Anticoagulants should be taken exactly as prescribed, at the same time each day, even if the patient is feeling well. Missed doses should be taken as soon as remembered the same day. Doses should not be doubled. The health-care provider should be informed of missed doses at the time of checkup or laboratory tests. Doses are highly individualized and are determined by the results of laboratory tests (INR for oral anticoagulants; aPTT, platelet counts, and Hct for heparin; and anti-factor Xa assays for LMWHs). Patients should not change the dose unless directed to do so by the health-care provider and should have the laboratory tests drawn each time they are ordered. If self-testing of INR is warranted, patients should be taught and demonstrate competence in accurately self-monitoring.

Differences in anticoagulation effect can occur between brands. The drug is prescribed by brand name and should be consistently filled that way. Warfarin tablets are color coded by dose, and patients should learn the color code for the brand used. For the heparins, which are injectable, the patient or a family member must be taught correct SC injection technique.

Oral anticoagulants may be taken without regard to timing of food intake. The type of food, however, is important. Ingestion of large quantities of foods high in vitamin K may antagonize the anticoagulant effect. This does not mean that these foods must be avoided entirely. They are part of a well-balanced diet. They should be eaten in consistent amounts so that anticoagulation levels can be maintained at a consistent level. Patients should be given written information regarding vitamin K content of common foods. The U.S. Department of Agriculture (USDA) has an extensive handout on vitamin K content in many common foods that is available on the Internet (www.nal.usda.gov/fnic/foodcomp/Data/SR17/wtrank/sr17w430.pdf). Some patients may need a nutrition consultation to manage their diet. Drug interactions may also occur with some over-the-counter (OTC) drugs, particularly aspirin, NSAIDs, and cold remedies that contain these products, and with alcohol. Many drugs are also prepared in an alcohol base. Some multivitamins contain vitamin K and should not be taken. The patient should consult with the primary care provider or pharmacist before taking any OTC medications or new prescription medications.

Some natural products, including some used as spices in cooking, have interactions with LMWHs and clopidogrel (see Table 18-2). Patients should be taught to avoid use of these

products or to use them in consistent amounts. They should also inform their health-care provider if they use them, because that may affect monitoring test results.

Clopidogrel should not be taken with proton pump inhibitors (PPI), such as OTC omeprazole (Prilosec OTC), because the PPI decreases the effectiveness of the clopidogrel.

Adverse Reactions

Unusual bleeding is the most common adverse effect for all anticoagulants. To prevent bleeding, the patient should use a soft toothbrush, avoid flossing, shave with an electric razor, and if cut, apply pressure for 5 to 10 minutes. If the bleeding does not stop, the patient should continue the pressure and contact the health-care provider. Whenever possible, IM injections should be avoided. If they must be given, apply pressure to the injection site for 2 to 5 minutes to prevent bleeding or hematoma formation. Applying ice to the site of an SC injection for about 30 seconds prior to injecting the heparin reduces the chances of bleeding and hematoma formation. The following should be reported to the health-care provider:

1. Any bleeding that does not stop within 5 minutes
2. Nosebleeds and bleeding gums
3. Red- or pink-tinged urine
4. Faintness or weakness
5. Headaches
6. Stomach pains
7. Skin rash or unusual bruising
8. Red, black, or tarry stools or diarrhea

Warfarin is contraindicated in pregnancy. This topic should be discussed with women who are capable of becoming pregnant, and contraception should be instituted before prescribing this drug.

To reduce the risk of adverse reactions, the patient should wear an identification bracelet that states the anticoagulant being taken. Inform all health-care providers about the anticoagulation therapy so that new prescriptions and any treatments can take it into account. The patient should consult the health-care provider before undergoing dental work or elective surgery.

Patient Education: Antiplatelets

Administration

Daily dosing is the usual way aspirin is taken for antiplatelet effects. Taking it with a full glass of water reduces the risk of the drug dissolving in the esophagus, causing irritation. If aspirin causes GI upset, it should be taken with food or after meals. Enteric-coated forms of aspirin are available and may be better tolerated by some patients. Patients taking enteric-coated aspirin require instruction that tablets should not be crushed or chewed. Aspirin is also available in a buffered form (Bufferin), which is aspirin buffered with calcium carbonate, magnesium carbonate, and magnesium oxide for those who have GI upset. For patients who have difficulty in swallowing, liquid forms are available. Aspirin that has a strong vinegar-like odor should not be used.

Ticlopidine may also cause GI upset and ought to be taken with a full glass of water and with food or after meals.

Adverse Reactions

In some patients toxicity to aspirin may occur even with small doses; they should immediately report to the health-care provider ringing in the ears (tinnitus), unusual headache, hyperventilation, agitation, mental confusion, lethargy, diarrhea, or sweating.

For ticlopidine, a decrease in the number of WBCs can occur, especially during the first 3 months of therapy. A severe decrease can increase risk for infection. Patients should obtain scheduled blood tests to detect reduced WBCs and report to the health-care provider any indications of infection, such as fever, chills, or sore throat. Ticlopidine can also affect liver function. Patients should promptly report severe or persistent diarrhea, skin rashes, yellow skin or sclerae, dark urine, or light-colored stools.

Unusual bleeding is the most common adverse effect of drugs that inhibit platelets, including aspirin, clopidogrel, ticlodipine, and ticagrelor. To prevent bleeding, the patient should use a soft toothbrush, avoid flossing, shave with an electric razor, and if cut, apply pressure for 5 to 10 minutes. They should also inform health-care providers, including dentists, that they are taking these drugs before any surgery or procedure is scheduled or any new drug is prescribed.

HEMATOPOIETIC GROWTH FACTORS

Hematopoietic growth factors are glycoprotein hormones that regulate the proliferation and differentiation of hematopoietic progenitor cells in bone marrow. Produced by recombinant DNA technology, these factors include erythropoietin, granulocyte colony–stimulating factor (G-CSF), granulocyte-macrophage colony–stimulating factor (GM-CSF), and thrombopoietic growth factor. Anemias due to deficiency in erythropoietin, such as those found in patients with end-stage renal disease or AIDS or patients undergoing chemotherapy; infections associated with myelosuppressive chemotherapy, myeloid cancers, and AIDS; and thrombocytopenia associated with all of these are among the most refractory to treatment. The introduction of these growth factors has made effective treatment possible. Erythropoietin is indicated for anemic patients (hemoglobin greater than 10 to less than or equal to 13 g/dL) with normal erythropoietin levels who wish to donate their own blood before high-risk, elective, noncardiac, nonvascular surgery for allogenic transfusions. G-CSF is used for neutropenic patients, particularly those with neutropenia caused by bone marrow transplant and some blood cancers (Sieff, 2012).

Pharmacodynamics

Stem cells in the hematopoietic bone marrow respond to various colony-stimulating factors; megakaryocyte stimulators; and erythropoietin to produce mature WBCs, platelets, and erythrocytes. Erythrocyte differentiation proceeds from erythroblasts through normoblasts to reticulocytes and finally to mature erythrocytes, based on stimulation from

erythropoietin, with additional support from GM-CSF and in-terleukin-3 (IL-3). Granulocytes (neutrophils, eosinophils, and basophils/mast cells) are fully matured in the bone marrow by stimulation from G-CSF, GM-CSF, and IL-3. The agranulo-cytes (monocytes and lymphocytes) are produced by the stim-ulation from GM-CSF, IL-3, and macrophage colony–stimulating factor (M-CSF) and are released into the blood-stream before they mature. Monocytes become mature macrophages within 1 or 2 days, and lymphocytes travel to the lymphoid tissues, where they are stimulated to differentiate into T cells or B cells. Platelets develop from megakaryocytes by a unique process of proliferations termed endomitosis. In this process, the megakaryocyte undergoes the nuclear phase of cellular division but fails to undergo the cytoplasmic phase. Without cytokinesis, the cell does not divide into two daughter cells. Rather, the megakaryocyte expands to accommodate the doubling of its DNA content and breaks up into platelets. Op-timal numbers of platelets and their precursors in the bone marrow are maintained by the actions of thrombopoietin, GM-CSF, and IL-11 (McCance & Huether, 2010). The development of these blood cells is shown in Figure 18-2 with the controlling factor indicated.

Endogenous erythropoietin is produced by the normal kidney in response to tissue hypoxia. In anemia, more eryth-ropoietin is produced, signaling the bone marrow to produce more erythrocytes. Unless a patient has an iron deficiency, a primary bone marrow disorder, or bone marrow suppres-sion from drugs and chronic disease, this stimulation of ery-throcyte production corrects the anemia. In addition to iron, erythropoiesis is dependent on sufficient amounts of vitamin B_{12} and folic acid. In end-stage renal disease, the kidney is unable to produce the erythropoietin necessary for the stim-ulation of erythrocyte growth. Epoetin alfa (Epogen, Eprex, Procrit) and darbepoetin alfa (Aranesp) have the same bio-logical effects as erythropoietin. Endogenous colony-stimu-lating factors respond to decreased leukocyte counts or the presence of infection to signal the production of leukocytes. G-CSF is lineage specific, supporting the proliferation and differentiation of neutrophils. GM-CSF is multipotential, stimulating proliferation and differentiation of early and late granulocyte progenitor cells, as well as erythroid and megakaryocyte progenitors. Filgrastim (Neupogen) and peg-filgrastim (Neulasta) have the same biological effects as G-CSF. Sargramostim (Leukine) has the same biological effect as GM-CSF.

Low platelet mass activates thrombopoietin (TPO), a human growth factor, increasing the number of megakary-ocytes. IL-11 is a thrombopoietic growth factor that directly stimulates the maturation of megakaryocytes. The biological effects of oprelvekin (Neumega) are the same as those of thrombopoietin and IL-11.

Pharmacokinetics

Absorption and Distribution

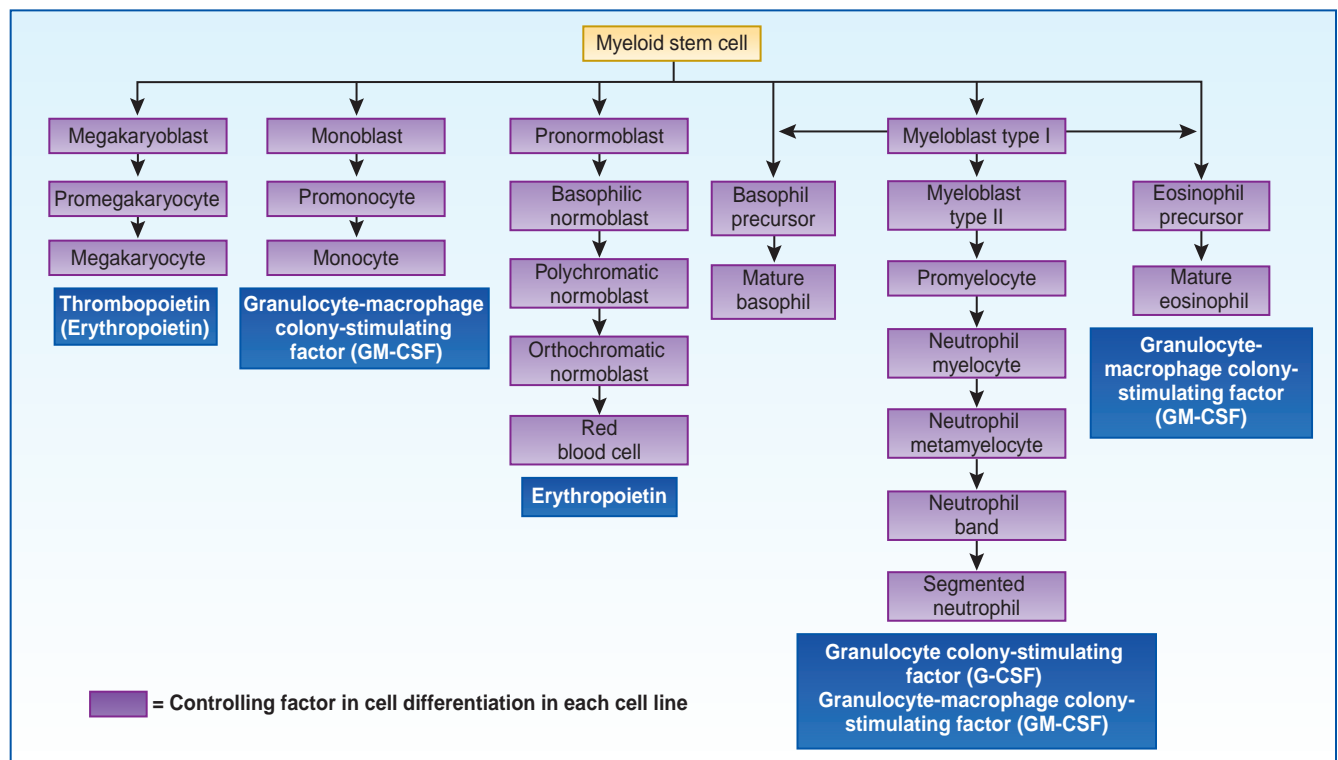
All hematopoietic growth factors are well absorbed following SC injection. Some can be given IV. Their distribution is sim-ilar to that of their endogenous equivalents (Table 18-5).


Figure 18–2. Development of blood cells.

Table 18–5 ⊞ Pharmacokinetics: Hematopoietic Growth Factors

Drug	Onset	Peak	Duration	Half-Life
Darbepoetin	2–6 wk (increase in reticulocytes)	34–90 h	UK	49 h (SC); 21 h (IV)
Epoetin alfa	7–10 d (increase in reticulocytes)	5–24 h	>24 h	4–13 h in chronic renal failure (about 20% shorter in healthy patients)
Filgrastim	–	2–8 h	–	3.5 h
Oprelvekin	5–9 d (increase in platelets)	3.2 h	7–14 d	6.9 h
Pegfilgrastim	–	2–8 h	–	15–80 h (SC)
Sargramostim	–	1–3 h	12 h	1.6–2.6 h

*Increase in reticulocytes.

Metabolism and Excretion

Darbepoetin alfa has a circulating half-life of about 49 hours post-SC injection. Following IV administration, the serum concentration is biphasic, with a distribution half-life of 1.4 hours and a mean terminal half-life of 21 hours. Epoetin alfa has a circulating half-life of 4 to 13 hours in patients with chronic renal failure (CRF). There is no apparent difference in half-life for patients on or not on dialysis. The half-life is about 20% shorter in healthy patients. Filgrastim has an elimination half-life of 3.5 hours in healthy patients and those with cancer. Oprelvekin has a half-life of 6.9 hours. Pegfilgrastim has a half-life of 15 to 80 hours. Sargramostim has a half-life after SC injection of 2.6 hours. All are eliminated by first-order kinetics. The exact method of metabolism and excretion is unknown in most of these drugs, with some elimination thought to occur in the kidneys.

Pharmacotherapeutics

Precautions and Contraindications

The only contraindication for darbepoetin alfa and epoetin alfa is uncontrolled HTN; increases in erythrocyte production may also be accompanied by increases in extracellular fluid (ECF) volume, which can increase blood pressure. Up to 80% of patients with CRF have HTN, which should be controlled before a patient starts therapy with these drugs and carefully monitored during such therapy. During early phases of therapy, when the Hct is increasing, about 25% of patients with CRF require initiation of or increases in antihypertensive therapy.

The FDA issued a safety announcement regarding the use of erythropoiesis-stimulating agents (ESAs) in February 2010. The FDA is requesting the manufacturers of ESAs to develop a risk-management plan regarding the increased risk of tumor growth and shortened survival in patients with cancer who receive these products. The FDA instituted a Risk Evaluation and Mitigation Strategy (REMS) requiring that all patients have the risk and benefits of ESAs explained before prescribing. The manufacturers of erythropoiesis-stimulating drugs (ESAs) implemented the ESA APPRISE (Assisting Providers and cancer Patients with Risk Information for the Safe use of ESAs) Oncology Program for health-care providers to use to inform patients of the risks associated with ESAs (www.esa-apprise.com).

Darbepoetin and epoetin alfa are Pregnancy Category C. Adverse effects have occurred in rats, and no adequate and well-controlled studies have been conducted in pregnant women. The drugs should be used only if the potential benefit clearly outweighs the risk to the fetus. Contraception may be appropriate prior to initiating therapy. Some women's menses have resumed after therapy with these drugs. Whether the drugs are excreted in breast milk is unknown. Caution is advised in prescribing to lactating women. Safety and efficacy have not been established in children.

The only contraindication for filgrastim and pegfilgrastim is hypersensitivity to *Escherichia coli*–derived proteins because this drug is derived from DNA manipulation of *E. coli*. Filgrastim and pegfilgrastim are Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. Adverse effects have been shown in studies of pregnant animals. These drugs should be used only if the potential benefit clearly outweighs the risk to the fetus. Contraception may be appropriate prior to initiating therapy. Whether these drugs are excreted in breast milk is unknown. Caution is advised in prescribing to lactating women.

Serious long-term risks associated with daily filgrastim have not been identified in children aged 4 months to 17 years with severe chronic neutropenia. The safety and efficacy in neonates and patients with autoimmune neutropenia have not been established. Safety and efficacy have not been established in children for pegfilgrastim. The 6 mg fixed-dose syringe formulation should not be used in infants, children, and adolescents weighing less than 45 kg.

Contraindications to sargramostim include excessive leukemic myeloid blasts in the bone marrow and known hypersensitivity to the product or to yeast-derived products. Occasional transient supraventricular arrhythmias have occurred, especially with patients who have a history of cardiac arrhythmias. Use with caution for patients with such a history. Sequestration of granulocytes in the pulmonary circulation with occasional dyspnea has occurred, especially in patients with preexisting lung diseases. Administer with

caution to patients with hypoxia. Fluid retention has occurred in a few patients. Use with caution for patients with preexisting fluid retention, pulmonary infiltrates, or congestive heart failure.

The only contraindication to oprelvekin is hypersensitivity to that drug. Fluid retention has occurred with this drug and a diuretic may be needed. Use with caution in patients with clinically evident congestive heart failure, patients receiving aggressive hydration, and patients who have a history of heart failure. In clinical trials, atrial arrhythmias occurred in 15% of the patients, especially with patients who have a history of cardiac arrhythmias. The rhythm stopped when the drug was stopped but recurred on rechallenge. This adverse effect may be related to fluid retention. Use with caution for patients with such a history.

Oprelvekin is Pregnancy Category C. Adverse effects were noted in animal studies and there are no adequate, well-controlled studies in pregnant women. Use only if the potential benefit clearly outweighs the risk to the fetus. Contraception may be appropriate prior to initiating therapy. It is not known whether this drug is excreted in breast milk. Caution is advised in prescribing to lactating women.

There are no controlled trials that have established a safe and effective dose of oprelvekin in children. The administration of this drug to children, particularly under age 12, should be reserved for clinical trials with closely monitored safety assessments. Limited data are available from one clinical trial for pediatric patients receiving 50 mcg/kg per day. Adverse effects in this study were the same as for adults. No studies have been done to assess the long-term effects of its use on growth and development. Animal studies have shown bone and joint changes.

Sargramostim is Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used only if the potential benefit clearly outweighs the risk to the fetus. Contraception may be appropriate prior to initiating therapy. Whether this drug is excreted in breast milk is unknown. Caution is advised in prescribing to lactating women. Safety and efficacy in children have not been established.

Adverse Drug Reactions

Seizures have been observed in some patients being treated with darbepoetin alfa and epoetin alfa (2.5% of patients undergoing dialysis during the first 90 days of therapy). The relationship with seizure is uncertain, and the risk appears to lessen when the rate of increase in Hct is slower. Recommendations are that the dose be decreased if the hemoglobin (Hgb) increase exceeds 1 g/dL in any 2-week period.

The major adverse reaction is HTN. The risk is higher in patients with CRF, and the reaction is discussed in the Precautions and Contraindications section. Both of these drugs may increase the risk for cardiovascular events, especially thrombogenesis. The higher risk has, once again, been associated with rates of rise in Hgb, and the target level of Hgb should be less than 12 g/dL.

As mentioned above, the FDA has issued a safety warning regarding the use of ESAs, and decreased overall survival and/or increased risk of tumor progression has been reported in patients with breast, non–small-cell lung, head and neck, lymphoid, and cervical cancers. The FDA is requiring that all patients have the risk and benefits of ESAs explained to them before the provider prescribes. Updates on the FDA warning can be found at the FDA Web site (www.fda.gov).

Allergic-type reactions have developed with filgrastim on initial and subsequent treatment in fewer than 1 in 4,000 patients. Skin, respiratory, and cardiovascular systems common to most hypersensitivity reactions are typical. Administration of antihistamines, steroids, bronchodilators, or epinephrine resulted in resolution. Symptoms recurred in more than 50% of the patients who were rechallenged with this drug. Such allergic reactions have not occurred in clinical trials of peg-filgrastim. Adult respiratory distress syndrome (ARDS) has been reported in neutropenic patients with sepsis receiving filgrastim and is postulated to be related to an influx of neutrophils to the sites of inflammation in the lungs. Patients receiving pegfilgrastim are also at risk. If ARDS develops, these drugs should be discontinued.

The adverse reactions with oprelvekin were mild to moderate in severity, reversible with discontinuance, and mainly similar to those of placebo groups when the dose was 50 mcg/kg. Tachycardia, edema, dizziness, conjunctival hemorrhage, and neutropenic fever were observed.

Adverse reactions to sargramostim include headache and transient pruritic rashes. Hypersensitivity reactions are rare. Cardiovascular, respiratory, and fluid retention problems are discussed in the Precautions and Contraindications section.

All of the hematopoietic growth factors can produce bone pain from the stimulation of the bone marrow. This may require analgesia.

Drug Interactions

Drug interactions for all the hematopoietic growth factors are minimal (Table 18-6). Only those drugs such as lithium that may potentiate myeloproliferative effects require avoidance of concurrent use or cautious use. There are no drug interactions reported with darbepoetin alfa or oprelvekin.

Clinical Use and Dosing

Anemia Associated With Chronic Renal Failure

Darbepoetin alfa and epoetin alfa are the drugs of choice to elevate and maintain erythrocyte levels and decrease the need for transfusions. Patients both on dialysis and not on dialysis benefit equally. They are not intended for immediate correction of severe anemia because it takes 7 to 10 days to see increases in reticulocyte counts. The starting dose for epoetin alfa is 50 to 100 U/kg given SC 3 times weekly. Maintenance doses are based on individual responses, and adjustments are based on Hct levels. The starting dose for darbepoetin alfa is 0.45 mcg/kg SC once weekly. Dosage adjustments are made no more frequently than once a month, because it takes that long to see increases in blood values. Table 18-7 shows guidelines for dosage adjustments for both drugs. Dosage

Table 18–6 ⚎ Drug Interactions: Hematopoietic Growth Factors

Drug	Interacting Drug	Possible Effect	Implications
Epoetin alfa	Heparin	May increase requirement for heparin anticoagulation during dialysis	Monitor aPTT carefully in dialysis patients
Filgrastim	Lithium	May potentiate the release of neutrophils	Drug interaction not fully studied; no recommendations at this time
Pegfilgrastim	Antineoplastic agents	Simultaneous use may have adverse effect on rapidly proliferating neutrophils	Avoid use 24 h before or 24 h after chemotherapy
Sargramostim	Lithium	May potentiate myeloproliferative effects of sargramostim	Avoid concurrent use or use cautiously

Table 18–7 ⚎ Dosage Schedule: Hematopoietic Growth Factors

Drug	Indication	Initial Dose	Maintenance Dose
Darbepoetin alfa	Anemia in chronic renal failure	0.45 mcg/kg SC once weekly	Individualized; goal Hgb is 12 g/dL; as goal is approached the dose is reduced by 25%. If Hgb continues to increase, doses are withheld until it begins to drop. Then drug is restarted at a dose about 25% below previous dose. If Hgb increase is <1 g/dL over 4 wk, and iron stores are adequate, dose may be increased by 25%. Further increases made at 4 wk intervals.
	Cancer patients receiving chemotherapy	2.25 mcg/kg SC once weekly	Individualized to target Hgb. If <1 g/dL increase in Hgb after 6 wk of therapy, increase dose to 4.5 mcg/kg. If Hgb exceeds 12 g/dL, reduce dose by 25%. If Hgb exceeds 13 g/dL, withhold dose until Hgb ≤12 g/dL. Restart at dose 25% below previous dose.
Epoetin alfa	Anemia in chronic renal failure	50–100 U/kg 3 times weekly	Individualized; reduced dose when hematocrit (Hct) approaches 36% or increases >4 points in any 2 wk period. Increase dose if Hct does not increase by 5–6 points after 8 wk of therapy and remains below target range of 30%–36%.
	Zidovudine-treated HIV-infected patients	100 U/kg 3 times weekly for 8 wk	Individualized; when the desired response is attained, titrate to maintain it. If response is too low, increase by 50–100 U/kg 3 times weekly. Evaluate response every 4–8 wk and adjust by 50–100 U/kg increments. If response is too low at 300 U/kg, response is unlikely. If Hct exceeds 40%, stop dose until Hct is 36%, then resume treatment with a dose reduced by 25%.
	Cancer patients on chemotherapy	150 U/kg 3 times weekly	If response is too low after 8 wk, increase dose up to 300 U/kg 3 times weekly; higher doses are not likely to produce a response. If Hct exceeds 40%, or increases >4% in any 2 wk period, stop dose until Hct is 36%, then resume treatment with a dose reduced by 25%.
	Presurgery	300 U/kg/d *or*	Given 10 d prior to surgery, day of surgery, and for 4 d after surgery
		600 U/kg once weekly	Given 21, 14, and 7 d prior to surgery and then day of surgery
Filgrastim	Myelosuppressive chemotherapy	5 mcg/kg/d no earlier than 24 h after or 24 h before next dose of chemotherapy	Dose given daily for up to 2 wk. Discontinue therapy if ANC >10,000 mm³ after expected nadir of chemotherapy
	Severe chronic neutropenia: Congenital cyclic/idiopathic	6 mcg/kg twice daily 5 mcg/kg daily	Individualized; reduce dose if ANC persistently >10,000 mm³
Oprelvekin	Myelosuppressive chemotherapy	50 mcg/kg SC once daily; 6–24 hours after completion of chemotherapy	Continue dosing until the postnadir platelet count is ≥50,000 mcL. Dosing beyond 21 d is not recommended
Pegfilgrastim	Myelosuppressive chemotherapy	Single injection of 6 mg SC administered once per chemotherapy cycle	Do not give between 14 d before and 24 h after administration of cytotoxic chemotherapy

adjustments are not to be made more than once monthly, based on the time it takes for erythroid progenitors to mature and red blood cell (RBC) survival time.

Anemia Related to Zidovudine Therapy

Epoetin alfa is the drug of choice to elevate and maintain erythrocyte levels and decrease the need for transfusions when the endogenous erythropoietin level is 500 mU/mL or less and the dose of zidovudine is 4,200 mg/week or less. The initial dose is 100 U/kg SC 3 times weekly for 8 weeks. Maintenance doses are based on individual responses, and adjustments are based on Hct levels. Table 18-7 shows the general guidelines for dosage adjustments. Dosage adjustments are timed as noted previously.

Anemia in Patients With Cancer on Chemotherapy

Darbepoetin alfa and epoetin alfa are drugs used to elevate and maintain erythrocyte levels and decrease the need for transfusions. The initial dose of darbepoetin is 2.25 mcg/kg SC once weekly for darbepoetin alfa or 500 mcg once every 3 weeks; and of epoetin alfa it is 150 U/kg given SC 3 times weekly or 40,000 U weekly for epoetin alfa. Patients with lower baseline serum erythropoietin levels tend to respond more vigorously to this drug. Treatment is not recommended for patients with serum erythropoietin levels below 200 mU/mL. Dosage adjustments are made after 6 weeks for darbepoetin alfa and after 8 weeks of therapy for epoetin alfa. Table 18-7 shows the general guidelines for dosage adjustments. Dosage adjustments are timed as noted previously.

Decreasing Blood Transfusions in Surgery Patients

Anemic patients (hemoglobin greater than 10 g/dL and less than 13 g/dL) scheduled to undergo elective, noncardiac, nonvascular surgery, with anticipated significant blood loss, benefit from epoetin alfa therapy to reduce the need for allogeneic blood transfusions. The recommended dose is 300 U/kg a day SC for 10 days prior to surgery, on the day of surgery, and for 4 days after surgery. An alternative dosing schedule is 600 U/kg once weekly at 21, 14, and 7 days before surgery, plus a fourth dose on the day of surgery. All patients on these regimens must receive adequate iron supplementation, beginning no later than the start of the epoetin therapy and continuing throughout the therapy. Prophylactic anticoagulant therapy is recommended for patients receiving epoetin alpha perioperatively.

Patients on Myelosuppressive Therapy

Filgrastim, pegfilgrastim, and sargramostim have been used for this indication. It is an off-labeled use for sargramostim. The recommended starting dose for filgrastim is 5 to 10 mcg/kg a day given as a single dose SC. Dosage adjustments are based on CBC and platelet data and are done in increments of 5 mcg/kg per day, according to the duration and severity of the absolute neutrophil count (ANC) nadir. It is given daily for up to 2 weeks until the ANC has reached 10,000 mm [3]. Clinical trials have shown effective doses to be 4 to 8 mcg/kg a day. Pegfilgrastim is given as a once-only dose of 6 mg beginning 24 to 72 hours after completion of each chemotherapy cycle. Sargramostim is started at least 24 hours after chemotherapy, dosed lower when starting therapy and gradually increased to avoid first-dose reaction (respiratory distress, hypoxia, flushing, syncope, and tachycardia). The initial dose is 125 to 250 mcg/m ^{2}/day daily for 21 days.

Severe Chronic Neutropenia

Severe chronic neutropenia (SCN) can be congenital, cyclic, or idiopathic. Chronic administration of filgrastim reduces the incidence and duration of sequelae of neutropenia, such as fever, infection, and oropharyngeal ulcers. The initial dose for congenital SCN is 6 mcg/kg twice daily SC. For cyclic or idiopathic SCN, the initial dose is 5 mcg/kg every day. Dosage adjustments are based on the patient's clinical course and ANC.

Prevention of Severe Thrombocytopenia

Oprelvekin is used for prevention of severe thrombocytopenia and reduced need for platelet transfusion post-myelosuppressive therapy. Adults are prescribed a dose of 50 mcg given as one dose 6 to 24 hours after the completion of chemotherapy and continued on a daily basis until the postnadir platelet count is above 50,000. Dosing duration is between 10 and 21 days and dosing beyond 21 days is not recommended.

Other indications for the use of these drugs, including bone marrow transplant, are beyond the scope of this book.

Rational Drug Selection

The drug choice is based on its indication because each drug has very specific uses.

Monitoring

Monitoring parameters are different for each drug and are discussed specific to that drug.

Darbepoetin Alfa

Hgb levels are determined weekly until they have stabilized and the maintenance dose has been established. After dosage adjustments, weekly Hgb levels are also drawn for at least 4 weeks until it has been determined that the Hgb has stabilized in response to the new dose. Hgb is then monitored at regular intervals. Iron status should also be evaluated before and during treatment, because the majority of patients will require supplemental iron. Supplemental iron is recommended when the serum ferritin is less than 100 mcg/L or the serum transferrin is less than 20%.

Epoetin Alfa

Patients with CRF not on dialysis require monitoring of blood pressure and Hct no less frequently than patients maintained on dialysis. Hct is monitored twice weekly until it is stabilized in the target zone and the maintenance dose has been established and then for at least 2 to 6 weeks after each dosage adjustment. Maintenance monitoring is individualized, based on patient stability. In some patients, increases in blood urea nitrogen (BUN), creatinine, uric acid, phosphorus, and potassium have been noted. These values are routinely monitored in patients with CRF and require no additional monitoring.

Patients on zidovudine therapy for HIV infection require monitoring of Hct weekly until it is stabilized. Periodic monitoring thereafter is based on the progression of the disease.

During therapy with epoetin alfa, absolute and functional iron deficiency may develop. Functional iron deficiency is presumed to be based on inability to mobilize iron stores rapidly enough to support increased erythropoiesis. Transferrin saturation should be at least 20%, and ferritin should be at least 100 mcg/mL. Prior to initiating therapy and at regular intervals during therapy, determine transferrin and ferritin levels. Virtually all patients at some point require supplemental iron. Delayed or diminished responses suggest referral to a hematologist. Possible common etiologies for patients who fail to respond or to maintain a response to doses within the recommended range for both darbepoetin alfa and epoetin alfa include the following:

1. Functional iron deficiency
2. Underlying infectious, inflammatory, or malignant disease
3. Occult blood loss
4. Underlying hematological diseases, such as thalassemia, refractory anemia, or myelodysplastic disorder
5. Vitamin B_{12} or folic acid deficiency
6. Hemolysis
7. Aluminum intoxication

Filgrastim

For patients on myelosuppressive chemotherapy, CBCs and platelet counts are done prior to initiating therapy and twice weekly during therapy. Following therapy, the same indicators are monitored around the time of the nadir of the chemotherapy. Filgrastim or pegfilgrastim therapy may be terminated when the ANC is 10,000 mm ^{3} or greater. For patients with SCN treated with filgrastim, CBCs with differential, platelet counts, and evaluation of bone marrow morphology and karyotype are done prior to initiating therapy. During the initial 4 weeks of therapy and for 2 weeks after any dosage adjustment, CBCs with differential and platelet counts are done. Once the patient is stable, monthly CBCs with differential and platelet counts are sufficient.

For oprelvekin, fluid balance needs to be monitored during dosing. If a diuretic is used, electrolyte balance may also need to be monitored. A CBC is drawn prior to chemotherapy and at regular intervals during therapy to monitor platelet counts. Monitoring continues during the time of expected nadir for the chemotherapy and until platelet counts are 50,000 or higher postnadir.

Patient Education

Administration

If the patient can safely and effectively self-administer these drugs, instruction is provided in correct SC injection technique and proper dosage (Table 18-8). Self-administration is common in patients with CRF. Detailed instructions on dilution and storage stability are included in the package insert.

Adverse Drug Reactions

HTN and allergic reactions are the two most common adverse reactions. Self-monitoring of blood pressure and signs and symptoms of an allergic reaction are taught.

IRON PREPARATIONS

Iron is an essential mineral in the production of Hgb, myoglobin, and a number of enzymes. Iron deficiency anemia results in problems with oxygen transport that affect the energy

Table 18–8 ✤ Available Dosage Forms: Hematopoietic Growth Factors

Drug	Dosage Form	Other Forms	Cost	
Darbepoetin alfa (Aranesp)	Solution for SC injection (in 1 mL single-dose vial): 25, 40, 60, 100, 150, 200, 300, and 500 mcg/mL		25 mcg = $124.69/vial 40 mcg = $199.50/vial 60 mcg = $299.25/vial 100 mcg = $498.75/vial 150 mcg = $748.13/vial 200 mcg = $997.50/vial	
Epoetin alfa (Epogen, Procrit)	Subcutaneous (in 1 mL single-dose vials): 2,000, 3,000, 4,000, 10,000, 20,000, 40,000 U/mL	—	*Epogen* $125.20/vial $269/vial $527.73/vial	*Procrit* $129.69/vial $259/vial $517/vial
Filgrastim (Neupogen)	Subcutaneous (in 1 and 1.6 mL single-dose vials; preservative-free): 300 mcg/mL	—	$202.50/1 mL vial $322.50/1.6 mL vial	
Oprelvekin (Neumega)	Powder for injection (in single-dose vial with diluent): 5 mg		No cost data	
Pegfilgrastim (Neulasta)	Solution for injection (in single-dose syringe with needle): 10 mg/mL		$2,850.56 for 6 mg/0.6 mL	
Sargramostim (Leukine)	Powder for injection (in vials): 250 mcg		No cost data	
	Liquid (in multidose vials): 500 mcg/mL			

metabolism of every cell in the body. Iron deficiency anemia is commonly seen in infants, particularly premature infants; in children during rapid growth periods; and in pregnant and lactating women. It may also occur after gastrectomy and with malabsorption disorders, particularly those of the small bowel. The most common cause in adults is blood loss. Menstruation may cause the loss of more than 30 mg of iron with each period. Occult blood loss may occur from GI bleeding and from cancer. In an attempt to replace blood lost, erythropoiesis may occur at an increased rate and increased iron may be used and drawn from storage. Prevention and treatment of iron deficiency anemia are accomplished by administration of supplemental iron.

Pharmacodynamics

Approximately 67% of total body iron is bound to heme in RBCs and muscle cells, and approximately 30% is stored bound to ferritin or hemosiderin mononuclear phagocytes and hepatic parenchymal cells. The remaining 3% is lost daily

> **On The Horizon**
>
> **INTERLEUKIN-3, STEM CELL FACTOR, AND MONOCYTE-MACROPHAGE COLONY–STIMULATING FACTOR**
>
> IL-3, stem cell factor, and monocyte-macrophage colony–stimulating factor are currently in clinical trials. **IL-3** would provide broad-based therapy because it is involved in the generation and stimulation of all progenitor cells. Stem cell factor would provide therapy at an even earlier stage in blood cell development. Monocyte-macrophage colony–stimulating factor would provide a targeted approach to patients who do not require such a broad stimulation of blood cell growth.

in urine, sweat, bile, and epithelial cells shed from the GI tract. Iron not lost is continuously recycled, as shown in Figure 18-3. Recycling is made possible by transferrin.

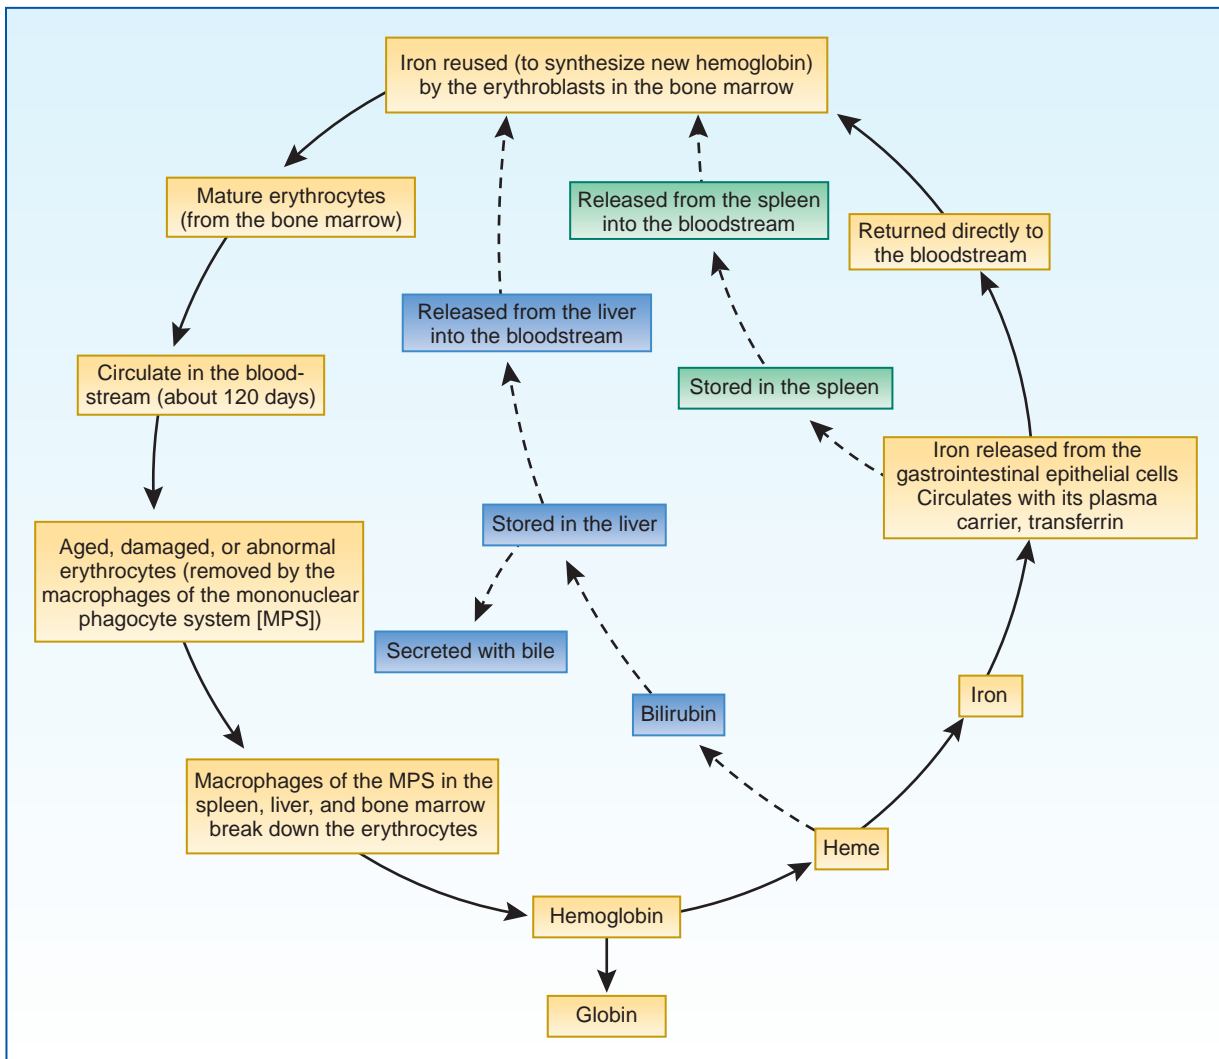
As iron deficiency develops, storage iron decreases and then disappears, followed by decreased serum ferritin and then serum iron. Finally, iron-binding capacity increases,


Figure 18–3. The iron cycle.

resulting in a decrease in transferrin saturation. At this point, anemia develops. Administration of iron reverses the process so that eventually not only is serum iron improved but also iron storage is replenished. Management of anemia is discussed in Chapter 27.

Pharmacokinetics

Absorption and Distribution

Only about 10% of the average daily dietary intake of iron is absorbed (1 to 2 mg/day) in patients with adequate iron stores. Absorption is enhanced in the presence of depleted iron stores and when erythropoiesis is increased. Iron is primarily absorbed in the duodenum and upper jejunum by an active transport mechanism. The ferrous form is absorbed 3 times more readily than the ferric form. The common ferrous forms (sulfate, gluconate, and fumarate) are absorbed almost on a milligram-for-milligram basis but differ in the amount of elemental iron each contains.

Factors that significantly affect absorption include sustained-release forms, dose, and the presence of food. Sustained-release or enteric-coated forms have less available iron because they transport the iron beyond the duodenum before it is released. As dose increases, the amount of iron absorbed increases, but the percentage of iron absorbed decreases. Food can decrease the absorption of iron by 40% to 66%, but gastric intolerance often requires administration with food. Concurrent administration of vitamin C may enhance absorption, but the literature is still controversial. Eggs and milk inhibit iron absorption.

Iron is transported via blood bound to transferrin. The transferrin–ferric iron complex is delivered to maturing erythroid cells, where transferrin receptors pick up and internalize the iron and release it within the cell.

Metabolism, Storage, and Excretion

Iron is stored as either ferritin or hemosiderin. Ferritin is more readily available and is water soluble. Hemosiderin is a particulate substance containing aggregates of ferric core crystals. Both are stored in macrophages in the liver, spleen, and bone marrow. Because the ferritin present in plasma is in equilibrium with stored ferritin, the plasma ferritin level can be used to estimate total-body iron stores.

There is no mechanism for excretion of iron. Iron is lost mainly through shedding of the GI mucosal cells, with small losses in urine, sweat, and bile. These losses total no more than 1 mg of iron per day. Because the body has no mechanism for excretion of iron, iron balance is achieved largely through control of the amount of iron absorbed in the gut.

Pharmacotherapeutics

Precautions and Contraindications

The only contraindications to the use of iron are hemochromatosis and hemolytic anemia. Tartrazine and sulfite are found in some iron formulations. Patients sensitive to them should not take these formulations.

Adverse Drug Reactions

GI symptoms are the most common adverse reactions and are usually mild. Irritation, anorexia, nausea and vomiting, constipation, or diarrhea may occur. Administering the iron with food reduces most of these problems. Stools may appear darker in color, which can present a problem in assessing GI bleeding. Iron-containing preparations may cause temporary staining of the teeth. Dilution of the drug reduces this problem.

