due to the underlying disorder (Maddali et al, 2013). Patients who have procedures with a low bleeding risk (for example, skin biopsies, cataract eye surgery, and most dental procedures) can remain on warfarin. For patients undergoing dental procedures, tranexamic acid mouthwash can be used without interrupting anticoagulant therapy (Maddali et al, 2013). If a patient is at low thromboembolic risk (for example, atrial fibrillation without prior stroke or remote history of venous thrombosis), warfarin may be stopped 5 days prior to surgery and resumed the evening of surgery. If the patient is at high thromboembolic risk (for example, prosthetic heart valves), bridging with a therapeutic dose of LMWH or unfractionated heparin may be indicated (Guyatt et al, 2012).

In the hospital, patients can be placed on IV heparin that can be discontinued 4 to 6 hours before surgery; the SC route is stopped 24 hours before surgery (Guyatt et al, 2012). The ACCP recommends that antiplatelets not be discontinued before surgery, which is a change from previous recommendations to stop antiplatelet therapy a week before surgery (Guyatt et al, 2012).

Rational Drug Selection

Cost

Although SC administration of an anticoagulant (heparin) is usually a short-term measure, cost is still a significant factor. The difference in cost between heparin and the newer LMWHs is significant; the newer drugs are much more expensive. Enoxaparin (Lovenox) is $442 for ten 30 mg syringes ($206 for generic enoxaparin) and fondaparinux (Arixtra) is $905 for ten 2.5 mg syringes, whereas heparin is $26 for a 5 mL vial of 10,000 unit/mL solution, a 10-day supply at 5,000 units per dose. When the cost of laboratory monitoring is factored into the equation, the difference in cost between the LMWHs and regular heparin is less dramatic. Of all the drugs used to prevent clotting, aspirin is by far the cheapest.

Routes of Administration

Oral anticoagulation is preferred because it does not require specialized equipment or skills to administer, and it is less expensive. For patients who cannot swallow or for other reasons cannot take an oral anticoagulant, SC injections of heparin in either standard or low-molecular-weight formulation can be used. Patients or their family members must be taught correct techniques for SC administration.

Brand

Anticoagulant effects may vary slightly by brand. Because even small variances can cause significant differences in anticoagulation, brands should not be interchanged. Warfarin comes in a variety of tablet strengths, making it possible to be exact in dosing, and it is the preferred oral anticoagulant. The tablets are color coded by dose, which also makes it easier to be certain the patient takes the correct dose, especially if the dose is prescribed over the telephone. LMWHs are not interchangeable. There is only one brand name for each, but the patient cannot be changed from one drug to another, as their actions and indications vary. The same is true for the antiplatelets.

Monitoring

Monitoring for dosage adjustments of warfarin is by INR blood tests. Daily INRs are done initially to guard against excessive anticoagulation in unusually sensitive patients and are continued until the therapeutic range is achieved and maintained for at least 2 consecutive days. The testing interval is then lengthened to 2 or 3 times weekly for 1 or 2 weeks, then less often, depending on the stability of the INR results. If the INR results remain stable, testing is reduced to as seldom as every 6 weeks. Drawing the blood in the morning with the patient taking the drug in the evening provides more stable results and allows rapid dosage changes if necessary.

Point-of-care patient self-testing is now possible with a variety of machines. The feasibility and accuracy of patient self-testing at home has been evaluated in several small studies with promising results. Such self-testing with associated self-management provides increased freedom for the patient, especially if they travel. The ACCP guidelines recommend patients who are on warfarin may use self-testing for monitoring INR if the patient can demonstrate competency in using the equipment (Guyatt et al, 2012).

Computer-assisted, validated, decision-support tools for warfarin dose regulation has been shown to be more effective than traditional dosing at maintaining therapeutic INR values (Holbrook et al, 2012). A systematic approach that includes evidence-based dosing tools, patient education, follow-up, and optimal patient communication have the best patient

outcomes. Many health systems have anticoagulant clinics that manage patients on anticoagulant therapy, leading to optimal outcomes for the patient.

Protocols for dosage adjustments vary, but to maximize safety and avoid wide swings in anticoagulation, 10% changes in weekly doses are best unless the INR is widely out of range. If the INR is too low, the total weekly dose is adjusted upward by 10% and the INR is rechecked in 2 weeks. If the INR is too high, the daily dose is held for 1 day and then the weekly dose is adjusted downward by 10% and the INR is rechecked in 2 weeks. If the INR is above therapeutic range but less than 5, the patient is not bleeding, and rapid reversal is not indicated for surgical intervention, then one dose can be omitted and daily INRs are drawn. Warfarin is then resumed at a lower dose when the INR is within therapeutic range. If the INR is greater than 4.5 but less than 10 and the patient is not bleeding, routing use of vitamin K is no longer recommended (Holbrook et al, 2012). When INR results are greater than 10 but with no serious bleeding, then 3 to 5 mg of vitamin K may be given orally, anticipating that the INR will fall within 24 to 48 hours. For serious bleeding, vitamin K should be given by slow IV infusion in a dose of 5 to 10 mg, supplemented with four-factor prothrombin complex concentrate (Holbrook et al, 2012). If the INR has frequent variability, external reasons, such as dietary changes, undisclosed drug use, poor adherence, and intermittent alcohol consumption, are evaluated, and the INR is drawn daily or weekly until a stable INR is reached. Once a stable dose is reached, monitoring may be done every 3 months.

Pharmacogenetic testing is not routinely recommended when starting warfarin therapy (Holbrook et al, 2012). If the patient's genotype is known, those with a CYP 2C9 or VKORC1 gene variant may require 2 to 4 weeks longer to reach target INR.

Monitoring for dosage adjustment of heparin is by aPTT blood tests. The goal of therapy is 1.5 to 2.5 times the control. Platelet counts and hematocrit (Hct) are done every 2 or 3 days initially. Thrombocytopenia tends to occur about the fourth day and resolves despite continued heparin therapy. Thrombocytopenia severe enough to require discontinuing therapy may occur about the eighth day of therapy. After this time, periodic testing of platelet and Hct levels and testing for occult blood in the stool are done during the course of heparin therapy regardless of the route of administration. Low doses of SC heparin (5,000 U bid) do not require monitoring because this regimen does not prolong the aPTT.

For the LMWHs, the same periodic monitoring of platelet and Hct levels is required, but the likelihood of thrombocytopenia is much less. The recommended test for monitoring these drugs is anti-factor Xa assay. A standard curve is constructed for each different LMWH preparation. Although the aPTT may be prolonged in patients on LMWH, it does not reliably reflect their activity. In general, routine monitoring of factor Xa is not recommended, except in pregnant patients.

The dose of aspirin for antiplatelet therapy is low to moderate. The serum salicylate level is approximately 100 mcg/mL. At low doses, no specific monitoring is required, although aspirin will prolong bleeding time. Clopidogrel has a safety profile similar to that of aspirin and no routine monitoring is required.

Severe neutropenia and thrombocytopenia have occurred with the administration of ticlopidine. The onset of these problems occurred 3 weeks to 3 months after the start of therapy, with no documented cases beyond that time. It is essential that complete blood counts (CBCs) and white blood cell (WBC) differential counts be performed every 2 weeks, starting from the second week to the end of the third month of therapy. More frequent monitoring is necessary for patients whose absolute neutrophil counts consistently decline or are 30% lower than baseline counts. After the first 3 months of therapy, CBCs are needed only for patients with signs or symptoms suggesting an infection.