Acute Toxicity

Acute iron toxicity is seen almost exclusively in children who have ingested many iron tablets. As few as 10 tablets of common oral iron preparations can be lethal in young children. Symptoms of iron toxicity occur in four stages:

1. Within 1 to 6 hours, lethargy, nausea, vomiting, abdominal pain, tarry stools, weak and rapid pulse, hypotension, acidosis, and coma occur.
2. If not immediately fatal, symptoms may subside for about 24 hours.
3. Symptoms return in 12 to 48 hours and may also include diffuse vascular congestion, pulmonary edema, shock, acidosis, convulsions, anuria, hyperthermia, and death.
4. If the patient survives, in 2 to 6 weeks, pyloric stenosis, hepatic cirrhosis, and central nervous system (CNS) damage may be seen.

Treatment involves maintaining airway, respiration, and circulation. Perform gastric lavage with 1% to 5% sodium bicarbonate to convert the ferrous sulfate to ferrous carbonate, which is poorly absorbed and less irritating. Systemic chelation with deferoxamine IM is recommended for patients with serum iron levels above 350 mcg/dL.

Drug Interactions

Drug interactions involve chelation (levodopa, penicillamine, quinolones) or competition for absorption (antacids, cimetidine, methyldopa, tetracyclines). Food interactions occur with vitamin C (enhances absorption) and calcium (decreases absorption unless calcium carbonate is used). Drug interactions are shown in Table 18-9.

Clinical Use and Dosing

Oral iron therapy is used to prevent and treat iron deficiency anemia. Because they are more efficiently absorbed, ferrous salts should be used. Sustained-release and enteric forms should not be used because iron is best absorbed in the duodenum and jejunum. Different ferrous salts provide different amounts of elemental iron. In an iron-deficient patient, about 50 to 100 mg of iron can be incorporated into hemoglobin daily. The adult dose for iron replacement is 150 to 300 mg of elemental iron daily in two or three divided doses to correct iron deficiency rapidly. About 25% of ferrous salt given orally can be absorbed. Premature neonates require 2 mg of elemental iron/kg/day orally until they are 12 months old (Baker, Greer, & the Committee on Nutrition, 2010). The American Academy of Pediatrics

Table 18–9 ▦ **Drug Interactions: Iron**

Drug	Interacting Drug	Possible Effect	Implications
Iron	Antacids	Absorption reduced	Separate administration by at least 2 h
	Ascorbic acid	Absorption enhanced	Increase may not be significant; must be given concurrently
	Calcium	Coadministration decreases absorption of both; calcium carbonate does not decrease iron absorption	Separate administration by at least 2 h or use calcium carbonate for calcium supplementation and take between meals
	Chloramphenicol	Serum iron levels may be increased	—
	Cimetidine	Absorption reduced	Separate administration by at least 2 h
	Levodopa	Forms chelates with iron salts, decreasing levodopa levels by up to 90%	Avoid concurrent use
	Methyldopa	Methyldopa absorption decreased	Avoid concurrent use
	Penicillamine	Marked reduction in penicillamine absorption	Avoid concurrent use
	Quinolones	Decreased absorption of quinolones by up to 90%	Choose different antibiotic
	Tetracyclines	Coadministration decreases absorption and serum levels of both by up to 90%	Separate administration by at least 2 h
	Vitamin C	Absorption enhanced	May not be significant and requires concurrent administration

recommends all breastfed infants receive 1 mg/kg/day of elemental iron beginning at age 4 months and continuing until the infant is consuming adequate iron-containing foods (Baker et al, 2010). Formula-fed infants do not need iron supplementation. Toddlers age 1 to 3 years need 7 mg/day ideally from iron-fortified foods. Toddlers who do not or are not able to ingest adequate iron in their diet can be supplemented with liquid or chewable iron (combined with multivitamins). Infants and young children require 4 to 6 mg/kg/day divided in three doses to treat severe iron deficiency and 3 mg/kg/day to treat mild to moderate iron deficiency. Doses for infants, children, and adults are provided in Table 18-10. If the patient cannot tolerate large doses, lower doses may be given, but resolving the deficiency takes longer. Treatment continues for 3 to 4 months after hemoglobin/hematocrit return to normal to correct the anemia and replenish iron stores.

Rational Drug Selection

Cost

Iron supplements are available OTC in generic form and are not very expensive. The most expensive ferrous sulfate is Fer-In-Sol, a liquid form used mostly for infants and small children.

Formulation

Ferrous salts come in tablets, capsules, suspensions, drops, and chewable formulations. Unless a patient's age or disease process makes swallowing difficult or impossible, the tablets are the cheapest, and they are easily digested and absorbed.

Monitoring

The reticulocyte count is measured 7 to 10 days after initiation of therapy because it is the first measurable response to iron therapy. A significant rise should be noted toward the normal 0.5% to 1.5% of the body's RBCs. Hemoglobin levels drawn at 2 weeks from initiation of therapy should indicate a rise in Hgb concentration of 0.1 to 0.2 g/100 mL per day of therapy. Normal Hgb levels of 14 to 18 g/dL in men and 12 to 16 g/dL in women should be reached in 1 to 3 months. Monitoring of RBC and Hgb levels thereafter is based on individual patient risk, response, and symptoms.

Patient Education

Prevention

Prevention of iron deficiency is the most important issue. The average American diet contains about 12 mg of iron daily. Twenty percent of this is absorbed in markedly deficient patients, but only 10% is absorbed in normal patients. This means that 0.6 to 1.2 mg of elemental iron is taken up under normal circumstances. This is an adequate requirement for men and postmenopausal women; however, menstruating women need 1.5 mg/day, and pregnant and lactating women need 2.5 mg/day. Eating iron-rich foods can prevent the need for iron supplements, especially in adults. Red meat is the best source of iron, but fish and iron-enriched breads and cereals are also good sources. The iron in eggs and green vegetables is not absorbed because it is bound to phosphates and phytates in these foods. Nutrition should be discussed, including iron-rich foods that are reasonable in cost. Most people who eat a balanced diet do not need iron supplements. Pregnant

Table 18–10 ⊗ Dosage Schedule: Iron

Drug	Indication	Dosage Form	Maintenance Dose
Iron	Replacement in iron-deficiency anemia		*Adults:*
Ferrous sulfate (20% elemental iron)		Ferrous sulfate: Tablets: 325 mg (65 mg elemental iron) Elixir: 220 mg/5 mL (44 mg iron/5 mL) Drops: 75 mg/0.6 mL (15 mg iron/0.6 mL) Feosol: Capsules: 325 mg (65 mg iron) FeroSul: Capsules: 325 mg (65 mg iron) Fer-In-Sol: Drops: 75 mg/0.6 mL (15 mg iron/0.6 mL) Fer-Gen-Sol: Drops: 75 mg/0.6 mL (15 mg iron/0.6 mL)	Ferrous sulfate 300–325 mg (60–65 mg of elemental iron) tid-qid Ferrous gluconate 300–325 mg (34–38 mg of elemental iron) qid Ferrous fumarate 200 mg (66 mg of elemental iron) tid-qid Ferrous fumarate 325 mg (106 mg elemental iron) bid-tid *Note:* Goal is 150–250 mg of elemental iron/d RDA: Male >18 yr: 10 mg/d Female 11–50 yr: 15 mg/d Female >50 yr: 10 mg/d
Ferrous sulfate (Dried)		Feosol: Tablet: 200 mg (65 mg iron) Feratab: Tablet: 300 mg (60 mg iron) Ferrous sulfate: Slow-release tablet: 160 mg (50 mg iron) Slow Fe: Slow-release tablet: 160 mg (50 mg iron)	*Children:* 2–12 yr: goal is 4 to 6 mg/kg/d of elemental iron in 3 divided doses. 6 mo–2 yr: goal is up to 6 mg/kg/d of elemental iron in 3 divided doses. RDA: <5 months: 5 mg/d 5 mo to 10 yr: 10 mg/d Males: 11 to 18 yr: 12 mg/d Females: 11 to 18 yr: 15 mg/d
Ferrous gluconate (12% elemental iron)		Ferrous gluconate: Tablet: 225 mg (28 mg iron) Fergon: Tablet: 225 mg (27 mg iron) Ferrous gluconate: Tablet: 300 mg (35 mg of iron); 324 mg (38 mg iron) Tablet: 325 mg (36 mg iron)	
Ferrous fumarate (33% elemental iron		Ferrous fumarate: Tablet: 90 mg (29.5 mg iron) Ferrous fumarate: Tablet: 324 mg (106 mg iron) Femiron: 63 mg (20 mg iron) Hemocyte: Tablet: 324 mg (106 mg iron) Ferrets: Tablet: 325 mg (106 mg iron) Nephro-Fer: Tablet: 350 mg (115 mg iron) Feostat: Chewable tablet: 100 mg (33 mg iron) Ferro-Sequels: Timed-release tablet: 150 mg (50 mg iron)	
Carbonyl iron (pure iron microparticles)		Feosol: Tablet: 45 mg iron Sundown tablet: 50 mg iron Ircon: Tablet: 66 mg iron Icar: Chewable tablet: 15 mg iron Suspension: 15 mg iron/1.25 mL	
	Iron supplement in pregnancy and lactation		30 mg elemental iron daily (not taken with meals)

women, infants, and children during rapid growth periods usually need iron supplementation.

Administration

Patients should take iron as directed. If a dose is missed, they should take it as soon as it is remembered within 12 hours but not double doses. Iron should be taken on an empty stomach. If GI upset occurs, iron can be taken with food, but the amount absorbed will be less. Taking it with vitamin C or citrus juice may enhance absorption. Patients should avoid taking iron at the same time as milk, antacids, tetracycline, or quinolones, which decrease absorption, and drink liquid iron preparations in water or citrus juice or through a straw to prevent discoloration of teeth. Do not use sustained-release preparations.

Adverse Responses

Constipation is the most common problem in patients taking iron. Increase fluids and fiber in the diet, especially iron-rich cereals. Stools may turn dark green or black. This color change is harmless. A stool softener may be used if needed to treat constipation.

Acute iron toxicity/poisoning can occur with an overdose. This is especially a problem with children, in whom as few as 10 of the commonly available iron tablets can be fatal. Patients should keep iron preparations in childproof containers and in a locked medicine cabinet and not refer to vitamins or drugs as candy. The local Poison Control Center should be contacted immediately if overdose is suspected.

Detailed discussion of the management of iron deficiency anemia as well as other forms of anemia is presented in Chapter 27.

FOLIC ACID

Folic acid deficiency is most often related to inadequate dietary intake of green vegetables or excessive boiling of these vegetables in cooking. Other sources of folic acid deficiency include impaired absorption because of ileal disease or phenytoin use; increased demand during pregnancy, hyperthyroidism, hemolytic anemia, or malignancy; and impaired utilization for patients taking methotrexate, triamterene, and trimethoprim.

Pharmacodynamics

Exogenous folate is required for nucleoprotein synthesis and maintenance of normal erythropoiesis. Folic acid stimulates the production of erythrocytes, WBCs, and platelets. Folic acid undergoes a series of oxidative-reductive changes that result in the formation of tetrahydrofolic acid, a cofactor in transformation reactions in the biosynthesis of purines and thymidylates. Impaired thymidylate synthesis is thought to be the mechanism behind neural tube defects in the offspring of pregnant women with folic acid deficiency. Within 3 months of inadequate intake of folates, megaloblastic changes and anemia can develop. Supplemental folic acid is useful in preventing folic acid deficiency in high-risk patients with high folate requirements, such as pregnant women, and in alcoholics and patients with liver disease, who may have deficient storage of folate.

Pharmacokinetics

Absorption and Distribution

Only about 50 to 200 mcg of folate are absorbed from the daily intake of 500 to 700 mcg in the average diet. Pregnant women may absorb as much as 300 to 400 mcg of folate daily. Oral folic acid supplements are well absorbed from the proximal jejunum, and IM or SC administration also results in excellent absorption.

Metabolism, Storage, and Excretion

Folic acid is converted by the liver to its active metabolite (dihydrofolate reductase). Approximately 5 to 20 mg of folate extensively bound to plasma proteins are stored in the liver and other tissues. Folates are excreted in the urine and stool and destroyed by catabolism so that serum levels fall within days when intake is inadequate.

Pharmacotherapeutics

Precautions and Contraindications

The only contraindication is administration when vitamin B_{12} is deficient. Folic acid in doses greater than 0.1 mg/day may mask the indications of pernicious anemia in that the hematological symptoms are gone, but the neurological symptoms continue to progress. Except in pregnancy and lactation, daily doses of folic acid should not exceed 0.4 mg/day until pernicious anemia has been ruled out.

Folic acid is Pregnancy Category A. Pregnant women are more prone to develop folic acid deficiencies, and their diet should be supplemented. The recommended dietary allowance (RDA) for folate during pregnancy is 0.4 mg/day.

Adverse Drug Reactions

Rare transient rashes are the only adverse drug reaction.

Drug Interactions

Sulfonamides, methotrexate, and triamterene interfere with the activity of folate reductase and prevent the activation of folic acid (Table 18-11). Absorption is decreased if it is given concurrently with sulfasalazine. Folic acid requirements are increased in the presence of estrogens, phenytoin, and glucocorticoids.

Clinical Use and Dosing

Anemia Due to Folic Acid Deficiency

After pernicious anemia has been ruled out, the initial dose is up to 1 mg/day in adults and children. When clinical symptoms have subsided and the laboratory studies have normalized, maintenance doses range from 0.1 mg/day for infants to 0.8 mg/day for pregnant and lactating patients. Table 18-12 shows these dosages by age group. Chapter 27 discusses the management of pernicious anemia.

Prevention of Folic Acid Deficiency

Maintenance doses of folic acid may be sufficient to prevent folic acid deficiency in these patients if the upper limit for each age is used. Doses of 0.4 mg prior to conception and throughout pregnancy have been associated with risk reductions of up to 50% for neural tube defects in the offspring. The U.S. Public Health Service recommends that all women of childbearing age who are capable of becoming pregnant consume 0.4 mg of folic acid daily. Because of the risks with higher doses of folic acid that B_{12} deficiency may be overlooked, total folate intake should not exceed 1 mg/day. Chapter 27 discusses the management of folic acid deficiency anemia with pregnancy considerations.

Folic Acid During Lactation

During lactation, folic acid requirements are markedly increased. Mothers who are breastfeeding and have folic acid deficiency require doses of 0.8 mg/day to prevent folic acid deficiency in their infants.

Table 18–11 ⚏ **Drug Interactions: Folic Acid**

Drug	Interacting Drug	Possible Effect	Implications
Folic Acid	Aminosalicylic acid	Decreased serum folate levels	Avoid concurrent use
	Oral contraceptives	May impair folate metabolism and produce folate depletion, but the effect is mild and not likely to cause anemia	Monitor for clinical indications of anemia
	Sulfonamides	Prevent the activation of folic acid by causing a dihydrofolate reductase deficiency	Avoid concurrent use
	Methotrexate	Signs of folate deficiency have been reported	Monitor for indications of anemia
	Triamterene		
	Sulfasalazine		
	Hydantoins	An increase in seizure activity and a decrease in serum concentrations of the hydantoin to subtherapeutic levels Phenytoin may cause a decrease in serum folate levels, but clinically important anemia occurs in <1% of patients on long-term therapy	If folic acid is administered, a higher dose of phenytoin may be needed

Table 18–12 ⚛ **Dosage Schedule: Folic Acid**

Drug	Indication	Initial Dose	Maintenance Dose
Folic acid	Treatment of megaloblastic anemia	Up to 1 mg/d until laboratory studies are normal	*Infants:* 0.1 mg/d *Children <4 yr:* 0.3 mg/d *Adults and children >4 yr:* 0.4 mg/d Pregnant and lactating women, patients who are alcoholic, and patients with liver disease: 0.8 mg/d
	Prevention of folic acid deficiency		*Infants:* 0.1 mg/d *Children <4 yr:* 0.3 mg/d *Adults and children >4 yr:* 0.4 mg/d Pregnant and lactating women, patients who are alcoholic, and patients with liver disease: 0.4 mg/d

Rational Drug Selection

Folic acid is available OTC at less cost than in prescription form (Table 18-13).

Monitoring

The only specific monitoring parameters are those associated with managing the anemia that is being treated.

Patient Education

Although folic acid is part of a normal diet, supplemental folic acid should be taken only after consultation with a health-care provider. In particular, pregnant women and those who may become pregnant should discuss the need for folic acid with their provider. Foods high in folate include green vegetables (especially asparagus, lettuce, spinach, and broccoli), liver, yeast, and mushrooms, which should be included in a balanced diet.

VITAMIN B$_{12}$

Vitamin B$_{12}$ deficiency can be caused by poor intake, impaired absorption, increased demand, or faculty utilization.

Poor intake is rare, except in strict vegetarians who do not eat eggs or use dairy products. Impaired absorption is most often related to the lack of intrinsic factor found in pernicious anemia. Absorption can also be impaired by diseases of the ileum, by bacterial overgrowth from stasis such as occurs with severe constipation, and by altered digestive enzymes associated with gastrectomy. Faulty utilization is associated with rare genetic defects.

Pharmacodynamics

Vitamin B$_{12}$ is critical to two essential enzyme systems. In one system, it is the cofactor in metabolism of methylmalonyl-CoA. When this metabolism does not take place, methylmalonyl-CoA accumulates, and abnormal fatty acids are synthesized. It is believed that these abnormal fatty acids in cell membranes of the CNS are responsible for the neurological manifestations of vitamin B$_{12}$ deficiency. The other system involves folate metabolism. In the presence of vitamin B$_{12}$ deficiency, the final steps in folate metabolism cannot occur, which explains why the megaloblastic anemia found in vitamin B$_{12}$ deficiency can be partially corrected by folic acid administration. Management of anemia is discussed in Chapter 27.

Table 18–13 ❋ **Available Dosage Forms: Folic Acid**

Drug	Dosage Form	Other Forms	Cost
Folic acid (OTC)	Tablets: 0.4, 0.8 mg		0.4 mg = $4.59/250 0.8 mg = $4.99/100
Folic acid (prescription)	Tablets: 1 mg	Multidose vial for injection (Folvite); 5 mg/mL	1 mg = $4.99/90 tablets

OTC = over the counter.

Pharmacokinetics

Absorption and Distribution

Approximately 1 to 5 mcg of the daily dietary intake of 5 to 30 mcg is absorbed. In the stomach and duodenum, vitamin B_{12} complexes with intrinsic factor are secreted by the parietal cells of the gastric mucosa. This complex is then separated in the terminal ileum in the presence of calcium and absorbed by a highly specific receptor-mediated transport system. Patients with intrinsic factor deficits require parenteral administration of vitamin B_{12} to bypass this absorption problem. Vitamin B_{12} is well absorbed following IM and SC injection or intranasal administration. Plasma level peaks within 1 hour after injection. Once absorbed, vitamin B_{12} is distributed throughout the body, bound to a plasma protein, transcobalamin II.

Metabolism, Storage, and Excretion

Excess vitamin B_{12} is stored mainly in the liver and released when needed to carry out normal cellular functions. Because the normal daily requirement of vitamin B_{12} is only about 2 mcg, it would take approximately 5 years for all the stored vitamin B_{12} to be exhausted and megaloblastic anemia to develop if vitamin B_{12} absorption stopped. After injection, vitamin B_{12} is stored in the liver for approximately 400 days. Within 48 hours after injection, 50% to 98% of the dose appears in the urine. The major portion is excreted within the first 8 hours.

Pharmacotherapeutics

Precautions and Contraindications

The only contraindications to injectable vitamin B_{12} are hypersensitivity to cobalt, B_{12}, or any component of these and the presence of Leber's disease, a hereditary optic nerve atrophy. Severe and swift optic nerve atrophy occurs in patients with this disease who are treated with cyanocobalamin.

Pulmonary edema, peripheral vascular thrombosis, and congestive heart failure may occur early in treatment with vitamin B_{12}. Cautious use and careful monitoring are suggested. Blunted or impeded therapeutic response may occur in the presence of uremia, folic acid deficiency, concurrent infection, or iron deficiency.

Vitamin B_{12} (parenteral) is Pregnancy Category C. Adequate and well-controlled studies have not been done with pregnant women.

Adverse Drug Reactions

Hypokalemia and sudden death have occurred in severe megaloblastic anemia treated intensely. Serum potassium levels should be carefully monitored, and supplementation provided as needed. Anaphylactic shock and death have occurred after parenteral administration. An interdermal test dose is given to patients sensitive to the cobalamins. Transient diarrhea, urticaria, and pruritus may occur but are not common. Pain is common at the injection site.

Drug Interactions

Injectable vitamin B_{12} has few drug interactions. Several drugs, extended-release potassium, and excessive intake of alcohol or vitamin C may decrease absorption of oral vitamin B_{12}. Table 18-14 shows these drug interactions.

Clinical Use and Dosing

Prevention of Vitamin B_{12} Deficiency

Vitamin B_{12} is an essential vitamin, and needs increase during pregnancy. The National Academy of Sciences recommends oral doses of 2.2 mcg/day during pregnancy. Vitamin B_{12} is excreted in breast milk in concentrations that approximate the mother's vitamin B_{12} blood level. The Food and Nutrition Board of the National Academy of Sciences—National Research Council recommends 2.6 mcg/day during lactation, 0.3 to 0.5 mcg/day for infants under age 1, and 0.7 to 1.4 mcg/day for children aged 1 to 10 (Table 18-15).

Pernicious Anemia

Because the underlying problem in almost all cases of pernicious anemia is malabsorption, therapy with vitamin B_{12} is required for life. Oral, IM, and intranasal replacement is available. Oral vitamin B_{12} is useful only for patients who cannot take the parenteral form. Initial dosing is 1,000 mcg daily for 7 days by IM or deep SC injection. The hematological response to injected vitamin B_{12} is usually rapid. Reticulocytosis begins on the second or third day and is usually maximal by the fifth to tenth day. If there is clinical improvement and an appropriate reticulocyte response has occurred after 7 days of therapy, then 100 to 1,000 mcg IM are given weekly for a month. Doses of 1,000 mcg may be used, as excess vitamin B_{12} is excreted in the urine. By this time, the hematological values should be normal. Hgb and Hct levels should return to normal within 1 to 2 months. It may take up to 6 months to resolve neurological symptoms. If neurological symptoms are present, a twice-monthly dose is recommended for

Table 18–14 ⚏ **Drug Interactions: Vitamin B$_{12}$**

Drug	Interacting Drug	Possible Effect	Implications
Vitamin B$_{12}$	Aminosalicylic acid	Reduced biological and therapeutic action of B$_{12}$ Abnormal Schilling test and symptoms of B$_{12}$ deficiency	Avoid concomitant administration
	Chloramphenicol	Hematological effects of B$_{12}$ may be decreased in patients with pernicious anemia	Choose a different antimicrobial
	Colchicine	May cause malabsorption of B$_{12}$ (oral)	If unable to avoid concomitant use, administer B$_{12}$ parenterally
	Aminoglycosides Extended-release potassium supplements Cimetidine Excessive intake of alcohol or vitamin C		

Table 18–15 ⚮ **Dosage Schedule: Vitamin B$_{12}$**

Drug	Indication	Initial Dose	Maintenance Dose
Vitamin B$_{12}$	Pernicious anemia	1,000 mcg/d for 7 d IM or deep SC	If clinical improvement and reticulocyte response, give 100 to 1,000 mcg IM weekly for a month. Then give 1,000 mcg monthly for life of patient. If neurological symptoms are present, a twice-monthly dose is recommended for 6 mo prior to beginning the monthly dose Nasal therapy would consist of 500 mcg cyanocobalamin weekly Oral therapy consists of 1,000 mcg daily for life
	Vitamin B$_{12}$ deficiency without pernicious anemia	Cyanocobalamin: Parenteral *Adults:* 30 mcg/d for 5–10 d *Children:* For hematological signs: 10–50 mcg/d for 5–10 d For neurological signs: 100 mcg/d for 10–15 d Oral 1,000 mcg/d Hydroxocobalamin: *Adults:* 30 mcg/d for 5–10 d *Children:* 100 mcg doses to equal 1–5 mg over 2 wk	Parenteral *Adults:* 100–200 mcg monthly *Children:* For hematological signs: 100–250 mcg/d every 2–4 wk For neurological signs: 100 mcg once or twice weekly for several months, then taper to 250–1,000 mcg monthly by 1 yr *Adults:* 100–200 mcg/mo *Children:* 30–50 mcg every 4 wk

6 months prior to beginning the monthly dose. Because pernicious anemia is not correctable, vitamin B$_{12}$ must be taken once monthly for the life of the patient. Parenteral, nasal, or oral therapy may be used once a patient's B$_{12}$ levels return to normal. Parenteral therapy consists of 1,000 mcg of vitamin B$_{12}$ monthly. Nasal therapy would consist of 500 mcg of cyanocobalamin weekly. Oral therapy consists of 1,000 mcg daily for life. Oral therapy should be tried because of ease of administration and cost. Further discussion is found in Chapter 27.

Patients With Vitamin B$_{12}$ Deficiency

For adults with vitamin B$_{12}$ deficiency that is not pernicious anemia, 1,000 mcg of oral cobalamin are given until normal B$_{12}$ levels are achieved—usually 6 to 12 weeks. In seriously ill patients, both vitamin B$_{12}$ and folic acid may need to be administered. Dosages for children vary, based on the presence of hematological versus neurological signs. Oral doses up to 1,000 mcg have been used; however, oral therapy is not usually recommended for deficiency states in children.

Unnecessary Vitamin B$_{12}$ Therapy

Some well-meaning health-care providers have given parenteral vitamin B$_{12}$ to patients with fatigue or other vague symptoms. Sometimes these patients report feeling better, in all probability related to a placebo effect. There is no indication that vitamin B$_{12}$ is useful for patients who do not have a

deficiency state. Although the risk in giving this drug is low, a better approach is to determine the patient's underlying problem, such as depression, anxiety, or the presence of an inflammatory disease or other disorder that may inhibit erythropoiesis.

Rational Drug Selection

Of the two main parenteral forms of vitamin B_{12}, cyanocobalamin (Crystamine, Cyanoject, Cyomin) is less protein bound and has a shorter duration of action than hydroxocobalamin (Hydrobexan, Hydro-Cobex, Hydro-Crysti-12) (Table 18-16). The latter form may mean less frequent injections, but antibody reactions are more common; either one works as well.

For patients with pernicious anemia, dietary deficiency, or inadequate secretion of intrinsic factor, intranasal cyanocobalamin (Nascobal) has been approved by the FDA for maintenance therapy of patients with hematological remission after initial treatment. Once-weekly dosing of cyanocobalamin gives a 500 mcg dose.

Oral replacement may be used once the patient has reached normal vitamin B_{12} levels via parenteral administration. Oral cyanocobalamin offers ease of administration and is inexpensive ($5.99 for 60 tablets at http://www.drugstore.com).

Monitoring

Sudden drops in serum potassium levels have been reported with vitamin B_{12} therapy. Serum potassium levels should be monitored closely for the first 48 hours and supplemental oral potassium given if needed. Reticulocyte counts, Hct, iron, folic acid, and vitamin B_{12} serum levels are obtained prior to treatment, between the fifth and the seventh day of therapy, at 1 month, then every 3 to 6 months. If folate levels are also low, folic acid may need to be administered. Monitoring for folic acid is discussed in the section on that drug. Relapse of symptoms is not uncommon in the presence of continuing therapy. Hematological evaluations should continue at regular intervals throughout the patient's lifetime, based on the individual's response to therapy.

Patient Education

Administration

Orally administered vitamin B_{12} should be taken with meals to increase absorption. It may be taken with fruit juices, but ascorbic acid alters the stability of the drug. Expensive vitamin preparations are no more efficacious than are less costly ones. Vitamins are not a substitute for a well-balanced diet.

Treating pernicious anemia requires administrating vitamin B_{12} for the rest of the patient's life. Failure to do so leads to the return of anemia and the development of incapacitating and irreversible damage to spinal cord nerves. IM injections should be given in large muscles such as the buttock or thigh, and SC injections should be given deeply in these same areas.

Adverse Drug Reactions

Diarrhea, itching, and urticaria may sometimes temporarily occur. Hypokalemia has occurred early in the treatment of severe anemia. Health-care providers should monitor for this problem. Diets high in potassium may help. Rare cardiac and pulmonary symptoms have occurred. Patients should report shortness of breath, swelling in the lower legs or ankles, and pain or redness in the calves.

Table 18–16 ❁ Available Dosage Forms: Vitamin B$_{12}$

Drug	Dosage Form	How Supplied	Cost
Vitamin B$_{12}$	Tablet: 100, 500, and 1,000-mcg	In bottles of 100	500 mcg = $5.99/100 tablets 1,000 mcg = $10.79/100 tablets
Big-Shot B$_{12}$	Tablet: 5,000 mcg	In bottles of 30 and 60	5,000 mcg = $34.99/120 tablets
Vitamin B$_{12}$	Lozenges: 100, 250, and 500 mcg	In bottles of 100 In bottles of 100 and 250	2,500 mcg = $6.49/50 lozenges 5,000 mcg = $6.49/30 lozenges
Nascobal	Intranasal: 500 mcg/0.1 mL (500 mcg in each activation)	In 2.3 mL bottle In 5 mL bottle	$277.97/2.3 mL
Hydroxocobalamin, crystalline (Hydro Cobex, Hydro-Crysti 12, LA-12)	Injection: 1,000 mcg/mL	In 30 mL multidose vial	
Cyanocobalamin, crystalline (vitamin B$_{12}$)	Tablet: 500 mcg and 1,000 mcg	In bottle of 100	
Cyanocobalamin, crystalline (vitamin B$_{12}$, Crystamine, Crysti 1000 Cyanojet, Cyomin, Rubesol-1000)	Injection: 1,000 mcg/mL	In 1 mL vial In 10 and 30 mL multidose vials	1 mL vial = $35.99/25 vials $19.99/30 mL $13.99/10 mL

DRUGS AFFECTING THE IMMUNE SYSTEM

Teri Moser Woo

Primary care providers prescribe immunizations frequently, with pediatric providers prescribing many vaccines daily. Although vaccination is typically associated with children, the Centers for Disease Control and Prevention (CDC) recommends a number of vaccines for adolescents and adults. A dramatic decrease is seen in vaccine-preventable diseases when mass campaigns are implemented, with cases of diphtheria decreasing 100%, invasive *Haemophilus influenzae* decreasing 99%, pertussis decreasing 86%, and hepatitis A dropping 93% (Hinman, Orenstein, & Schuchat, 2011). A recent study reviewing weekly reports of infectious diseases in the United States from 1888 to 2011 estimates 103.1 million cases of infectious disease have been prevented since 1924 due to vaccines (van Panhuis et al, 2013).

The immunization schedules may change, but the underlying premise of preventing the spread of infectious disease through mass immunization of susceptible populations does not change. The success of mass vaccination is measured not only in decreased numbers of vaccine-preventable illnesses but also in the resurgence of diseases such as polio and measles when programs are halted (Andre et al, 2008; Hinman et al, 2011). This chapter discusses immunizations, immune

globulin (IG) serums, and the diagnostic drugs used in primary care, such as purified protein derivative (PPD) for tuberculosis (TB) screening. The immunomodulators cyclosporine and azathioprine are addressed. The use of interferon is not discussed here because it is usually prescribed by specialty care providers.

IMMUNIZATIONS

Vaccination is the single best technique for preventing infectious disease. Vaccines exist for many diseases that affect adults and children. This section of the chapter discusses active immunization with either attenuated or inactivated infective agents, the recommended schedule of immunizations for adults and children, and the true precautions and contraindications to immunization. Issues such as barriers surrounding immunization are discussed, as well as immunization of special populations and travel immunizations.

Vaccines are divided into two different types: those that are made from attenuated ("modified-live") or inactivated ("killed") infective agents. Attenuated vaccines include measles, mumps, and rubella (MMR); oral polio (OPV); varicella virus (Varivax, ProQuad); yellow fever (YF-Vax); live, attenuated virus influenza vaccine (Flumist); rotavirus (Rotarix, RotaTeq); varicella zoster (Zostavax); and bacilli Calmette–Guérin (BCG). Inactivated vaccines include diphtheria, tetanus, and pertussis (DTP, DTaP, DT, Td, Tdap), *H. influenzae* type B (HIB), hepatitis A and B, influenza (Fluzone), meningococcal (Menactra, Menomune, Trumenba, Bexsero), inactivated polio vaccine (IPV), human papillomavirus vaccine (Gardasil, Cervarix), pneumococcal polysaccharide (PPV23), and pneumococcal conjugate vaccine (PCV13). Cholera, Japanese encephalitis virus, and plague vaccines are other inactivated vaccines. Typhoid vaccine is available in an inactivated form and an oral live, attenuated form. The pharmacodynamics of each vaccine is discussed according to its category.

ATTENUATED VACCINES

INFLUENZA LIVE, ATTENUATED INFLUENZA VACCINE

Pharmacodynamics

Influenza reaches epidemic levels in the winter months in temperate areas and was responsible for 23,607 deaths per year in the United States between 1976 and 2007 (Thompson et al, 2010). Influenza live, attenuated influenza vaccine (LAIV3) (Flumist) was a trivalent vaccine containing two strains of influenza A and one of influenza B, the strains depending on the predicted circulating influenza virus strains. In 2013, a quadravalent vaccine became available. The quadravalent attenuated influenza vaccine (LAIV4) (Flumist Quadravalent) contains two strains of influenza A and two strains of influenza B, strains of which vary by season. The vaccine is cold-adapted, meaning the virus replicates easily in the mucosa of the nasopharynx, and temperature-sensitive so it does not replicate effectively at core body temperature (38°C to 39°C).

Pharmacokinetics

LAIV4 (Flumist Quadravalent) vaccine is administered intranasally, with half of the dose administered in each nostril. In radiolabeled studies 89.7% of the vaccine remains in the nasal cavity. After administration of LAIV4, viral shedding measured at 11 days was present in 0.9% of 19- to 49-year-olds and 7% of children 6 to 23 months of age (MedImmune, 2013).

Pharmacotherapeutics

Precautions and Contraindications

LAIV is contraindicated in patients with egg or egg product hypersensitivity. LAIV is contraindicated in persons with asthma, reactive airways disease, or other chronic disorders of the pulmonary or cardiovascular systems; persons with other underlying medical conditions, including such metabolic diseases as diabetes, renal dysfunction, and hemoglobinopathies; and persons with known or suspected immunodeficiency diseases or who are receiving immunosuppressive therapies (MedImmune, 2013). Patients who are immunocompromised or who have HIV should not be vaccinated with LAIV. LAIV should not be administered to patients who have had Guillain–Barré syndrome.

LAIV is Pregnancy Category C, and pregnant women should not be vaccinated with influenza LAIV.

Use of live influenza vaccine is contraindicated in children under age 2 years owing to significant increased incidence of reactive airway disease and asthma. The vaccine is also contraindicated in children or adolescents receiving aspirin or other salicylates because of the association of Reye syndrome with wild-type influenza infection.

Adverse Drug Reactions

LAIV is usually well tolerated with generally mild and transient adverse effects. Adults in clinical trials of LAIV4 (Flumist Quadravalent) reported respiratory symptoms at the same rate as LAIF3 (Flumist), with 44% reporting runny nose or nasal congestion, 28% headache, 19% sore throat, 14% cough, and 10% reporting muscle aches (MedImmune, 2013). No serious adverse reactions have been reported in either children (older than age 2 years) or adult vaccine recipients.

Drug Interactions

The administration of LAIV and concurrent use of antivirals active against influenza A and/or B viruses have not been studied. The manufacturer recommends waiting 48 hours after discontinuing antivirals before administering LAIV.

LAIV should not be administered to children under age 17 years on aspirin therapy owing to the theoretical increased risk for Reye syndrome.

LAIV may be concurrently administered with measles, mumps, rubella (MMR), and varicella with no problems noted in developing an immune response. LAIV may be simultaneously administered with any of the inactivated vaccines. Inactivated or live vaccines may be administered the same day as LAIV, but if not administered the same day, the two live vaccines need to be separated by 4 weeks.

Clinical Use and Dosing

Children and adults aged 9 through 49 years should receive 0.2 mL of LAIV as soon as it becomes available in the fall. Children aged 5 to 8 who have not had previous influenza vaccination should receive two doses (0.2 mL each) separated by 4 weeks (Grohskopf et al, 2013). Children 8 years and younger who have previously received two doses of influenza vaccine in the same year need only one dose (0.2 mL) annually.

LAIV (FluMist Quadravalent) comes prepackaged in prefilled single-use sprayers. The vaccine is thawed by holding the sprayer in the palm of the hand. It may also be thawed in the refrigerator and stored for up to 24 hours before use. Half of the dose is administered in one nostril while the patient is in an upright position; then the second half is administered in the second nostril.

Monitoring

Laboratory monitoring is not necessary after LAIV administration.

Patient Education

Because LAIV is a live-virus vaccine, recipients should be advised to stay away from close contact with immunocompromised persons for 7 days after administration, although the risk is theoretical. Patients should report serious or moderate reactions, such as difficulty breathing, wheezing, hives, swelling, unusual weakness, and temperature 38.9°C or higher to their health-care provider.

MEASLES, MUMPS, AND RUBELLA VACCINE

Pharmacodynamics

Immunization with MMR or measles vaccine alone stimulates the immune system to produce disease-specific antibodies by inducing a subclinical infection with attenuated virus particles. This subclinical infection is not contagious. The vaccine-induced antibodies are capable of virus neutralization by complement activation, induction of cell-mediated immunity, and opsonization. Measles and measles and rubella live-virus vaccine (M-R-Vax II) is the commonly used combined vaccine. In 2009 Merck discontinued production of single-agent vaccines based on input from the Advisory Committee on Immunization Practices (ACIP), professional societies, scientific leaders, including measles virus vaccine (Attenuvax), mumps live-virus vaccine (Mumpsvax), rubella (Meruvax II). In 2005, a vaccine (ProQuad) that added varicella to MMR (MMRV) received licensing; it is discussed in the next section.

Pharmacokinetics

The MMR vaccine is administered SC. Following SC injection, antibodies are detectable in 2 weeks (rubella may take 2 to 6 wk) in 95% of patients vaccinated, and immunity occurs in about 10 days. Immunity persists for 15 years or more, with permanent immunity developing in most patients. More than 99% of people who receive two doses of MMR separated by at least 1 month develop evidence of immunity to measles, which is why the current recommendation is for two doses. Mumps outbreaks in New York in 2005 and Iowa in late 2005 and early 2006 indicate that the effectiveness of MMR against mumps is 80% after one dose and 90% after two doses, based on limited data (CDC, 2006a). An outbreak of 3,502 cases of mumps that occurred in 2009–2010 among a well-vaccinated population in the Northeast United States (85% of those infected had had two doses of MMR) demonstrated 94.8% protection against mumps after two doses of MMR (Fiebelkorn, Lawler, Curns, Brandeburg, & Wallace, 2013). Outbreaks of mumps on college campuses in California in 2011 and in Virginia and Maryland in 2013 indicated two doses of MMR are 80% to 92% effective in preventing clinical disease (CDC, 2013a). Mumps antibodies are present in 74% to 95% of persons 12 years after the second dose of MMR vaccine (CDC, 2013a).

Pharmacotherapeutics

Precautions and Contraindications

MMR contains live, attenuated virus, and virus has been detected for 1 to 4 weeks after vaccination in the pharynx or nose of most patients who receive the vaccine; however, this does not appear to cause virus transmission.

According to the CDC (2013a), there are relatively few true contraindications to administering MMR vaccine. They include previous anaphylactic reaction to the MMR vaccine or any component of the vaccine, including neomycin (topically or systemically administered) or gelatin. A history of contact dermatitis to neomycin is not a contraindication to MMR. Anaphylactic reaction or hypersensitivity to eggs is no longer a contraindication to MMR.

Immunosuppression can potentiate virus production, and therefore, MMR vaccination is not recommended for immunocompromised patients. In patients with HIV infection, MMR vaccine can be administered if the patient is asymptomatic or without evidence of severe immunosuppression (CDC, 2013a). MMR should not be given to patients who are severely immunocompromised because of cancer, leukemia, or lymphoma or who are on immunosuppressive drug therapy, including high-dose steroids (prednisone greater than 2 mg/kg/day or 20 mg/day in patients weighing more than 10 kg) or radiation therapy (American Academy of Pediatrics [AAP], 2012a; CDC, 2013a). MMR may be given to close contacts of immunosuppressed patients, including health-care workers.

MMR vaccination is generally deferred if a patient has a moderate or severe febrile illness and is given when the patient recovers from the acute phase of the illness. Minor illnesses, with or without fever (diarrhea, upper respiratory infection, or otitis media), are not contraindications to MMR vaccination, and vaccination should not be postponed (AAP, 2012).

Patients who receive blood products should wait 3 months before being administered MMR (CDC, 2013a). MMR should be given at least 2 weeks before IG. Patients who receive IG should wait 3 to 11 months before being administered MMR (AAP, 2012).

MMR vaccine should not be given to pregnant women or women who may become pregnant within 3 months after administration. There is a theoretical possibility of congenital rubella syndrome in the infant if the mother is given rubella vaccine when pregnant. Women should be asked if they are pregnant before administration of MMR and advised to avoid pregnancy for 3 months after administration of the vaccine. Pregnancy in the mother of a patient receiving MMR is not a contraindication. MMR may be administered to breastfeeding women.

The MMR vaccine may be safely administered to children of all ages, although it may not be immunogenic in infants under age 12 months. If MMR vaccine is administered to a child under age 12 months, then the child should be revaccinated with MMR at 12 to 15 months of age and receive a third dose of MMR at age 4 to 6 years.

Adverse Drug Reactions

Approximately 5% to 15% of children develop a fever of at least 103°F (39.5°C) after vaccination with MMR. The fever usually occurs 7 to 12 days after MMR vaccination (CDC, 2013a). The fever usually lasts 1 to 2 days, and the patient is otherwise asymptomatic. MMR may cause a transient maculopapular rash 7 to 10 days after vaccination in 5% of patients. MMR vaccine may cause a febrile seizure with the fever that occurs post-vaccination, with the highest risk of febrile seizure 6 to 14 days after administration. The risk of febrile seizure is 1 per 3,000 to 4,000 doses of MMR. The risk of febrile seizures is higher if the patient receives MMRV as their first dose of MMR (CDC, 2013a).

Thrombocytopenia is a rare adverse reaction that may occur within 2 months of administration of MMR vaccine. The incidence of thrombocytopenia is 1 case per 1 million doses upon passive surveillance in the United States and 1 case per 30,000 to 40,000 doses in prospective studies. The clinical course of thrombocytopenia is generally benign and transient.

In times of mumps outbreak a third dose of MMR has been administered with minimal adverse effects, including injection site pain, redness and swelling (2% to 4%), muscle or joint aches (2% to 3%), and dizziness or light-headedness (2%) (CDC, 2013a).

Drug Interactions

MMR should not be administered to patients receiving immunosuppressants, including high-dose corticosteroids, interferon, and antineoplastic drugs, because they may have insufficient response to immunization. Patients may remain susceptible despite immunization. The AAP states, "Children receiving <2 mg/kg per day of prednisone or its equivalent, or <20 mg/day if they weigh more than 10 kg, can receive attenuated live-virus vaccines during corticosteroid treatment" (AAP, 2013a).

The MMR vaccine may be inactivated by IG. To avoid inactivation of the attenuated virus, administer the MMR vaccine at least 14 to 30 days before or 3 months after the IG. If IG is being given in preparation for international travel, the MMR vaccine should be administered at least 2 weeks before IG (AAP, 2012b).

MMR is not contraindicated if a PPD was done recently. PPD should be delayed for 4 to 6 weeks after an MMR has been given because it may interfere with the tuberculin skin test, causing a temporary decrease in tuberculin skin sensitivity (CDC, 2013a).

Administration of the MMR and varicella vaccines is compatible if done on the same day, with different needles and at separate sites. If the two live vaccines are not given at the same time, an interval of 1 month between MMR and varicella vaccine is indicated. MMRV (ProQuad) is indicated for simultaneous vaccination against measles, mumps, rubella, and varicella in children 12 months to 12 years of age, although for the first dose separate MMR and varicella vaccines are recommended due to increased risk of febrile seizures with MMRV (CDC, 2013a). MMR may be administered with LAIV (Flumist Quadravalent) vaccine on the same day (Grohskopf et al, 2013). Administration of two live vaccines should be separated by 4 weeks if not given the same day.

Clinical Use and Dosing

MMR is routinely given SC at 12 to 15 months of age with a repeat dose at age 4 to 6 years (CDC, 2013a). The second dose of MMR may be given as soon as 4 weeks after the first dose, which is indicated during an epidemic or before international travel. The CDC recommends the second dose be administered as MMRV (CDC, 2013a). Those children who have not received their second dose of MMR by age 12 should have it at that time. Adults born in 1957 or later who are at least age 18 (including those born outside the United States) should receive at least one dose of MMR if there is no serological proof of immunity or documentation of a dose given on or after the patient's first birthday. Health-care workers and other adults in high-risk groups, such as students entering college, military recruits, and international travelers, should receive a total of two doses of MMR. Adults born before 1957 are considered immune, but proof of immunity may be desirable for health-care workers. See Table 19-1 for further information on routine dosing. The catch-up schedule for dosing children who are behind in the routine vaccine schedule is found in Table 19-2.

Monitoring

Laboratory monitoring is not necessary after MMR administration if the patient received two age-appropriate doses of MMR. Rubella titer may be drawn to determine if a patient is immune. Health-care providers born after 1957 who cannot provide documented evidence of two doses of MMR require serologic testing to determine immunity (Shefer et al, 2011).

Patient Education

All patients or the parents or guardians of the patients are required by law to receive Vaccine Information Statements (VISs) that are developed by the CDC. They are available in a variety of languages, and every effort to provide adequate information to the patient or parent before immunization

Table 19–1 ⚬⚬ Recommended Immunization Schedule for Persons Aged 0 Through18 Years—United States, 2015

Figure 1. Recommended immunization schedule for persons aged 0 through 18 years – United States, 2015.
(FOR THOSE WHO FALL BEHIND OR START LATE, SEE THE CATCH-UP SCHEDULE [FIGURE 2]).

These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars in Figure 1. To determine minimum intervals between doses, see the catch-up schedule (Figure 2). School entry and adolescent vaccine age groups are shaded.

Vaccine	Birth	1 mo	2 mos	4 mos	6 mos	9 mos	12 mos	15 mos	18 mos	19–23 mos	2-3 yrs	4-6 yrs	7-10 yrs	11-12 yrs	13-15 yrs	16-18 yrs

Inactivated poliovirus[7] (IPV: <18 yrs)			1st dose	2nd dose	3rd dose							4th dose				
Influenza[8] (IIV; LAIV) 2 doses for some: See footnote 8					See footnote 9	Annual vaccination (IIV only) 1 or 2 doses				Annual vaccination (LAIV or IIV) 1 or 2 doses		Annual vaccination (LAIV or IIV) 1 dose only				
Measles, mumps, rubella[9] (MMR)							1st dose					2nd dose				
Varicella[10] (VAR)							1st dose					2nd dose				
Hepatitis A[11] (HepA)							2-dose series, See footnote 11									
Human papillomavirus[12] (HPV2: females only; HPV4: males and females)														(3-dose series)		
Meningococcal[13] (Hib-MenCY ≥ 6 weeks; MenACWY-D ≥9 mos; MenACWY-CRM ≥ 2 mos)						See footnote 13								1st dose		Booster

Legend:

☐ Range of recommended ages for all children

☐ Range of recommended ages for catch-up immunization

☐ Range of recommended ages for certain high-risk groups

☐ Range of recommended ages during which catch-up is encouraged and for certain high-risk groups

☐ Not routinely recommended

This schedule includes recommendations in effect as of January 1, 2015. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at http://www.cdc.gov/vaccines/hcp/acip-recs/index.html. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (http://www.vaers.hhs.gov) or by telephone (800-822-7967). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm) or by telephone (800-CDC-INFO [800-232-4636]).

This schedule is approved by the Advisory Committee on Immunization Practices (http://www.cdc.gov/vaccines/acip), the American Academy of Pediatrics (http://www.aap.org), the American Academy of Family Physicians (http://www.aafp.org), and the American College of Obstetricians and Gynecologists (http://www.acog.org).

NOTE: The above recommendations must be read along with the footnotes of this schedule.

Continued

Table 19–1 ⚛ Recommended Immunization Schedule for Persons Aged 0 Through18 Years—United States, 2015—cont'd

Footnotes — Recommended immunization schedule for persons aged 0 through 18 years—United States, 2015

For further guidance on the use of the vaccines mentioned below, see: http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.
For vaccine recommendations for persons 19 years of age and older, see the Adult Immunization Schedule.

Additional information

- For contraindications and precautions to use of a vaccine and for additional information regarding that vaccine, vaccination providers should consult the relevant ACIP statement available online at http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.
- For purposes of calculating intervals between doses, 4 weeks = 28 days. Intervals of 4 months or greater are determined by calendar months.
- Vaccine doses administered 4 days or less before the minimum interval are considered valid. Doses of any vaccine administered ≥5 days earlier than the minimum interval or minimum age should not be counted as valid doses and should be repeated as age-appropriate. The repeat dose should be spaced after the invalid dose by the recommended minimum interval. For further details, see *MMWR, General Recommendations on Immunization and Reports / Vol. 60 / No. 2: Table 1. Recommended and minimum ages and intervals between vaccine doses available online at* http://www.cdc.gov/mmwr/pdf/rr/rr6002.pdf.
- Information on travel vaccine requirements and recommendations is available at http://wwwnc.cdc.gov/travel/destinations/list.
- For vaccination of persons with primary and secondary immunodeficiencies, see Table 13, *"Vaccination of persons with primary and secondary immunodeficiencies," in General Recommendations on Immunization* (ACIP), available at http://www.cdc.gov/mmwr/pdf/rr/rr6002.pdf; and American Academy of Pediatrics. "Immunization in Special Clinical Circumstances," in Pickering LK, Baker CJ, Kimberlin DW, Long SS eds. *Red Book: 2012 report of the Committee on Infectious Diseases. 29th ed.* Elk Grove Village, IL: American Academy of Pediatrics.

1. **Hepatitis B (HepB) vaccine. (Minimum age: birth)**
   Routine vaccination:
   At birth:
   - Administer monovalent HepB vaccine to all newborns before hospital discharge.
   - For infants born to hepatitis B surface antigen (HBsAg)-positive mothers, administer HepB vaccine and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth. These infants should be tested for HBsAg and antibody to HBsAg (anti-HBs) 1 to 2 months after completion of the HepB series at age 9 through 18 months (preferably at the next well-child visit).
   - If mother's HBsAg status is unknown, within 12 hours of birth administer HepB vaccine regardless of birth weight. For infants weighing less than 2,000 grams, administer HBIG in addition to HepB vaccine within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if mother is HBsAg-positive, also administer HBIG for infants weighing 2,000 grams or more as soon as possible, but no later than age 7 days.

   Doses following the birth dose:
   - The second dose should be administered at age 1 or 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks.
   - Infants who did not receive a birth dose should receive 3 doses of a HepB-containing vaccine on a schedule of 0, 1 to 2 months, and 6 months starting as soon as feasible. See Figure 2.
   - Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks), administer the third dose at least 8 weeks after the second dose AND at least 16 weeks after the **first** dose. The final (third or fourth) dose in the HepB vaccine series should be administered **no earlier than age 24 weeks.**
   - Administration of a total of 4 doses of HepB vaccine is permitted when a combination vaccine containing HepB is administered after the birth dose.

   Catch-up vaccination:
   - Unvaccinated persons should complete a 3-dose series.
   - A 2-dose series (doses separated by at least 4 months) of adult formulation Recombivax HB is licensed for use in children aged 11 through 15 years.
   - For other catch-up guidance, see Figure 2.

2. **Rotavirus (RV) vaccines. (Minimum age: 6 weeks for both RV1 [Rotarix] and RV5 [RotaTeq])**
   Routine vaccination:
   Administer a series of RV vaccine to all infants as follows:
   1. If Rotarix is used, administer a 2-dose series at 2 and 4 months of age.
   2. If RotaTeq is used, administer a 3-dose series at ages 2, 4, and 6 months.
   3. If any dose in the series was RotaTeq or vaccine product is unknown for any dose in the series, a total of 3 doses of RV vaccine should be administered.

   Catch-up vaccination:
   - The maximum age for the first dose in the series is 14 weeks, 6 days; vaccination should not be initiated for infants aged 15 weeks, 0 days or older.
   - The maximum age for the final dose in the series is 8 months, 0 days.
   - For other catch-up guidance, see Figure 2.

3. **Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine. (Minimum age: 6 weeks. Exception: DTaP-IPV [Kinrix]; 4 years)**
   Routine vaccination:
   - Administer a 5-dose series of DTaP vaccine at ages 2, 4, 6, 15 through 18 months, and 4 through 6 years. The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose. However, the fourth dose of DTaP need not be repeated if it was administered at least 4 months after the third dose of DTaP.

3. **Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine (cont'd)**
   Catch-up vaccination:
   - The fifth dose of DTaP vaccine is not necessary if the fourth dose was administered at age 4 years or older.
   - For other catch-up guidance, see Figure 2.

4. **Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine. (Minimum age: 10 years for both Boostrix and Adacel)**
   Routine vaccination:
   - Administer 1 dose of Tdap vaccine to all adolescents aged 11 through 12 years.
   - Tdap may be administered regardless of the interval since the last tetanus and diphtheria toxoid-containing vaccine.
   - Administer 1 dose of Tdap vaccine to pregnant adolescents during each pregnancy (preferred during 27 through 36 weeks' gestation) regardless of time since prior Td or Tdap vaccination.

   Catch-up vaccination:
   - Persons aged 7 years and older who are not fully immunized with DTaP vaccine should receive Tdap vaccine as 1 dose (preferably the first) in the catch-up series; if additional doses are needed, use Td vaccine. For children 7 through 10 years who receive a dose of Tdap as part of the catch-up series, an adolescent Tdap vaccine dose at age 11 through 12 years should NOT be administered. Td should be administered instead 10 years after the Tdap dose.
   - Persons aged 11 through 18 years who have not received Tdap vaccine should receive a dose followed by tetanus and diphtheria toxoid (Td) booster doses every 10 years thereafter.
   - Inadvertent doses of DTaP vaccine:
     - If administered inadvertently to a child aged 7 through 10 years may count as part of the catch-up series. This dose may count as the adolescent Tdap dose, or the child can later receive a Tdap booster dose at age 11 through 12 years.
     - If administered inadvertently to an adolescent aged 11 through 18 years, the dose should be counted as the adolescent Tdap booster.
   - For other catch-up guidance, see Figure 2.

5. **Haemophilus influenzae type b (Hib) conjugate vaccine. (Minimum age: 6 weeks for PRP-T [ACTHIB, DTaP-IPV/Hib (Pentacel) and Hib-MenCY (MenHibrix)], PRP-OMP [PedvaxHIB or COMVAX], 12 months for PRP-T [Hiberix])**
   Routine vaccination:
   - Administer a 2- or 3-dose Hib vaccine primary series and a booster dose (dose 3 or 4 depending on vaccine used in primary series) at age 12 through 15 months to complete a full Hib vaccine series.
   - The primary series with ActHIB, MenHibrix, or Pentacel consists of 3 doses and should be administered at 2, 4, and 6 months of age. The primary series with PedvaxHib or COMVAX consists of 2 doses and should be administered at 2 and 4 months of age; a dose at age 6 months is not indicated.
   - One booster dose (dose 3 or 4 depending on vaccine used in primary series) of any Hib vaccine should be administered at age 12 through 15 months. An exception is Hiberix vaccine. Hiberix should only be used for the booster (final) dose in children aged 12 months through 4 years who have received at least 1 prior dose of Hib-containing vaccine.
   - For recommendations on the use of MenHibrix in patients at increased risk for meningococcal disease, please refer to the meningococcal vaccine footnotes and also to *MMWR* February 28, 2014 / 63(RR01);1-13, available at http://www.cdc.gov/mmwr/PDF/rr/rr6301.pdf.

For further guidance on the use of the vaccines mentioned below, see: http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.

5. *Haemophilus influenzae* **type b (Hib) conjugate vaccine (cont'd)**

Catch-up vaccination:

- If dose 1 was administered at ages 12 through 14 months, administer a second (final) dose at least 8 weeks after dose 1, regardless of Hib vaccine used in the primary series.
- If both doses were PRP-OMP (PedvaxHIB or COMVAX), and were administered before the first birthday, the third (and final) dose should be administered at age 12 through 59 months and at least 8 weeks after the second dose.
- If the first dose was administered at age 7 through 11 months, administer the second dose at least 4 weeks later and a third (and final) dose at age 12 through 15 months or 8 weeks after second dose, whichever is later.
- If first dose is administered before the first birthday and second dose administered at younger than 15 months, a third (and final) dose should be given 8 weeks later.
- For unvaccinated children aged 15 months or older, administer only 1 dose.
- For other catch-up guidance, see Figure 2. For catch-up guidance related to MenHibrix, please see the meningococcal vaccine footnotes and also *MMWR* February 28, 2014 / 63(RR01);1–13, available at http://www.cdc.gov/mmwr/PDF/rr/rr6301.pdf.

Vaccination of persons with high-risk conditions:

- Children aged 12 through 59 months who are at increased risk for Hib disease, including chemotherapy recipients and those with anatomic or functional asplenia (including sickle cell disease), human immunodeficiency virus (HIV) infection, immunoglobulin deficiency, or early component complement deficiency, who have received either no doses or only 1 dose of Hib vaccine before 12 months of age, should receive 2 additional doses of Hib vaccine 8 weeks apart; children who received 2 or more doses of Hib vaccine before 12 months of age should receive 1 additional dose.
- For patients younger than 5 years of age undergoing chemotherapy or radiation treatment who received a Hib vaccine dose(s) within 14 days of starting therapy or during therapy, repeat the dose(s) at least 3 months following therapy completion.
- Recipients of hematopoietic stem cell transplant (HSCT) should be revaccinated with a 3-dose regimen of Hib vaccine starting 6 to 12 months after successful transplant, regardless of vaccination history; doses should be administered at least 4 weeks apart.
- A single dose of any Hib-containing vaccine should be administered to unimmunized* children and adolescents 15 months of age and older undergoing an elective splenectomy; if possible, vaccine should be administered at least 14 days before procedure.
- Hib vaccine is not routinely recommended for patients 5 years or older. However, 1 dose of Hib vaccine should be administered to unimmunized* persons aged 5 years or older who have anatomic or functional asplenia (including sickle cell disease) and unvaccinated persons 5 through 18 years of age with human immunodeficiency virus (HIV) infection.

Patients who have not received a primary series and booster dose or at least 1 dose of Hib vaccine after 14 months of age are considered unimmunized.

6. **Pneumococcal vaccines. (Minimum age: 6 weeks for PCV13, 2 years for PPSV23)**

Routine vaccination with PCV13:

- Administer a 4-dose series of PCV13 vaccine at ages 2, 4, and 6 months and at age 12 through 15 months.
- For children aged 14 through 59 months who have received an age-appropriate series of 7-valent PCV (PCV7), administer a single supplemental dose of 13-valent PCV (PCV13).

Catch-up vaccination with PCV13:

- Administer 1 dose of PCV13 to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- For other catch-up guidance, see Figure 2.

Vaccination of persons with high-risk conditions with PCV13 and PPSV23:

- All recommended PCV13 doses should be administered prior to PPSV23 vaccination if possible.
- For children 2 through 5 years of age with any of the following conditions: chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure); chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy); diabetes mellitus; cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin's disease; solid organ transplantation; or congenital immunodeficiency:
  1. Administer 1 dose of PCV13 if any incomplete schedule of 3 doses of PCV (PCV7 and/or PCV13) were received previously.
  2. Administer 2 doses of PCV13 at least 8 weeks apart if unvaccinated or any incomplete schedule of fewer than 3 doses of PCV (PCV7 and/or PCV13) were received previously.
  3. Administer 1 supplemental dose of PCV13 if 4 doses of PCV7 or other age-appropriate complete PCV7 series was received previously.
  4. The minimum interval between doses of PCV (PCV7 or PCV13) is 8 weeks.
  5. For children with no history of PPSV23 vaccination, administer PPSV23 at least 8 weeks after the most recent dose of PCV13.

6. **Pneumococcal vaccines (cont'd)**

- For children aged 6 through 18 years who have cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin's disease; generalized malignancy; solid organ transplantation; or multiple myeloma:
  1. If neither PCV13 nor PPSV23 has been received previously, administer 1 dose of PCV13 now and 1 dose of PPSV23 at least 8 weeks later.
  2. If PCV13 has been received previously but PPSV23 has not, administer 1 dose of PPSV23 at least 8 weeks after the most recent dose of PCV13.
  3. If PPSV23 has been received but PCV13 has not, administer 1 dose of PCV13 at least 8 weeks after the most recent dose of PPSV23.
- For children aged 6 through 18 years with chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure), chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy), diabetes mellitus, alcoholism, or chronic liver disease, who have not received PPSV23, administer 1 dose of PPSV23. If PCV13 has been received previously, then PPSV23 should be administered at least 8 weeks after any prior PCV13 dose.
- A single revaccination with PPSV23 should be administered 5 years after the first dose to children with sickle cell disease or other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin's disease; generalized malignancy; solid organ transplantation; or multiple myeloma.

7. **Inactivated poliovirus vaccine (IPV). (Minimum age: 6 weeks)**

Routine vaccination:

- Administer a 4-dose series of IPV at ages 2, 4, 6 through 18 months, and 4 through 6 years. The final dose in the series should be administered on or after the fourth birthday and at least 6 months after the previous dose.

Catch-up vaccination:

- In the first 6 months of life, minimum age and minimum intervals are only recommended if the person is at risk of imminent exposure to circulating poliovirus (i.e., travel to a polio-endemic region or during an outbreak).
- If 4 or more doses are administered before age 4 years, an additional dose should be administered at age 4 through 6 years and at least 6 months after the previous dose.
- A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months after the previous dose.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age. IPV is not routinely recommended for U.S. residents aged 18 years or older.
- For other catch-up guidance, see Figure 2.

8. **Influenza vaccines. (Minimum age: 6 months for inactivated influenza vaccine [IIV], 2 years for live, attenuated influenza vaccine [LAIV])**

Routine vaccination:

- Administer influenza vaccine annually to all children beginning at age 6 months. For most healthy, nonpregnant persons aged 2 through 49 years, either LAIV or IIV may be used. However, LAIV should NOT be administered to some persons, including 1) persons who have experienced severe allergic reactions to LAIV, any of its components, or to a previous dose of any other influenza vaccine; 2) children 2 through 17 years receiving aspirin or aspirin-containing products; 3) persons who are allergic to eggs; 4) pregnant women; 5) immunosuppressed persons; 6) children 2 through 4 years of age with asthma or who had wheezing in the past 12 months; or 7) persons who have taken influenza antiviral medications in the previous 48 hours. For all other contraindications and precautions to use of LAIV, see *MMWR* August 15, 2014 / 63(32);691-697 [40 pages] available at http://www.cdc.gov/mmwr/pdf/wk/mm6332.pdf.

For children aged 6 months through 8 years:

- For the 2014-15 season, administer 2 doses (separated by at least 4 weeks) to children who are receiving influenza vaccine for the first time. Some children in this age group who have been vaccinated previously will also need 2 doses. For additional guidance, follow dosing guidelines in the 2014-15 ACIP influenza vaccine recommendations, *MMWR* August 15, 2014 / 63(32);691-697 [40 pages] available at http://www.cdc.gov/mmwr/pdf/wk/mm6332.pdf.
- For the 2015-16 season, follow dosing guidelines in the 2015 ACIP influenza vaccine recommendations.

For persons aged 9 years and older:

- Administer 1 dose.

Continued

Table 19–1 ✂ **Recommended Immunization Schedule for Persons Aged 0 Through 18 Years—United States, 2015—cont'd**

For further guidance on the use of the vaccines mentioned below, see: http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.

9. Measles, mumps, and rubella (MMR) vaccine. (Minimum age: 12 months for routine vaccination)

Routine vaccination:

- Administer a 2-dose series of MMR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose.
- Administer 1 dose of MMR vaccine to infants aged 6 through 11 months before departure from the United States for international travel. These children should be revaccinated with 2 doses of MMR vaccine, the first at age 12 through 15 months (12 months if the child remains in an area where disease risk is high), and the second dose at least 4 weeks later.
- Administer 2 doses of MMR vaccine to children aged 12 months and older before departure from the United States for international travel. The first dose should be administered on or after age 12 months and the second dose at least 4 weeks later.

Catch-up vaccination:

- Ensure that all school-aged children and adolescents have had 2 doses of MMR vaccine; the minimum interval between the 2 doses is 4 weeks.

10. Varicella (VAR) vaccine. (Minimum age: 12 months)

Routine vaccination:

- Administer a 2-dose series of VAR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 3 months have elapsed since the first dose. If the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.

Catch-up vaccination:

- Ensure that all persons aged 7 through 18 years without evidence of immunity (see *MMWR 2007 / 56* [No. RR-4], available at http://www.cdc.gov/mmwr/pdf/rr/rr5604.pdf) have 2 doses of varicella vaccine. For children aged 7 through 12 years, the recommended minimum interval between doses is 3 months (if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid); for persons aged 13 years and older, the minimum interval between doses is 4 weeks.

11. Hepatitis A (HepA) vaccine. (Minimum age: 12 months)

Routine vaccination:

- Initiate the 2-dose HepA vaccine series at 12 through 23 months; separate the 2 doses by 6 to 18 months.
- Children who have received 1 dose of HepA vaccine before age 24 months should receive a second dose 6 to 18 months after the first dose.
- For any person aged 2 years and older who has not already received the HepA vaccine series, 2 doses of HepA vaccine separated by 6 to 18 months may be administered if immunity against hepatitis A virus infection is desired.

Catch-up vaccination:

- The minimum interval between the two doses is 6 months.

Special populations:

- Administer 2 doses of HepA vaccine at least 6 months apart to previously unvaccinated persons who live in areas where vaccination programs target older children, or who are at increased risk for infection. This includes persons traveling to or working in countries that have high or intermediate endemicity of infection; men having sex with men; users of injection and non-injection illicit drugs; persons who work with HAV-infected primates or with HAV in a research laboratory; persons with clotting-factor disorders; persons with chronic liver disease; and persons who anticipate close personal contact (e.g., household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity. The first dose should be administered as soon as the adoption is planned, ideally 2 or more weeks before the arrival of the adoptee.

12. Human papillomavirus (HPV) vaccines. (Minimum age: 9 years for HPV2 [Cervarix] and HPV4 [Gardasil])

Routine vaccination:

- Administer a 3-dose series of HPV vaccine on a schedule of 0, 1-2, and 6 months to all adolescents aged 11 through 12 years. Either HPV4 or HPV2 may be used for females, and only HPV4 may be used for males.
- The vaccine series may be started at age 9 years.
- Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks); administer the third dose 24 weeks after the first dose and 16 weeks after the second dose (minimum interval of 12 weeks).

Catch-up vaccination:

- Administer the vaccine series to females (either HPV2 or HPV4) and males (HPV4) at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals (see Routine vaccination above) for vaccine series catch-up.

13. Meningococcal conjugate vaccines. (Minimum age: 6 weeks for Hib-MenCY [MenHibrix], 9 months for MenACWY-D [Menactra], 2 months for MenACWY-CRM [Menveo])

Routine vaccination:

- Administer a single dose of Menactra or Menveo vaccine at age 11 through 12 years, with a booster dose at age 16 years.
- Adolescents aged 11 through 18 years with human immunodeficiency virus (HIV) infection should receive a 2-dose primary series of Menactra or Menveo with at least 8 weeks between doses.
- For children aged 2 months through 18 years with high-risk conditions, see below.

Catch-up vaccination:

- Administer Menactra or Menveo vaccine at age 13 through 18 years if not previously vaccinated.
- If the first dose is administered at age 13 through 15 years, a booster dose should be administered at age 16 through 18 years with a minimum interval of at least 8 weeks between doses.
- If the first dose is administered at age 16 years or older, a booster dose is not needed.
- For other catch-up guidance, see Figure 2.

Vaccination of persons with high-risk conditions and other persons at increased risk of disease:

- Children with anatomic or functional asplenia (including sickle cell disease):

 1. Menveo
    o *Children who initiate vaccination at 8 weeks through 6 months:* Administer doses at 2, 4, 6, and 12 months of age.
    o *Unvaccinated children 7 through 23 months:* Administer 2 doses, with the second dose at least 12 weeks after the first dose AND after the first birthday.
    o *Children 24 months and older who have not received a complete series:* Administer 2 primary doses at least 8 weeks apart.
 2. MenHibrix
    o *Children 6 weeks through 18 months:* Administer doses at 2, 4, 6, and 12 through 15 months of age.
    o If the first dose of MenHibrix is given at or after 12 months of age, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.
 3. Menactra
    o *Children 24 months and older who have not received a complete series:* Administer 2 primary doses at least 8 weeks apart. If Menactra is administered to a child with asplenia (including sickle cell disease), do not administer Menactra until 2 years of age and at least 4 weeks after the completion of all PCV13 doses.

- Children with persistent complement component deficiency:

 1. Menveo
    o *Children who initiate vaccination at 8 weeks through 6 months:* Administer doses at 2, 4, 6, and 12 months of age.
    o *Unvaccinated children 7 through 23 months:* Administer 2 doses, with the second dose at least 12 weeks after the first dose AND after the first birthday.
    o *Children 24 months and older who have not received a complete series:* Administer 2 primary doses at least 8 weeks apart.
 2. MenHibrix
    o *Children 6 weeks through 18 months:* Administer doses at 2, 4, 6, and 12 through 15 months of age.
    o If the first dose of MenHibrix is given at or after 12 months of age, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.
 3. Menactra
    o *Children 9 through 23 months:* Administer 2 primary doses at least 12 weeks apart.
    o *Children 24 months and older who have not received a complete series:* Administer 2 primary doses at least 8 weeks apart.

- For children who travel to or reside in countries in which meningococcal disease is hyperendemic or epidemic, including countries in the African meningitis belt or the Hajj, administer an age-appropriate formulation and series of Menactra or Menveo for protection against serogroups A and W meningococcal disease. Prior receipt of MenHibrix is not sufficient for children traveling to the meningitis belt or the Hajj because it does not contain serogroups A or W.
- For children at risk during a community outbreak attributable to a vaccine serogroup, administer or complete an age- and formulation-appropriate series of MenHibrix, Menactra, or Menveo.
- For booster doses among persons with high-risk conditions, refer to *MMWR 2013 / 62(RR02),*1–22, available at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6202a1.htm.

For other catch-up recommendations for these persons, and complete information on use of meningococcal vaccines, including guidance related to vaccination of persons at increased risk of infection, see MMWR March 22, 2013 / 62(RR02);1-22, available at http://www.cdc.gov/mmwr/pdf/rr/rr6202.pdf.

Table 19–2 ⚒ **Catch-Up Immunization Schedule for Persons Aged 4 Months Through 18 Years Who Start Late or Who Are More Than 1 Month Behind – United States, 2015**

FIGURE 2. Catch-up immunization schedule for persons aged 4 months through 18 years who start late or who are more than 1 month behind —United States, 2015.
The figure below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age. Always use this table in conjunction with Figure 1 and the footnotes that follow.

Vaccine	Minimum Age for Dose 1	Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
		Minimum Interval Between Doses			
		Children age 4 months through 6 years			
Hepatitis B[1]	Birth	4 weeks	8 weeks *and* at least 16 weeks after first dose. Minimum age for the final dose is 24 weeks.		
Rotavirus[2]	6 weeks	4 weeks	4 weeks[2]		
Diphtheria, tetanus, and acellular pertussis[3]	6 weeks	4 weeks	4 weeks	6 months	6 months[3]
Haemophilus influenzae type b[4]	6 weeks	4 weeks if first dose was administered before the 1st birthday. 8 weeks (as final dose) if first dose was administered at age 12 through 14 months. No further doses needed if first dose was administered at age 15 months or older.	4 weeks[5] if current age is younger than 12 months **and** first dose was administered at younger than age 7 months, **and** at least 1 previous dose was PRP-T (ActHib, Pentacel) or unknown. 8 weeks *and* age 12 through 59 months (as final dose)[5] • if current age is younger than 12 months **and** first dose was administered at age 7 through 11 months; OR • if current age is 12 through 59 months **and** first dose was administered before the 1st birthday, **and** second dose administered at younger than 15 months; OR • if both doses were PRP-OMP (PedvaxHIB; Comvax) **and** were administered before the 1st birthday. No further doses needed if previous dose was administered at age 15 months or older.	8 weeks (as final dose) This dose only necessary for children age 12 through 59 months who received 3 doses before the 1st birthday.	
Pneumococcal[6]	6 weeks	4 weeks if first dose administered before the 1st birthday. 8 weeks (as final dose for healthy children) if first dose was administered at the 1st birthday or after. No further doses needed for healthy children if first dose administered at age 24 months or older.	4 weeks if current age is younger than 12 months and previous dose given at <7months old. 8 weeks (as final dose for healthy children) if previous dose given between 7–11 months (wait until at least 12 months old); OR if current age is 12 months or older and at least 1 dose was given before age 12 months. No further doses needed for healthy children if previous dose administered at age 24 months or older.	8 weeks (as final dose) This dose only necessary for children aged 12 through 59 months who received 3 doses before age 12 months or for children at high risk who received 3 doses at any age.	
Inactivated poliovirus[7]	6 weeks	4 weeks[7]	4 weeks[7]	6 months[7] (minimum age 4 years for final dose).	
Meningococcal[13]	6 weeks	8 weeks[13]	See footnote 13	See footnote 13	
Measles, mumps, rubella[9]	12 months	4 weeks			
Varicella[10]	12 months	3 months			
Hepatitis A[11]	12 months	6 months			
		Children and adolescents age 7 through 18 years			
Tetanus, diphtheria; tetanus, diphtheria, and acellular pertussis[3]	7 years[4]	4 weeks	4 weeks if first dose of DTaP/DT was administered before the 1st birthday. 6 months (as final dose) if first dose of DTaP/DT was administered at or after the 1st birthday.	6 months if first dose of DTaP/DT was administered before the 1st birthday.	
Human papillomavirus[12]	9 years		Routine dosing intervals are recommended.[12]		
Hepatitis A[11]	Not applicable (N/A)	6 months			
Hepatitis B[1]	N/A	4 weeks	8 weeks **and** at least 16 weeks after first dose.		
Inactivated poliovirus[7]	N/A	4 weeks	4 weeks[7]	6 months[7]	
Meningococcal[13]	N/A	8 weeks[13]			
Measles, mumps, rubella[9]	N/A	4 weeks			
Varicella[10]	N/A	3 months if younger than age 13 years. 4 weeks if age 13 years or older.			

NOTE: The above recommendations must be read along with the footnotes of this schedule.

Continued

Table 19–2 Catch-Up Immunization Schedule for Persons Aged 4 Months Through 18 Years Who Start Late or Who Are More Than 1 Month Behind – United States, 2015—cont'd

Footnotes — Recommended immunization schedule for persons aged 0 through 18 years—United States, 2015

For further guidance on the use of the vaccines mentioned below, see: http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.

For vaccine recommendations for persons 19 years of age and older, see the Adult Immunization Schedule.

Additional information

- For contraindications and precautions to use of a vaccine and for additional information regarding that vaccine, vaccination providers should consult the relevant ACIP statement available online at http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.
- For purposes of calculating intervals between doses, 4 weeks = 28 days. Intervals of 4 months or greater are determined by calendar months.
- Vaccine doses administered 4 days or less before the minimum interval are considered valid. Doses of any vaccine administered ≥5 days earlier than the minimum interval or minimum age should not be counted as valid doses and should be repeated as age-appropriate. The repeat dose should be spaced after the invalid dose by the recommended minimum interval. For further details, see *MMWR, General Recommendations on Immunization and Reports / Vol. 60 / No. 2; Table 1. Recommended and minimum ages and intervals between vaccine doses available online at* http://www.cdc.gov/mmwr/pdf/rr/rr6002.pdf.
- Information on travel vaccine requirements and recommendations is available at http://wwwnc.cdc.gov/travel/destinations/list.
- For vaccination of persons with primary and secondary immunodeficiencies, see Table 13, *"Vaccination of persons with primary and secondary immunodeficiencies," in General Recommendations on Immunization* (ACIP), available at http://www.cdc.gov/mmwr/pdf/rr/rr6002.pdf; and American Academy of Pediatrics.. "Immunization in Special Clinical Circumstances," in Pickering LK, Baker CJ, Kimberlin DW, Long SS eds. *Red Book: 2012 report of the Committee on Infectious Diseases. 29th ed.* Elk Grove Village, IL: American Academy of Pediatrics.

1. **Hepatitis B (HepB) vaccine. (Minimum age: birth)**

   Routine vaccination:

   At birth:

   - Administer monovalent HepB vaccine to all newborns before hospital discharge.
   - For infants born to hepatitis B surface antigen (HBsAg)-positive mothers, administer HepB vaccine and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth. These infants should be tested for HBsAg and antibody to HBsAg (anti-HBs) 1 to 2 months after completion of the HepB series at age 9 through 18 months (preferably at the next well-child visit).
   - If mother's HBsAg status is unknown, within 12 hours of birth administer HepB vaccine regardless of birth weight. For infants weighing less than 2,000 grams, administer HBIG in addition to HepB vaccine within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if mother is HBsAg-positive, also administer HBIG for infants weighing 2,000 grams or more as soon as possible, but no later than age 7 days.

   Doses following the birth dose:

   - The second dose should be administered at age 1 or 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks.
   - Infants who did not receive a birth dose should receive 3 doses of a HepB-containing vaccine on a schedule of 0, 1 to 2 months, and 6 months starting as soon as feasible. See Figure 2.
   - Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks), administer the third dose at least 8 weeks after the second dose AND at least 16 weeks after the **first** dose. The final (third or fourth) dose in the HepB vaccine series should be administered **no earlier than age 24 weeks**.
   - Administration of a total of 4 doses of HepB vaccine is permitted when a combination vaccine containing HepB is administered after the birth dose.

   Catch-up vaccination:

   - Unvaccinated persons should complete a 3-dose series.
   - A 2-dose series (doses separated by at least 4 months) of adult formulation Recombivax HB is licensed for use in children aged 11 through 15 years.
   - For other catch-up guidance, see Figure 2.

2. **Rotavirus (RV) vaccines. (Minimum age: 6 weeks for both RV1 [Rotarix] and RV5 [RotaTeq])**

   Routine vaccination:

   Administer a series of RV vaccine to all infants as follows:

   1. If Rotarix is used, administer a 2-dose series at 2 and 4 months of age.
   2. If RotaTeq is used, administer a 3-dose series at ages 2, 4, and 6 months.
   3. If any dose in the series was RotaTeq or vaccine product is unknown for any dose in the series, a total of 3 doses of RV vaccine should be administered.

   Catch-up vaccination:

   - The maximum age for the first dose in the series is 14 weeks, 6 days; vaccination should not be initiated for infants aged 15 weeks, 0 days or older.
   - The maximum age for the final dose in the series is 8 months, 0 days.
   - For other catch-up guidance, see Figure 2.

3. **Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine. (Minimum age: 6 weeks. Exception: DTaP-IPV [Kinrix]: 4 years)**

   Routine vaccination:

   - Administer a 5-dose series of DTaP vaccine at ages 2, 4, 6, 15 through 18 months, and 4 through 6 years. The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose. However, the fourth dose of DTaP need not be repeated if it was administered at least 4 months after the third dose of DTaP.

3. **Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine (cont'd)**

   Catch-up vaccination:

   - The fifth dose of DTaP vaccine is not necessary if the fourth dose was administered at age 4 years or older.
   - For other catch-up guidance, see Figure 2.

4. **Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine. (Minimum age: 10 years for both Boostrix and Adacel)**

   Routine vaccination:

   - Administer 1 dose of Tdap vaccine to all adolescents aged 11 through 12 years.
   - Tdap may be administered regardless of the interval since the last tetanus and diphtheria toxoid-containing vaccine.
   - Administer 1 dose of Tdap vaccine to pregnant adolescents during each pregnancy (preferred during 27 through 36 weeks' gestation) regardless of time since prior Td or Tdap vaccination.

   Catch-up vaccination:

   - Persons aged 7 years and older who are not fully immunized with DTaP vaccine should receive Tdap vaccine as 1 dose (preferably the first) in the catch-up series; if additional doses are needed, use Td vaccine. For children 7 through 10 years who receive a dose of Tdap as part of the catch-up series, an adolescent Tdap vaccine dose at age 11 through 12 years should NOT be administered. Td should be administered instead 10 years after the Tdap dose.
   - Persons aged 11 through 18 years who have not received Tdap vaccine should receive a dose followed by tetanus and diphtheria toxoid (Td) booster doses every 10 years thereafter.
   - Inadvertent doses of DTaP vaccine:
     - If administered inadvertently to a child aged 7 through 10 years may count as part of the catch-up series. This dose may count as the adolescent Tdap dose, or the child can later receive a Tdap booster dose at age 11 through 12 years.
     - If administered inadvertently to an adolescent aged 11 through 18 years, the dose should be counted as the adolescent Tdap booster.
   - For other catch-up guidance, see Figure 2.

5. ***Haemophilus influenzae* type b (Hib) conjugate vaccine. (Minimum age: 6 weeks for PRP-T [ACTHIB, DTaP-IPV/Hib (Pentacel) and Hib-MenCY (MenHibrix)], PRP-OMP [PedvaxHIB or COMVAX], 12 months for PRP-T [Hiberix])**

   Routine vaccination:

   - Administer a 2- or 3-dose Hib vaccine primary series and a booster dose (dose 3 or 4 depending on vaccine used in primary series) at age 12 through 15 months to complete a full Hib vaccine series.
   - The primary series with ActHIB, MenHibrix, or Pentacel consists of 3 doses and should be administered at 2, 4, and 6 months of age. The primary series with PedvaxHib or COMVAX consists of 2 doses and should be administered at 2 and 4 months of age; a dose at age 6 months is not indicated.
   - One booster dose (dose 3 or 4 depending on vaccine used in primary series) of any Hib vaccine should be administered at age 12 through 15 months. An exception is Hiberix vaccine. Hiberix should only be used for the booster (final) dose in children aged 12 months through 4 years who have received at least 1 prior dose of Hib-containing vaccine.
   - For recommendations on the use of MenHibrix in patients at increased risk for meningococcal disease, please refer to the meningococcal vaccine footnotes and also to *MMWR* February 28, 2014 / 63(RR01);1-13, available at http://www.cdc.gov/mmwr/PDF/rr/rr6301.pdf.

For further guidance on the use of the vaccines mentioned below, see: http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.

5. *Haemophilus influenzae* type b (Hib) conjugate vaccine (cont'd)

Catch-up vaccination:

- If dose 1 was administered at ages 12 through 14 months, administer a second (final) dose at least 8 weeks after dose 1, regardless of Hib vaccine used in the primary series.
- If both doses were PRP-OMP (PedvaxHIB or COMVAX), and were administered before the first birthday, the third (and final) dose should be administered at age 12 through 59 months and at least 8 weeks after the second dose.
- If the first dose was administered at age 7 through 11 months, administer the second dose at least 4 weeks later and a third (and final) dose at age 12 through 15 months or 8 weeks after second dose, whichever is later.
- If first dose is administered before the first birthday and second dose administered at younger than 15 months, a third (and final) dose should be given 8 weeks later.
- For unvaccinated children aged 15 months or older, administer only 1 dose.
- For other catch-up guidance, see Figure 2. For catch-up guidance related to MenHibrix, please see the meningococcal vaccine footnotes and also *MMWR* February 28, 2014 / 63(RR01);1-13, available at http://www.cdc.gov/mmwr/PDF/rr/rr6301.pdf.

Vaccination of persons with high-risk conditions:

- Children aged 12 through 59 months who are at increased risk for Hib disease, including chemotherapy recipients and those with anatomic or functional asplenia (including sickle cell disease), human immunodeficiency virus (HIV) infection, immunoglobulin deficiency, or early component complement deficiency, who have received either no doses or only 1 dose of Hib vaccine before 12 months of age, should receive 2 additional doses of Hib vaccine 8 weeks apart; children who received 2 or more doses of Hib vaccine before 12 months of age should receive 1 additional dose.
- For patients younger than 5 years of age undergoing chemotherapy or radiation treatment who received a Hib vaccine dose(s) within 14 days of starting therapy or during therapy, repeat the dose(s) at least 3 months following therapy completion.
- Recipients of hematopoietic stem cell transplant (HSCT) should be revaccinated with a 3-dose regimen of Hib vaccine starting 6 to 12 months after successful transplant, regardless of vaccination history; doses should be administered at least 4 weeks apart.
- A single dose of any Hib-containing vaccine should be administered to unimmunized* children and adolescents 15 months of age and older undergoing an elective splenectomy; if possible, vaccine should be administered at least 14 days before procedure.
- Hib vaccine is not routinely recommended for patients 5 years or older. However, 1 dose of Hib vaccine should be administered to unimmunized* persons aged 5 years or older who have anatomic or functional asplenia (including sickle cell disease) and unvaccinated persons 5 through 18 years of age with human immunodeficiency virus (HIV) infection.

    Patients who have not received a primary series and booster dose or at least 1 dose of Hib vaccine after 14 months of age are considered unimmunized.

6. Pneumococcal vaccines. (Minimum age: 6 weeks for PCV13, 2 years for PPSV23)

Routine vaccination with PCV13:

- Administer a 4-dose series of PCV13 vaccine at ages 2, 4, and 6 months and at age 12 through 15 months.
- For children aged 14 through 59 months who have received an age-appropriate series of 7-valent PCV (PCV7), administer a single supplemental dose of 13-valent PCV (PCV13).

Catch-up vaccination with PCV13:

- Administer 1 dose of PCV13 to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- For other catch-up guidance, see Figure 2.

Vaccination of persons with high-risk conditions with PCV13 and PPSV23:

- All recommended PCV13 doses should be administered prior to PPSV23 vaccination if possible.
- For children 2 through 5 years of age with any of the following conditions: chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure); chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy); diabetes mellitus; cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin's disease; solid organ transplantation; or congenital immunodeficiency:

    1. Administer 1 dose of PCV13 if any incomplete schedule of 3 doses of PCV (PCV7 and/or PCV13) were received previously.

    2. Administer 2 doses of PCV13 at least 8 weeks apart if unvaccinated or any incomplete schedule of fewer than 3 doses of PCV (PCV7 and/or PCV13) were received previously.

    3. Administer 1 supplemental dose of PCV13 if 4 doses of PCV7 or other age-appropriate complete PCV7 series was received previously.

    4. The minimum interval between doses of PCV (PCV7 or PCV13) is 8 weeks.

    5. For children with no history of PPSV23 vaccination, administer PPSV23 at least 8 weeks after the most recent dose of PCV13.

6. Pneumococcal vaccines (cont'd)

- For children aged 6 through 18 years who have cerebrospinal fluid leak; cochlear implant; sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin's disease; generalized malignancy; solid organ transplantation; or multiple myeloma:

    1. If neither PCV13 nor PPSV23 has been received previously, administer 1 dose of PCV13 now and 1 dose of PPSV23 at least 8 weeks later.

    2. If PCV13 has been received previously but PPSV23 has not, administer 1 dose of PPSV23 at least 8 weeks after the most recent dose of PCV13.

    3. If PPSV23 has been received but PCV13 has not, administer 1 dose of PCV13 at least 8 weeks after the most recent dose of PPSV23.

- For children aged 6 through 18 years with chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure), chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy), diabetes mellitus, alcoholism, or chronic liver disease, who have not received PPSV23, administer 1 dose of PPSV23. If PCV13 has been received previously, then PPSV23 should be administered at least 8 weeks after any prior PCV13 dose.

- A single revaccination with PPSV23 should be administered 5 years after the first dose to children with sickle cell disease or other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas, and Hodgkin's disease; generalized malignancy; solid organ transplantation; or multiple myeloma.

7. Inactivated poliovirus vaccine (IPV). (Minimum age: 6 weeks)

Routine vaccination:

- Administer a 4-dose series of IPV at ages 2, 4, 6 through 18 months, and 4 through 6 years. The final dose in the series should be administered on or after the fourth birthday and at least 6 months after the previous dose.

Catch-up vaccination:

- In the first 6 months of life, minimum age and minimum intervals are only recommended if the person is at risk of imminent exposure to circulating poliovirus (i.e., travel to a polio-endemic region or during an outbreak).
- If 4 or more doses are administered before age 4 years, an additional dose should be administered at age 4 through 6 years and at least 6 months after the previous dose.
- A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months after the previous dose.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age. IPV is not routinely recommended for U.S. residents aged 18 years or older.
- For other catch-up guidance, see Figure 2.

8. Influenza vaccines. (Minimum age: 6 months for inactivated influenza vaccine [IIV], 2 years for live, attenuated influenza vaccine [LAIV])

Routine vaccination:

- Administer influenza vaccine annually to all children beginning at age 6 months. For most healthy, nonpregnant persons aged 2 through 49 years, either LAIV or IIV may be used. However, LAIV should NOT be administered to some persons, including 1) persons who have experienced severe allergic reactions to LAIV, any of its components, or to a previous dose of any other influenza vaccine; 2) children 2 through 17 years receiving aspirin or aspirin-containing products; 3) persons who are allergic to eggs; 4) pregnant women; 5) immunosuppressed persons; 6) children 2 through 4 years of age with asthma or who had wheezing in the past 12 months; or 7) persons who have taken influenza antiviral medications in the previous 48 hours. For all other contraindications and precautions to use of LAIV, see *MMWR* August 15, 2014 / 63(32);691-697 [40 pages] available at http://www.cdc.gov/mmwr/pdf/wk/mm6332.pdf.

For children aged 6 months through 8 years:

- For the 2014-15 season, administer 2 doses (separated by at least 4 weeks) to children who are receiving influenza vaccine for the first time. Some children in this age group who have been vaccinated previously will also need 2 doses. For additional guidance, follow dosing guidelines in the 2014-15 ACIP influenza vaccine recommendations. *MMWR* August 15, 2014 / 63(32);691-697 [40 pages] available at http://www.cdc.gov/mmwr/pdf/wk/mm6332.pdf.
- For the 2015-16 season, follow dosing guidelines in the 2015 ACIP influenza vaccine recommendations.

For persons aged 9 years and older:

- Administer 1 dose.

Continued

Table 19–2 ⚸ **Catch-Up Immunization Schedule for Persons Aged 4 Months Through 18 Years Who Start Late or Who Are More Than 1 Month Behind – United States, 2015—cont'd**

For further guidance on the use of the vaccines mentioned below, see: http://www.cdc.gov/vaccines/hcp/acip-recs/index.html.

9. Measles, mumps, and rubella (MMR) vaccine. (Minimum age: 12 months for routine vaccination)

Routine vaccination:

- Administer a 2-dose series of MMR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose.
- Administer 1 dose of MMR vaccine to infants aged 6 through 11 months before departure from the United States for international travel. These children should be revaccinated with 2 doses of MMR vaccine, the first at age 12 through 15 months (12 months if the child remains in an area where disease risk is high), and the second dose at least 4 weeks later.
- Administer 2 doses of MMR vaccine to children aged 12 months and older before departure from the United States for international travel. The first dose should be administered on or after age 12 months and the second dose at least 4 weeks later.

Catch-up vaccination:

- Ensure that all school-aged children and adolescents have had 2 doses of MMR vaccine; the minimum interval between the 2 doses is 4 weeks.

10. Varicella (VAR) vaccine. (Minimum age: 12 months)

Routine vaccination:

- Administer a 2-dose series of VAR vaccine at ages 12 through 15 months and 4 through 6 years. The second dose may be administered before age 4 years, provided at least 3 months have elapsed since the first dose. If the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.

Catch-up vaccination:

- Ensure that all persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007 / 56 [No. RR-4], available at http://www.cdc.gov/mmwr/pdf/rr/rr5604.pdf) have 2 doses of varicella vaccine. For children aged 7 through 12 years, the recommended minimum interval between doses is 3 months (if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid); for persons aged 13 years and older, the minimum interval between doses is 4 weeks.

11. Hepatitis A (HepA) vaccine. (Minimum age: 12 months)

Routine vaccination:

- Initiate the 2-dose HepA vaccine series at 12 through 23 months; separate the 2 doses by 6 to 18 months.
- Children who have received 1 dose of HepA vaccine before age 24 months should receive a second dose 6 to 18 months after the first dose.
- For any person aged 2 years and older who has not already received the HepA vaccine series, 2 doses of HepA vaccine separated by 6 to 18 months may be administered if immunity against hepatitis A virus infection is desired.

Catch-up vaccination:

- The minimum interval between the two doses is 6 months.

Special populations:

- Administer 2 doses of HepA vaccine at least 6 months apart to previously unvaccinated persons who live in areas where vaccination programs target older children, or who are at increased risk for infection. This includes persons traveling to or working in countries that have high or intermediate endemicity of infection; men having sex with men; users of injection and non-injection illicit drugs; persons who work with HAV-infected primates or with HAV in a research laboratory; persons with clotting-factor disorders; persons with chronic liver disease; and persons who anticipate close personal contact (e.g., household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity. The first dose should be administered as soon as the adoption is planned, ideally 2 or more weeks before the arrival of the adoptee.

12. Human papillomavirus (HPV) vaccines. (Minimum age: 9 years for HPV2 [Cervarix] and HPV4 [Gardasil])

Routine vaccination:

- Administer a 3-dose series of HPV vaccine on a schedule of 0, 1-2, and 6 months to all adolescents aged 11 through 12 years. Either HPV4 or HPV2 may be used for females, and only HPV4 may be used for males.
- The vaccine series may be started at age 9 years.
- Administer the second dose 1 to 2 months after the first dose (minimum interval of 4 weeks); administer the third dose 24 weeks after the first dose and 16 weeks after the second dose (minimum interval of 12 weeks).

Catch-up vaccination:

- Administer the vaccine series to females (either HPV2 or HPV4) and males (HPV4) at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals (see Routine vaccination above) for vaccine series catch-up.

13. Meningococcal conjugate vaccines. (Minimum age: 6 weeks for Hib-MenCY [MenHibrix], 9 months for MenACWY-D [Menactra], 2 months for MenACWY-CRM [Menveol])

Routine vaccination:

- Administer a single dose of Menactra or Menveo vaccine at age 11 through 12 years, with a booster dose at age 16 years.
- Adolescents aged 11 through 18 years with human immunodeficiency virus (HIV) infection should receive a 2-dose primary series of Menactra or Menveo with at least 8 weeks between doses.
- For children aged 2 months through 18 years with high-risk conditions, see below.

Catch-up vaccination:

- Administer Menactra or Menveo vaccine at age 13 through 18 years if not previously vaccinated.
- If the first dose is administered at age 13 through 15 years, a booster dose should be administered at age 16 through 18 years with a minimum interval of at least 8 weeks between doses.
- If the first dose is administered at age 16 years or older, a booster dose is not needed.
- For other catch-up guidance, see Figure 2.

Vaccination of persons with high-risk conditions and other persons at increased risk of disease:

- Children with anatomic or functional asplenia (including sickle cell disease):

  1. Menveo
     - ○ *Children who initiate vaccination at 8 weeks through 6 months:* Administer doses at 2, 4, 6, and 12 months of age.
     - ○ *Unvaccinated children 7 through 23 months:* Administer 2 doses, with the second dose at least 12 weeks after the first dose AND after the first birthday.
     - ○ *Children 24 months and older who have not received a complete series:* Administer 2 primary doses at least 8 weeks apart.
  2. MenHibrix
     - ○ *Children 6 weeks through 18 months:* Administer doses at 2, 4, 6, and 12 through 15 months of age.
     - ○ If the first dose of MenHibrix is given at or after 12 months of age, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.
  3. Menactra
     - ○ *Children 24 months and older who have not received a complete series:* Administer 2 primary doses at least 8 weeks apart. If Menactra is administered to a child with asplenia (including sickle cell disease), do not administer Menactra until 2 years of age and at least 4 weeks after the completion of all PCV13 doses.

- Children with persistent complement component deficiency:

  1. Menveo
     - ○ *Children who initiate vaccination at 8 weeks through 6 months:* Administer doses at 2, 4, 6, and 12 months of age.
     - ○ *Unvaccinated children 7 through 23 months:* Administer 2 doses, with the second dose at least 12 weeks after the first dose AND after the first birthday.
     - ○ *Children 24 months and older who have not received a complete series:* Administer 2 primary doses at least 8 weeks apart.
  2. MenHibrix
     - ○ *Children 6 weeks through 18 months:* Administer doses at 2, 4, 6, and 12 through 15 months of age.
     - ○ If the first dose of MenHibrix is given at or after 12 months of age, a total of 2 doses should be given at least 8 weeks apart to ensure protection against serogroups C and Y meningococcal disease.
  3. Menactra
     - ○ *Children 9 through 23 months:* Administer 2 primary doses at least 12 weeks apart.
     - ○ *Children 24 months and older who have not received a complete series:* Administer 2 primary doses at least 8 weeks apart.

- For children who travel to or reside in countries in which meningococcal disease is hyperendemic or epidemic, including countries in the African meningitis belt or the Hajj, administer an age-appropriate formulation and series of Menactra or Menveo for protection against serogroups A and W meningococcal disease. Prior receipt of MenHibrix is not sufficient for children traveling to the meningitis belt or the Hajj because it does not contain serogroups A or W.
- For children at risk during a community outbreak attributable to a vaccine serogroup, administer or complete an age- and formulation-appropriate series of MenHibrix, Menactra, or Menveo.
- For booster doses among persons with high-risk conditions, refer to *MMWR* 2013 / 62(RR02);1-22, available at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6202a1.htm.

For other catch-up recommendations for these persons, and complete information on use of meningococcal vaccines, including guidance related to vaccination of persons at increased risk of infection, see MMWR March 22, 2013 / 62(RR02);1-22, available at http://www.cdc.gov/mmwr/pdf/rr/rr6202.pdf.

CS 244083-B

should be made. These statements are available at the CDC Web site or at www.immunize.org in multiple languages (Table 19-3).

The SC injection of MMR may sting the patient, who may have post-injection discomfort. The VIS states that 5% to 15% of patients may experience a fever of up to 103°F (39.5°C) approximately 7 to 12 days after administration of MMR. The patient may also experience rash, malaise, or sore throat.

Table 19–3 Vaccine Information Statements

Vaccine Information Statements (VISs) are available from the Centers for Disease Control and Prevention (CDC) or your local health department for the following vaccines. They have also been translated into the languages listed below. A PDF version of these VISs (English and other languages) can be found at www.immunize.org.

Vaccines	
Anthrax	Meningococcal
Chickenpox	Measles, mumps, and rubella
Diphtheria, tetanus, and pertussis	Pneumococcus
HIB	Polio (oral and inactivated)
Hepatitis A	Rabies
Hepatitis B	Rotavirus
Influenza	Smallpox
Japanese encephalitis	Td, Tdap
Lyme disease	Typhoid
Varicella	Yellow fever

MEASLES, MUMPS, RUBELLA, AND VARICELLA VACCINE

Pharmacodynamics

Similar to MMR, the MMRV (ProQuad) vaccine is a live, attenuated virus vaccine that produces a subclinical infection, creating active immunity to measles, mumps, rubella, and varicella viruses.

Pharmacokinetics

The MMRV vaccine is administered SC. Following SC injection of the first dose, the response rate at 6 weeks for patients is 91.2% for varicella, 97.4% for measles, 98.8% for mumps, and 98.5% for rubella (Merck, 2013). More than 99% of people who receive two doses of MMRV separated by at least 3 months develop evidence of immunity to all four covered viruses; for that reason, the current recommendation is for two doses.

Pharmacotherapeutics

Precautions and Contraindications

The contraindications for MMRV are the same as for MMR, including a history of anaphylactic reaction to neomycin or gelatin or any other component of the vaccine. Immediate treatment for anaphylaxis reaction should be available when administering MMRV.

MMRV is contraindicated in patients with primary or acquired immunodeficiency, including patients with immunosuppression associated with HIV/AIDS and patients with blood dyscrasias, leukemia, lymphomas of any type, or other malignant neoplasms affecting the bone marrow or lymphatic system. Immunosuppressive therapy, including high-dose steroids, may result in a more extensive vaccine-associated rash or disseminated disease. Low-dose, replacement, or short-burst therapy for asthma, are not contraindications for MMRV administration.

MMRV is Pregnancy Category C and MMRV (ProQuad) should not be administered to a pregnant patient. The manufacturer recommends pregnancy should be avoided for at least 3 months following vaccination (Merck, 2013). Merck Sharp & Dohme maintains a registry to monitor fetal outcomes if a woman is administered ProQuad during pregnancy. Inadvertent exposure during pregnancy should be reported to Merck & Co., Inc., at 1-877-888-4231 or VAERS at 1-800-822-7967, or www.vaers.hhs.gov.

If a patient has untreated tuberculosis or a febrile illness with temperature greater than 101.3°F (38.5°C), then vaccination with MMRV should be deferred until the patient is well. Because of the increased risk of fever and febrile seizures with MMRV, it should be used with caution in patients with a history of cerebral injury, seizures, or other conditions in which physiological stress due to fever should be avoided.

No data is available on the development of thrombocytopenia in patients vaccinated with MMRV (ProQuad). Because of the known risk for thrombocytopenia with MMR, use caution when administering MMRV.

Vaccination with MMRV should be avoided for 3 months after a blood transfusion or immune globulin administration.

Adverse Drug Reactions

The adverse drug reactions seen in MMRV are similar to those for MMR, except patients are more likely to develop fever and rash. There is a risk for developing a fever 7 to 12 days after MMR administration. In pre-licensure studies MMRV fever (equal to or greater than 102°F; equal to or greater than 39°C) was seen in 21.5% of patients, compared to 14.9% of patients receiving MMR (CDC, 2013a). Post-licensure studies of febrile seizures post-MMRV vaccination indicate one additional febrile seizure occurred 5 to 12 days after vaccination per 2,300 to 2,600 children aged 12 to 23 months who had received the first dose of MMRV vaccine compared with children who had received the first dose of MMR vaccine and varicella vaccine administered as separate injections at the same visit (CDC, 2013a). This increased risk of febrile seizure is not seen after the second dose of MMRV administered at the 4- to 6-year visit.

There is a slightly increased risk of developing a measles-like rash from 2.1% with MMR alone to 3% with MMRV. Additional adverse reactions include pain at injection site (22%), erythema (14.4%), and swelling (8.4%), similar to what is seen in patients receiving MMR (Merck, 2013).

Drug Interactions

Drug interactions with MMRV are the same as for MMR: immunosuppressants, IG, tuberculin skin tests, and salicylates.

Clinical Use and Dosing

MMRV is given SC at 12 to 15 months of age. The first dose may be given any time before age 12 years. Use of MMRV for the repeat dose at 4 to 6 years is well tolerated and results in higher levels of varicella antibodies (Reisinger et al, 2006). Three months should elapse before a second dose of MMRV is administered. MMRV may be administered 1 month after a dose of MMR.

Patient Education

The CDC recommends providers administering MMRV to children have a conversation with parents regarding the increased risk of fever and febrile seizures with the combination vaccine (CDC, 2013a). Parents of children should be informed about the slightly increased risk of febrile seizures 5 to 12 days after receiving the MMRV combination (Marin, Broder, Temte, Snider, & Seward, 2010). This risk will need to be weighed against the discomfort of two injections.

ORAL POLIOVIRUS VACCINE

Although oral polio vaccine (OPV) is no longer used in the United States, it is still used in other countries because of administrative ease and low cost.

Pharmacodynamics

OPV stimulates the immune system to produce antipoliovirus antibodies against Sabin poliovirus types 1, 2, and 3.

After oral administration, the live, attenuated virus enters the small intestine, where it replicates in the villous epithelial cells. These specialized epithelial cells transport the viral antigens to the B cells and macrophages, which process and produce antipoliovirus antibodies. In 1 to 2 weeks after a dose of OPV, antibodies are present. The live, attenuated poliovirus lingers in the gastrointestinal (GI) tract for 4 to 6 weeks, inducing both mucosal and serum antipoliovirus antibodies. The local secretory (intestinal) immune responses to OPV are greater than those induced by IPV. OPV induces intestinal immunity against wild strains of poliovirus; IPV does not. At least two doses of OPV are necessary for intestinal immunity. OPV may induce a herd-type of immunity because of the spread of live, attenuated viruses to susceptible contacts during the viral shedding period of 4 to 6 weeks after dosing. Three doses of OPV result in sustained, lifelong immunity.

Pharmacokinetics

After oral administration of OPV, antibody stimulation occurs within 7 to 10 days. Poliovirus antibodies have been found in serum, nasal secretions, saliva, duodenal fluids, urine, and feces. Poliovirus antibodies are distributed into breast milk.

Pharmacotherapeutics

Precautions and Contraindications

An anaphylactic reaction to any previous dose of OPV is a contraindication to its use. Patients with neomycin or streptomycin hypersensitivity also should not receive OPV because these agents are contained in OPV in small quantities.

OPV should be delayed if a patient has a moderate or severe febrile illness or severe respiratory infection. Administration of OPV with current viral GI infection, ongoing diarrhea, or vomiting is contraindicated. Vomiting may prevent the vaccine from reaching the stomach and small intestine. Diarrhea may increase transit time, preventing proper contact of the vaccine viruses with villous intestinal cells, and lead to decreased immune response. Vaccine administration should be delayed until the vomiting and diarrhea have been resolved.

There is a risk that immunocompromised individuals may develop poliomyelitis from use of live poliovirus, which is in OPV. Cancer, leukemia, lymphoma, radiation therapy, and immunodeficiency, including HIV or AIDS, are contraindications to OPV use. Drugs that affect the immune system, including high-dose steroids, are also a contraindication to OPV use. There is a chance that immunosuppressed individuals may contract OPV-associated poliomyelitis from coming in contact with a patient who is shedding the virus. IPV is the drug of choice in immunocompromised patients. IPV should also be used if household members are immunocompromised.

Vaccination of pregnant women with OPV should be avoided. OPV is Pregnancy Category C. If exposure to poliomyelitis is imminent and immediate protection is needed, vaccinate with OPV or IPV according to the adult dosing schedule. OPV is safe during breastfeeding and is routinely given during infancy.

Adverse Drug Reactions

The administration of OPV is associated with a low incidence (1 case/2.6 million doses) of paralytic poliomyelitis in patients who receive the vaccine and in household contacts. Vaccine-associated paralytic poliomyelitis (VAPP) is most likely to occur after the first dose of OPV. Household contacts are put at risk of developing VAPP because poliovirus is shed in the feces for 6 to 8 weeks after a dose of OPV. There is no risk of VAPP with the use of IPV, which is why, as of January 2000, IPV is the drug of choice for routine childhood immunization against polio in the United States.

Drug Interactions

OPV should not be administered to patients receiving immunosuppressants, including corticosteroids, interferon, and antineoplastic drugs, because there may be insufficient response to immunization. Patients may remain susceptible despite immunization. IPV is the recommended drug to use in these patients.

The CDC recommends that administration of live-virus vaccines be separated by intervals of at least 1 month, unless data are available regarding simultaneous vaccination (MMR, MMRV, hepatitis B vaccine [HBV], DTP, DTaP, influenza, and HIB may be given with OPV). Concurrent administration of OPV and cholera vaccine, parenteral typhoid vaccine, or plague vaccine should generally be avoided because of increased adverse effects. Concurrent administration of live oral typhoid vaccine may result in decreased immune responses to OPV. IG may be given with OPV.

Clinical Use and Dosing

To eliminate the risk of VAPP, the CDC recommended in January 2000 an all-IPV schedule for childhood immunizations. OPV may be used only for special circumstances, such as mass vaccination campaigns to control outbreaks of paralytic polio and in unvaccinated children who will be traveling in less than 4 weeks to areas where polio is endemic or epidemic. OPV may be used in children who have received at least two doses of IPV and whose parents do not accept the recommended number of vaccine injections. VAPP should be discussed with these parents before administering OPV. See Tables 19-1, 19-2, and 19-3 for dosing schedules.

Patient Education

All patients or their parents or guardians are required by law to receive CDC VISs, which are available in a variety of languages. Every effort should be made to provide adequate information to patients and parents before immunization. If a patient receives OPV, the patient and family should be instructed that virus is shed in the stools for 6 to 8 weeks and that good hand washing is crucial to preventing the small chance of contracting VAPP from the infected feces. As previously mentioned, VAPP should be discussed with the parent or, if applicable, the patient before administering OPV.

ROTAVIRUS VACCINE

Pharmacodynamics

Rotavirus is the leading cause of gastroenteritis in infants and young children worldwide. Almost every child in the United States will become infected with rotavirus by age 5 years, causing 400,000 doctor visits, and 55,000 to 70,000 hospital admissions (Cortese & Parashar, 2009). RotaTeq is a live oral vaccine that contains five strains of rotavirus (G1, G2, G3 or G4, P7). Rotarix is indicated for the prevention of rotavirus gastroenteritis caused by G1, G3, G4, and G9. Both vaccines are live vaccines that replicate in the small intestine and induce active immunity against rotavirus.

Pharmacokinetics

Pharmacokinetic information regarding rotavirus vaccine is not available.

Pharmacotherapeutics

Precautions and Contraindications

Because rotavirus vaccine is a live-virus vaccine, it should not be administered to infants who are or may be potentially immunocompromised, including infants with blood dyscrasias, leukemia, lymphomas, or other malignant neoplasms; infants on immunosuppressive therapy; infants with primary and acquired immunodeficiency states including HIV/AIDS; and infants who have received blood transfusions or blood products in the past 42 days.

Infants who have a febrile illness should have the vaccine delayed, except when withholding the vaccine creates greater risk to the patient. A minor upper respiratory infection with low-grade fever (under 100.5°F) is not a reason for withholding rotavirus vaccine. The virus should not be administered to infants with acute gastroenteritis until it improves.

Rotavirus may be shed in the stools of patients receiving the vaccine (8.9% of patients in clinical trials); therefore, it is prudent to use caution if the infant will have close contact with persons with malignancies or who are otherwise immunocompromised and contacts who are receiving immunosuppressive therapy.

A history of intussusception is a contraindication for the rotavirus vaccine because there may be an increased risk of intussusception following the first dose of rotavirus vaccine (CDC, 2011a).

Adverse Drug Reactions

A previous live rhesus rotavirus–based vaccine (RotaShield) was withdrawn from the market after it was found to be associated with intussusception. The risk for intussusception was evaluated in a large preclinical trials of more than 70,000 infants, which found no association with intussusception and administration of RotaTeq or Rotarix (Cortese & Parashar, 2009). Postmarketing studies in Mexico found a slight increased risk (0 to 4 cases per 100,000 vaccinated infants) of developing intussusception in the 31 days after administration of the first dose of rotavirus vaccine, with highest risk in the first 7 days after vaccine dose (Food and Drug Administration [FDA], 2012).

GI symptoms are the major reported adverse effects in the clinical trials of RotaTeq. There was a slight increased incidence of vomiting in the RotaTeq patients (6.7% versus 5.4% for placebo after dose 1, 5.0% versus 4.4% for placebo after dose 2, and 3.6% versus 3.2% for placebo after dose 3), as well as a slight increase in reports of diarrhea in the RotaTeq group (10.4% versus 9.1% in placebo after dose 1, 8.6% versus 6.4% in placebo group after dose 2, and 6.1% versus 5.4% in placebo after dose 3). Symptoms of irritability did not differ between RotaTeq and placebo infants in all three doses.

Rotarix clinical trials found no increase in fever, diarrhea, or fussiness in patients who received Rotarix over placebo. Patients who received Rotarix had a slightly increased (13% versus 11%) incidence of vomiting in the week after administration.

Drug Interactions

During clinical trials, RotaTeq and Rotarix were routinely administered concurrently with DTaP, IPV, HIB, HBV, and pneumococcal conjugate vaccine. There was no evidence of reduced antibody response to these vaccines when administered with RotaTeq or Rotarix (Cortese & Parashar, 2009).

Clinical Use and Dosing

RotaTeq vaccination consists of a series of three ready-to-use oral liquid doses. The vaccine is administered orally beginning at 6 to 12 weeks of age with the second and third doses delivered in 4- to 10-week intervals. All doses of the vaccine should be delivered by age 32 weeks. RotaTeq was administered to preterm infants (25- to 36-weeks' gestation) according to their age in weeks, and there was no difference in adverse effects between the vaccine and the placebo. There are insufficient data on safety and efficacy outside of these age ranges.

Rotarix is a two-dose schedule of 1 mL per dose given at 2 to 4 months of age. The two doses may be administered between 6 and 24 weeks of age. The two doses should be administered at least 4 weeks apart.

The CDC has recommendations for both rotavirus vaccines, including the maximum age for the first dose, which is 14 weeks 6 days (Cortese & Parashar, 2009). If a child is inadvertently given the first dose after 15 weeks and 0 days, then the series should be continued and completed by 8 months 0 days (Cortese & Parashar, 2009). Rotavirus vaccine may be administered before, after, or concurrently with any blood product or antibody-containing product (IG). Ideally, the series should all be the same rotavirus product, but if it is unknown whether the patient received RotaTeq or Rotarix, then the series should be completed with the product available to the clinic (Cortese & Parashar, 2009). If the patient regurgitates, spits out, or vomits the rotavirus vaccine, it should not be readministered. Children who have had rotavirus gastroenteritis before completing the series should start or complete the series according to the standard schedule.

Patient Education

All patients or their parents or guardians are required by law to receive CDC VISs, which are available in a variety of languages. Every effort should be made to provide adequate information to patients and their parents before immunization. Because rotavirus vaccine is a live vaccine shed in the stool, caregivers should encourage strict hand-washing practices.

Parents should be instructed to report any adverse reactions to their health-care provider. Providers should fill out a Vaccine Adverse Event Reporting System (VAERS) form, available at www.vaers.hhs.gov/.

VARICELLA VIRUS VACCINE

Pharmacodynamics

Varicella virus vaccine (Varivax) is a live vaccine that produces an IgG antibody humoral immune response to varicella zoster virus (VZV). Vaccinated patients also have a cell-mediated immune response, with activation of both CD41 helper T cells and CD81 T lymphocytes. Efficacy of varicella vaccine is measured by protection against disease and by protection against severe disease. The efficacy of one dose of varicella vaccine is 94.4% over a 10-year period, with protection against household exposure of 90.2% (CDC, 2007). The two-dose regimen is 98.3% effective against any disease and 96.4% effective against household exposure (CDC, 2007). Vaccination appears to prevent serious disease even in patients who do not seroconvert. Post-vaccination cases of varicella are mild (less than 50 lesions, frequently not vesicular, mild or no fever) and patients recover quicker than when infected with wild virus (CDC, 2007).

Pharmacokinetics

A single SC dose of varicella virus vaccine given to children aged 12 months to 12 years stimulates IgG antibody production and results in seroconversion rates of 85.7% 6 weeks after the first dose (CDC, 2007). According to the CDC (2007), in children aged 12 months to 12 years who are administered a second dose with 3 months between doses, there is a 99.6% seroconversion response rate. When the second dose is given at age 4 to 6 years, the response is a 99.4% seroconversion rate. In patients, aged 13 and older, seroconversion rates are 78% to 82%; a second dose results in 99% seroconversion in adolescents and adults. Waning immunity has not been demonstrated, with high antibody levels measured for at least 10 years after vaccination.

Post-exposure prophylaxis with varicella vaccine is effective in preventing varicella disease. Administration to unvaccinated children within 3 days of exposure to varicella rash is 90% effective in preventing varicella and 70% effective if administered within 5 days of exposure (CDC, 2007). Post-exposure prophylaxis is 100% effective in decreasing the severity of disease.

Pharmacotherapeutics
Precautions and Contraindications

Patients with neomycin or gelatin hypersensitivity should not receive varicella vaccine because there are small quantities of each in the vaccine. Varicella vaccine should be delayed if a patient has a moderate or severe illness, with or without fever.

There is a risk that immunocompromised individuals will develop varicella from use of live virus for vaccination. Cancer, leukemia, lymphoma, radiation therapy, and immunodeficiency are contraindications to varicella vaccine use. Patients with symptomatic HIV infection should not receive varicella vaccine. Regarding asymptomatic HIV-infected children, the CDC states, "HIV-infected children with CD4+ T-lymphocyte percentage >15 percent should be considered for vaccination with the single antigen varicella vaccine" (CDC, 2007, p 24).

Drugs that affect the immune system, including high-dose steroids, also contraindicate varicella vaccine use. Patients who are on systemic steroids (e.g., for asthma) may be vaccinated if they are receiving less than 2 mg/kg or less than 20 mg per day of prednisone and are not otherwise immunocompromised (CDC, 2007). Varicella vaccine may be given to a patient if an immunocompromised person is in the household. The patient who develops a rash after vaccination should avoid contact with the immunocompromised person for the duration of the rash, although there has been no evidence of transmission of virus to an immunocompromised person in post-licensure monitoring of more than 55 million doses (CDC, 2007).

Vaccination of pregnant women should be avoided. Varicella vaccine is Pregnancy Category C. Pregnancy should be avoided for 1 to 3 months after vaccination. The manufacturer of Varivax has established a pregnancy registry to monitor maternal–fetal outcomes of pregnant women inadvertently administered the live varicella virus vaccine 3 months before or during pregnancy. For information about the registry, call 1-800-986-8999. In 10 years of monitoring via the pregnancy registry, no cases of congenital varicella syndrome or congenital varicella birth defects have been documented (CDC, 2007). Varicella vaccine may be given if there is a pregnant household contact, such as the patient's mother. Varicella vaccine may be given to a nursing mother if the risk of exposure to natural VZV is high. It is not known if it is excreted in breast milk.

Adverse Drug Reactions

The reactions reported most frequently in children and adults that can be attributed to varicella vaccine include fever, injection site reaction, and a vesicular rash. In healthy children, fever of 102°F or higher is reported in 14.7% of vaccine recipients. Pain or discomfort at the injection site is reported in 19.3%, with 3.4% of patients developing a vesicular rash at the injection site. A generalized vesicular rash developed in 3.8% of patients, with the median number of five or fewer lesions in healthy children. The vesicular rash occurs within 26 days of injection with varicella vaccine.

Adult and adolescent patients require two injections and have similar adverse reactions. Fever in vaccine recipients aged 12 years and older was defined as a temperature of 100°F or higher. After the first dose of varicella vaccine, 10.2% reported fever, and 9.5% reported fever after the second dose. Localized reaction at the injection site was reported in 3% of adolescent and adult patients after the first dose and in 1% after the second dose. A generalized vesicular rash was reported by 5.5% after the first dose and 0.9% after the second dose.

Drug Interactions

Varicella vaccine should not be administered to patients receiving immunosuppressants, including high-dose corticosteroids, interferon, and antineoplastic drugs, because response to immunization may be insufficient, that is, patients may remain susceptible despite immunization. Patients receiving prednisone up to 20 mg per day or less than 2 mg/kg per day for less than 2 weeks may receive varicella vaccine (CDC, 2007).

Whether varicella vaccine may be inactivated by IG is unknown, although other live-virus vaccines may be inactivated. Varicella vaccine should not be given for 3 to 11 months after IG is administered depending on the IG produced (CDC, 2007). The CDC recommends that IG preparations should not be administered for 2 weeks after varicella vaccine is given; the manufacturer recommends waiting 2 months. If IG is given in the interval after vaccination, the recipient should be either revaccinated in 5 months or tested for varicella immunity 6 months later and revaccinated if indicated.

The MMR and varicella vaccines are compatible if they are administered on the same day, with different needles, and at separate sites, or in the form of MMRV. If the two live vaccines are not given at the same time, an interval of 1 month between MMR and varicella vaccine is indicated. Varicella vaccine may be given simultaneously with DTaP, DT, Td, HIB, IPV, OPV, PCV13, or HBV, using separate sites of injection.

Although no adverse effects from the use of salicylates or aspirin (ASA) have been reported, the manufacturer recommends avoidance of ASA for 6 weeks after vaccination. Reye syndrome, which affects children younger than age 15 exclusively, has been associated with aspirin use following active varicella infection. Children who are on therapeutic ASA therapy may be vaccinated with the varicella vaccine, with close clinical monitoring. According to the CDC (2007), vaccination is thought to present less risk than natural varicella vaccine in these children.

Clinical Use and Dosing

The CDC and the AAP recommend that all healthy children who lack a reliable history of varicella infection be routinely vaccinated at age 12 to 15 months. A second dose of varicella vaccine is recommended at age 4 to 6 years (before entering kindergarten). The second dose may be administered earlier, as long as the interval between the two doses is more than 3 months. Healthy adolescents age 13 and older, who have no history of varicella infection and who have not previously received varicella vaccine, should be administered two doses 4 to 8 weeks apart.

Administration error: If a child is accidentally administered zoster vaccine (Zostavax) instead of varicella vaccine (Varivax), then it should be counted as a valid vaccine and reported to the VAERS whether or not an adverse reaction occurs. The child will still require two doses of varicella vaccine.

The ACIP of the CDC recommends that all healthy adults be screened for varicella immunity and adults without immunity should receive varicella vaccine. Attention should be given to those adults at high risk of exposure or transmission of varicella disease. They include adults who live in households with children, live or work in an environment in which varicella transmission is likely (teachers, health-care workers, day-care workers) or could occur (college dorm, correctional institution, military), or have household contact with an immunocompromised person; nonpregnant women of childbearing age; and international travelers. Performing serological testing of adults before administering is optional and may be cost-effective. The varicella vaccine dose for adults is two doses separated by 4 to 8 weeks.

Monitoring

There is no need to do post-vaccination titers after patients receive the varicella vaccine. At this time there is no commercially available test to determine immunity from varicella vaccine, just disease-induced immunity; therefore, the test may detect a false-positive outcome (CDC, 2007).

Patient Education

All patients or their parents or guardians are required by law to receive CDC VISs, which are available in a variety of languages. Every effort should be made to provide adequate information to patients and their parents before immunization.

There may be transient burning or stinging at administration. Patients should be informed that there is a small chance that they may develop a fever, reaction at the injection site, or vesicular rash after administration of varicella vaccine.

ZOSTER VACCINE

Pharmacodynamics

Shingles is a localized and painful cutaneous eruption caused by the reactivation of varicella zoster virus, the same virus that causes chickenpox in children. The varicella virus becomes latent in the neuronal cell bodies and when reactivated causes shingles. The triggers for reactivation are not well understood, but it is known that cell-mediated immunity may prevent reactivation. The lifetime incidence of shingles is 1 in 3 and it affects approximately 1 million patients in the United States annually (CDC, 2008).

Zoster vaccine (Zostavax) is a live, attenuated varicella zoster vaccine from the same strain used to develop the varicella vaccine (Varivax, ProQuad). The zoster vaccine reduced the risk of developing zoster by 51.3% in pre-licensure trials and was 66.5% effective in preventing post-herpetic neuralgia in the study group that was followed for 3 years. The vaccine also reduces severity of zoster by 57% in the vaccine recipients who developed post-herpetic neuralgia.

The zoster vaccine has been studied and approved by the U.S. Food and Drug Administration (FDA) for adults aged 50 years and older (CDC, 2011b). The vaccine is most effective in patients aged 60 to 69 years and least effective in patients over age 80 years (CDC, 2008).

CLINICAL PEARL

Administering Multiple Vaccines
Currently a child from age 12 to 18 months should receive six possible injections. This can be traumatic for patient and parent. Most public health officials recommend giving all the recommended vaccines at one visit; therefore, the child who is 15 months old could be getting as many as all six injections at that visit. Using combined vaccines is best (Pediarix, Pentacel) to decrease the number of injections or spread the administration of the vaccines over two or three visits. If it is necessary to give all the vaccines in one visit, as in the case of upcoming international travel or a history of unreliable attendance at well-child examinations, two people can administer the vaccines simultaneously. Giving the vaccines simultaneously makes the process faster and simpler for the patient and the person administering the vaccine. The CDC guidelines for administering multiple injections to infants are located in Appendix D of the *Pink Book* at www.cdc.gov/vaccines/pubs/pinkbook/index.html.

Pharmacokinetics

A single SC 0.65-mL dose of zoster vaccine produces a peak in cell-mediated response to varicella zoster in 1 to 3 weeks. Patients in the 60-to-69 age group demonstrated a better immune response to the vaccine than patients over age 70.

Pharmacotherapeutics

Precautions and Contraindications

Zoster vaccine should not be administered to patients with a history of anaphylactic reaction to neomycin, gelatin, or any other component of the vaccine. Patients with primary immunodeficiency states should not be administered zoster vaccine. As zoster vaccine is a live, attenuated virus, patients with leukemia, lymphoma, cancer of the bone marrow or lymphatic system, or AIDS should not be given the vaccine, because they may develop disseminated disease. Patients receiving high-dose corticosteroids (greater than 20 mg/day of prednisone) for more than 2 weeks should wait at least a month after prednisone is stopped to get the zoster vaccine.

Zoster vaccine (Zostavax) is not approved for women of childbearing age and should not be administered to pregnant women. Zoster vaccine should not be administered to patients with active tuberculosis or acute illness, or with fever.

Adverse Drug Reactions

The most common adverse drug reactions to zoster vaccine reported during the clinical trials were related to the injection site. Pain/tenderness (33.4%), erythema (33.7%), swelling (24.9%), and pruritus (6.6%) are all reported by patients receiving zoster vaccine. Headache was reported by 1.4% of patients who received the zoster vaccine versus 0.8% of patients who received a placebo.

Drug Interactions

Antiviral drugs (acyclovir, famciclovir, and valacyclovir) should be stopped at least 24 hours before zoster vaccine is administered. Antivirals should not be used for at least 14 days after vaccination (CDC, 2008).

Zoster vaccine can be administered before, after, or at the same time as blood product or antibody-containing products.

Patients who are taking high-dose corticosteroids (greater than 20 mg/d prednisone) should not be vaccinated and need to be off prednisone for a month before vaccination. Patients on short-term corticosteroids (less than 14 d) or low-dose (less than 20 mg/d) prednisone may be vaccinated with zoster virus.

Patients taking low-doses of methotrexate (less than or equal to 0.4 mg/kg/wk), azathioprine (less than or equal to 3.0 mg/kg/d), or 6-mercaptopurine (less than or equal to 1.5 mg/kg/d) for treatment of rheumatoid arthritis, psoriasis, polymyositis, sarcoidosis, or inflammatory bowel disease may be vaccinated with zoster vaccine (CDC, 2008).

Clinical Use and Dosing

A single dose of zoster vaccine is recommended by the ACIP for all adults aged 60 years or older. The zoster vaccine may be administered to adults age 50 years or older who request the vaccine or who are at risk of poor outcomes if they contract herpes zoster or post-herpetic neuralgia (CDC, 2011b). The dose is 0.65 mL administered in the SC tissue of the deltoid region. The vaccine is given even if a patient has a history of herpes zoster (CDC, 2008). It is not necessary to screen for history of varicella disease or vaccine, nor is it necessary to test for varicella immunity prior to immunization. Zoster vaccine may be administered with other common vaccines in this age group: Td, Tdap, and pneumococcal. Administration of zoster vaccine and other live-virus vaccines should be separated by 4 weeks. Zoster vaccine is not recommended for patients who have received the varicella vaccine, although patients in the approved age range have most likely had wild varicella infection.

Patients with chronic medical conditions (e.g., chronic renal failure, diabetes mellitus, rheumatoid arthritis, and chronic pulmonary disease) may be vaccinated (CDC, 2008). Zoster vaccine should be deferred in patients with severe illness or with fever. It may be administered if the patient has a minor acute illness without fever (that is, an upper respiratory infection).

Patients who are immunosuppressed have greater morbidity and mortality from herpes zoster. If patients will be initiating immunosuppressive therapy or have diseases that might lead to immunodeficiency, zoster vaccine should be administered as soon as possible while their immunity is still intact. Zoster vaccine should be administered at least 14 days before immunosuppressive therapy is started. Zoster vaccine should be avoided for at least 24 months after stem cell transplant (CDC, 2008).

Antiviral medications should be avoided for 14 days after zoster vaccine.

Administration error: If a child is accidentally administered zoster vaccine (Zostavax) instead of varicella vaccine (Varivax), then it should be counted as a valid vaccine and reported to the VAERS whether or not an adverse reaction occurs. If an adult over age 60 is administered the varicella vaccine (Varivax), it is not considered a valid dose and the patient is administered zoster vaccine (Zostavax) the same day (CDC, 2008). If the zoster vaccine is not administered the same day, then a dose of zoster vaccine should be administered at least 28 days later.

Monitoring

There is no specific monitoring of patients after receiving the zoster vaccine.

Patient Education

All patients who receive vaccines are required by law to receive a VIS in the appropriate language. Patients should be informed they may have discomfort at the injection site, including pain, swelling, erythema, and pruritus. See Table 19-4.

ORAL TYPHOID VACCINE

Pharmacodynamics

Typhoid vaccines are used to increase resistance to enteric fever caused by *Salmonella typhi.* Typhoid fever is spread by ingesting water contaminated by feces from infected persons. Worldwide, an estimated 22 million cases of typhoid fever occur annually (Newton & Mintz, 2014). The risk is greatest in travelers to South Asia, although the disease can be seen in East and Southeast Asia, Africa, the Caribbean, and Central and South America (Newton & Mintz, 2014). Oral typhoid vaccine (Vivotif Berna) is a live, attenuated vaccine, Ty21a. The oral vaccine is ingested and works in the small intestine to synthesize a lipopolysaccharide that evokes a protective immune response. The vaccine is estimated to be 50% to 80% effective in preventing typhoid fever. The efficacy of protective immunity depends on the size of the bacterial inoculum consumed.

Pharmacokinetics

The absorption, distribution, and metabolism of oral typhoid vaccine are unknown.

Pharmacotherapeutics

Precautions and Contraindications

Hypersensitivity to typhoid vaccine is a contraindication to its use. Because oral typhoid vaccine is a live, attenuated virus, it should not be administered to immunocompromised patients, including those who are HIV-infected. Do not administer it to a patient with acute febrile illness or an acute GI illness (diarrhea).

Oral typhoid vaccine is Pregnancy Category C. It is not known if the vaccine is harmful to the fetus. If it is necessary to vaccinate a pregnant patient, inactivated vaccine is recommended.

Oral typhoid vaccine is not recommended for use in children younger than age 6 years. Use inactivated vaccine in young children.

Table 19–4 ✇ Recommended Adult Immunization Schedule – United States, 2015

Recommended Adult Immunization Schedule—United States - 2015

Note: These recommendations must be read with the footnotes that follow
containing number of doses, intervals between doses, and other important information.

Figure 1. Recommended adult immunization schedule, by vaccine and age group[1]

VACCINE ▼ AGE GROUP ▶	19-21 years	22-26 years	27-49 years	50-59 years	60-64 years	≥ 65 years
Influenz *,2	1 dose annually					
Tetanus, diphtheria, pertussis (Td/Tdap)*,3	Substitute 1-time dose of Tdap for Td booster; then boost with Td every 10 yrs					
Varicella*,4	2 doses					
Human papillomavirus (HPV) Female*,5	3 doses					
Human papillomavirus (HPV) Male*,5	3 doses					
Zoster6					1 dose	
Measles, mumps, rubella (MMR)*,7	1 or 2 doses					
Pneumococcal 13-valent conjugate (PCV13)*,8					1-time dose	
Pneumococcal polysaccharide (PPSV23)8	1 or 2 doses					1 dose
Meningococcal*,9	1 or more doses					
Hepatitis A*,10	2 doses					
Hepatitis B*,11	3 doses					
Haemophilus influen ae type b (Hib)*,12	1 or 3 doses					

*Covered by the Vaccine Injury Compensation Program

For all persons in this category who meet the age requirements and who lack documentation of vaccination or have no evidence of previous infection; zoster vaccine recommended regardless of prior episode of zoster

Recommended if some other risk factor is present (e.g., on the basis of medical, occupational, lifestyle, or other indication)

No recommendation

Report all clinically significant postvaccination reactions to the Vaccine Adverse Event Reporting System (VAERS). Reporting forms and instructions on filing a VAERS report are available at www.vaers.hhs.gov or by telephone, 800-822-7967.

Information on how to file a Vaccine Injury Compensation Program claim is available at www.hrsa.gov/vaccinecompensation or by telephone, 800-338-2382. To file a claim for vaccine injury, contact the U.S. Court of Federal Claims, 717 Madison Place, N.W., Washington, D.C. 20005; telephone, 202-357-6400.

Additional information about the vaccines in this schedule, extent of available data, and contraindications for vaccination is also available at www.cdc.gov/vaccines or from the CDC-INFO Contact Center at 800-CDC-INFO (800-232-4636) in English and Spanish, 8:00 a.m. - 8:00 p.m. Eastern Time, Monday - Friday, excluding holidays.

Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

The recommendations in this schedule were approved by the Centers for Disease Control and Prevention's (CDC) Advisory Committee on Immunization Practices (ACIP), the American Academy of Family Physicians (AAFP), the America College of Physicians (ACP), American College of Obstetricians and Gynecologists (ACOG) and American College of Nurse-Midwives (ACNM).

Figure 2. Vaccines that might be indicated for adults based on medical and other indications[1]

VACCINE ▼ INDICATION ▶	Pregnancy	Immuno-compromising conditions (excluding human immunodeficiency virus [HIV]) 4,6,7,8,13	HIV infection CD4+ T lymphocyte count 4,6,7,8,13 < 200 cells/µL	HIV infection CD4+ T lymphocyte count 4,6,7,8,13 ≥ 200 cells/µL	Men who have sex with men (MSM)	Kidney failure, end-stage renal disease, receipt of hemodialysis	Heart disease, chronic lung disease, chronic alcoholism	Asplenia (including elective splenectomy and persistent complement component deficiencies) 8,12	Chronic liver disease	Diabetes	Healthcare personnel
Influenz *,2	1 dose IIV annually				1 dose IIV or LAIV annually	1 dose IIV annually					1 does IIV or LAIV annually
Tetanus, diphtheria, pertussis (Td/Tdap)*,3	1 dose Tdap each pregnancy	Substitute 1-time dose of Tdap for Td booster; then boost with Td every 10 yrs									
Varicella*,4	Contraindicated			2 doses							
Human papillomavirus (HPV) Female*,5	3 doses through age 26 yrs				3 doses through age 26 yrs						
Human papillomavirus (HPV) Male*,5	3 doses through age 26 yrs				3 doses through age 21 yrs						
Zoster6	Contraindicated			1 dose							
Measles, mumps, rubella (MMR)*,7	Contraindicated			1 or 2 doses							
Pneumococcal 13-valent conjugate (PCV13)*,8		1 dose									
Pneumococcal polysaccharide (PPSV23)8	1 or 2 doses										
Meningococcal*,9	1 or more doses										
Hepatitis A*,10	2 doses										
Hepatitis B*,11	3 doses										
Haemophilus influen ae type b (Hib)*,12		post-HSCT recipients only	1 or 3 doses								

*Covered by the Vaccine Injury Compensation Program

For all persons in this category who meet the age requirements and who lack documentation of vaccination or have no evidence of previous infection; zoster vaccine recommended regardless of prior episode of zoster

Recommended if some other risk factor is present (e.g., on the basis of medical, occupational, lifestyle, or other indications)

No recommendation

These schedules indicate the recommended age groups and medical indications for which administration of currently licensed vaccines is commonly recommended for adults ages 19 years and older, as of February 1, 2015. For all vaccines being recommended on the Adult Immunization Schedule: a vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Licensed combination vaccines may be used whenever any components of the combination are indicated and when the vaccine's other components are not contraindicated. For detailed recommendations on all vaccines, including those used primarily for travelers or that are issued during the year, consult the manufacturers' package inserts and the complete statements from the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/hcp/acip-recs/index.html). Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

Control and Prevention

Table 19–4 ✥ Recommended Adult Immunization Schedule – United States, 2015—cont'd

Footnotes—Recommended Immunization Schedule for Adults Aged 19 Years or Older: United States, 2015

1. Additional information
- Additional guidance for the use of the vaccines described in this supplement is available at www.cdc.gov/vaccines/hcp/acip-recs/index.html.
- Information on vaccination recommendations when vaccination status is unknown and other general immunization information can be found in the General Recommendations on Immunization at www.cdc.gov/mmwr/preview/mmwrhtml/rr6002a1.htm.
- Information on travel vaccine requirements and recommendations (e.g., for hepatitis A and B, meningococcal, and other vaccines) is available at wwwnc.cdc.gov/travel/destinations/list.
- Additional information and resources regarding vaccination of pregnant women can be found at www.cdc.gov/vaccines/adults/rec-vac/pregnant.html.

2. Influenza vaccination
- Annual vaccination against influenza is recommended for all persons aged 6 months or older.
- Persons aged 6 months or older, including pregnant women and persons with hives-only allergy to eggs can receive the inactivated influenza vaccine (IIV). An age-appropriate IIV formulation should be used.
- Adults aged 18 years or older can receive the recombinant influenza vaccine (RIV) (FluBlok). RIV does not contain any egg protein and can be given to age-appropriate persons with egg allergy of any severity.
- Healthy, nonpregnant persons aged 2 to 49 years without high-risk medical conditions can receive either intranasally administered live, attenuated influenza vaccine (LAIV) (FluMist) or IIV.
- Health care personnel who care for severely immunocompromised persons who require care in a protected environment should receive IIV or RIV; health care personnel who receive LAIV should avoid providing care for severely immunosuppressed persons for 7 days after vaccination.
- The intramuscularly or intradermally administered IIV are options for adults aged 18 through 64 years.
- Adults aged 65 years or older can receive the standard-dose IIV or the high-dose IIV (Fluzone High-Dose).
- A list of currently available influenza vaccines can be found at www.cdc.gov/flu/protect/vaccine/vaccines.htm.

3. Tetanus, diphtheria, and acellular pertussis (Td/Tdap) vaccination
- Administer 1 dose of Tdap vaccine to pregnant women during each pregnancy (preferably during 27 to 36 weeks' gestation) regardless of interval since prior Td or Tdap vaccination.
- Persons aged 11 years or older who have not received Tdap vaccine or for whom vaccine status is unknown should receive a dose of Tdap followed by tetanus and diphtheria toxoids (Td) booster doses every 10 years thereafter. Tdap can be administered regardless of interval since the most recent tetanus or diphtheria-toxoid containing vaccine.
- Adults with an unknown or incomplete history of completing a 3-dose primary vaccination series with Td-containing vaccines should begin or complete a primary vaccination series including a Tdap dose.
- For unvaccinated adults, administer the first 2 doses at least 4 weeks apart and the third dose 6 to 12 months after the second.
- For incompletely vaccinated (i.e., less than 3 doses) adults, administer remaining doses.
- Refer to the ACIP statement for recommendations for administering Td/Tdap as prophylaxis in wound management (see footnote 1).

4. Varicella vaccination
- All adults without evidence of immunity to varicella (as defined below) should receive 2 doses of single-antigen varicella vaccine or a second dose if they have received only 1 dose.
- Vaccination should be emphasized for those who have close contact with persons at high risk for severe disease (e.g., health care personnel and family contacts of persons with immunocompromising conditions) or are at high risk for exposure or transmission (e.g., teachers; child care employees; residents and staff members of institutional settings, including correctional institutions; college students; military personnel; adolescents and adults living in households with children; nonpregnant women of childbearing age; and international travelers).
- Pregnant women should be assessed for evidence of varicella immunity. Women who do not have evidence of immunity should receive the first dose of varicella vaccine upon completion or termination of pregnancy and before discharge from the health care facility. The second dose should be administered 4 to 8 weeks after the first dose.
- Evidence of immunity to varicella in adults includes any of the following:
  - documentation of 2 doses of varicella vaccine at least 4 weeks apart;
  - U.S.-born before 1980, except health care personnel and pregnant women;
  - history of varicella based on diagnosis or verification of varicella disease by a health care provider;
  - history of herpes zoster based on diagnosis or verification of herpes zoster disease by a health care provider; or
  - laboratory evidence of immunity or laboratory confirmation of disease.

5. Human papillomavirus (HPV) vaccination
- Two vaccines are licensed for use in females, bivalent HPV vaccine (HPV2) and quadrivalent HPV vaccine (HPV4), and one HPV vaccine for use in males (HPV4).
- For females, either HPV4 or HPV2 is recommended in a 3-dose series for routine vaccination at age 11 or 12 years and for those aged 13 through 26 years, if not previously vaccinated.

- For males, HPV4 is recommended in a 3-dose series for routine vaccination at age 11 or 12 years and for those aged 13 through 21 years, if not previously vaccinated. Males aged 22 through 26 years may be vaccinated.
- HPV4 is recommended for men who have sex with men through age 26 years for those who did not get any or all doses when they were younger.
- Vaccination is recommended for immunocompromised persons (including those with HIV infection) through age 26 years for those who did not get any or all doses when they were younger.
- A complete series for either HPV4 or HPV2 consists of 3 doses. The second dose should be administered 4 to 8 weeks (minimum interval of 4 weeks) after the first dose; the third dose should be administered 24 weeks after the first dose and 16 weeks after the second dose (minimum interval of at least 12 weeks).
- HPV vaccines are not recommended for use in pregnant women. However, pregnancy testing is not needed before vaccination. If a woman is found to be pregnant after initiating the vaccination series, no intervention is needed; the remainder of the 3-dose series should be delayed until completion or termination of pregnancy.

6. Zoster vaccination
- A single dose of zoster vaccine is recommended for adults aged 60 years or older regardless of whether they report a prior episode of herpes zoster. Although the vaccine is licensed by the U.S. Food and Drug Administration for use among and can be administered to persons aged 50 years or older, ACIP recommends that vaccination begin at age 60 years.
- Persons aged 60 years or older with chronic medical conditions may be vaccinated unless their condition constitutes a contraindication, such as pregnancy or severe immunodeficiency.

7. Measles, mumps, rubella (MMR) vaccination
- Adults born before 1957 are generally considered immune to measles and mumps. All adults born in 1957 or later should have documentation of 1 or more doses of MMR vaccine unless they have a medical contraindication to the vaccine or laboratory evidence of immunity to each of the three diseases. Documentation of provider-diagnosed disease is not considered acceptable evidence of immunity for measles, mumps, or rubella.

Measles component:
- A routine second dose of MMR vaccine, administered a minimum of 28 days after the first dose, is recommended for adults who:
  - are students in postsecondary educational institutions,
  - work in a health care facility, or
  - plan to travel internationally.
- Persons who received inactivated (killed) measles vaccine or measles vaccine of unknown type during 1963–1967 should be revaccinated with 2 doses of MMR vaccine.

Mumps component:
- A routine second dose of MMR vaccine, administered a minimum of 28 days after the first dose, is recommended for adults who:
  - are students in a postsecondary educational institution,
  - work in a health care facility, or
  - plan to travel internationally.
- Persons vaccinated before 1979 with either killed mumps vaccine or mumps vaccine of unknown type who are at high risk for mumps infection (e.g., persons who are working in a health care facility) should be considered for revaccination with 2 doses of MMR vaccine.

Rubella component:
- For women of childbearing age, regardless of birth year, rubella immunity should be determined. If there is no evidence of immunity, women who are not pregnant should be vaccinated. Pregnant women who do not have evidence of immunity should receive MMR vaccine upon completion or termination of pregnancy and before discharge from the health care facility.

Health care personnel born before 1957:
- For unvaccinated health care personnel born before 1957 who lack laboratory evidence of measles, mumps, and/or rubella immunity or laboratory confirmation of disease, health care facilities should consider vaccinating personnel with 2 doses of MMR vaccine at the appropriate interval for measles and mumps or 1 dose of MMR vaccine for rubella.

8. Pneumococcal (13-valent pneumococcal conjugate vaccine [PCV13] and 23-valent pneumococcal polysaccharide vaccine [PPSV23]) vaccination
- General information
  - When indicated, only a single dose of PCV13 is recommended for adults.
  - No additional dose of PPSV23 is indicated for adults vaccinated with PPSV23 at or after age 65 years.
  - When both PCV13 and PPSV23 are indicated, PCV13 should be administered first; PCV13 and PPSV23 should not be administered during the same visit.
  - When indicated, PCV13 and PPSV23 should be administered to adults whose pneumococcal vaccination history is incomplete or unknown.
- Adults aged 65 years or older who
  - Have not received PCV13 or PPSV23: Administer PCV13 followed by PPSV23 in 6 to 12 months.
  - Have not received PCV13 but have received a dose of PPSV23 at age 65 years or older: Administer PCV13 at least 1 year after the dose of PPSV23 received at age 65 years or older.

Continued

Table 19–4 🅧 **Recommended Adult Immunization Schedule – United States, 2015—cont'd**

Footnotes—Recommended Immunization Schedule for Adults Aged 19 Years or Older: United States, 2015

8. Pneumococcal vaccination (continued)
— Have not received PCV13 but have received 1 or more doses of PPSV23 before age 65: Administer PCV13 at least 1 year after the most recent dose of PPSV23; administer a dose of PPSV23 6 to 12 months after PCV13, or as soon as possible if this time window has passed, and at least 5 years after the most recent dose of PPSV23.
— Have received PCV13 but not PPSV23 before age 65 years: Administer PPSV23 6 to 12 months after PCV13 or as soon as possible if this time window has passed.
— Have received PCV13 and 1 or more doses of PPSV23 before age 65 years: Administer PPSV23 6 to 12 months after PCV13, or as soon as possible if this time window has passed, and at least 5 years after the most recent dose of PPSV23.
• Adults aged 19 through 64 years with immunocompromising conditions or anatomical or functional asplenia (defined below) who
— Have not received PCV13 or PPSV23: Administer PCV13 followed by PPSV23 at least 8 weeks after PCV13; administer a second dose of PPSV23 at least 5 years after the first dose of PPSV23.
— Have not received PCV13 but have received 1 dose of PPSV23: Administer PCV13 at least 1 year after the PPSV23; administer a second dose of PPSV23 at least 8 weeks after PCV13 and at least 5 years after the first dose of PPSV23.
— Have not received PCV13 but have received 2 doses of PPSV23: Administer PCV13 at least 1 year after the most recent dose of PPSV23.
— Have received PCV13 but not PPSV23: Administer PPSV23 at least 8 weeks after PCV13; administer a second dose of PPSV23 at least 5 years after the first dose of PPSV23.
— Have received PCV13 and 1 dose of PPSV23: Administer a second dose of PPSV23 at least 5 years after the first dose of PPSV23.
• Adults aged 19 through 64 years with cerebrospinal fluid leaks or cochlear implants: Administer PCV13 followed by PPSV23 at least 8 weeks after PCV13.
• Adults aged 19 through 64 years with chronic heart disease (including congestive heart failure and cardiomyopathies, excluding hypertension), chronic lung disease (including chronic obstructive lung disease, emphysema, and asthma), chronic liver disease (including cirrhosis), alcoholism, or diabetes mellitus: Administer PPSV23.
• Adults aged 19 through 64 years who smoke cigarettes or reside in nursing home or long-term care facilities: Administer PPSV23.
• Routine pneumococcal vaccination is not recommended for American Indian/ Alaska Native or other adults unless they have the indications as above; however, public health authorities may consider recommending the use of pneumococcal vaccines for American Indians/Alaska Natives or other adults who live in areas with increased risk for invasive pneumococcal disease.
• Immunocompromising conditions that are indications for pneumococcal vaccination are: Congenital or acquired immunodeficiency (including B- or T-lymphocyte deficiency, complement deficiencies, and phagocytic disorders excluding chronic granulomatous disease), HIV infection, chronic renal failure, nephrotic syndrome, leukemia, lymphoma, Hodgkin disease, generalized malignancy, multiple myeloma, solid organ transplant, and iatrogenic immunosuppression (including long-term systemic corticosteroids and radiation therapy).
• Anatomical or functional asplenia that are indications for pneumococcal vaccination are: Sickle cell disease and other hemoglobinopathies, congenital or acquired asplenia, splenic dysfunction, and splenectomy. Administer pneumococcal vaccines at least 2 weeks before immunosuppressive therapy or an elective splenectomy, and as soon as possible to adults who are newly diagnosed with asymptomatic or symptomatic HIV infection.

9. Meningococcal vaccination
• Administer 2 doses of quadrivalent meningococcal conjugate vaccine (MenACWY [Menactra, Menveo]) at least 2 months apart to adults of all ages with anatomical or functional asplenia or persistent complement component deficiencies. HIV infection is not an indication for routine vaccination with MenACWY. If an HIV-infected person of any age is vaccinated, 2 doses of MenACWY should be administered at least 2 months apart.
• Administer a single dose of meningococcal vaccine to microbiologists routinely exposed to isolates of *Neisseria meningitidis*, military recruits, persons at risk during an outbreak attributable to a vaccine serogroup, and persons who travel to or live in countries in which meningococcal disease is hyperendemic or epidemic.
• First-year college students up through age 21 years who are living in residence halls should be vaccinated if they have not received a dose on or after their 16th birthday.
• MenACWY is preferred for adults with any of the preceding indications who are aged 55 years or younger as well as for adults aged 56 years or older who a) were vaccinated previously with MenACWY and are recommended for revaccination, or b) for whom multiple doses are anticipated. Meningococcal polysaccharide vaccine (MPSV4 [Menomune]) is preferred for adults aged 56 years or older who have not received MenACWY previously and who require a single dose only (e.g., travelers).
• Revaccination with MenACWY every 5 years is recommended for adults previously vaccinated with MenACWY or MPSV4 who remain at increased risk for infection (e.g., adults with anatomical or functional asplenia, persistent complement component deficiencies, or microbiologists).

10. Hepatitis A vaccination
• Vaccinate any person seeking protection from hepatitis A virus (HAV) infection and persons with any of the following indications:
— men who have sex with men and persons who use injection or noninjection illicit drugs;
— persons working with HAV-infected primates or with HAV in a research laboratory setting;
— persons with chronic liver disease and persons who receive clotting factor concentrates;
— persons traveling to or working in countries that have high or intermediate endemicity of hepatitis A; and
— unvaccinated persons who anticipate close personal contact (e.g., household or regular babysitting) with an international adoptee during the first 60 days after arrival in the United States from a country with high or intermediate endemicity. (See footnote 1 for more information on travel recommendations.) The first dose of the 2-dose hepatitis A vaccine series should be administered as soon as adoption is planned, ideally 2 or more weeks before the arrival of the adoptee.
• Single-antigen vaccine formulations should be administered in a 2-dose schedule at either 0 and 6 to 12 months (Havrix), or 0 and 6 to 18 months (Vaqta). If the combined hepatitis A and hepatitis B vaccine (Twinrix) is used, administer 3 doses at 0, 1, and 6 months; alternatively, a 4-dose schedule may be used, administered on days 0, 7, and 21 to 30 followed by a booster dose at month 12.

11. Hepatitis B vaccination
• Vaccinate persons with any of the following indications and any person seeking protection from hepatitis B virus (HBV) infection:
— sexually active persons who are not in a long-term, mutually monogamous relationship (e.g., persons with more than 1 sex partner during the previous 6 months); persons seeking evaluation or treatment for a sexually transmitted disease (STD); current or recent injection drug users; and men who have sex with men;
— health care personnel and public safety workers who are potentially exposed to blood or other infectious body fluids;
— persons with diabetes who are younger than age 60 years as soon as feasible after diagnosis; persons with diabetes who are age 60 years or older at the discretion of the treating clinician based on the likelihood of acquiring HBV infection, including the risk posed by an increased need for assisted blood glucose monitoring in long-term care facilities, the likelihood of experiencing chronic sequelae if infected with HBV, and the likelihood of immune response to vaccination;
— persons with end-stage renal disease, including patients receiving hemodialysis, persons with HIV infection, and persons with chronic liver disease;
— household contacts and sex partners of hepatitis B surface antigen– positive persons, clients and staff members of institutions for persons with developmental disabilities, and international travelers to countries with high or intermediate prevalence of chronic HBV infection; and
— all adults in the following settings: STD treatment facilities, HIV testing and treatment facilities, facilities providing drug abuse treatment and prevention services, health care settings targeting services to injection drug users or men who have sex with men, correctional facilities, end-stage renal disease programs and facilities for chronic hemodialysis patients, and institutions and nonresidential day care facilities for persons with developmental disabilities.
• Administer missing doses to complete a 3-dose series of hepatitis B vaccine to those persons not vaccinated or not completely vaccinated. The second dose should be administered 1 month after the first dose; the third dose should be given at least 2 months after the second dose (and at least 4 months after the first dose). If the combined hepatitis A and hepatitis B vaccine (Twinrix) is used, give 3 doses at 0, 1, and 6 months; alternatively, a 4-dose Twinrix schedule, administered on days 0, 7, and 21 to 30 followed by a booster dose at month 12 may be used.
• Adult patients receiving hemodialysis or with other immunocompromising conditions should receive 1 dose of 40 mcg/mL (Recombivax HB) administered on a 3-dose schedule at 0, 1, and 6 months or 2 doses of 20 mcg/mL (Engerix-B) administered simultaneously on a 4-dose schedule at 0, 1, 2, and 6 months.

12. *Haemophilus influenza* type b (Hib) vaccination
• One dose of Hib vaccine should be administered to persons who have anatomical or functional asplenia or sickle cell disease or are undergoing elective splenectomy if they have not previously received Hib vaccine. Hib vaccination 14 or more days before splenectomy is suggested.
• Recipients of a hematopoietic stem cell transplant (HSCT) should be vaccinated with a 3-dose regimen 6 to 12 months after a successful transplant, regardless of vaccination history; at least 4 weeks should separate doses.
• Hib vaccine is not recommended for adults with HIV infection since their risk for Hib infection is low.

13. Immunocompromising conditions
• Inactivated vaccines generally are acceptable (e.g., pneumococcal, meningococcal, and inactivated influenza vaccine) and live vaccines generally are avoided in persons with immune deficiencies or immunocompromising conditions. Information on specific conditions is available at www.cdc.gov/vaccines/hcp/acip-recs/index.html.

Adverse Drug Reactions

Adverse effects of oral typhoid vaccine are infrequent and transient and resolve with intervention. Abdominal pain, diarrhea, vomiting, fever, headache, and rash have been reported.

Drug Interactions

The antimalarial drug mefloquine (Lariam) can inhibit the growth of the live Ty21a strain in vitro. It is recommended that oral typhoid vaccine be given either 24 hours before or 24 hours after mefloquine. Immunosuppressants may cause insufficient response to the vaccine.

The manufacturer recommends that oral typhoid vaccine not be administered to individuals receiving sulfonamides and antibiotics, which may be active against the vaccine strains and prevent a sufficient degree of multiplication to induce a protective immune response.

Clinical Use and Dosing

Oral typhoid vaccine is used for primary immunization against *S. typhi* infection in the following:

1. Travelers to areas where a risk of exposure to *S. typhi* is recognized
2. People who have household contact with a documented typhoid fever carrier
3. Laboratory workers who have frequent contact with *S. typhi*

For primary immunization of patients over age 6 years, the dose is one capsule on alternate days (every 48 hours; days 1, 3, 5, 7) for a total of four doses (Newton & Mintz, 2014). The capsule needs to be taken 1 hour before meals with a glass of cold water (not warmer than body temperature). The vaccine capsule should be swallowed whole. Ideally, the patient should finish the four doses at least 1 week prior to exposure or travel. A booster dose of four capsules, given every other day, is recommended every 5 years under conditions of repeated exposure (Newton & Mintz, 2014).

Monitoring

There is no specific monitoring of patients after receiving oral typhoid vaccine.

Patient Education

The oral typhoid vaccine should be taken exactly as prescribed. It must be taken on an empty stomach with cold water. Every-other-day dosing should be explained. The patient must understand that all four doses must be taken, at least 1 week prior to travel, to provide the best protection.

Although the possible adverse effects of the vaccine are mild and usually transient, the patient should be informed about them. The best protection against typhoid fever is food and water precautions to prevent contracting *S. typhi.*

YELLOW FEVER VACCINE

Pharmacodynamics

Yellow fever is a viral illness spread by some species of mosquitoes in Central and South America and in tropical regions of Africa. Yellow fever is endemic in sub-Saharan Africa and tropical South America (Gershman & Staples, 2014). The CDC estimates the risk of an unvaccinated traveler contracting yellow fever during a 2-week visit to West Africa as 10 cases per 100,000 and in travelers to South America 1 case per 100,000 (Gershman & Staples, 2014). Yellow fever produces a hemorrhagic fever and is fatal in 20% to 50% of severe cases (Staples, Gershman, & Fischer, 2010). All travelers should use personal protective measures to avoid mosquito bites to prevent yellow fever transmission.

Vaccination is recommended for travel to endemic areas. Endemic regions may change, therefore, travelers and healthcare providers should refer to the current CDC *Yellow Book* (www.cdc.gov/travel) to determine the need for vaccination. Certification of yellow fever vaccine may be required for all persons aged 9 months or older to enter certain countries in endemic areas. Current recommendations are listed at the CDC Travel Web site: *Yellow Book* (www.cdc.gov/travel). Yellow fever vaccine (YF-Vax) is a live, attenuated virus that is prepared by culturing the 17D strain virus in a living chick embryo.

Pharmacokinetics

After SC administration of the vaccine, active immunity to yellow fever occurs in 7 to 10 days and lasts for 10 years or more. The World Health Organization publishes international health regulations requiring revaccination at 10-year intervals for those at high risk.

Pharmacotherapeutics

Precautions and Contraindications

Yellow fever vaccine should be avoided in any patient with a history of egg hypersensitivity or sensitivity to chicken protein or gelatin (Gershman & Staples, 2014). Because yellow fever vaccine is a live, attenuated virus, it is contraindicated in immunocompromised patients, including those who are HIV-infected with a CD4 T-lymphocyte less than 15%, patients with primary immunodeficiencies, malignant neoplasms, transplant patients, or other patients on immunosuppressive therapies (Gershman & Staples, 2014). The vaccine should be used with caution in HIV-infected patients with CD4 counts of 15% to 24%. Yellow fever vaccine is contraindicated in patients with a thymus disorder that affects immune function. Defer vaccination with yellow fever vaccine for 8 weeks following blood or plasma transfusion.

Yellow fever vaccine is Pregnancy Category C. It is not known if the vaccine is harmful to the fetus. Vaccinate only those pregnant women who are at high risk of contracting the disease. Use with caution in breastfeeding women.

Yellow fever vaccine is contraindicated in infants younger than 6 months due to increased risk for vaccine-associated neurologic disease (Gershman & Staples, 2014). Use with caution in infants aged 6 to 8 months. Rare cases of encephalitis have occurred in infants of this age who have received yellow fever vaccine.

Yellow fever vaccine should be used with caution in patients who are aged 60 years or older. VAERS reports indicate an increase in serious adverse events after vaccination

of patients in this age group. If patients are traveling to endemic areas, vaccination risks need to be weighed against the risk of exposure to the yellow fever virus.

Adverse Drug Reactions

Up to 10% of patients experience fever or malaise, usually 7 to 14 days after administration of yellow fever vaccine. Myalgia or headache is reported in 2% to 5% of vaccine recipients. Incidence of mild adverse events has been 25% or less in clinical trials (Gershman & Staples, 2014). Anaphylaxis may occur and epinephrine should be on hand when administering the vaccine.

A very rare reaction is yellow fever vaccine–associated viscerotropic disease, with symptoms of fever and multiple organ failure (Gershman & Staples, 2014). The rate is higher among persons 60 years or older, 1/100,000 in 60- to 69-year-olds and 2.3/100,000 in persons aged 70 or older (Brunette et al, 2010). The case-fatality ratio for yellow fever vaccine–associated viscerotropic disease is 53%. The onset of illness is an average of 3.5 days after vaccination.

Yellow fever vaccine–associated neurological disease is a conglomerate of clinical syndromes, including meningoencephalitis, Guillain–Barré syndrome, encephalomyelitis, bulbar palsy, and Bell's palsy. Adverse neurological outcomes are usually seen among infants as encephalitis but may occur at any age.

Drug Interactions

Concurrent vaccination with yellow fever vaccine and hepatitis A vaccine (HAV) and hepatitis B vaccine (HBV), meningococcal vaccine (Menomune), typhoid fever vaccine (Typhim Vi), diphtheria, tetanus and pertussis (DTaP, Tdap), and measles vaccine does not appear to affect response to yellow fever vaccine (Staples et al, 2010).

Immunosuppressants may cause insufficient response to the yellow fever vaccine. Yellow fever vaccine should be reconstituted with the diluent supplied with the vaccine. Preservatives in diluent of other vaccines may kill the live virus in the yellow fever vaccine.

Clinical Use and Dosing

Immunization against yellow fever is recommended for all people over age 9 months who are living in or traveling to endemic areas. Vaccination is required by international regulations for travel to certain countries. The dose is a single 0.5 mL dose given SC. The vaccine should be repeated every 10 years (Gershman & Staples, 2014).

Monitoring

There is no specific monitoring of patients needed after receiving yellow fever vaccine other than for the rare adverse drug reactions listed previously.

Patient Education

Patients should be educated about the mild transient adverse effects that can occur from vaccine administration. Patients should be instructed about protecting themselves against mosquitoes. Insect repellent and proper protective clothing and netting provide the best defense against insect-borne diseases.

BACILLUS CALMETTE–GUÉRIN VACCINE

Pharmacodynamics

Immunization with bacillus Calmette–Guérin (BCG) vaccine lowers the risk of serious complications of primary TB in children. It is not widely used in the United States but is given to infants and young children in countries where TB is endemic (CDC, 2012a). Vaccination with BCG stimulates natural infection with *Mycobacterium tuberculosis* and results in a T-cell–mediated immune reaction and immunity against TB, but with variable degrees of protection. The protective effect of BCG use in children against miliary and meningeal TB is about 80%; it is less effective in adults.

Pharmacokinetics

BCG is administered percutaneously (CDC, 1996a). Specific pharmacokinetic information is not available. The duration of protection against TB varies according to the potency of the strain of BCG used. TB sensitivity may last up to 10 years.

Pharmacotherapeutics

Precautions and Contraindications

Patients with active TB should not receive BCG. PPD skin testing should be performed on all patients over 2 months of age who are receiving BCG. Cancer, leukemia, lymphoma, radiation therapy, and immunodeficiency are contraindications to BCG use. Patients with symptomatic or asymptomatic HIV infection should not receive BCG. Drugs that affect the immune system, including high-dose steroids, are also a contraindication to BCG use.

Precautions should be taken to avoid accidental exposure to BCG solutions during preparation and administration because these solutions contain live, attenuated *M. tuberculosis.*

BCG is Pregnancy Category C. The CDC does not recommend the use of BCG in pregnant women.

The World Health Organization recommends that HIV-infected infants not receive BCG even in areas of high TB activity because of the risk of disseminated BCG disease (WHO, 2010).

Adverse Drug Reactions

A normal reaction to the BCG vaccine is skin lesions that appear within 10 to 14 days after the multiple-puncture disc application of BCG. The lesions consist of small red papules at the site of administration. The papules reach maximum diameter (3 mm) after 4 to 6 weeks and then scale away and slowly subside. Six months after vaccination, there is usually no visible sign of vaccination, although faint disc marks may be noted.

Lymphadenopathy may occur in a regional lymph node and resolves spontaneously. Osteomyelitis is a rare occurrence (1/1 million doses). BCG-induced osteomyelitis affects the epiphyses of the long bones and can occur from 4 months to 2 years after administration. Rarely, lupoid-like skin reactions have occurred. It has been recommended that patients who experience lupus-like symptoms after BCG administration be treated with isoniazid (INH) for 3 months. Disseminated BCG

infection and death are very rare (about 0.06 to 1.56 cases/1 million doses) and usually occur in patients with impaired immune systems (CDC, 1996a).

Drug Interactions

Antituberculosis agents (rifampin, INH, streptomycin) and immunosuppressives may interfere with the development of an appropriate immune response to BCG administration. BCG administration will cause PPD skin tests to give false-positive readings for up to 10 years after administration. After 10 years, a positive PPD usually indicates infection with *M. tuberculosis.*

Clinical Use and Dosing

In the United States, BCG is administered only in very special circumstances, such as unavoidable risk of exposure to *M. tuberculosis* and failure of other methods of prevention and control of TB (CDC, 2012a). The ACIP has set clear criteria for the use of BCG in the United States: "BCG vaccination should be considered for infants and children who reside in settings in which the likelihood of *M. tuberculosis* transmission and subsequent infection is high provided no other measures can be implemented (e.g., removing child from the source of infection). In addition, BCG vaccination may be considered for health-care workers who are employed in settings in which the likelihood of transmission and subsequent infection with *M. tuberculosis* strains resistant to INH and rifampin is high" (CDC, 1996a, 2012a).

BCG is given to healthy infants from birth to 2 months without TB skin testing. After that, BCG is given only to children with negative Mantoux skin tests.

The administration of BCG must be exactly as the manufacturer directs. The vaccine is dropped onto clean, dry skin over the deltoid muscle and spread over the area to be punctured, using the edge of the multipuncture disc. The prongs of the disc are coated with the virus by lightly dipping them into the spread vaccine. The prongs of the disc are pressed into the skin and held for 5 to 10 seconds. After the disc is removed, the vaccine is respread to fill all the puncture areas. Additional vaccine may be applied to ensure a "wet" vaccine site. The vaccinated area needs to be kept dry for 24 hours. No dressing is required. The person administering the vaccine should take precautions against coming into contact with the live virus.

The dose for infants 1 month or younger is diluted to 50% by adding 2 mL of sterile water to the vaccine.

Monitoring

There is no specific monitoring of patients who receive BCG, although providers are reminded it may affect TB test results.

Patient Education

The patient or parent should be instructed that the vaccine contains live virus and that the site should not be touched. The vaccine site should be kept clean until the local reaction has resolved. Clear instructions regarding the normal skin reaction should be given to the patient or parent prior to administration.

INACTIVATED VACCINES

DIPHTHERIA, TETANUS, AND PERTUSSIS VACCINE

Pharmacodynamics

Various combinations of diphtheria, tetanus, and pertussis vaccines are available on the market. Regardless of the combination of vaccines, the basic pharmacodynamic principles are the same.

Diphtheria toxoid induces the production of antibodies against the exotoxin excreted by *Corynebacterium diphtheriae.* Complete immunization (four doses, then boosters every 10 years) induces specific antibodies and reduces the incidence of diphtheria by more than 95%. Immunized persons who develop diphtheria have milder illness. Infection with *C. diphtheriae* does not confer immunity, and previously infected persons should still receive toxoid.

Adsorbed tetanus toxoid contains antigens that induce the production of antibodies against the exotoxin excreted by *Clostridium tetani.* The duration of immunity against *C. tetani* is about 10 years. Natural immunity to *C. tetani* does not occur in the United States, and even patients with previous *C. tetani* infection should receive the tetanus toxoid.

Pertussis vaccine contains inactivated pertussis antigens. Acellular pertussis vaccine contains one or more immunogens derived from *Bordetella pertussis* and, unlike whole-cell vaccine, contains little or no endotoxin. Immunization with pertussis vaccine produces antibodies against *B. pertussis.* The efficacy of whole-cell pertussis vaccine for children exposed to pertussis who received at least three doses of DPT is estimated at 59% to 90%. Whole-cell pertussis vaccine, DPT, is no longer available in the United States. Acellular pertussis vaccine has a clinical efficacy of 79% to 93% in protecting against clinical pertussis after household exposure. Vaccinated patients who do contract pertussis usually have a milder case. Pertussis vaccine is always given in combination with diphtheria and tetanus vaccines (DTaP, Tdap, Tdap).

Pharmacokinetics

The DTaP and Tdap vaccines are given IM. Ninety percent of patients who receive three doses of DTaP develop protective immunity against diphtheria and tetanus. Patients who receive four doses of DTaP have immunity that persists for 10 years or more. In patients who receive four doses of DTaP, immunity to pertussis begins to wane after 4 to 6 years (Tartof et al, 2013). Ten years after immunization, fewer than 50% of vaccine recipients have protective antibodies against *B. pertussis,* which is why a booster dose of Tdap is recommended in adolescents (CDC, 2006d). Vaccination is also recommended for all adults, including health-care workers and caregivers of infants younger than 12 months of age (CDC, 2006c).

Pharmacotherapeutics

Precautions and Contraindications

In the United States, it is currently recommended that DTaP be used for primary immunization of infants and children.

Therefore, the precautions and contraindications to DTaP are discussed here, and DTP is not discussed, although the contraindications are the same for each vaccine. Tdap is discussed later in this section.

The true contraindication to DTaP vaccination is a patient who experienced an immediate anaphylactic reaction with a previous dose. Encephalopathy that occurred within 7 days of a previous dose, unexplained by another cause, is a possible contraindication to further pertussis vaccine use (CDC, 2006c). In this case, DT should be substituted for DTaP. Patients with unstable, progressive, neurological problems may have the vaccine deferred until the neurologic status is clarified.

Precautions associated with DTaP include a previous temperature of 105°F (40.5°C) or higher within 48 hours after a dose, history of continuous crying (more than 3 hours) within 48 hours of a dose, convulsions within 3 days of a previous dose, and collapse or shock-like state (hypotonic-hyporesponsive episode) within 48 hours of a previous dose. Although these precautions were once considered contraindications, they are now considered precautions because they have not been proved to cause permanent sequelae.

Additional precautions include seizures 3 days or less after a previous dose of DTaP, persistent or inconsolable crying lasting more than 3 hours within 48 hours of a previous dose, Guillain–Barré syndrome (GBS) less than 6 weeks after a previous dose of tetanus toxoid–containing vaccine, or moderate or severe acute illness with or without fever (CDC, 2006c). A temperature less than 104°F (less than 40.5°C), fussiness, or mild drowsiness after a previous dose of DTaP, family history of seizures, family history of an adverse event after a DTP vaccine, or a stable neurological condition are not contraindications to vaccinating with DTaP.

DTaP may be given to immunocompromised patients or patients on immunosuppressive therapy, although the immune response to the vaccine may be less than optimal. Patients with HIV infection may be immunized. Patients with a minor acute or febrile illness, including otitis media, may be immunized. Immunization should be delayed in cases of moderate or severe illnesses, with or without fever.

Infants born prematurely should begin the vaccine series based on their date of birth, with the first vaccine given routinely at age 2 months.

The ACIP has recommended that pregnant women, including pregnant adolescents, receive a booster of Tdap with each pregnancy, ideally between 27 and 36 weeks' gestation to provide passive pertussis immunity to the infant (CDC, 2013b). Infants born to women given pertussis vaccine during the third trimester have measurable antibodies that protect them from pertussis during the first 2 to 3 months of life (Vilajeliu et al, 2015). Td and Tdap are Pregnancy Category C, but they have been used extensively worldwide in pregnant women with no adverse effects reported.

The contraindications to DT include patients older than age 7 years, who should be given Td or Tdap, as appropriate. The contraindications to DT or Td include hypersensitivity to any component of the vaccine and moderate-to-severe illness, with or without fever. Do not postpone for minor illness, including otitis media.

The contraindications to Tdap include Guillain–Barré syndrome 6 weeks or sooner after previous use of tetanus toxoid–containing vaccine, previous arthus reaction after receiving tetanus or diphtheria vaccine, or a progressive neurological disorder (CDC, 2006c). Tdap or Td should be deferred in a patient with moderate or severe illness, with or without fever. Fever with previous DTaP vaccine is not a reason to withhold DTaP or Tdap vaccine (CDC, 2006c).

Adverse Drug Reactions

Injection site reactions of mild to moderate pain, erythema, swelling, and induration may last for a few days after injection. Transient low-grade fever, chills, malaise, generalized aches and pains, and headache may occur. Fever was common after DPT and less common after DTaP. Drowsiness, fretfulness, and GI upset may occur. Pain at the injection site is the most frequent adverse event reported for Tdap (CDC, 2006b, 2006c).

Seizures may occur and are more likely in children with a history of seizures, although less common now that DPT is no longer used in the United States. Seizures may be related to fever, and antipyretic prophylaxis is recommended after DTaP administration every 4 to 6 hours in children with a history of febrile seizures to decrease the incidence of febrile seizure after vaccination.

Drug Interactions

Coadministration of radiation therapy, antineoplastic agents, or immunosuppressives can decrease the immunological response to the DTaP vaccine. DTaP, DT, and Td should not be administered concurrently with cholera vaccine, typhoid vaccine, or plague vaccine because there may be accentuated adverse effects. DTaP, DT, Tdap, or Td may be coadministered with HBV, HIB, meningococcal, influenza, hepatitis A, and pneumococcal vaccines.

Clinical Use and Dosing

DTaP is routinely given at age 2, 4, 6, and 15 to 18 months and 4 to 6 years. DT, if used, is given on the same schedule.

As a booster, Tdap is recommended at age 11 to 12 years. Tdap (ADACEL) is labeled for use in persons aged 11 to 64 years. Tdap (BOOSTRIX) is labeled for persons 10 to 64 years. Patients should receive a booster dose of Td or Tdap every 10 years. If a patient older than age 7 has never been immunized, the primary series is one dose of Tdap followed by 2 doses of Td. The first dose of Tdap is followed by the second dose 4 weeks later. The third dose is given 6 to 12 months after the second dose. Every adult needs a booster every 10 years after completion of the primary series of three doses.

Pregnant women and adolescents should receive a dose of Tdap, ideally between 27 and 36 weeks' gestation, with every pregnancy to provide passive immunity for the infant (CDC, 2013b). If Tdap is not administered during pregnancy, it should be administered immediately postpartum.

The ACIP recommends "cocooning," where parents, siblings, grandparents, child-care providers, and health-care personnel who care for infants younger than 12 months

receive Tdap vaccine to protect the infant against exposure to pertussis (CDC, 2013b).

Monitoring

There is no laboratory monitoring needed with DTaP, DT, Tdap, or Td vaccine.

Patient Education

The parent or patient should receive a VIS prior to administration of vaccine. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reaction after DTaP, Tdap, or Td injection is pain and erythema at the injection site. Advise the patient to take acetaminophen for discomfort for the first 24 hours after injection. Post-vaccination fever, myalgia, and headache can be treated with acetaminophen or ibuprofen prophylaxis. Premedicating with antipyretics before vaccination is not routinely recommended.

HAEMOPHILUS B CONJUGATE VACCINE

Pharmacodynamics

HIB conjugate vaccine consists of the HIB capsular polysaccharide covalently linked to another antigen to increase immunogenicity. HIB conjugate vaccine exposure stimulates the immune system to produce HIB capsule–specific antibodies that destroy the capsule. This makes the organism vulnerable to antibody- and cell-mediated immunity. Unconjugated capsule polysaccharide vaccines cause B-cell stimulation only. By conjugating the capsule polysaccharide, T-cell stimulation occurs as well. HIB conjugate vaccine comes singly (ActHIB, Hiberix) and in combination with other vaccines (HBV/HIB [Comvax], DTaP/HIB [TriHibit], DTaP/IPV/HIB [Pentacel], meningococcal/HIB [MenHibrix]).

Pharmacokinetics

HIB is administered IM. Antibodies are detected approximately 1 to 2 weeks after administration. The HIB is more immunogenic in older children; therefore, only one dose is needed for children receiving their first dose at age 15 months or older.

Ideally, the patient should receive the same conjugate vaccine product for all of the primary series of immunizations. However, when different products are given for the series, serum antibodies are similar to those of patients who received all the same formula.

The anticapsular antibodies may cross the placenta and are distributed in breast milk.

Pharmacotherapeutics

Precautions and Contraindications

Anaphylactic reaction to the vaccine or any component is a contraindication to HIB. Moderate to severe illness, with or without fever, may be a reason to delay vaccination. Minor illness, including otitis media, is not a reason to delay administration. HIB vaccine should be administered only to children under the age of 6.

Adverse Drug Reactions

The most common adverse reaction following HIB is pain, redness, and swelling at the injection site. These symptoms are mild and usually last less than 24 hours. Systemic reactions are infrequent, and when HIB is given with DTaP, there is no increased incidence of systemic reaction over DTaP given alone.

Drug Interactions

There are no known interactions.

Clinical Use and Dosing

Dosing of HIB depends on the vaccine used. HibTITER (HbOC) and ActHib (PRP-T) are given at 2, 4, and 6 months and a booster at 12 to 15 months. PedvaxHIB (PRP-OMP) is given at 2 and 4 months and a booster at 12 to 15 months. HIB/HBV (Combax) is given at 2, 4 and 12 to 15 months. Pentacel (DTaP/OPV/HIB) can be administered at 2, 4, 5 and 15 to 18 months. TriHIBit (DTaP/HIB) can be administered as the booster DTaP dose at 12 to 18 months if the primary HIB series was completed at least 6 months before. The first dose of HIB can be given at age 6 weeks but no earlier. Any HIB vaccine, including Hiberix (HIB), can be used for the booster dose at age 12 to 15 months. If a child receives the first dose at age 15 months or older but younger than 5 years, only one dose of HIB is needed. MenHibrix is administered at 2, 4, 6, and 12 to 15 months of age.

Monitoring

No laboratory monitoring is necessary.

Patient Education

Parents should receive a VIS prior to administration of the vaccine. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reaction after HIB injection is pain and erythema at the injection site. Advise the parent to give acetaminophen for discomfort for the first 24 hours after injection.

INACTIVATED POLIOVIRUS VACCINE

Pharmacodynamics

IPV is a parenteral noninfectious suspension of three types of inactivated poliovirus. The IPV available in the United States since the late 1980s is of enhanced potency and is highly immunogenic. In 1999, the ACIP recommended that all polio virus in the United States be administered as inactivated polio

---

CLINICAL PEARL

Patients With Shot Phobia
In older children and adults who have a true phobia of injections, use EMLA cream to anesthetize the injection area. Have the patient apply the disk or cream 1 hour prior to the scheduled administration time, or the cream can be applied in the clinic and the injection administered after 1 hour.

vaccine to eliminate the risk of vaccine-associated polio (CDC, 2009a). IPV inhibits pharyngeal acquisition of poliovirus and, to a lesser extent, provides gut immunity. IPV is available in combination with diphtheria, tetanus, pertussis, and hepatitis B (Pediarix) or in combination with DTaP and HIB (Pentacel).

Pharmacokinetics

After IM administration of two doses, approximately 95% of patients have antibodies to polio. After three doses, 99% to 100% of patients have high antibody titers.

Pharmacotherapeutics

Precautions and Contraindications

A history of immediate hypersensitivity reaction after receiving IPV is a contraindication. Patients with neomycin, streptomycin, or polymyxin B hypersensitivity should not receive the vaccine because there are small amounts of these substances in the vaccine.

IPV is the preferred drug (over OPV) in immunosuppressed patients, although a protective immune response cannot be guaranteed. IPV can be administered to patients with HIV disease. If it is needed to protect the patient, IPV may be administered during pregnancy. IPV is Pregnancy Category C. IPV can be used in infants as young as 6 weeks of age.

Adverse Drug Reactions

Injection site reaction is reported in 13% of patients. Systemic reactions are infrequent, and when IPV is given with DTaP, there is no increased incidence of systemic reaction over DTaP given alone.

Drug Interactions

The immune response to IPV may be diminished if the patient is taking immunosuppressant medication. Revaccinate 3 months after discontinuing immunosuppressants. IPV can be coadministered with all other childhood vaccines.

Clinical Use and Dosing

The primary series of IPV is four doses administered at 2, 4, and 6 to 18 months and 4 to 6 years (CDC, 2009a). The minimum age for the first dose is 6 weeks. The final dose of IPV should be administered after the fourth birthday regardless of the number of previous doses. The minimal interval between doses 1 and 2 and doses 2 to 3 is 4 weeks. The minimal interval between dose 3 and dose 4 is 6 months (CDC, 2009a).

Monitoring

There is no need for laboratory monitoring after administration of IPV.

Patient Education

Parents should receive a VIS prior to administration of the vaccine. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reaction after IPV injection is pain and erythema at the injection site. Advise the parent to give acetaminophen for discomfort.

HEPATITIS B VIRUS VACCINE

Pharmacodynamics

HBV is produced by recombinant DNA technology from common baker's yeast that is genetically modified to synthesize HbsAg. Active immunization with HBV stimulates the immune system to produce antihepatitis B surface antigen antibodies (anti-HBs). HBV is available in combination with diphtheria, tetanus, acellular pertussis, and inactivated polio vaccine (Pediarix), in combination with HAV (Twinrix), and in combination with HIB (Comvax).

Pharmacokinetics

Three doses of HBV induce protective antibody response in more than 95% of infants, children, and adolescents and in more than 90% of adults. Anti-HBs appear in the serum 2 weeks after IM administration. The minimum anti-HB titer needed to provide protection against hepatitis B is 10 milli-international units (mIU)/mL.

Pharmacotherapeutics

Precautions and Contraindications

The only true contraindication to HBV is hypersensitivity to yeast or other components of the vaccine. Moderate or severe illness, with or without fever, is a contraindication to HBV. Patients with renal disease requiring hemodialysis or patients with immunosuppression may require larger doses to achieve adequate serum levels of anti-HBs.

HBV is Pregnancy Category C. The CDC (2013c) has stated that pregnancy is not a contraindication to HBV and it may be given in pregnancy if indicated.

Adverse Drug Reactions

Localized reaction at the injection site is reported by 17% of HBV vaccine recipients. Approximately 15% of patients report systemic complaints, including fatigue, weakness, malaise, fever, headache, nausea or vomiting, diarrhea, and pharyngitis. Serum sickness has occurred days to weeks after administration of HBV. A very rare side effect is alopecia (occurs 5/1 billion doses).

Drug Interactions

Patients who are taking immunosuppressants or antineoplastic agents may require larger doses or additional doses of HBV to achieve adequate anti-HB titers.

Clinical Use and Dosing

Vaccination with HBV is recommended for all ages, particularly patients at high risk of contracting hepatitis B. Those at high risk include IV drug users, infants born to mothers who are HbsAg-positive, hemodialysis patients, sexually active people with multiple partners, incarcerated people, international travelers, household contacts of hepatitis B carriers, and sexual contacts of hepatitis B carriers. Patients who are getting tattoos or who share razors, toothbrushes, or body-piercing jewelry are

> ### CLINICAL PEARL
>
> **Administering Injections**
> A technique to help older children, adolescents, or adults who are anxious about receiving injections is to encourage them to take slow, deep breaths. Younger children (5-year-olds) can be told to pretend they are blowing up a balloon. Have the patient inhale and exhale two or three times, and then, on the third or fourth exhalation, administer the injection.

also at risk of contracting hepatitis B. Health-care workers, day-care staff, and other people who may have exposure to body fluids also have a greater risk of contracting hepatitis B. Patients with diabetes are at increased risk of contracting HBV and it is recommended they receive the HBV series (CDC, 2011c).

The ACIP and the AAP recommend universal vaccination of all infants as a comprehensive strategy to control hepatitis B. The current recommendations for childhood immunizations include administering the three-dose HBV series to newborns or at age 11 to 12 years to children not previously vaccinated. The series can be started at any age, although it

is recommended that preterm infants be at least 1 month of age before starting HPV series (CDC, 2005a). Some states are requiring proof of HBV series completion for entry to the seventh grade.

Vaccination with HBV is recommended for all adults who are at high risk of contracting hepatitis B infection. The ACIP has issued a recommendation that HBV be offered to unvaccinated adults assumed to be at risk, including patients of sexually transmitted disease treatment clinics, HIV treatment facilities, drug abuse treatment programs, correctional facilities, chronic hemodialysis treatment centers, and services providing care to developmentally delayed adults (CDC, 2005a).

The recommended schedule for vaccinating infants with HBV is to give the first dose at birth or before age 2 months. The second dose is given at age 1 to 4 months. Dose 3 is given at age 6 to 18 months. The rules regarding minimum HBV dose spacing in older children and adults are that there must be 4 weeks between doses 1 and 2, 2 months between doses 2 and 3, and 4 months between doses 1 and 3, allowing the series to be completed in as little as 4 months. The series is never restarted, no matter how long it has been since the previous dose. The recommended dosing of HBV is provided in Table 19-5.

*Combined hepatitis B–*Haemophilus influenzae* type b conjugate vaccine. This vaccine cannot be administered at birth, before age 6 wk, or after age 71 mo.

†Combined hepatitis B–diphtheria, tetanus, and acellular pertussis-inactivated poliovirus vaccine. This vaccine cannot be administered at birth, before age 6 wk, or at age = 7 yr.

§Combined hepatitis A and hepatitis B vaccines. This vaccine is recommended for persons aged =18 yr who are at increased risk for both hepatitis B virus and hepatitis A virus infections.

¶Recombinant hepatitis B surface antigen protein dose.

**Not applicable.

‡Adult formulation administered on a two-dose schedule.

§§Higher doses might be more immunogenic, but no specific recommendations have been made.

¶¶Dialysis formulation administered on a three-dose schedule at age 0, 1, and 6 mo.

***Two 1.0 mL doses administered at one site, on a four-dose schedule, at ages 0, 1, 2, and 6 mo.

(Centers for Disease Control, 2005a).

HBV is generally given IM but may be given SC if IM injections are contraindicated (as in hemophiliacs). HBV should be given IM in the deltoid or anterolateral thigh. The immunogenicity of HBV is decreased when given in the buttock. HBV should not be given with the same syringe or at the same site as hepatitis B immune globulin (H-BIG).

Patients who do not develop a serum anti-HB antibody response (greater than or equal to 10 mIU/mL) after three doses of HBV should be revaccinated with one to three doses. If the patient does not respond after three additional doses, he or she is unlikely to respond to any additional doses.

Monitoring

Susceptibility testing before HBV vaccination is not routinely indicated for children or adolescents. Testing for previous infection may be considered in adults in high-risk groups with high rates of hepatitis B infection, such as users of IV drugs, men who have sex with men, and household contacts of hepatitis B carriers.

Routine post-vaccination testing for anti-HBs is not necessary. Post-vaccination testing is advised 1 to 2 months after the third dose of HBV for those whose subsequent management is determined by their anti-HB status: (1) those at risk for occupational exposure risk from sharp injuries, (2) those with HIV infection, (3) hemodialysis patients, (4) immunocompromised patients at risk of contracting hepatitis B, (5) regular sexual contact of hepatitis carriers, and (6) infants born to HbsAg-positive mothers.

Patient Education

Parents should receive a VIS prior to administration of the vaccine. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reaction after HBV injection is pain and erythema at the injection site. Advise the parent to give acetaminophen for discomfort for the first 24 hours after injection.

HEPATITIS A VIRUS VACCINE

Pharmacodynamics

HAV vaccine is used to confer immunity to hepatitis A in people at risk of contracting the disease. With HAV administration, stimulation of specific antibodies takes place without producing disease symptoms. Serum antibody titers after HAV are lower than those resulting from hepatitis A infection. Serum antibody titer of 20 mIU/mL is considered protective. There are two HAV products available; both provide immunity with a two-dose schedule.

Pharmacokinetics

HAV is administered IM. One dose of HAV can induce seroconversion in 88% of patients by 15 days and 99% of patients by 1 month. This rapid seroconversion from a single dose can provide protection for at least 12 months (CDC, 2006d). Administration of a second dose at 6 to 12 months after the first dose provides 100% protection. The duration of the vaccine protection has not been determined yet, as long-term efficacy has not been established. Theoretically, antibody levels should last 20 years or more. The CDC does not recommend any post-vaccination monitoring of serological response because of the high vaccine response in children and adults (CDC, 2006d).

Pharmacotherapeutics

Precautions and Contraindications

HAV should not be administered to patients with a previous history of severe reaction to HAV. Moderate or severe illness, with or without fever, is a contraindication to HAV. Patients with immunosuppression may be given HAV, but they may have lower antibody titers than immunocompetent people.

HAV is Pregnancy Category C. The CDC (2013c) has stated HAV may be given in pregnancy if indicated and that it poses no risk to the fetus. The safety and effectiveness of HAV in children under age 12 months has not been established.

Adverse Drug Reactions

The most frequently reported adverse reaction to HAV is soreness at the injection site (56% in adults and 15% in children). Headache and malaise are other minor adverse reactions that have been reported.

Drug Interactions

Patients who are taking immunosuppressants or antineoplastic agents may have a decreased immunological response to HAV.

Clinical Use and Dosing

HAV vaccine provides pre-exposure protection from hepatitis A infection in adults and children. HAV is recommended for people who are at increased risk for infection and for any person wishing to obtain immunity. The ACIP, AAP, and American Academy of Family Physicians (AAFP) recommend that all children begin HAV series at age 12 months. People at increased risk for hepatitis A infection who should be routinely vaccinated include the following:

1. People over age 1 year who are traveling or working in countries that have high or intermediate endemic infection. All of South America, Africa, Greenland, and Asia have a high incidence of hepatitis A infection. Russia and eastern Europe are areas of intermediate prevalence. IG is recommended for children under age 1 who are traveling to these areas.
2. Men who have sex with men.
3. Illegal drug users.
4. People who have an occupational risk for infection, including those who work with hepatitis A–infected primates or with hepatitis A in a research laboratory setting.
5. People with clotting factor disorders.
6. People with chronic liver disease.
7. Household members and close personal contacts of internationally adopted children from countries with high or intermediate hepatitis A endemicity.

The ACIP recommends administering the first dose of HAV as soon as the adoption planning process begins, ideally at least 2 weeks before the arrival of the adoptee (CDC, 2009b).

Two different HAV products are currently available, HAVrix and VAQTA, as well as a combination product that combines HAV and HBV, Twinrix. HAVrix is available in two strengths: 1,440 enzyme-linked immunoassay units (EL.U) and 720 EL.U. The adult (age 19 years and older) dose is 1,440 EL.U administered in a two-dose schedule, 6 to 12 months apart. The pediatric (age 1 to 18 years) dose of HAVrix is 720 EL.U, administered in a two-dose schedule 6 to 12 months apart. VAQTA is available in two strengths: adult, which has 50 antigen U/1 mL dose, and pediatric-adolescent strength, which has 25 U/0.5 mL dose. The dose for adults is 50 U administered 6 months apart. The dose for children aged 1 to 18 years is 25 U administered 6 to 18 months apart. Twinrix is HAVrix (720 EL.U) combined with Engerix-B (20 mcg) and is approved for persons 18 years and older. The dosing schedule of Twinrix is 1.0 mL in three doses, at 0, 1, and 6 months.

HAV is injected IM into the deltoid muscle in adults and children age 3 years or older and in the vastus lateralis muscle (anterolateral thigh) in children age 12 months to 36 months. Injection in the gluteal region results in suboptimal response. Patients with an impaired immune system may require additional doses to obtain an adequate anti–hepatitis A response.

> **CLINICAL PEARL**
>
> **Bioterrorism**
> Providers need to have a basic understanding of vaccines available against possible biological weapons. The CDC Web site has an area dedicated to bioterrorism located at www.bt.cdc.gov/bioterrorism/. There are vaccines available for anthrax and smallpox, although this chapter does not discuss them because they are not currently recommended. Full prescribing information for both the anthrax and the smallpox vaccines are available at the CDC National Immunization Web site at www.cdc.gov/nip/publications/acip-list.htm.

Monitoring

Pre-immunization testing of children for hepatitis A antibodies is generally not recommended. Pretesting may be cost-effective in adults who have a high likelihood of immunity from prior infection, such as those who have lived in areas of high hepatitis incidence, those older than 40, and those with a history of jaundice that potentially may have been hepatitis A infection (CDC, 2006d).

Post-immunization testing is not indicated in immunocompetent persons because of the high seroconversion rates in children and adults who receive HAV. Post-immunization testing is warranted in immunocompromised patients who may have suboptimal response to the vaccine.

Patient Education

Parents should receive a VIS prior to administration of the vaccine. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reaction after HAV injection is pain and erythema at the injection site. Advise the patient to take acetaminophen for discomfort for the first 24 hours after injection.

HUMAN PAPILLOMAVIRUS VACCINE

Pharmacodynamics

Human papillomavirus (HPV) causes cervical cancer, the second-biggest cause of female cancer mortality worldwide, with an estimated 288,000 deaths yearly (WHO, 2011). "Genital HPV infection is extremely common and most often remains subclinical, but a proportion of the infected individuals with low-risk HPV types such as HPV-6 or HPV-11 will develop genital warts, whereas a subset of women with high-risk HPVs such as HPV-16 or HPV-18 will develop preneoplastic lesions of cervical intraepithelial neoplasia (CIN)" (WHO, 2005, p 85). Approximately 500,000 cases of genital warts occur in men and women in the United States annually (CDC, 2010a, 2010b). Two vaccines to treat HPV are currently available: Gardisil is a quadrivalent human papillomavirus recombinant vaccine that provides immunity against types 6, 11, 16, and 18; Gardisil 9 provides immunity against types 16, 18, 31, 33, 45, 52 and 58. and Cervarix, a bivalent vaccine against HPV strains 16 and 18.

Pharmacokinetics

Cervarix (HPV2) is well tolerated after IM injection at 0, 1, and 6 months with a 99.8% antibody response, providing 100% efficacy against HPV 16 cervical infections and 89.6% efficacy against HPV 16 plus HPV 18 cervical infections (Pagliusi & Aguado, 2004; Markowitz et al, 2014). Gardasil (HPV4) has also demonstrated 100% efficacy in women against HPV 16 infection (median follow-up 17.4 months) using a 0-, 2-, and 6-month schedule of vaccination (Markowitz et al, 2014). Gardasil (HPV4) is 89.4% effective in preventing genital warts in males caused by HPV 6, 11, 16, and/or 18 strains (CDC, 2010b; Markowitz et al, 2014).

Pharmacotherapeutics
Precautions and Contraindications

The only true contraindication to HPV vaccine is severe allergic reactions to any component of the vaccine. Gardasil should not be administered to patients allergic to yeast. Both vaccines have a reported adverse effect of syncope. Patients should be observed for 15 minutes after administration and put in a supine or Trendelenburg position if they become symptomatic.

Both HPV vaccines are rated Pregnancy Category B. They are not recommended for use in pregnancy. No causally associated adverse pregnancy outcome has been reported in preclinical or post-licensure studies. If a patient is administered

HPV vaccine during pregnancy, a registry has been set up by both manufacturers to report exposure (Gardasil: Merck & Co. at 800-986-8999; Cervarix: GlaxoSmithKline at 888-452-9622). Pregnancy testing is not needed before vaccination.

Adverse Drug Reactions

Pain, redness, and swelling at the injection site were the most commonly reported local adverse reaction, reported in over 20% of subjects receiving the vaccines. The most common general adverse events were fatigue, headache, myalgias, and arthalgias. The most common serious reaction to HPV vaccine is syncopal episodes. Reports of falling with injury due to syncope after receiving HPV have been recorded; recommendations are that all patients who receive the HPV vaccine be observed for 15 minutes after administration.

Drug Interactions

No known drug interactions occur with HPV vaccine. Immunosuppressants may reduce the immune response to the vaccine.

Clinical Use and Dosing

Dosing of the HPV vaccines varies with the drug and the gender of the patient. HPV4 (Gardasil) is approved for use in girls and women ages 9 to 26 years to prevent cervical, vulvar, and vaginal cancer caused by HPV types 16 and 18 and genital warts (condyloma acuminata) caused by HPV types 6 and 11. HPV9 (Gardasil 9) is approved for use in girls and women ages 9 to 26 years to prevent cervical, vulvar, and vaginal cancer caused by HPV types 16, 18, 33, 45, 52 and 58; and genital warts (condyloma acuminata) caused by HPV types 6 and 11. HPV4/HPV9 is recommended for all girls starting at age 11 to 12 years but may be started as young as age 9 years. The dosing schedule is three doses of 0.5 mL given IM at 0, 2, and 6 months.

HPV4 (Gardasil) is approved for the prevention of genital warts caused by HPV types 6 and 11 in males. HPV9 (Gardasil 9) is approved for anal warts caused by HPV types 16, 18, 31, 33, 45, 52 and 58; and genital warts (condyloma acuminata) caused by HPV types 6 and 11. The dosing schedule for HPV4/HPV9 in males is 0.5 mL given IM at 0, 2, and 6 months.

HPV2 (Cervarix) is approved to prevent cervical cancer caused by HPV types 16 and 18 in females aged 10 to 25 years. HPV2 is recommended by the ACIP as one of the two HPV vaccines for routine vaccination of females beginning at age 11 to 12 (CDC, 2010a). The dose of HPV2 (Cervarix) is three 0.5 mL doses at 0, 1, and 6 months.

After patients receive HPV vaccine, they should be monitored for 15 minutes because of the risk for syncope after the vaccine.

Monitoring

No ongoing monitoring of patients is needed after vaccination with HPV vaccine.

Patient Education

Parents should receive a VIS prior to administration of the vaccine. Any questions or concerns regarding the vaccine should be addressed. Patients should be informed of the risk for syncope and why they need to be monitored after administration of HPV. The most common adverse reactions after HPV injection are pain, erythema, and swelling at the injection site. Advise the patient to take acetaminophen for discomfort for the first 24 hours after injection.

INFLUENZA VACCINE

Pharmacodynamics

Influenza vaccine (Afluria, Fluarix, Flucelvax, FluLaval, Fluvirin, Fluzone, Fluzone Intradermal, Fluzone High-dose) is a multivalent vaccine that contains three different viral subtypes. It is available as a trivalent or quadravalent vaccine (Fluarix Quadrivalent, Flulaval Quadrivalent, Fluzone Quadrivalent). Flucelvax, a trivalent vaccine, is the first cell-based influenza vaccine. FluBlok is a trivalent recombinant hemagluten (HA) influenza vaccine containing purified HA proteins, which uses cell-based technology.

Each year, the World Health Organization recommends to the FDA's Vaccines and Related Biologic Products Advisory Committee what strains will be included in the following year's vaccine. Data from the WHO Influenza Surveillance Network are used to determine the composition of the Northern and Southern Hemisphere influenza vaccine for the following season. Because influenza viruses are constantly changing and immunity wanes over time, annual immunization is required. The previous year's vaccine cannot be used for the current year. Influenza virus vaccine imparts immunity by stimulating production of antibodies that are specific to the disease strain. Patients who receive the vaccine are immune only to the strains included in the vaccine for that year.

Pharmacokinetics

The influenza vaccine is administered IM. The vaccine produces protective antibodies within 10 to 14 days. The duration of immunity generally lasts from 6 months to 1 year.

Pharmacotherapeutics

Precautions and Contraindications

Anaphylactic reaction to the influenza vaccine, eggs, or egg products is a contraindication to the use of influenza vaccine. The CDC has developed an algorithm to be used with patients who report an allergy to eggs (Grohskopf et al, 2013). The recommendation includes administering the inactivated influenza vaccine to patients who can eat lightly cooked eggs without a reaction. If patients age 18 to 49 only experience hives from eating eggs, the recommendations are to administer recombinant influenza vaccine (Flucelvax, FluBlok) or inactivated influenza vaccine and observe the patient for at least 30 minutes following vaccination (Grohskopf et al, 2013). Patients who have severe hypersensitivity to eggs should only be administered the recombinant influenza vaccine (Flucelvax, FluBlok), which is produced using non-egg technologies.

Thimerosal is used as a preservative in the vaccine; therefore, patients with hypersensitivity to thimerosal should not receive the influenza vaccine. Some of the influenza vaccines contain sulfites; care should be taken to check the ingredients listed on the packaging prior to administering vaccine to a patient with sulfite hypersensitivity.

Patients with an active neurological disorder should defer the vaccine until the condition stabilizes. Any patient with a history of Guillain–Barré syndrome (GBS) less than 6 weeks after a previous dose of influenza vaccine should not receive the vaccine. Patients with HIV disease may be immunized with influenza vaccine, but they may have lower vaccine-induced antibody levels. Patients with an acute febrile illness should defer the vaccine until their symptoms subside.

Influenza vaccine is Pregnancy Category C, but according to the CDC (2013c) influenza vaccine may be safely administered to pregnant women. Influenza vaccine may be administered to lactating women with no effect on the infant.

The safety of influenza vaccine has not been established in children younger than 6 months of age.

Administration error: The dosing schedules for children and adults for injectable influenza vaccine are different. If an adult is accidentally administered a pediatric dose (0.25 mL), the adult should receive an additional pediatric dose (0.25 mL) the same day. If the mistake is not discovered until later, a full adult dose is administered. If a child is administered an adult dose, no action needs to be taken.

Adverse Drug Reactions

Adverse reactions to the influenza vaccine are usually mild and more common in children than in adults. Local injection site reaction occurs in about 23% percent of patients. In addition, 5% to 10% of patients experience mild adverse systemic effects, including low-grade fever, malaise, and myalgia.

Rarely, a patient has an immediate hypersensitivity reaction to the vaccine, including urticaria, angioedema, bronchospasm, and/or anaphylactic shock. These reactions are most likely the result of hypersensitivity to residual egg protein.

Drug Interactions

Patients who are taking immunosuppressants or antineoplastic agents may have a decreased immunological response to influenza vaccine. Medications that may have inhibited clearance after administration of influenza vaccine include the -ophylline, phenytoin, and warfarin. Reports concerning impaired drug clearance are conflicting, and the concurrent administration of influenza vaccine to patients taking these medications is not contraindicated.

Clinical Use and Dosing

The influenza vaccine should be administered annually to all persons aged 6 months and older, including pregnant women. The optimal time for organized vaccination programs is October through mid-November. Travelers to areas in which influenza is endemic should be vaccinated 2 to

4 weeks prior to travel. The dosing of influenza vaccine is as follows:

1. Patients aged 9 years or older are given one 0.5 mL dose of influenza vaccine annually.
2. Adults aged 65 years or older may receive high-dose influenza vaccine (Fluzone High-Dose).
3. Previously vaccinated children aged 3 to 8 are given one 0.5 mL dose.
4. Children aged 3 to 8 who have never been vaccinated receive 0.5 mL, with a repeat dose in 4 weeks.
5. Children aged 6 to 35 months who have been previously vaccinated receive 0.25 mL of vaccine.
6. Children aged 6 to 35 months who have not been previously vaccinated with influenza vaccine receive 0.25 mL, with a second dose in 4 weeks.

Patients who experience only hives when eating eggs or egg-containing foods can be administered FluBlok or Flucelvax and observed for 30 minutes. Patients who have symptoms of anaphylaxis when eating eggs may be administered FluBlok or referred to an allergist.

Monitoring

There is no laboratory monitoring needed after patients receive the influenza vaccine.

Patient Education

Parents should receive a VIS prior to administration of vaccine. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reaction after influenza vaccine injection is pain and erythema at the injection site. Some patients may also experience low-grade fever and malaise. Advise the patient to take acetaminophen for discomfort for the first 24 hours after injection.

PNEUMOCOCCAL VACCINE

Pharmacodynamics

There are two types of pneumococcal vaccine currently available (Pneumovax 23, Prevnar). Polyvalent pneumococcal polysaccharide vaccine (PPV) contains 23 highly purified capsular polysaccharides from *Streptococcus pneumoniae.* These are the 23 most prevalent or invasive pneumococcal types, accounting for at least 90% of all blood isolates associated with clinical infection. PPV stimulates the immune system to produce pneumococcus capsule–specific antibodies. These antibodies presumably destroy the capsule, making the pneumococcus vulnerable to antibody- and cell-mediated immunity. Clinical trials suggest a protective efficacy of 60% to 90%. The 23-valent PPV has limited immunogenicity in children younger than 2 years. The 23-valent vaccine was approved by the FDA in 1977.

In February 2000, the FDA approved the first vaccine to prevent invasive pneumococcal disease in infants and children, pneumococcal 7-valent conjugate vaccine (Prevnar). The vaccine targeted the seven most common strains of pneumococcus, which accounted for 80% of invasive disease in

infants. With universal vaccination of children under the age of 5 years with PCV7, invasive pneumococcol disease decreased by 76% over 10 years of use (CDC, 2010c). In spite of this reduction, there were still cases of invasive pneumococcal disease in children caused by strains not in the PCV7 vaccine.

In 2010, the FDA approved a 13-valent conjugate vaccine (Prevnar13; PCV13), which is active against six additional strains of pneumococcus, responsible for 64% of invasive pneumococcal disease in children vaccinated with PCV7 (CDC, 2010c). In 2011 PCV13 was approved for use in adults age 50 and older; and in 2012 PCV13 was approved for age 19 and older with immunocompromising conditions, functional or anatomic asplenia, cerebrospinal fluid leak, or cochlear implants. PCV13 not meant to replace the 23-valent vaccine.

Pharmacokinetics

PPV is administered either SC or IM. Immunity after SC or IM injection occurs in 2 to 3 weeks. Serotype-specific antibodies decline after 5 to 10 years. Children may decline to pre-vaccination levels in 3 to 5 years, especially asplenic children and children with sickle cell disease.

PCV13 is administered IM, with measurable titers present 1 month after the fourth dose in children. Antibodies were measured in adults one month after a dose of PCV13 was administered.

Pharmacotherapeutics

Precautions and Contraindications

Previous anaphylactic reaction to the vaccine or any component is a contraindication to its use. Moderate to severe illness, with or without fever, is a reason to defer the vaccine until the patient has improved.

Pneumococcal vaccine should be given at least 10 to 14 days before elective splenectomy, organ transplant, immunosuppressive therapy, or chemotherapy. Patients with Hodgkin's disease and immunosuppressed patients have suboptimal antibody response to vaccination.

Use PPV cautiously in patients with idiopathic thrombocytopenic purpura (ITP), as PPV has been associated with relapse of ITP.

PPV is Pregnancy Category C. Use of the vaccine during the first trimester should be avoided. It is not known if the vaccine is excreted in breast milk.

PCV13 is Pregnancy Category B. There are no adequate, well-controlled studies in pregnant women.

PPV 23-valent vaccine is not recommended in children under 2 years. PCV13 is not for use in adults.

Adverse Drug Reactions

Seventy-two percent of PPV recipients report local injection site reactions of erythema, induration, and soreness that last up to 48 hours. Occasionally, low-grade fever and arthralgia have been reported. High fever is rare.

During clinical trials of Prevnar, adverse effects were generally mild and included local injection site reaction,

irritability, drowsiness, and decreased appetite. Approximately 21% of children in the vaccine group had a fever of 100.8°F or higher, compared with 14% of the control group. During clinical trials of PCV13 (Prevnar 13) infants had redness (24.3%), swelling (20.1%), and tenderness (62.5%) at the injection site and experienced fever (24.3%), irritability (85.6%), and increased sleep (71.5%) after the first dose at approximately the same rate as infants who received PCV7 (CDC, 2010e).

Drug Interactions

No known drug interactions have occurred.

Clinical Use and Dosing

Dosing of PPV is based on the age and medical condition of the patient:

1. PPV is recommended for all adults aged 65 or older. The dose is 0.5 mL IM or SC. Revaccinate (a second dose) if the original vaccination was 5 years or more ago *and* the patient was under age 65 when the dose was given.
2. People aged 2 to 65 years who have chronic illness and who are at increased risk of morbidity or mortality from pneumococcal disease should receive PPV. These risk factors include chronic cardiac or pulmonary disease, chronic liver disease or alcoholism, diabetes mellitus, and cerebrospinal fluid leaks. The dose of PPV is 0.5 mL given IM or SC once. Revaccination is not recommended in these populations.
3. Immunocompetent patients aged 2 to 65 years with functional or anatomic asplenia (including sickle cell anemia) should receive 0.5 mL IM or SC. Revaccination is recommended 5 years or more after the first dose; if the patient is under 10 years old, revaccination should be considered 5 years after the first dose.
4. Immunocompromised patients (including HIV infection); those with chronic renal failure, hematological malignancy, Hodgkin's disease, lymphoma, or multiple myeloma; patients receiving immunosuppressive therapy; and patients who have received an organ or bone marrow transplant should receive a dose of 0.5 mL IM or SC. Revaccination should be considered if the first vaccine was 5 years or more ago; in children under age 10, revaccination is considered 5 years after the first dose.
5. Adult smokers between the ages of 19 and 64 years should be given one dose of PPV.
6. Patients with asthma between the ages of 19 and 64 years should receive one dose of PPV.
7. One dose of PPV should be administered at 12 and 24 months following bone marrow transplant.
8. A dose of PPV is administered 2 or more months after last dose of PCV13 to children age 2 years or older.

The dosing schedule for PCV13 is:

1. Infants and toddlers: four doses given at 2, 4, 6, and 12 to 15 months of age.

2. Children up to age 59 months who are not vaccinated with PCV 13 at the routine infant vaccine times should be dosed following the Catch-Up schedule with a minimum dosing (see Table 19-2).

3. Children age 6 to 18 years with anatomic or functional asplenia (including SCD), HIV infection, cochlear implant, CSF leak, or other immunocompromising conditions who have not previously received PCV13 should receive one dose of PCV13, followed by PPV 8 weeks later.

4. Immunocompromised adults age 19 years or older who have not received pneumococcal vaccine should receive a dose of PCV13, followed by a dose of PPV at least 8 weeks later.

5. Immunocompromised adults age 19 years or older who have received PPV should receive a dose of PCV13 at least one year after last PPV dose.

6. All adults age 65 or older should receive a dose of PCV13. If they have not had any doses of pneumococcal vaccine they should receive a dose of PCV13, followed by a dose of PPV in 6 to 12 months.

7. Persons age 65 or older who have previously received PPV should be administered a dose of PCV13 at least a year after the last dose of PPV.

Monitoring

No laboratory monitoring is necessary.

Patient Education

Parents should receive a VIS prior to administration of the vaccine. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reaction after pneumococcal vaccine injection is pain and erythema at the injection site. Advise the patient to take acetaminophen for discomfort for the first 24 hours after injection.

MENINGOCOCCAL VACCINE

Pharmacodynamics

Meningococcal polysaccharide vaccine (MPSV) for groups A, C, Y, and W-135 (Menomune A/C/Y/W-135) is currently approved in the United States for use against meningococcemia and meningitis caused by *Neisseria meningitidis* serogroups A, C, Y, and W-135. MCV4 (Menactra, Menveo) is a tetravalent meningococcal conjugate vaccine that also provides protection against serogroups A, C, Y, and W-135. In 2012, Hib-MenCY (MenHibrix) was approved and provides coverage against *Neisseria meningitidis* serogroups C and Y and *Haemophilus influenzae* type b. In 2014 the FDA approved a serogroup B meningococcal vaccine Trumemba for use in 10- to 25-year-olds. A second meningococcal serotype B vaccine Bexero was approved in 2015 for use in 10- to 25-year-olds.

In the United States, *N. meningitidis* serogroup C, Y, and W accounts for 73% of meningococcal disease in persons 11 years of age or older and serogroup B for 60% of cases in children 0 to 59 months (Cohn et al, 2013). Serogroup A is rare in the United States but is the most common cause of epidemics in Africa and Asia. There were two major outbreaks of serotype B disease on college campuses in 2013 and 2014 (CDC, 2015).

All of the meningococcal vaccines induce the formation of bactericidal antibodies to meningococcal antigens. Post-immunization seroconversion rates for Menomune A/C/Y/W-135 reported by the manufacturer in children aged 2 to 12 years were group A, 72%; group C, 58%; group Y, 90%; and group W-135, 82%. Among 20,000 military recruits under epidemic conditions, the vaccine demonstrated 90% efficacy against serogroup C. MCV4 (Menactra, Menveo) demonstrated similar efficacy in patients age 11 to 55 years in clinical trials (Cohn et al, 2013). Two doses of Hib-MenCY demonstrated 94% efficacy for serotype C and 83% for serotype Y (Cohn et al, 2013). Two doses of serotype B vaccine demonstrate efficacy, with Bexsero demonstrating 62% to 88% efficacy against three serotype B strains, and 82% demonstrate antibodies to four serotype B strains after receiving Trumenba.

Limitations of the meningococcal polysaccharide vaccine (Menomune) include the following. Serogroup C polysaccharide is poorly immunogenic among children aged less than 2 years, it does not confer long-lasting immunity, and it does not cause a sustainable reduction of nasopharyngeal carriage of *N. meningitidis* (Cohn et al, 2013). Conjugation of polysaccharide (as in MCV4) to a protein carrier changes the immune response from T-cell independent to T-cell dependent, leading to stronger response to the vaccine and reduction of the asymptomatic carrier state (CDC, 2006b).

Pharmacokinetics

Protective antibody levels may be achieved within 7 to 10 days after vaccination. The measurable levels of antibodies to serogroups A and C are measured 3 to 5 years following vaccination (Cohn et al, 2013). This decrease occurs more rapidly in infants and young children than it does in adults.

Pharmacotherapeutics
Precautions and Contraindications

Previous anaphylactic reaction to any component of the vaccine is a contraindication to its use. Moderate to severe illness, with or without fever, is a reason to defer the vaccine until the patient has improved.

A history of Guillain–Barré Syndrome (GBS) is listed as a precaution for MCV4 in the package insert, although the ACIP removed GBS as a precaution in 2010 because the benefits of meningococcal vaccination outweigh the risk for recurrent GBS (Cohn et al, 2013).

The expected immune response may not be obtained if the vaccine is used in patients on immunosuppressive therapy.

Menomune A/C/Y/W-135 should not be given to pregnant women. It is not recommended for children under age 2 years. MCV4 (Menactra) is approved for use in children

aged 9 months or older and in adults; it is not recommended in adults older than 55 years. MCV4 (Menveo) is not recommended for children younger than 2 years or adults older than 55 years.

HibMenCY is approved for children aged 6 weeks to 18 months and is not approved in older children or adults.

MPSV (Menomune) is the only vaccine approved for adults older than age 55 years.

Both serotype B vaccines (Bexsero, Trumenba) are Pregnancy Category B. Neither serotype B vaccine is approved for children younger than age 10 years.

Adverse Drug Reactions

Adverse reactions to either vaccine are mild and consist of pain and tenderness at the injection site for 1 to 2 days.

Drug Interactions

There are no known drug interactions to this vaccine.

Clinical Use and Dosing

The ACIP (Cohn et al, 2013) recommends routine vaccination of young adolescents (defined as aged 11 to 12 years) with MCV4 at the preadolescent health-care visit or on entering high school (age 15). One booster dose of MCV4 is administered between age 16 and 18 years to adolescents who receive the first dose before age 16 years. While MCV4 is not routinely recommended for those older than 19 years, a catch-up dose can be administered to those aged 19 to 21 years who have not received a dose after their 16th birthday.

HibMenCY is recommended for routine vaccination of infants aged 2 to 18 months with persistent complement deficiencies or functional or anatomic asplenia (Cohn et al, 2013). HibMenCY may also be used to vaccinate infants aged 2 to 18 months during an outbreak of meningitis covered by the vaccine.

The ACIP also recommends that the following high-risk groups receive meningococcal vaccine:

1. Patients with deficiencies in late complement components (C3, C5, to C9).
2. Persons with functional or actual asplenia.
3. Research, industrial, and clinical laboratory personnel who routinely are exposed to *N. meningitidis* in solutions that may be aerosolized.
4. Travelers to, and residents of, hyperendemic areas such as sub-Saharan Africa. Epidemics have occurred recently in Saudi Arabia, Kenya, Tanzania, Burundi, and Mongolia.
5. College freshmen living in dorms.
6. Military recruits.

HibMenCY is administered as a primary series IM at age 2, 4, 6, and 12 through 15 months. MCV4 is administered IM as a single 0.5 mL dose with a second dose in 12 weeks in children aged 9 to 23 months and at 8 to 12 weeks in patients aged 2 to 55 years The dose of Menomune for all ages is a single SC 0.5 mL dose. In patients aged 9 months to 10 years, MCV4 (Menactra) is the preferred vaccine. Adults over age 55 years should receive MPSV.

Revaccination may be indicated for persons at high risk for infection (travel to or living in epidemic areas) who were previously vaccinated with MPSV or MCV4. Children who were vaccinated between age 2 months and 6 years old should be revaccinated with Menactra in 3 years if they remain at high risk. If a previous dose was given at age 7 years or older, either brand of MCV4 may be given after 5 years. Revaccination with MCV4 of high-risk older children and adults is recommended every 5 years after the first dose of MPSV or MCV4.

A booster dose of MCV4 is recommended at age 16 years in children who received their first dose of MCV4 at age 11 to 12 years. Adolescents who receive their first dose of MCV4 at age 13 to 15 years should receive a booster dose at age 16 to 18 years. The minimum interval between doses of MCV4 is 8 weeks (Cohn et al, 2013).

Serotype B vaccine is administered to 10- to 25-year-olds during an outbreak, or to those at increased risk for meningococcal disease, including those with persistent complement component deficiencies, with anatomic or functional asplenia, and microbiologists routinely exposed to isolates of *N. meningitides.* Bexsero is administered in two doses 1 month apart. Trumenba is administered in three doses at 1, 2, and 6 months.

Monitoring

Laboratory monitoring is not necessary with this vaccine.

Patient Education

Parents should receive information regarding the benefits and risks of the vaccine prior to administration. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reaction after vaccine injection is pain and erythema at the injection site. Advise the patient to take acetaminophen for discomfort for the first 24 hours after injection.

LYME DISEASE VACCINE

Pharmacodynamics

Lyme disease is a vector-borne illness caused by ticks infested with *Borrelia burgdorferi.* Recombinant Lyme disease vaccine (LYMErix, Immulyme) imparts immunity against *B. burgdorferi* by stimulating production of antibodies to the lipoprotein OspA. OspA is a lipoprotein of the *B. burgdorferi* spirochete. The mechanism by which Lyme disease vaccine works is thought to be by antibody killing of the spirochete in the tick. Transmission of the OspA antibody occurs while the tick is feeding on the blood of an immunized host, and the antibodies kill the spirochete even before transmission occurs. In February 2002, SmithKline Beecham, the maker of the only approved Lyme disease vaccine, LYMErix, discontinued its production after there were concerns about the side effects of the vaccine, although an FDA investigation did not find the vaccine to be dangerous. The long-term immunity for patients who previously received the vaccine is unknown. A new vaccine active against *B. burgdorferi* is undergoing clinical trials in Austria and Germany, with promising early results (Wressnigg et al, 2013).

TYPHOID VACCINE

Pharmacodynamics

Typhoid vaccines (Typhoid Vaccine, Typhim Vi) are used to increase resistance to enteric fever caused by *S. typhi.* The efficacy of protective immunity depends on the size of the bacterial inoculum consumed.

There are two parenteral typhoid vaccines available, a heat- and phenol-inactivated vaccine (Typhoid Vaccine) and a purified Vi polysaccharide (Typhim Vi). The efficacy of Typhoid Vaccine is 71% to 77%. The efficacy of Typhim Vi is 49% to 87% in reducing disease incidence. Typhim Vi is used in the United States, and a second brand of Vi polysaccharide, Typherix, is used in Canada.

Pharmacokinetics

The absorption, distribution, and metabolism of typhoid vaccine are unknown.

Pharmacotherapeutics

Precautions and Contraindications

Hypersensitivity to typhoid vaccine is a contraindication to its use. Do not administer to a patient with acute febrile illness.

Typhoid vaccine is Pregnancy Category C. It is not known if the vaccine is harmful to the fetus. If vaccinating a pregnant patient is necessary, inactivated vaccine is recommended.

Typhim Vi and Typherix are not recommended for children under age 2.

Adverse Drug Reactions

Vaccine recipients report local injection site reactions of erythema, induration, and soreness that begin within 24 hours and last 1 to 2 days. Systemic symptoms including low-grade fever, headache, and myalgias have been reported. High fever is rare.

Drug Interactions

If possible, plague vaccine should not be given at the same time as typhoid vaccine to avoid the possibility of accentuated adverse effects. Immunosuppressants may cause insufficient response to the vaccine.

Clinical Use and Dosing

Typhoid vaccine is used for primary immunization against *S. typhi* infection in the following:

1. Travelers to areas where a risk of exposure to *S. typhi* is recognized
2. Persons with household contact with a documented typhoid fever carrier
3. Laboratory workers with frequent contact with *S. typhi*

The dose of Typhim Vi and Typherix in children older than age 2 years and adults is 0.5 mL SC. A booster dose should be administered every 2 years to patients at continued risk of contracting typhoid.

Monitoring

There is no laboratory monitoring needed after typhoid vaccine.

Patient Education

Parents should receive information regarding the benefits and risks of the vaccine prior to administration. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reaction after typhoid vaccination injection is pain and erythema at the injection site. Advise the patient to take acetaminophen for discomfort for the first 24 hours after injection.

The best protection against typhoid fever is food and water precautions to prevent contracting *S. typhi.*

CHOLERA VACCINE

Pharmacodynamics

Cholera vaccine is a suspension of equal parts inactivated Ogawa and Inuba serotypes of killed *Vibrio cholerae* and provides active immunity against cholera. The vaccine is 50% effective in reducing disease in endemic areas. The manufacture and sale of the only licensed cholera vaccine in the United States (Wyeth-Ayerst) has been discontinued. It has not been recommended for travelers because of the brief and incomplete immunity it offers. No cholera vaccination requirements exist for entry or exit in any country (CDC, 2005b).

JAPANESE ENCEPHALITIS VIRUS VACCINE

Pharmacodynamics

Japanese encephalitis (JE) is the most common form of viral encephalitis in Asia and is spread by mosquitoes. An estimated 35,000 to 50,000 cases occur annually. JE is usually severe, resulting in death in 20% to 30% of cases, miscarriage in pregnant women, and serious neurological outcomes in 30% to 50% of infected patients (CDC, 2010d). Currently the only vaccine in production in the United States for JE is an inactivated Vero cell culture–derived vaccine (JE-VC) or IXIARO.

Pharmacokinetics

JE-VC is administered via a two-dose schedule at 0 and 28 days; 96% of vaccine recipients demonstrated an adequate level of immunity against JE. The length of full protection against JE is unknown

Pharmacotherapeutics

Precautions and Contraindications

Previous anaphylactic reaction to any component of the vaccine, including thimerosal, is a contraindication to its use. Pregnancy is a contraindication to JE-VC use. There are no adequate trials investigating safety during pregnancy. IXIARO was approved for children age 2 months through 16 years in 2013 (CDC, 2013d).

Adverse Drug Reactions

IXIARO appears to have the same reported adverse reactions as placebo or comparison vaccine (PCV7 or HAV). Injection site tenderness is reported in approximately 10% to 37% of children receiving the vaccine and fever is reported in 2% to 7% of children (CDC, 2013d). Report any significant adverse effects to the VAERS.

Drug Interactions

There are no known drug interactions.

Clinical Use and Dosing

The best way to avoid JE is to prevent mosquito bites (Hills, Weber, & Fischer, 2013). The ACIP recommends that JE-VC be administered to those who plan on residing for more than a month in areas in which JE is endemic or epidemic. The probability of JE viral infection and illness increases with the duration of the stay in rural endemic areas. Current information on locations of JE virus transmission can be obtained from the CDC *Yellow Book* or Travel Web site (www.cdc.gov/travel).

JE-VC is not recommended for all travelers to Asia. The vaccine should be offered to people spending a month or longer in endemic areas during the transmission season, especially if they are traveling to rural areas (Hills et al, 2013). It should also be offered to those who will be spending extensive time outdoors during their travel.

The dose of JE-VC in adults is two 0.5 mL doses administered IM 28 days apart. For children aged 2 months through 2 years, each dose is 0.25 mL (CDC, 2013d). The series should be completed at least 1 week before potential exposure to Japanese encephalitis virus. The need for a booster is not known because the vaccine is newly approved. Providers are referred to the CDC Travel Web site for dosing information (www.cdc.gov/travel).

Monitoring

There is no monitoring needed after the vaccine.

Patient Education

Patients should receive information regarding the benefits and risks of the vaccine prior to administration. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reactions after vaccination are pain and erythema at the injection site and low-grade systemic symptoms. Adverse reactions may occur up to 10 days after immunization. Patients are advised not to travel outside the United States for 10 days after administration in case of adverse reaction.

Personal protection against mosquitoes is essential for all travelers to endemic areas. Patients should be advised to protect themselves by wearing long-sleeved shirts and long pants. Use of insect repellent should be encouraged. Permethrin should be applied to clothing.

PLAGUE VACCINE

Pharmacodynamics

Plague vaccine, a whole-cell vaccine consisting of a suspension of inactivated plague bacilli (*Yersinia pestis*), is no longer available in the United States. Vaccination against plague is not required by any country as a condition for entry. Travelers who may be exposed to plague should carry prophylactic antibiotics (doxycycline, or trimethoprim-sulfamethoxazole for children under 8 years of age) and use them according to the CDC guidelines for plague, which can be found at the CDC Traveler's Health Web site, www.cdc.gov/travel.

RABIES VACCINE

Pharmacodynamics

Rabies vaccine (Imovax, RabAvert) is a preparation of inactivated rabies virus that induces active immunity. The two products available differ only in the cell culture used to develop the vaccine. Imovax uses human diploid cell (HDC) culture, and RabAvert uses purified chick embryo cell culture.

Pharmacokinetics

An antibody response to rabies vaccine can be measured in 7 to 10 days after administration. Antibodies persist for 2 years.

Pharmacotherapeutics

Precautions and Contraindications

Previous anaphylactic reaction to any component of the vaccine, including neomycin, is a contraindication to its use. Moderate to severe illness, with or without fever, is a reason to defer the vaccine until the patient has improved. The expected immune response may not be obtained if the vaccine is used in patients on immunosuppressive therapy.

Rabies vaccine is Pregnancy Category C. Pregnancy is not a contraindication to post-exposure vaccination of pregnant women. Safety in children under age 6 has not been established.

Adverse Drug Reactions

Local reactions, including pain, erythema, and swelling of the injection site, have been reported by 30% to 70% of vaccine recipients. Systemic reactions have been reported by 5% to 40% of recipients. Systemic reactions include headache, nausea, abdominal pain, muscle aches, and dizziness. Three cases of a neurological illness resembling Guillain–Barré syndrome have been reported. A serum sickness–like reaction has been reported among about 6% of patients who received booster doses of Imovax.

Drug Interactions

Long-term therapy with chloroquine (Aralen) can interfere with the active antibody response to rabies vaccine. Patients who are taking immunosuppressants or antineoplastic agents may have a decreased immunological response to rabies vaccine.

Rabies IG (RIG) can partially suppress the antibody response to rabies vaccine. Follow the CDC recommendations for simultaneous administration exactly, and give no more than the recommended dose of RIG.

Clinical Use and Dosing

Rabies vaccine can be given for primary or pre-exposure vaccination or as part of post-exposure prophylaxis. Pre-exposure vaccination is recommended to high-risk groups, such as veterinarians, animal handlers, and certain laboratory workers. Post-exposure prophylaxis is recommended if the patient has a bite from a rabid animal that penetrates the skin. Post-exposure vaccine administration should always be accompanied by the use of RIG.

Pre-exposure vaccine dosing consists of three 1 mL IM injections of vaccine in the deltoid muscle. The doses are given on day 0, day 7, and either day 21 or day 28. A booster dose of 1 mL is given every 2 years to those considered at frequent risk if their serum antibody titer is less than 1:5. Persons considered at frequent risk include veterinarians, animal control officers, wildlife officers, and staff where rabies is enzootic. In very high-risk patients, those who work in research laboratories or vaccine production facilities, a serum rabies antibody test should be done every 6 months and vaccine administered if levels are less than 1:5.

Post-exposure prophylaxis always includes administration of both passive antibody and vaccine, with the exception of those who have previously received complete vaccination (pre-exposure or post-exposure). For post-exposure vaccination, the ACIP recommends four doses of rabies vaccine. The dose is 1 mL given IM on days 0, 3, 7, and 14, with RIG given on day 0 (Rupprecht et al, 2010). For those who have previously been vaccinated, two doses of rabies vaccine are given on days 0 and 3, with no RIG needed.

Monitoring

Patients who receive a four-dose schedule of rabies vaccine do not need post-vaccination serological testing (Rupprecht et al, 2010).

Patient Education

Patients should receive information regarding the benefits and risks of the vaccine prior to administration. Any questions or concerns regarding the vaccine should be addressed. The need for repeated doses should be discussed. The most common adverse reactions after rabies vaccination injection are pain and erythema at the injection site and systemic symptoms including headache, nausea, abdominal pain, muscle aches, and dizziness. Advise the patient to take acetaminophen for discomfort.

Table 19-6 presents issues concerning immunizations.

Table 19–6 Issues in Immunization

Childhood Immunization

Ideally, immunizations should be given as a part of comprehensive child health care. It is widely recognized that childhood immunizations are the most cost-effective way of preventing infectious diseases in children. Identified barriers to childhood immunization include the following:
1. Financial, with low socioeconomic status placing a child at risk of underimmunization
2. Family structure issues, such as single or teen parenthood
3. Perceived attitudes regarding the benefit of immunization
4. Provider policies and practices that lead to missed vaccine opportunities during clinic visits

Standards for Child and Adolescent Immunization Practices (National Vaccine Advisory Committee, 2009)

AVAILABILITY OF VACCINES
1. Vaccination services are readily available.
2. Vaccinations are coordinated with other health-care services and provided in a medical home when possible.
3. Barriers to vaccination are identified and minimized.
4. Patient costs are minimized.

ASSESSMENT OF VACCINATION STATUS
1. Health-care professionals review the vaccination and health status of patients at every encounter to determine which vaccines are indicated.
2. Health-care professionals assess for and follow only medically indicated contraindications.

EFFECTIVE COMMUNICATION ABOUT VACCINE BENEFITS AND RISKS
1. Parents/guardians and patients are educated about the benefits and risks of vaccination in a culturally appropriate manner and in easy-to-understand language.

PROPER STORAGE AND ADMINISTRATION OF VACCINES AND DOCUMENTATION OF VACCINATIONS
1. Health-care professionals follow appropriate procedures for vaccine storage and handling.
2. Up-to-date, written vaccination protocols are accessible at all locations where vaccines are administered.
3. Persons who administer vaccines and staff who manage or support vaccine administration are knowledgeable and receive ongoing education.
4. Health-care professionals simultaneously administer as many indicated vaccine doses as possible.
5. Vaccination records for patients are accurate, complete, and easily accessible.
6. Health-care professionals report adverse events following vaccination promptly and accurately to the Vaccine Adverse Events Reporting System (VAERS) and are aware of a separate program, the National Vaccine Injury Compensation Program (NVICP).
7. All personnel who have contact with patients are appropriately vaccinated.

IMPLEMENTATION OF STRATEGIES TO IMPROVE VACCINATION COVERAGE
1. Systems are used to remind parents/guardians, patients, and health-care professionals when vaccinations are due and to recall those who are overdue.
2. Office- or clinic-based patient record reviews and vaccination coverage assessments are performed annually.
3. Health-care professionals practice community-based approaches.

Continued

Table 19–6 Issues in Immunization—cont'd

Standards for Adult Immunization Practices (National Vaccine Advisory Committee, 2013)

MAKE VACCINATIONS AVAILABLE.

1. Adult vaccination services are readily available.
2. Barriers to receiving vaccines are identified and minimized.
3. Patient "out-of-pocket" vaccination costs are minimized.

ASSESS PATIENTS' VACCINATION STANDARDS.

1. Health-care professionals routinely review the vaccination status of patients.
2. Health-care professionals assess for valid contraindications.

COMMUNICATE EFFECTIVELY WITH PATIENTS.

1. Patients are educated about risks and benefits of vaccination in easy-to-understand language.

ADMINISTER AND DOCUMENT VACCINATIONS PROPERLY.

1. Written vaccination protocols are available at all locations where vaccines are administered.
2. Persons who administer vaccines are properly trained.
3. Health-care professionals recommend simultaneous administration of indicated vaccine doses.
4. Vaccination records for patients are accurate and easily accessible.
5. All personnel who have contact with patients are appropriately vaccinated.

IMPLEMENT STRATEGIES TO IMPROVE VACCINATION RATES.

1. Systems are developed and used to remind patients and health-care professionals when vaccinations are due and to recall patients who are overdue.
2. Standing orders for vaccinations are employed.
3. Regular assessments of vaccination coverage levels are conducted in a provider's practice.

PARTNER WITH THE COMMUNITY.

1. Patient-oriented and community-based approaches are used to reach the target.

Immunization in Special Populations

PREGNANT PATIENTS

The ACIP has published guidelines for vaccinating pregnant women (CDC, 2013c): "The risk from vaccination during pregnancy is largely theoretical. The benefit of vaccination among pregnant women usually outweighs the potential risk for disease when (a) the risk for disease exposure is high, (b) infections would pose a special risk for the mother or fetus, and (c) the vaccine is unlikely to cause harm."

Generally, live-virus vaccines are contraindicated in pregnant women because of the possible risk of transmission to the fetus. If a woman is inadvertently given live-virus vaccine while pregnant, she should be counseled about the potential effects on the fetus. It is not normally an indication to terminate pregnancy.

Recommendations for Vaccination During Pregnancy Include the Following:			
Vaccine	**May Be Given if Indicated**	**Contraindicated During Pregnancy**	**Comments**
Routine			
Hepatitis A	X		
Hepatitis B	X		The theoretical risk to the fetus is low from the inactivated vaccine.
Human papillomavirus			Not recommended during pregnancy.
Influenza (Inactivated)	X		Recommended for all women pregnant during flu season
Influenza (LAIV)		X	
MMR		X	
Meningococcal	X		Safety has not been evaluated in pregnant women.
PCV13			Inadequate data available
PPSV23	X		Inadequate data available
Polio	X		
Td	X		
Tdap	X		Pregnancy is not a contraindication for Tdap administration. ACIP recommends pregnant women receive the Tdap vaccine with every pregnancy.

Table 19–6   Issues in Immunization—cont'd

Vaccine	May Be Given if Indicated	Contraindicated During Pregnancy	Comments
Varicella		X	
Pneumococcal	X		The safety of the pneumococcal vaccine in the first trimester of pregnancy has not been determined.
Travel and Others			
Anthrax			Vaccinate only if benefits outweigh risks to fetus.
BCG		X	
Japanese encephalitis (JE)			The vaccine should not be routinely administered during pregnancy. If a pregnant woman will be moving to an area of high risk of JE, then vaccination should be considered.
Meningococcal (MPSV)	X		
Rabies	X		
Typhoid (parenteral and oral)			It is not known if the vaccine is harmful to the fetus. If necessary to vaccinate a pregnant patient, inactivated vaccine is recommended.
Vaccinia (smallpox)			Vaccinia vaccine should not be administered to pregnant women for routine nonemergency indications. Pregnant women who have had a definite exposure to smallpox virus (i.e., face-to-face, household, or close-proximity contact with a smallpox patient) and are, therefore, at high risk for contracting the disease, should be vaccinated.
Yellow fever			It is not known if the vaccine is harmful to the fetus. Only vaccinate pregnant women who are at high risk of contracting disease.
Zoster		X	

Immunocompromised Patients

For practical considerations, persons with immunocompromising conditions may be divided into three groups:

1. Persons who are severely immunocompromised not as a result of HIV infection
2. Persons with HIV infection
3. Persons with conditions that cause limited immune deficits (e.g., asplenia, renal failure) that may require use of special vaccines or higher doses of vaccines but that do not contraindicate use of any particular vaccine
    ACIP recommendation for vaccinations is based on where the patient falls within these three groups.
1. Persons who are severely immunocompromised not as a result of HIV infection: In general, these patients should not be administered live vaccines. Measles, mumps, and rubella (MMR) vaccine is not contraindicated for the close contacts. Passive immunization with immune globulin should be considered for immunocompromised persons instead of or in addition to vaccination.
2. In general, persons known to be HIV-infected should not receive live-virus or live-bacteria vaccines. MMR vaccination is recommended for all children and for adults when otherwise indicated, regardless of their HIV status. Enhanced inactivated polio vaccine (eIPV) is the preferred polio vaccine for persons known to have HIV infection. Pneumococcal vaccine is indicated for all HIV-infected persons ≥2 yr of age.
3. Persons with conditions that cause limited immune deficits (e.g., asplenia, renal failure) that may require use of special vaccines or higher doses of vaccines but that do not contraindicate use of any particular vaccine. Persons with these conditions are generally not considered immunosuppressed for the purposes of vaccination and should receive routine vaccinations with both live and inactivated vaccines according to the usual schedules.

Travel Immunization

International travel is becoming more common, with jet travel allowing people to travel great distances in a few hours. With international travel comes exposure to infectious diseases not common in the United States. Patients should be advised to begin to prepare for their trip at least 8 wk prior to departure. To determine what vaccines the traveling patient will need, the provider can consult with a local travel clinic or the CDC. The CDC Web site has a travel information section, maintained by the National Center for Infectious Disease (http://www.cdc.gov/travel/). The Web site allows the provider or patient to inquire into recommendations based on the region the patient will be traveling to. Information on traveling with children, outbreaks, and special needs travelers is also located at this site. The CDC also publishes an annual guide, *The Yellow Book: Health Information for International Travel*.

In addition to special immunizations required by travel, patients should also have all of the recommended routine immunizations for their age, including influenza vaccine. Patients should have a copy of their current immunizations included with their travel documents.

IMMUNE GLOBULIN SERUMS

IG serums provide passive immunity to infectious diseases. The choice of IG is determined by the types of products available, the type of antibody desired, route of administration, timing, and other considerations. IG products that may be used in primary care include immune globulin IM (IGIM, BayGam; GamaSTAN S/D), hepatitis B immune globulin (H-BIG, HepaGam B), tetanus immune globulin (TIG, HyperTET S/D), respiratory syncytial virus immune globulin (RSV-IGIV, RespiGam), varicella-zoster immune globulin (VZIG, VariZIG), rabies immune globulin (RIG, HyperRab S/D, Imogam), $Rh_o(D)$ immune globulin (RhoGAM, HyperRHO-S/D), and vaccinia immune globulin (VIG).

Pharmacodynamics

IGs are derived from the pooled plasma of adults, processed by cold ethanol fractionation. It consists primarily of immunoglobulin fraction (95% IgG) and is not known to transmit hepatitis, HIV, or other infectious diseases. The concentrated protein solution contains specific antibodies in proportion to the infectious and immunization experience of the donor population from which the plasma was derived. IG serums undergo processing to remove and inactivate viruses, including hepatitis A, B, and C; parvovirus B-19; and HIV. Specific IGs differ from IGIM, which is sometimes referred to as gamma globulin, in that they have high levels of a specific IG.

IGIM (BayGam; GamaSTAN S/D) is a sterile preparation of concentrated antibodies. IGIM provides protection against hepatitis A and measles through passive transfer of antibody. It may be used for pre-exposure prophylaxis or post-exposure prevention in the treatment of hepatitis A; it is used post-exposure in measles.

Hepatitis B immune globulin (HBIG, HepaGam B) is a sterile solution of IGs (10% to 18%) against HbsAg. Anti-HBsAg antibodies are collected from donors with high titers of anti-HBsAg. HBIG is used to provide passive immunity to patients following exposure to blood infected with hepatitis B, sexual and household contacts with people infected with hepatitis B virus, and infants born to HbsAg-positive mothers.

Tetanus immune globulin (TIG, HyperTET S/D) is prepared from the plasma of adults who are hyperimmunized with tetanus toxoid. TIG contains antibodies that neutralize the exotoxin produced by *C. tetani.* The passive immunity bestowed by TIG is capable of attenuating or preventing tetanus infection by binding free exotoxin.

Respiratory syncytial virus immune globulin (RSV-IGIV) is a polyclonal human hyperimmune globulin. The product is prepared by extracting IgG antibodies from the plasma of humans who have high titers of antibodies against respiratory syncytial virus (RSV). Resistance to RSV disease is via cellular and humoral immunity. RSV-IGIV does not protect the nasal mucosa from RSV and thus does not prevent acquired immunity to RSV.

Varicella-zoster immune globulin (VZIG) was approved in 2013 and is derived from human plasma and consists of IgG that contains antibodies to varicella-zoster virus. VZIG is used primarily for passive immunization of high-risk susceptible patients after exposure to chickenpox or herpes zoster. High-risk groups include pregnant women, newborns of women with varicella shortly before or after delivery, immunocompromised children and adults, neonates and infants younger than 12 months, and adults without evidence of immunity. The administration of VZIG has shown to significantly reduce the mortality in untreated patients.

Rabies immune globulin (RIG, HyperRab S/D, Imogam) is primarily gamma globulin. RIG is used to provide passive immunity to rabies in patients exposed to the virus. Rabies antibodies neutralize the rabies virus to retard its spread and to inhibit its effectiveness.

$Rh_o(D)$ immune globulin (RhoGAM, HyperRHO S/D) is used to prevent isoimmunization in $Rh_o(D)$-negative women exposed to $Rh_o(D)$-positive blood. $Rh_o(D)$ immune globulin is a solution containing IgG antibodies against erythrocyte antigen $Rh_o(D)$, collected from the plasma of human donors. It is believed that the anti-$Rh_o(D)$ antibodies in $Rh_o(D)$ immune globulin interact directly with the $Rh_o(D)$ antigens, preventing interaction between the antigens and the maternal immune system. $Rh_o(D)$ immune globulin prevents the development of erythroblastosis fetalis in current or subsequent pregnancies.

Vaccinia immune globulin intravenous (VIGIV) provides passive immunity for smallpox-associated eczema vaccinatum, severe or progressive vaccinia, and vaccinia infections in patients with skin conditions (impetigo, poison ivy, eczema, varicella zoster) that would lead to severe rash with smallpox infection.

Pharmacokinetics

IGIM, when used for pre-exposure prophylaxis for hepatitis A, confers protection for less than 3 months. It is greater than 85% effective in preventing hepatitis A if given within 2 weeks after exposure. IGIM can be given to prevent or modify measles in susceptible persons if used within 6 days of exposure.

HBIG is slowly absorbed, with antibodies appearing in 1 to 6 days and peak levels reached in 3 to 9 days. The antibodies remain in the serum for up to 2 months. HBIG probably crosses the placenta and may be distributed in breast milk.

TIG is given IM, with peak levels of IgG noted 2 days after administration. The half-life of IgG in circulation is 3.5 to 4.5 weeks.

RSV-IGIV is administered IV on a monthly basis. The serum half-life of RSV-IGIV is 22 to 28 days.

VZIG is administered IM, with peak IgG levels obtained in 2 days after administration. It is the most effective if administered within 4 days of exposure to VZV. Antibody protection lasts 3 weeks.

RIG is administered by infiltrating the wound with half of the dose and giving the other half of the dose IM in a separate limb from the injury.

$Rh_o(D)$ immune globulin pharmacokinetics is not well described. Peak antibody levels are reached in 5 to 10 days after

IM administration. Anti-Rh$_o$(D) antibodies are not detectable 6 months after administration of Rh$_o$(D) immune globulin.

VIGIV peaks in 2 hours and has a half-life of 30 days.

Pharmacotherapeutics

Precautions and Contraindications

An allergic response to IGIM or anti-IGA antibodies is a contraindication to IG serum use, as is thimerosal allergy. Patients with IgA deficiency often develop antibodies against IgA and are more likely to have anaphylactic or immune-mediated adverse reaction to pooled IG products.

RSV-IGIV is contraindicated in patients with cyanotic congenital heart disease.

Live-virus vaccines should not be administered within 3 months of an IG serum.

Pregnancy is not a contraindication to most IG serums.

VIGIV is contraindicated in patients with vaccinia keratitis. VIGIV may cause falsely high blood glucose readings on some test systems due to the maltose in the preparation. Blood glucose testing should be done with a glucose-specific method.

Adverse Drug Reactions

Local reactions include tenderness and pain in the injection site that may last for several hours. Systemic reactions include urticaria and angioedema. Less frequently reported adverse reactions include emesis, chills, fever, myalgia, lethargy, and nausea.

Drug Interactions

IG serums interfere with the immune response to live-virus vaccines. Live virus vaccines should not be administered within 3 months of an IG serum.

Clinical Use and Dosing

IG serums are used to prevent disease by either pre-exposure or post-exposure administration. The clinical use and dosing of the IG serums are detailed in Table 19-7.

Table 19–7 ⚘ **Dosage Schedule: Immune Globulins**

Drug	Indication	Dose	Comments
I/gamma globulin	Hepatitis A prophylaxis	Length of stay: <3 mo, give 0.02 mL/kg IM. Prolonged (>3 mo), give 0.06 mL/kg and repeat every 4 to 6 mo.	Effective if given before exposure or within 2 wk of exposure
	Measles	Give 0.25 mL/kg IM. If child is also immunocompromised, give 0.5 mL/kg IM.	Must be given within 6 d of exposure to measles
	Immunoglobulin	Deficiency 0.66 mL/kg every 3–4 wk	
Hepatitis B immune globulin (HBIG)	After exposure to blood infected with hepatitis B (HBV)	*Children ≥12 mo and adults:* Administer 0.06 mL/kg IM within 24 h; repeat in 28–30 d *Children <12 mo:* 0.5 mL × 1	Give hepatitis B vaccine within 7 d and repeat at 1 and 6 mo
	Sexual contacts of HBV-infected people	Administer 0.06 mL/kg IM within 14 d of sexual contact	Give hepatitis B vaccine within 7 d and repeat at 1 and 6 mo
	Infants born to HbsAg-positive mothers	Administer 0.5 mL IM within 12 h of birth	Give hepatitis B vaccine within 12 h of birth and repeat at 1 or 2 and at 6 mo
Tetanus immune globulin (TIG)	Passive immunization against tetanus	Clean minor wounds: No TIG necessary. Give Td/DTaP if indicated. All other wounds (may be contaminated with dirt, feces, soil, saliva, and puncture wounds): Unknown or <3 doses of DTaP/Td: Give adults 250 U TIG, children 4 U/kg of TIG, give a booster dose of TD/DTaP. History of >3 doses of tetanus toxoid: No TIG, no Td/DTaP booster.	
Respiratory syncytial virus immune globulin (RSV-IGIV)	RSV prophylaxis in high-risk children	*Children <24 mo with bronchopulmonary dysplasia or chronic lung disease:* Give 750 mg/kg IV once monthly throughout RSV season *Infants <6 mo born at 32 wk gestation or earlier or infants <12 mo of age if less than 28 wk gestation:* Give 750 mg/kg IV once monthly throughout RSV season	Medication should be infused at a rate of 1.5 mL/kg/h for the first 15 min, then increase to 3 mL/kg/h for 15 min; maximum rate of 6 mL/kg/h

Continued

Table 19–7 ⊗ **Dosage Schedule: Immune Globulins—cont'd**

Drug	Indication	Dose	Comments
Varicella-zoster immune globulin (VZIG)	Passive immunization for high-risk patients exposed to varicella	Administer VZIG within 96 h of exposure *Adults and adolescents:* 125 U/10 kg, up to 625 U maximum	VZIG administration is recommended in the following groups: Immunocompromised patients (patients with HIV, cancer, or receiving immunosuppressive therapy), neonates of women who have symptoms of varicella at delivery, premature neonates exposed postnatally, pregnant women
		Children and infants: 125 U/10 kg, rounded to nearest 125 U >40 kg: 625 U IM 30.1–40 kg: 500 U 20.1–30 kg: 375 U 10.1–20 kg: 250 U <10 kg: 125 U	Patients should meet the additional requirements: 1. Not immune to varicella 2. Significant exposure <96 h prior to VZIG administration; significant exposure defined as household contact, playmate contact (>1 h contact), hospital contact (in same room)
Rabies immune globulin (RIG)	Provides passive immunity to rabies	Previously unvaccinated against rabies: Administer 20 IU/kg up to 7 d after the first dose of rabies vaccine	Post-exposure prophylaxis always includes administration of both passive antibody and vaccine, with the exception of those who have previously received complete vaccination. For post-exposure vaccination, the ACIP recommends that 4 doses of rabies vaccine be given, with RIG given at the same time as the first vaccine dose
Rh_o (D) immune globulin (RhoGAM)	Rh isoimmunization prophylaxis	Administer 300 mcg IM at 28 wk gestation and/or within 72 h of an Rh-incompatible delivery, miscarriage, abortion, or transfusion accident Administer 50 mcg IM if pregnancy terminated prior to 13 wk gestation	Each vial or syringe (~300 mcg) prevents sensitization to a volume of up to 15 mL of Rh-positive red blood cells

Monitoring

Laboratory monitoring is not necessary. The patient's Rh status should be determined prior to administering Rh_o(D) immune globulin.

Patient Education

Patients should receive information regarding the benefits and risks of the IG prior to administration. Any questions or concerns regarding the vaccine should be addressed. The most common adverse reactions after IG administration are pain and erythema at the injection site.

DIAGNOSTIC BIOLOGICALS

TUBERCULIN PURIFIED PROTEIN DERIVATIVE

The diagnostic biological agent that is commonly used in primary care is tuberculin PPD. PPD is used to screen asymptomatic individuals for infection with *M. tuberculosis.*

Pharmacodynamics

PPD is administered intradermally to asymptomatic individuals. Once a person has become sensitized to mycobacterial antigens, a hypersensitivity reaction occurs to the administration of the intradermal PPD. In sensitive people, the reaction includes induration and erythema at the site of administration. A positive reaction to PPD indicates that the person at some time has had a TB infection. A positive test does not indicate an active infection but rather that further testing is indicated. See Chapter 45 for more information regarding TB evaluation.

Pharmacotherapeutics

Precautions and Contraindications

Do not administer PPD to known tuberculin-positive reactors because they may have a severe reaction, including ulceration and necrosis at the site of administration. SC administration should be avoided, as a general febrile reaction or acute inflammation may occur.

Skin testing of immunodeficient people may not be accurate because skin-test responsiveness may be suppressed. Skin test responsiveness may be delayed in the older adult patient.

PPD testing is safe in pregnancy, during lactation, and in children of all ages, including infants.

Adverse Drug Reactions

In highly sensitive people, vesiculation, ulceration, and necrosis can occur at the administration site. A normal adverse reaction is a minimal amount of bleeding at the administration site.

Drug Interactions

Live-virus vaccines (MMR, varicella) can suppress the reaction to PPD if given within 4 to 6 weeks prior to the PPD. PPD can be administered at the time that MMR and varicella vaccines are administered. Patients who have been vaccinated with BCG generally are sensitive to PPD. Immunosuppressant medications can suppress the reaction to PPD testing.

Clinical Use and Dosing

The Mantoux PPD test containing 5 tuberculin units (TU) is the preferred test because the interpretation of the reaction has been standardized. Previously, multiple puncture tests were used, and there were many problems with interpretation. The test consists of injecting 5 TU of PPD intradermally. A small white bleb should appear at the injection site if it is done correctly. Reactions are read in 48 to 72 hours after administration. For patients who may be highly sensitized, a test dose of 1 TU is used.

Determining the results of the skin test is based on the likelihood of infection and the risk of active TB if infection has occurred. If the patient is HIV-positive or has fibrotic lesions on chest x-ray, a reaction of 5 mm or more induration is considered positive. A reaction of 10 mm or more induration is considered positive in other at-risk patients, including infants and children. In patients who are not in any high-risk category or high-risk environment, a result of 15 mm or more induration is considered positive.

Patients are considered high risk if they have any of the following: (1) diabetes mellitus; (2) prolonged therapy with adrenocorticosteroids; (3) immunosuppressive therapy; (4) hematological and/or reticuloendothelial diseases, such as leukemia or Hodgkin's disease; (5) injection drug users known to be HIV-seronegative; (6) end-stage renal disease; or (6) any clinical presentation that includes substantial rapid weight loss or chronic malnutrition.

People who are in a high-incidence group with a skin test reaction of 10 mm or more induration are candidates for preventive therapy, even if they do not have any of the risk factors. High-incidence groups include the following: (1) foreign-born persons from high-prevalence countries, (2) medically underserved low-income populations, and (3) residents of facilities for long-term care.

Monitoring

The PPD should be read by an experienced health-care professional who has been trained in the proper method of interpreting the results.

Patient Education

Patients must have an understanding of the reason for PPD testing and why the test must be read in 48 to 72 hours. Adverse reactions are rare in patients who are not already sensitized to TB.

IMMUNOMODULATORS

Although not generally prescribed by primary care providers, two immunomodulator medications commonly prescribed to patients by specialty providers are covered in this chapter—cyclosporine and azathioprine. Cyclosporine (Sandimmune) is prescribed to organ transplant patients and is used for severe rheumatoid arthritis. Azathioprine (Imuran) is also prescribed for transplant patients and patients with severe rheumatoid arthritis. The topical immunomodulators pimecrolimus (Elidel) and tacrolimus (Protopic) are discussed in the chapter on integumentary medications (Chap. 23).

Pharmacodynamics

Cyclosporine is an oral and parenteral immunosuppressive agent. It is believed to act by inhibiting the production or release of various lymphokines. The actions of the T-helper cell, the mediators of cellular immunity and tissue rejection, are impaired. Cyclosporine may inhibit T-suppressor cells. Cyclosporine also inhibits the synthesis of gamma-interferon. Cyclosporine does not cause myelosuppression.

Azathioprine is an oral and parenteral immunosuppressive that decreases the metabolism of purines and may inhibit DNA and RNA synthesis. It may interfere with coenzyme functioning, decreasing cellular metabolism. Azathioprine has the ability to inhibit the delayed hypersensitivity reaction and cellular cytotoxic activity that occur during renal transplantation.

Pharmacokinetics

Absorption and Distribution

After oral administration, approximately 20% to 50% of cyclosporine is absorbed. Absorption from the GI tract is highly variable. It is widely distributed throughout the body, crosses the placenta, and is excreted in breast milk. Azathioprine is well absorbed following oral administration. It is widely distributed and crosses the placenta.

Metabolism and Excretion

Cyclosporine undergoes extensive first-pass metabolism. It is metabolized extensively by the liver cytochrome P450 3A (CYP450 3A) enzyme system. Elimination of cyclosporine and its metabolites is primarily through the bile and feces, with only 6% excreted renally. Azathioprine is metabolized in the liver to its active metabolite, mercaptopurine. The metabolites and some unchanged azathioprine are excreted in the urine.

Pharmacotherapeutics

Precautions and Contraindications

Hypersensitivity to the medication or components of the product is a contraindication to its use. Cyclosporine has a Black-Box Warning regarding anaphylaxis with IV administration. Oral cyclosporine preparations contain corn, castor oil, and/or olive oil, and patients with hypersensitivity to these food products should avoid its use. Patients with renal dysfunction should be monitored for worsening renal function while taking cyclosporine. Azathioprine can accumulate in patients with renal impairment, possibly causing toxicity. Hepatic dysfunction can affect the metabolism of both drugs.

Both cyclosporine and azathioprine are contraindicated in pregnancy and breastfeeding.

Cyclosporine has a Black-Box Warning regarding increased susceptibility for severe, even fatal infections. Azathioprine has a Black-Box Warning regarding increased risk of developing neoplasms.

Adverse Drug Reactions

Nephrotoxicity is the most common adverse effect of cyclosporine therapy. Cyclosporine may also cause hypertension; headaches; GI upset; hirsutism (50% of patients); gingival hyperplasia (4% to 16%); hypercholesterolemia; and neurological effects such as seizures, tremor, paresthesias, and mood changes.

Hepatic failure can occur with azathioprine use. Nausea and vomiting occurred in 12% of patients. Patients taking azathioprine should be monitored for bone marrow suppression. Other adverse effects reported are fever, rash, pancreatitis, alopecia, and retinopathy.

Drug Interactions

Cyclosporine interacts with many drugs, especially those metabolized by the hepatic enzymes. Azathioprine suppresses the immune system; therefore, live or inactivated vaccines should not be given to patients receiving this drug. OPV should not be administered to household contacts of patients taking azathioprine. It may take the immune system 3 to 12 months to return to normal after administration of azathioprine. Other drug interactions are shown in Table 19-8.

Clinical Use and Dosing

Cyclosporine and azathioprine are usually prescribed by specialty providers. If in consultation with a specialist, the primary care provider is prescribing these products for

Table 19–8 Drug Interactions: Immunomodulators

Drug	Interacting Drug	Possible Effect	Implications
Azathioprine	Live vaccines (MMR, varicella)	Decreased antibody response to vaccine	Wait 3 mo to 1 yr after stopping azathioprine before administering live vaccines
	Allopurinol	Increased pharmacological and toxic effects of azathioprine	Avoid concurrent use, or reduce dose of azathioprine by one-third to one-half
	Angiotensin-converting enzyme (ACE) inhibitors	May induce severe leukopenia or anemia	
	Methotrexate	May increase plasma levels of azathioprine metabolite 6-MP	Avoid concurrent use
	Anticoagulants	Decreased effectiveness of anticoagulants	Avoid concurrent use
	Alkylating agents/antineoplastic agents	Prior treatment with alkylating agents puts patient at higher risk of developing neoplasms or infection	
	Cyclosporine	Cyclosporine plasma levels might be decreased	
Cyclosporine	*Nephrotoxic drugs:* amphotericin B, acyclovir, aminoglycosides, foscarnet, NSAIDs, vancomycin, ganciclovir	Additive nephrotoxicity	
	Immunosuppressants	Increased risk of lymphoma and infection	
	Potassium-sparing diuretics: amiloride, spironolactone, triamterene	Hyperkalemia	Monitor potassium levels
	Drug metabolized by CYP450 3A isoenzyme inhibitors: calcium channel blockers, androgens, clarithromycin, azole antifungals, methylprednisolone,	Increased cyclosporine levels, leading to cyclosporine toxicity	Monitor cyclosporine levels

Table 19–8 ⊞ **Drug Interactions: Immunomodulators—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
	allopurinol, bromocriptine, danazol, erythromycin, dalfopristin, metoclopramide		
	Drugs metabolized by CYP450 3A isoenzyme inducers: nafcillin, modanil, troglitazone, rifampin, carbamazepine, pentobarbital, phenytoin, octreotide, ticlopidine, primidone	Decreased cyclosporine levels	Monitor cyclosporine levels if any of these drugs are added or deleted from medication regimen
	Vaccines	Decreased effectiveness of vaccines	Wait at least 3 mo after therapy with cyclosporine is completed to administer live vaccines
	Digoxin	Increased digoxin levels	Monitor digoxin levels
	Prednisolone	Increased prednisolone levels	
	Lovastatin	Increased lovastatin levels	
	Grapefruit juice	Increased cyclosporine levels	
	Protease inhibitors	Cyclosporine toxicity	
	SMX/TMP	Decreased blood levels of cyclosporine	
	Clonidine	Interferes with clonidine pharmacokinetics	
	Metoclopramide (oral)	Increases oral bioavailability of cyclosporine by 30%	Monitor cyclosporine concentrations
	Colchicine	Nephrotoxicity and azotemia	Avoid concurrent use
	Orlistat	Altered bioavailability of cyclosporine	Monitor if using concurrently

rheumatoid arthritis, the dosing is as follows: Cyclosporine is started at 1.25 mg/kg twice daily and may increase by 0.5 to 0.75 mg/kg/day at 8 weeks and at 12 weeks, if indicated. The maximum dose is 4 mg/kg/day. Decrease the dose by 25% to 50% if adverse effects occur. Azathioprine is begun at 1 mg/kg/day in one to two divided doses. The dose can be increased in 6 to 8 weeks, by 0.5 mg/kg/day. The dose can be increased every 4 weeks to a maximum of 2.5 mg/kg/day.

Monitoring

Patients prescribed these medications need monitoring of their blood pressure, renal function, and hepatic function. Patients taking cyclosporine also need to have serum cyclosporine levels checked periodically. Patients taking azathioprine need a complete blood count (CBC) and serum amylase drawn periodically.

Patient Education

Patients should be instructed to take the medication exactly as prescribed. Any symptoms of adverse reactions should be reported to the provider immediately. The patient should be cautioned to report any flu-like symptoms, which may be a sign of hepatic or renal dysfunction.

DRUGS AFFECTING THE GASTROINTESTINAL SYSTEM

Teri Moser Woo

There is a wide variety of drugs used to treat disorders affecting the gastrointestinal (GI) tract. Cholinergic drugs increase gastric acid secretion and increase peristalsis; anticholinergic drugs inhibit gastric acid secretion and decrease peristalsis. These drugs are discussed in Chapter 15. Phenothiazines have antiemetic properties; some narcotic analgesics or their derivatives are used to treat diarrhea and are discussed in Chapter 16. Several groups of drugs are used almost exclusively to treat GI disorders, such as antacids, antidiarrheals, antiemetics, laxatives, and drugs used to decrease gastric acid production. These drugs are discussed in this chapter. IV forms of GI drugs not used in primary care are not discussed in this chapter.

ANTACIDS

Antacids are weak bases that react with hydrochloric acid (HCl) to form a salt and water. They are used to reduce gastric acidity in the treatment of gastroesophageal reflux and peptic ulcer disease. Antacids contain various combinations of metallic cation (aluminum, calcium, magnesium, and sodium) and basic anion (hydroxide, bicarbonate, carbonate, citrate, and trisilicate). Most in current use have as their cation aluminum, calcium, or magnesium, and their anion is usually hydroxide (OH), bicarbonate (HCO$_3$), or carbonate (CO$_3$). The buffering capacity of the other two anions is too limited to be clinically effective.

Pharmacodynamics

Antacids neutralize gastric acidity, which causes an increase in the pH of the stomach and duodenal bulb. They also inhibit the proteolytic activity of pepsin and increase lower esophageal sphincter tone. Aluminum-based products inhibit smooth muscle contraction and thus slow gastric emptying. Calcium-based antacids are also used to treat calcium-deficiency states, such as those that occur post-menopause and in chronic renal failure. They are also used to bind phosphates in chronic renal failure, as are aluminum-based antacids. Magnesium-based antacids are used to treat magnesium deficiencies from malnutrition, alcoholism, or magnesium-depleting drugs. The use of drugs as nutrient therapy is discussed in Chapter 9.

Acid-neutralizing capacity (ANC) varies between products and is expressed in milliequivalents (mEq) of HCl required to keep an antacid suspension at pH 3.5 for 10 minutes in vitro. Antacids must neutralize at least 5 mEq per dose. Those with higher ANC values are more likely to be effective in vivo. Sodium bicarbonate and calcium carbonate have the highest ANC but are not used for chronic therapy because of their systemic effects. Suspensions have greater ANC than do powders or tablets.

Pharmacokinetics

Absorption and Distribution

Aluminum- and magnesium-based antacids are not absorbable with routine use. With chronic use, 5% to 20% of magnesium and smaller amounts of aluminum may be absorbed. These small absorbed amounts are widely distributed, cross the placenta, and appear in breast milk. Aluminum concentrates in the central nervous system. Calcium-based antacids require vitamin D for absorption from the GI tract. The small amount that is absorbed enters the extracellular fluid, crosses the placenta, and enters breast milk.

If ingested in a fasting state, antacids reduce acidity for approximately 20 to 40 minutes. If taken 1 hour after a meal, acidity is reduced for 2 to 3 hours. A second dose given 3 hours after a meal maintains the reduced acidity for more than 4 hours after the meal.

Metabolism and Excretion

The action of antacids occurs locally in the GI tract with minimal absorption, and so there is minimal metabolism. Magnesium-based antacids are excreted in the urine. Aluminum-based antacids bind with phosphate ions in the intestine to form insoluble aluminum phosphate, which is excreted in the feces. Calcium-based antacids are excreted mainly in feces, with 20% eliminated in urine. Table 20-1 shows the pharmacokinetic properties of selected antacids.

Pharmacotherapeutics

Precautions and Contraindications

All antacids are contraindicated in the presence of severe abdominal pain of unknown cause, especially if accompanied by fever. Calcium-based antacids are contraindicated in the presence of hypercalcemia and renal calculi.

Renal impairment presents several issues for patients who take antacids. Magnesium-based antacids are contraindicated in patients with renal failure and used with caution for patients with any degree of renal insufficiency because the malfunctioning kidney is unable to excrete magnesium and hypermagnesemia may result. Prolonged use of aluminum-based antacids for patients with renal failure may result in or worsen dialysis osteomalacia. Aluminum is not easily removed by dialysis because it is bound to albumin and transferrin, which do not cross the dialysis membrane. As a result, aluminum is deposited in bone and osteomalacia occurs. Elevated tissue aluminum levels also contribute to the development of dialysis encephalopathy.

Many antacids have high sodium content. Patients with hypertension (HTN), congestive heart failure (CHF), marked renal failure, or on low-sodium diets should use a low-sodium preparation.

Table 20–1 ⬛ Pharmacokinetics: Selected Antacids

Drug	Onset	Peak	Duration	Acid-Neutralizing Capacity (ANC)	Half-Life	Elimination
Aluminum hydroxide	Slightly delayed	30 min	30 min–1 h on empty stomach; 3 h after meals	3.2 (AlternaGEL) 2.0 (Amphojel) 10.6	Unknown	As aluminum phosphate in feces
Magnesium hydroxide	Immediate	30 min	30 min–1 h on empty stomach; 3 h after meals	11.4	Unknown	In urine
Aluminum hydroxide-magnesium hydroxide combinations	Immediate	30 min	30 min–1 h on empty stomach; 3 h after meals	2.7 (Maalox) 5.7 (Maalox HRF) 5.1 (Mylanta)	Unknown	In urine and feces
Calcium carbonate	Slightly delayed	30 min	30 min–1 h on empty stomach; 3 h after meals	10	Unknown	Mostly in feces; 20% in urine

Adverse Drug Reactions

Aluminum- and calcium-based antacids cause constipation; magnesium-based antacids cause diarrhea. Alkalosis may occur but tends to be a clinically significant problem only for patients with renal impairment.

Drug Interactions

All antacids have drug interactions with orally administered weakly acidic and weakly basic drugs, decreasing or increasing their absorption and, therefore, their effects. Enteric coating on drugs is used to protect them from the acid of the stomach, and the coating dissolves in the more basic medium of the duodenum. Concurrent administration of antacids with enteric-coated drugs destroys the coating, alters their absorption, and increases the risk for adverse reactions. Some antacids adsorb or bind to the surface of other drugs, resulting in decreased bioavailability. Magnesium hydroxide (Milk of Magnesia, Maalox, Mylanta) has the greatest ability to adsorb, and calcium carbonate and aluminum hydroxide (AlternaGEL, Amphojel) have intermediate ability to adsorb certain drugs.

Increasing urinary pH affects the rate of elimination by inhibiting the excretion of weakly basic drugs and increasing the elimination of weakly acidic ones. Separating the administration of the antacid and the interacting drug by at least 2 hours and giving the interacting drug first in this sequence often can avoid these problems. Table 20-2 provides specific information on drug interactions with selected antacids.

Clinical Use and Dosing

Hyperacidity

Antacids are used for symptomatic relief of stomach upset associated with the hyperacidity of heartburn, acid indigestion, and "sour stomach." Because they are sold over the counter (OTC), doses may vary, as patients choose the amount they think they need to relieve symptoms. Generally, dosing is one to two tablets or 1 to 2 tablespoons of suspension taken intermittently. Dosing of common antacids is found in Table 20-3.

Peptic Ulcer Disease

Although the main factor in most duodenal ulcers and many gastric ulcers is infection with *Helicobacter pylori,* hyperacidity

Table 20–2 Drug Interactions: Selected Antacids

Drug	Interacting Drug	Possible Effect	Implications
All antacids	Weakly acidic drugs (e.g., digoxin, phenytoin, chlorpromazine, isoniazid, ketoconazole)	Decreased absorption with possible decreased drug effects	Separate administration by at least 2 h, giving the antacid after the drug
	Weakly basic drugs (e.g., pseudoephedrine, levodopa)	Increased absorption with possible toxicity or adverse reactions	Separate administration by at least 2 h, giving the antacid after the drug
	Drugs acidic at the time of excretion (e.g., salicylates)	Enhanced excretion	May be used therapeutically to treat salicylate toxicity. Otherwise, avoid concurrent use or alter dosage of drug.
	Drugs basic at the time of excretion (e.g., quinidine, amphetamines)	Decreased excretion	Avoid concurrent use or alter dosage of drug
	Drugs with enteric coating	Antacids may destroy the coating, resulting in altered absorption or adverse reactions	Avoid concurrent use or separate administration by at least 2 h, giving the antacid after the drug
	Buffered aspirin products	Alkalinization of urine accelerates aspirin excretion, and systemic alkalosis and increased sodium load may occur	Caution against use of these antacid-analgesic combinations in chronic pain syndromes. Not an issue if used only intermittently.
Aluminum-based antacids	Allopurinol, chloroquine, corticosteroids, ethambutol, histamine$_2$ blockers, iron salts, phenothiazines, tetracyclines, thyroid hormones, ticlopidine	Decreased pharmacological effect of the drug	Avoid concurrent use or separate administration by at least 2 h, giving the antacid after the drug
	Benzodiazepines	Increased pharmacological effect of the drug	Avoid concurrent use

Continued

Table 20–2 ⚏ **Drug Interactions: Selected Antacids—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
Calcium-based antacids	Fluoroquinolones, hydantoins, iron salts, salicylates, tetracyclines	Decreased pharmacological effect of the drug	Avoid concurrent administration
	Quinidine	Increased pharmacological effect of the drug	Avoid concurrent administration
Magnesium-based antacids	Benzodiazepines, cortico-steroids, histamine$_2$ blockers, hydantoins, iron salts, nitrofu-rantoin, phenothiazines, tetra-cyclines, ticlopidine	Decreased pharmacological effect of the drug	Avoid concurrent administration
	Quinidine, sulfonylureas	Increased pharmacological effect of the drug	Avoid concurrent administration

Table 20–3 ⚭ **Dosage Schedule: Selected Antacids**

Drug	Indication	Dosage Form	Dosage Schedule
Aluminum hydroxide	Hyperphosphatemia		*Adolescents or adults:* 300–600 mg 3 or 4 times a day, max 3,000 mg/day *Children:* 30 mg/kg/day
AlternaGEL Amphojel Alu-Tab Alu-Cap Generic	Hyperacidity	Liquid: 600 mg/5 mL Tablets: 300 mg, 600 mg Tablets: 500 mg Capsules: 500 mg (sodium content <1.2 mg) Suspension: 320 mg/5 mL Concentrated suspension: 450 mg/5 mL Concentrated suspension: 675 mg/5 mL Concentrated liquid: 600 mg/5 mL	*Adults:* Tablets or capsules: 500–1,500 mg 3–6 times daily between meals and at bedtime Suspension: 5–30 mL prn between meals and at bedtime *Children:* 300–900 mg per dose between meals and at bedtime
Calcium carbonate	Calcium deficiency in chronic renal failure		*Adults:* 1–2 g/day in divided doses *Children:* 45–65 mg/kg/day in 4 divided doses Adjust dose based on serum calcium concentration
Alka-Mints Tums Maalox Chewables Generic	Postmenopause or osteoporosis Hyperacidity	Tablets, chewable: 850 mg (sodium content <5 mg) Tablets, chewable: 500 mg (sodium content <2 mg) Extra-strength, chewable: 750 mg (sodium content <4 mg) Ultra, chewable: 1,000 mg (sodium content <4 mg) Tablets: 600 mg Tablets: 500, 600, 650, 1,250 mg	*Adults:* 1,000–1,500 mg elemental calcium/d *Children >11 yr and adults:* TUMS (500 mg calcium carbonate) chew 2–4 tablets for symptoms, not to exceed 15 tablets/d; TUMS E-X (750 mg calcium carbonate) chew 2–4 tablets for symptoms, not to exceed 10 tablets/d *Children 5 yr to 11 yr:* 800 mg calcium carbonate for symptoms; do not exceed 4,800 mg/d *Children 2–5 yr:* 400 mg as needed; do not exceed 1,200 mg/d
Magnesium hydroxide Phillips' Chewables Phillips' Milk of Magnesia Generic	Hyperacidity	Tablets: 311 mg Liquid: 400 mg/5 mL Concentrated liquid: 800 mg/5 mL Liquid: 400 mg/5 mL	*Children >12 yr and adults*: Tablets: 622–1,244 mg up to qid Liquid: 5–15 mL up to qid with water Liquid concentrate: 2.5–7.5 mL up to qid with water
Phillips' Caplets Phillips' Milk of Magnesia	Laxative	Caplets: 500 mg Liquid: 400 mg/5 mL	*Adults:* 30–60 mL at bedtime with water *Adults and children ≥ 12 yrs:* 2 to 4 caplets daily

Table 20–3 ⊗ **Dosage Schedule: Selected Antacids—cont'd**

Drug	Indication	Dosage Form	Dosage Schedule
Generic		Liquid: 400 mg/5 mL	*Children:* 2–5 yr: 5–15 mL/d at bedtime 6–11 yr: 15–30 mL/d at bedtime
Aluminum hydroxide- magnesium hydroxide combinations Maalox Maalox Advanced Extra Strength Mylanta Regular Strength Mylanta Ultimate Strength Generic	Hyperacidity	Aluminum hydroxide 200 mg and magnesium hydroxide 200 mg and simethicone 20 mg per 5 mL Aluminum hydroxide 400 mg and magnesium hydroxide 400 mg and simethicone 40 mg per 5 mL Aluminum hydroxide 200 mg and magnesium hydroxide 200 mg and simethicone 20 mg per 5 mL Aluminum hydroxide 500 mg and magnesium hydroxide 500 mg per 5 mL	Tablets: 1 or 2 prn *Adults and children >12 yr:* 2–4 tsp bid, max *Adults and children >12 yr:* 2–4 tsp bid, max 8 tsp /24 h *Adults and children >12 yr:* 2–4 tsp between meals and at bedtime, max 24 tsp/24 h *Adults and children >12 yr:* 2–4 tsp between meals and at bedtime, max 9 tsp/24 h
Maalox Mylanta Regular Strength	Peptic ulcer disease	Aluminum hydroxide 200 mg and mag- nesium hydroxide 200 mg and simethicone 20 mg per 5 mL	Suspension: 15–30 mL prn Suspension: 15–30 mL 1 h and 3 h after meals and at bedtime
	Gastroesophageal reflux disease		*Children >12 yr and adults*: Suspension: 5–30 mL every 30–60 min for acute management; 5–30 mL 1 h and 3 h after meals and at bedtime for maintenance *Infants and children <12 yr*: Suspension: 0.5 mL/kg (average dose 2–15 mL) 1–2 h after meals or feedings; max 15 mL/dose

is also a factor in peptic ulcer disease (PUD). Antacids were formerly considered step 1 in PUD management, but the current guidelines follow a stepped-down approach and treatment is begun with a proton pump inhibitor. Patients with uncomplicated PUD can benefit from 15 to 30 mL of antacid suspension 1 to 3 hours after meals and at bedtime and often select to do this before consulting a health-care provider. Additional doses may be used for recurring symptoms. Because ANC is higher in patients with uncomplicated PUD, combined antacids with both aluminum hydroxide and magnesium hydroxide are best unless the patient also has renal insufficiency or failure. Further discussion of PUD occurs in Chapter 34.

Gastroesophageal Reflux Disease

Lifestyle management and drugs to increase lower esophageal sphincter tone are central to the management of gastro-esophageal reflux disease (GERD), but there is a role for antacids in mild disease. Antacids (calcium carbonate, aluminum hydroxide) and antacids/alginic acid (Gaviscon) are more effective than placebo for daytime GERD symptoms, with up to 20% of patients with mild symptoms responding to OTC antacids (Heidelbaugh, Harrison, McQuillan, & Nostrant, 2012). For acute management, antacid doses may be given every 30 to 60 minutes until symptoms are relieved; for maintenance, doses are given 1 and 3 hours after meals and at bedtime. Additional doses may be given for recurring symptoms. Dosing of antacids is found in Table 20-3. Further discussion of GERD occurs in Chapter 35.

Hyperphosphatemia

Aluminum carbonate (Basalgel) and aluminum hydroxide have been used, along with a low-phosphate diet, to treat hyperphosphatemia in patients with chronic renal failure. They have also been used to prevent the formation of phosphate urinary stones. The dose is 30 mL of suspension with each meal.

Calcium Deficiency

Calcium carbonate (Tums) is routinely used to treat calcium deficiency states associated with chronic renal failure, post-menopause, and osteoporosis. Tablets, often in chewable form, are commonly used. A dose of 1,000 mg/day of calcium carbonate is sufficient to provide adequate calcium for patients with chronic renal failure. Higher doses are needed for osteoporosis prevention: 1,000 mg daily for men and for premenopausal women and 1,500 mg/day of calcium for postmenopausal women. Doses higher than 2,000 mg/day are not advised because of increased adverse effects. Patients with osteoporosis require a combination of calcium, vitamin D, and another bone density–building medication such as a bisphosphonate.

Rational Drug Selection

In addition to consideration of adverse drug reactions and the indications discussed previously, other major factors used to choose among antacids are ANC, sodium content, and cost.

Acid-Neutralizing Capacity

Combination products that contain aluminum hydroxide and magnesium hydroxide have the highest ANC (see Table 20-1). When moderate to severe hyperacidity is a factor in the disease process under treatment, these drugs are chosen over other antacids.

Sodium Content

The sodium content of antacids may be significant. Patients who must restrict sodium intake (e.g., those with HTN, CHF, or marked renal failure) should use a low-sodium antacid. The sodium content is listed on the product label.

Cost

Antacids are sold OTC. In general, they are inexpensive, but the cost of a high-dose regimen varies significantly. Costs of OTC antacids may vary and "shopping" different stores and using generic forms of the drug may yield cost savings.

Monitoring

No specific monitoring is required beyond that related to the disease process for which the patient is being treated. Serum phosphate, potassium, and calcium levels may be monitored periodically during chronic use. These drugs may cause increased serum calcium and decreased serum phosphate. Chronic magnesium hydroxide use may cause elevated magnesium levels in patients with renal failure or the elderly with decreased renal function.

Patient Education

Administration

Antacids should be taken as prescribed, especially related to mealtimes. For best effects, they should be taken 1 to 3 hours after meals and at bedtime. To prevent chewable tablets from entering the small intestine in undissolved form, they must be chewed thoroughly before they are swallowed and followed with half a glass of water. Suspensions should be shaken before administration (see Table 20-3).

Antacids have many drug interactions when taken concurrently with other drugs because the altered acidity of the stomach affects acid-labile drugs. Antacids bind with many drugs affecting their absorption. The dose of antacid may need to be separated from the dose of another drug by as much as 2 hours. Health-care providers should instruct the patient in timing the administration of such drugs. Patients should be told not to begin taking OTC antacids on their own without first consulting their health-care provider or the pharmacist to discuss any potential drug interactions.

Calcium-based antacids should not be administered with food containing large amounts of oxalic acid (e.g., spinach, rhubarb) or phytic acid (e.g., bran, cereals). These foods decrease the absorption of calcium. Taking these antacids with food that contains phosphorus (milk or other dairy products) may lead to milk-alkali syndrome (nausea, vomiting, confusion, and headache). Taking calcium-based antacids with an acidic fruit juice may improve absorption.

Adverse Reactions

Patients should be told to consult their health-care provider before taking antacids for more than 2 weeks if a problem recurs, if relief is not obtained, or if symptoms of GI bleeding (black, tarry stools; coffee-ground emesis) occur.

Aluminum- and calcium-based antacids may cause constipation. Methods of preventing constipation such as increased bulk in the diet, greater fluid intake, and more mobility should be recommended. A stool softener may be needed to treat constipation related to antacid use. Magnesium-based antacids may cause diarrhea. Increased fiber in the diet may help this problem.

Lifestyle Management

Lifestyle management issues related to the disease process should be discussed. They often include avoiding: smoking, flat-lying body position while sleeping, foods that irritate the gastric mucosa (e.g., spicy foods) or stimulate acid production (e.g., alcohol), and foods that decrease lower esophageal sphincter tone (e.g., fatty food, chocolate, and caffeine).

ANTIDIARRHEALS

Diarrhea is a common reason for self-treatment and for patients to seek treatment from a health-care provider. Much of the diarrhea seen in a primary care setting has an infectious etiology, is food- or drug-induced, or is the result of inflammatory bowel disease. Diarrhea that lasts for less than 2 weeks is considered acute; if it lasts more than 2 weeks, it is considered chronic. Most episodes are acute and self-limiting, with few serious consequences. The exception is diarrhea in children, for whom dehydration can occur rather quickly, even with short-term diarrhea. Chronic diarrhea can result in weight loss, dehydration, perianal skin breakdown, and nutritional deficits.

Diarrhea that is drug-induced may be treated simply by removal of the offending drug. Food-induced diarrhea related to food poisoning and other diarrheas of an infectious etiology may require antimicrobial therapy, depending on the pathogen. Drugs used to treat infectious diseases are the subject of Chapter 25. The focus of this chapter is drugs used for symptomatic relief. Some drugs used to treat diarrhea are chemically related to opioids. Opioids are discussed further in Chapter 16. Anticholinergic agents are also sometimes used to treat diarrhea and are discussed in Chapter 15. This chapter does not discuss the diagnosis of diarrhea.

Pharmacodynamics

Three main classes of drugs used to treat diarrhea are absorbent preparations (kaolin and pectin [Kapectolin] and bismuth subsalicylate [Pepto-Bismol, Kaopectate Liquid]), opiates (diphenoxylate with atropine [Lomotil], diphenoxin with atropine [Motofen], and loperamide [Imodium]), and anticholinergics. Anticholinergics are useful only for inflammatory bowel disease. In 2012, a new antidiarrheal drug, crofelemer (Fulyzaq), was approved by the U.S. Food and Drug

Administration (FDA) to treat diarrhea in patients with HIV/AIDS taking antiretroviral therapy.

Kaolin is a clay-like powder that attracts and holds onto bacteria, and pectin thickens the stool by absorbing moisture in the stool. The combination product does not affect total water loss, however. Commonly used to treat simple diarrhea, the combination was rated by the FDA in 1986 as "safe and effective"; however, there are no specific trials to demonstrate this.

Bismuth subsalicylate appears to have antisecretory and antimicrobial effects in vitro and may have some anti-inflammatory effects. The salicylate moiety provides the antisecretory effect, and the bismuth moiety may exert direct antimicrobial effects against bacterial and viral enteropathogens. Because of these effects, it is also used as part of a multidrug regimen for the eradication of *H. pylori.*

Diphenoxylate with atropine is a constipating meperidine congener that lacks analgesic activity. High doses (4 to 60 mg), however, can cause opioid activity, including euphoria, and physical dependence with chronic use. The addition of atropine provides anticholinergic effects that decrease secretion in the bowel and slow peristalsis.

Loperamide binds to the opiate receptors of the intestinal wall, leading to slowed gastric motility. It also reduces fecal volume, increases viscosity and bulk, and diminishes the loss of fluid and electrolytes.

Crofelemer (Fulyzaq) is a botanical blocking chloride secretion from the epithelial cells in the intestinal lumen, decreasing water loss in diarrhea and normalizing the flow of chloride and water in the intestinal tract.

Pharmacokinetics

Absorption and Distribution

Kaolin and pectin act locally in the bowel and are not systemically absorbed (Table 20-4). Bismuth subsalicylate undergoes chemical dissociation in the GI tract; the salicylate moiety is absorbed, with plasma levels similar to those of aspirin. There is only negligible absorption of the bismuth moiety. Diphenoxylate with atropine and difenoxin with atropine are both well absorbed from the GI tract. Their distribution is unknown, but they do enter breast milk. The atropine in the drug readily crosses the blood–brain barrier and the placenta and enters breast milk. It also produces mild to moderate anticholinergic effects. Forty percent of loperamide is absorbed after oral administration, but it does not cross the blood–brain barrier well, so there are limited central nervous system (CNS) effects. Minimal amounts of crofelemer are absorbed after oral administration.

Metabolism and Excretion

The salicylate portion of bismuth subsalicylate is metabolized in the liver and more than 90% is excreted in urine. Diphenoxylate with atropine is rapidly and extensively metabolized to diphenoxylic acid, which is biologically active and its main metabolite. It is excreted in urine and feces. Difenoxin with atropine is rapidly metabolized to an inactive hydroxylated metabolite. Both the drug and its metabolite are excreted, mainly as conjugates, in the urine and feces. Loperamide is partially metabolized by the liver and undergoes enterohepatic recirculation to be completely metabolized. Most is eliminated in feces, with a minimal amount excreted in urine. Metabolism and excretion of crofelemer are not known.

Pharmacotherapeutics

Precautions and Contraindications

Drugs that reduce intestinal motility or delay intestinal transit time have induced toxic megacolon, especially in patients with inflammatory bowel disease. Diphenoxylate with atropine, difenoxin with atropine, and loperamide should be used cautiously for these patients and promptly discontinued if abdominal distention occurs. Because of their hepatic metabolism and renal excretion, these drugs should also be used with extreme caution in patients with advanced hepatorenal disease and in all patients with abnormal liver function studies because hepatic coma may occur.

The atropine component of diphenoxylate and difenoxin contraindicates their use in narrow-angle glaucoma and requires cautious use in prostatic hyperplasia. Children, especially

Table 20–4 ⠿ Pharmacokinetics: Selected Antidiarrheals

Drug	Onset	Peak	Duration	Half-Life	Elimination
Bismuth subsalicylate	—	—	—	2–3 h for low doses; 15–30 h for larger doses	>90% of salicylate in urine
Crofelemer	—	—	—	Unknown	Unknown
Difenoxin with atropine		20–40 min	3–4 h	24–72 h	Excreted as conjugates in urine and feces
Diphenoxylate with atropine	45–60 m	2 h	3–4 h	2.5 h (12–14 h for the metabolite)	14% of drug and metabolites in urine; 49% in feces
Loperamide	1 h	2.5–5 h	10 h	10.8 h (range 9.1–14.4 h)	25% unchanged in feces; 1.3% in urine as free drug and glucuronic acid conjugate

those with Down syndrome, have increased sensitivity to atropine. This drug should be avoided or used with extreme caution in children. It is not recommended for use in children younger than 12 years. This drug may prolong or aggravate diarrhea associated with organisms that penetrate the intestinal mucosa, such as *Escherichia coli, Salmonella,* and *Shigella,* or in pseudomembranous colitis associated with broad-spectrum antimicrobial therapy. It should not be used in these conditions.

The salicylate component of bismuth subsalicylate contraindicates its use in children or teenagers during or after recovery from chickenpox or flu-like illness. It is also contraindicated for patients with aspirin hypersensitivity.

All antidiarrheals (except crofelemer) require cautious use in older adults and others in whom impaction is a high risk. Older adults are especially sensitive to diphenoxylate or difenoxin because of the atropine content and anticholinergic properties.

There are no contraindications for the use of crofelemer in patients with HIV/AIDS–associated diarrhea.

Pregnancy categories vary among the antidiarrheal drugs. Kaolin and pectin are Pregnancy Category B. All others are Pregnancy Category C except loperamide, which is Pregnancy Category B. Crofelemer is Pregnancy Category C. However, there are no adequate and well-controlled studies in pregnant women for any of these drugs, and safety during pregnancy has not been established. Some of the drugs are excreted in breast milk, and the safety of any of the antidiarrheals has not been established in lactating women. They should be avoided or used with caution.

None of the antidiarrheals has established safety for children younger than age 2 years. All except crofelemer have published children's doses. It is important to keep in mind that dehydration may influence younger children's response to these drugs. Antidiarrheals are contraindicated in the treatment of diarrhea in most children; the standard of care is oral rehydration therapy (ORT) to treat the electrolyte and fluid loss of diarrhea. The safety and effectiveness of crofelemer in children with or without HIV/AIDS have not been established.

Adverse Drug Reactions

The main adverse drug reaction for all traditional antidiarrheals is rebound constipation. For bismuth subsalicylate, additional reactions that all patients should be warned about are gray/black stools and black tongue, the results of the bismuth. Patients should be told to expect this reaction and that it does not indicate GI bleeding.

The adverse reactions associated with the diphenoxylate and difenoxin drugs are related to their anticholinergic and opioid-like effects. Diphenoxylate and difenoxin (both with atropine) may exhibit anticholinergic adverse reactions such as dry mouth and mucous membranes, flushing, tachycardia, and urinary retention, especially in children. Loperamide also exhibits these reactions, but to a lesser degree. Both drugs have CNS reactions of dizziness and drowsiness, loperamide less so than diphenoxylate or difenoxin (both with atropine). Because they cross the blood–brain barrier better,

diphenoxylate and difenoxin (both with atropine) also exhibit sedation, headache, and, in higher doses or with chronic use, euphoria or depression, although difenoxin exhibits these slightly less so than diphenoxylate.

Patients treated with crofelemer in clinical trials were more likely to have upper respiratory infections (5.7%), bronchitis (3.9%), and cough (3.5%) than those taking placebo (Salix Pharmaceuticals, 2013). Patients treated with crofelemer also experienced GI adverse effects including flatulence (3.1%), increased bilirubin (3.1%), and nausea (2.6%).

Drug Interactions

Bismuth subsalicylate may potentiate the risk for toxicity if taken with aspirin, and the risk for hypoglycemia if given in large doses with insulin or oral hypoglycemics. Diphenoxylate with atropine, difenoxin with atropine, and loperamide all have additive or potentiating CNS effects with other CNS depressants and additive anticholinergic effects with other drugs that share these effects. There are few other drug interactions (Table 20-5).

Crofelemer has a theoretical potential to inhibit CYP 3A isoenzyme but is not absorbed enough to inhibit CYP isoenzymes. Crofelemer does not interact with the antiretrovirals nelfinavir, zidovudine, or lamivudine.

Clinical Use and Dosing

Simple, Acute Diarrhea

After the cause of the diarrhea has been determined and, if possible, eliminated, absorbent preparations are commonly used for relief of symptoms in adults. Kaolin-pectin or bismuth subsalicylate taken after each loose stool may be effective. The majority of acute diarrheal illnesses are self-limiting, and the main concern is to maintain hydration.

Hydration can usually be maintained in adults, even with profuse diarrhea, by the use of oral fluids. Commercial hydrating fluids (Pedialyte, Rehydralyte) or powdered salts are available; adding a pinch of table salt and a half-teaspoon of honey to an 8 ounce glass of fruit juice also makes a hydrating solution for older children and adults. Nondiet colas that have been allowed to lose their carbonation may also be used in older children and adults. Alternate these solutions with 8 ounce glasses of water to which has been added one-quarter teaspoon of baking soda to replenish the electrolytes commonly lost in acute, infectious diarrhea (sodium, potassium, bicarbonate, and chloride).

Children with severe diarrhea need oral rehydrating solutions (ORS) to prevent dehydration. Examples include Infalyte, Kao-Lectrolyte, and Pedialyte. These OTC products are available in pharmacies or supermarkets. If the child does not like the flavor, one-quarter teaspoon of sugar-free Kool-Aid powder may be added. Jell-O, water, or sports drinks should be avoided because they do not contain enough sodium. For infants, a homemade recipe includes one-half cup infant rice cereal mixed with 16 ounces of water and one-quarter teaspoon of salt. Children should be given ORS to satisfy their thirst for at least 6 hours and often

Table 20–5 ⠿ **Drug Interactions: Selected Antidiarrheals**

Drug	Interacting Drug	Possible Effect	Implications
Bismuth subsalicylate	Aspirin	May potentiate salicylate toxicity	Avoid concurrent use
	Tetracycline	May decrease GL absorption	Separate administration by 2 h
	Thrombolytics, warfarin, heparin	Large doses may increase risk for bleeding	Avoid concurrent use or use small doses; monitor clotting studies closely
	Insulin, oral hypoglycemics	Large doses increase risk of hypoglycemia	Avoid concurrent use or use small doses
Crofelemer	Potential to inhibit CYP450 3A		Monitor patient if given concurrently
Diphenoxylate with atropine	CNS depressants, including alcohol, antihistamines, opioids, sedative hypnotics	Additive/potentiating CNS depression	Monitor patient closely if these drugs must be given concurrently
	Monoamine oxidase inhibitors (MAOIs)	Because chemical structure is similar, concurrent use may precipitate hypertensive crisis	Avoid concurrent use or within 14 d of use of MAOIs
	Drugs that have anticholinergic properties	Additive anticholinergic effect	Monitor for toxicity; treat symptoms with good oral hygiene, hard candy, sugarless gum
Kaolin-pectin	Digoxin, chloroquine	Decreases GL absorption	Avoid concurrent use or separate doses by at least 2 h, giving kaolin-pectin last
Loperamide	CNS depressants, including alcohol, antihistamines, opioids, sedative hypnotics Drugs that have anticholinergic properties	Additive/potentiating CNS depression Additive anticholinergic effect	Monitor patient closely if these drugs must be given concurrently Monitor for toxicity; treat symptoms with good oral hygiene, hard candy, sugarless gum

for 24 hours. Infants and young children need electrolyte replacement with their fluids, whereas older children and adults may be able to be rehydrated with fluids alone. Full management of acute diarrhea is not within the scope of this chapter.

If the absorbents do not resolve the diarrhea, diphenoxylate or difenoxin (both with atropine) or loperamide may be added. Diphenoxylate with atropine is given 3 to 4 times daily rather than after each loose stool. Difenoxin with atropine is dosed both after each stool or every 3 to 4 hours as needed to avoid exceeding the maximum 24-hour dose. Antidiarrheals are generally not recommended in children.

CLINICAL PEARL

Oral Rehydration Therapy
Evaluation of the effectiveness of oral rehydration is based on at least three wet diapers per 24 hours in infants. For children older than 1 year, avoid all fruit juices and other drinks that contain fructose because they usually make the diarrhea worse. If the infant or child is drinking milk or lactose-based formula, try withholding milk or lactose products. Probiotics may decrease the duration of diarrhea. Resolution of the diarrhea suggests lactose intolerance.

Unlike acute diarrhea, chronic diarrhea requires etiological diagnosis and specific therapy for that diagnosis. Simply suppressing symptoms is not sufficient.

Chronic Diarrhea Associated With Inflammatory Bowel Disease

Steroids and sulfasalazine are needed to control diarrhea exacerbated by inflammatory bowel disease. Loperamide, 4 mg initially followed by doses of 2 to 4 mg 4 times a day, may be used as adjunct therapy, and it may lead to substantial clinical improvement, especially if combined with added fiber in the diet and anticholinergics. If clinical improvement is not observed with doses of 16 mg/day for at least 10 days, symptoms are unlikely to be controlled by further use of this drug.

Chronic Diarrhea Associated With Pancreatic Insufficiency

Malabsorption due to pancreatic insufficiency requires use of enzyme supplements. Antidiarrheal medications are not generally used for this indication.

Chronic Infantile Diarrhea

Bismuth subsalicylate has been used to treat chronic infantile diarrhea. The dose is 2.5 mL every 4 hours for children 2 to 24 months; 5 mL for children 24 to 48 months; and 10 mL for children 48 to 70 months (Taketomo, Hodding, & Kraus, 2009).

Diarrhea in HIV/AIDS Patients Taking Antiretroviral Drugs

Crofelemer (Fulyzaq) is indicated for the symptomatic relief of noninfectious diarrhea in adult patients with HIV/AIDS on antiretroviral therapy. Dosing is one 125 mg tablet twice a day, without regard for food. The mean duration of therapy during clinical trials was 141 days (Salix Pharmaceuticals, 2013).

Traveler's Diarrhea

Bismuth subsalicylate appears to have antibacterial and antisecretory properties and is used to treat traveler's diarrhea in doses of two tablets or 2 fluid oz before each meal and at bedtime (4 times/d) for up to 3 weeks during brief periods of high risk (Centers for Disease Control and Prevention [CDC], 2014). The management of traveler's diarrhea can be divided into prevention and treatment. The most important risk factor for acquiring this disorder is the patient's destination. High-risk areas include Central and South America, Africa, the Middle East, Mexico, and Asia. Intermittent-risk areas include Eastern Europe, South Africa, and a number of the Caribbean islands. Enterotoxigenic *E. coli* is the most common causative organism found in traveler's diarrhea,

followed by *Campylobacter, Shigella,* and *Salmonella.* Oral antimicrobials are also used for both prevention and treatment of this disorder; the provider should refer to the CDC Travel Web site (www.cdc.gov/travel) for current antimicrobial recommendations. Table 20-6 provides adults' and children's doses of selected antidiarrheals.

Rational Drug Selection

Indication

For acute diarrhea, any of the antidiarrheals is appropriate. The more severe the diarrhea is, the less likely it will be that absorbent agents will help. Bismuth subsalicylate and loperamide are the only drugs indicated for traveler's diarrhea. Loperamide is the only drug with an indication for use with inflammatory bowel disease.

Cost

Brand names are more expensive than generic formulations, and there is no significant clinical difference between the two. Diphenoxylate with atropine generic is $13.99 for 30 tablets, whereas the brand Lomotil is $41.99 (http://drugstore.com). Loperamide (Imodium) is available OTC and is $9.99 for 24 tablets, or the generic loperamide at $5.99

Table 20–6 Dosage Schedule: Selected Antidiarrheals

Drug	Indication	Dosage Form	Initial Dose	Additional Doses
Bismuth subsalicylate*† Pepto-Bismol Kaopectate	Acute diarrhea	Tablets/chewable: 262 mg Liquid: 262 mg/15 mL Liquid: 524 mg/15 mL	*Adults:* 524 mg every 30 min or 1,048–1,200 mg every 60 min as needed *Children 9–12 yr:* 262–300 mg every 30–60 min as needed *Children 6–9 yr:* 176 mg every 30–60 min as needed *Children 3–6 yr:* 88 mg every 30–60 min as needed *Children <3 yr weighing >13 kg:* 88 mg *Children <3 yr weighing 6.4–8 kg:* 44 mg May repeat q4h; not to exceed 6 doses/24 h	Not to exceed 4.2 g/24 h Not to exceed 2.4 g/24 h Not to exceed 1.4 g/24 h Not to exceed 704 mg/24 h May repeat q4h; not to exceed 6 doses/24 h
	Traveler's diarrhea		524 mg (2 tablets or 30 mL of 262 mg/15 mL liquid) every 30 min for up to 8 doses	Not to be used for more than 48 h
Crofelemer (Fulyzaq)	Symptomatic relief of noninfectious diarrhea in adult patients with HIV/AIDS on antiretroviral therapy	125 mg delayed-release tablet	1 tablet bid, with or without food	
Difenoxin with atropine Motofen	Acute diarrhea	Tablets: 1 mg difenoxin and 0.025 mg atropine sulfate	*Adults:* 2 mg	1 mg after each loose stool or 1 mg every 3–4 h as needed. Total 24 h dose not to exceed 8 mg
Diphenoxylate with atropine Lomotil	Acute diarrhea	Tablets: 2.5 mg diphenoxylate, 0.025 mg atropine sulfate	*Adults:* 5 mg tid to qid initially	5 mg daily as needed; not to exceed 20 mg/d

Table 20–6 ⊗ **Dosage Schedule: Selected Antidiarrheals—cont'd**

Drug	Indication	Dosage Form	Initial Dose	Additional Doses
		Liquid: 2.5 mg diphenoxylate, 0.025 mg atropine sulfate/5 mL	*Children 2–12 yr:* all doses qid and in liquid form *2 yr/11–14 kg:* 1.5–3 mL *3 yr/12–16 kg:* 2–3 mL *4 yr/14–20 kg:* 2–4 mL *5 yr/16–23 kg:* 2.5–4.5 mL *6–8 yr/17–32 kg:* 2.5–5.5 mL *9–12 yr/23–55 kg:* 3.5–5 mL	Not recommended for children <2 yr Reduce dosage as soon as control of symptoms is achieved; maintenance dosage may be as low as one-fourth of initial daily dose; maximum daily dose 20 mg Overdosage may result in respiratory depression
Kaolin-pectin Kapectolin Kao-Spen	Acute diarrhea	Suspension: 5.2 g kaolin plus 260 mg pectin/30 mL; 5.85 mg kaolin plus 130 mg pectin/30 mL Also comes in combinations with paregoric, bismuth, carboxy-methylcellulose, and others	*Adults:* 60–120 mL after each loose stool *Children >12 yr:* 40–60 mL after each loose stool *Children 6–12 yr:* 30–60 mL after each loose stool *Children 3–6 yr:* 15–30 mL after each loose stool	
Loperamide Imodium A-D Imodium Generic	Acute diarrhea, traveler's diarrhea	Tablets/capsule: 2 mg Liquid: 1 mg/5 mL	*Adults:* 4 mg initially *Children 9–11 yr or 30–47 kg:* 2 mg initially *Children 6–8 yr or 24–30 kg:* 1 mg initially	2 mg after each loose stool; not to exceed 8 mg/d for OTC use or 16 mg/d for prescription use 1 mg after each loose stool; not to exceed 6 mg/24 h; OTC use not to exceed 48 h 1 mg after each loose stool; not to exceed 4 mg/24 h; OTC use not to exceed 48 h
	Chronic diarrhea associated with inflammatory bowel disease		*Adults only:* 4 mg initially	2 mg after each loose stool until symptoms resolved; maintenance dose is usually 4–8 mg/d in divided doses; not to exceed 16 mg/d

*The dosage schedule for eradication of *H. pylori* is discussed in Chapter 34.

†Avoid bismuth subsalicylate in pediatric patients with influenza or chicken pox because of the risk of Reye syndrome.

(http://drugstore.com). Crofelemer (Fulyzaq) costs $290 for 30 tablets or 15 days of therapy (goodrx.com).

Monitoring

There is no specific monitoring beyond that required for the disease process being treated. Patients with chronic diarrhea may benefit from monitoring of hydration status and electrolyte studies.

Patient Education

Administration

Despite the fact that many of these drugs are available OTC, they are not innocuous. Patients need to be informed that they should take the antidiarrheal exactly as directed; to not make up missed doses or double the doses, and to not exceed the maximum number of doses recommended for 24 hours. The health-care provider should be notified if the diarrhea continues beyond 48 hours or if abdominal pain, fever, or distention occurs.

Tablets may be administered with food if GI irritation occurs (see Table 20-6). They may also be crushed and taken with fluid. Chewable tablets may be chewed or allowed to dissolve. Calibrated measuring devices should be used for liquid preparations. Suspensions should be shaken before they are measured and administered.

Drug interactions may occur, especially with diphenoxylate with atropine and loperamide. Patients should be told not to take any OTC antidiarrheal if they are taking other drugs, especially digoxin, cephalosporin antimicrobials, warfarin or heparin, or CNS depressants (including alcohol) without first contacting their health-care provider. Patients concurrently taking aspirin and bismuth subsalicylate are at risk for salicylate poisoning.

Adverse Reactions

All antidiarrheals have the potential for rebound constipation. As soon as symptoms of diarrhea are reduced, the dosage of the antidiarrheal drug should be reduced; it should be stopped as soon as symptoms resolve.

Bismuth subsalicylate can turn the tongue and stools gray/black. Patients should be told that this reaction can be expected and that it does not indicate GI bleeding.

Diphenoxylate and difenoxin (both with atropine) can cause dry mouth and mucous membranes. These symptoms can be improved by good oral hygiene, sucking hard candy, or chewing sugarless gum. Flushing, tachycardia, and urinary retention may also occur. These symptoms are especially notable in children and in older men. They may necessitate stopping the drug. Loperamide also exhibits these reactions but to a lesser degree. Both drugs can produce CNS reactions of dizziness and drowsiness, loperamide less so than diphenoxylate or difenoxin (both with atropine). Driving or other activities requiring mental alertness should be avoided until the patient's response to the drug is known.

Crofelemer (Fulyzaq) may cause upper respiratory infection or cough, as well as GI symptoms such as nausea and flatulence.

Lifestyle Management

Adding fiber to the diet and using oral rehydrating solutions were discussed previously. The importance of washing one's hands after each bowel movement should be stressed. Education about maintaining nutritional intake is also important. Sometimes patients think that they can stop their diarrhea by stopping their food intake. Resting the GI tract briefly (e.g., for 24 hours) may be appropriate, but reducing fluid intake is never appropriate, and food intake should be restarted after the GI rest.

A bland food diet can assist in maintaining nutrition and is also helpful in reducing the diarrhea. Stopping milk or other lactose-based food products for a few days may give an indication whether the diarrhea is associated with lactose intolerance.

CYTOPROTECTIVE AGENTS

Peptic ulceration can be caused by a variety of conditions, some of which are iatrogenic. The administration of NSAIDs, for example, has been associated with gastric mucosal damage and ulcer formation. Ulcer formation and GI bleeding related to NSAID use often occur without warning.

Patients at high risk are those with a previous history of ulcers; also those on steroids, on high doses of NSAIDS, concurrently taking anticoagulants, or older than 75 years. Among the agents used to treat or prevent ulcer formation are two cytoprotective agents, sucralfate (Carafate) and misoprostol (Cytotec). These drugs are the focus of this section.

Pharmacodynamics

Sucralfate is a basic aluminum salt of a sulfated disaccharide, which is believed to act by polymerization and selective binding to necrotic ulcer tissue, where it covers the ulcer site and acts as a barrier to acid, pepsin, and bile salts. It has no acid-neutralizing activity, and little is absorbed, although some aluminum salts are released. In addition, the drug may directly absorb bile salts and stimulate endogenous prostaglandin synthesis. Prostaglandins are central to the formation and maintenance of the protective mucosa of the GI tract.

Misoprostol is a methyl analogue of prostaglandin E_1. The principal mechanism of action of this drug appears to be inhibition of gastric secretion through inhibition of histamine-stimulated cyclic adenosine monophosphate (AMP) production. Over a dosage range of 50 to 200 mcg, it inhibits basal and nocturnal gastric acid secretion and acid secretion in response to a variety of stimuli, including meals, histamine, and coffee by binding to prostaglandin E receptors. It has no significant effect on fasting or postprandial gastrin or on intrinsic factor output; however, it produces a moderate decrease in pepsin concentration during basal conditions.

Misoprostol also has mucosal protective qualities. Prostaglandin E receptors have a high affinity for misoprostol and for its acid metabolite. These receptors facilitate the production of mucus and bicarbonate. They also allow the drug taken with food to be effective, despite the lower serum concentration. Misoprostol also produces uterine contractions that may endanger pregnancy. See the discussion below.

Pharmacokinetics

Absorption and Distribution

Sucralfate is minimally absorbed (Table 20-7). Its action is largely topical. Misoprostol is rapidly and extensively absorbed after oral administration. Distribution of this drug is unknown.

Table 20–7 ⊞ Pharmacokinetics: Cytoprotective Agents

Drug	Onset	Peak	Duration	Protein Binding	Half-Life	Elimination
Misoprostol	Minutes	12–15 min	3–6 h	<90%	20–40 min (doubles in renal impairment)	80% in urine
Sucralfate	30 min	UK	5 h	UK	6–20 h	90% in feces

UK = unknown.

Metabolism and Excretion

Sucralfate is essentially not absorbed; more than 90% is excreted in feces. Misoprostol is rapidly converted to its free acid, which is responsible for its clinical activity. It does not affect the cytochrome P450 (CYP450) enzyme systems. The half-life of this drug is 20 to 40 minutes, but renal impairment results in a doubling of this half-life. The metabolite is excreted in urine.

Pharmacotherapeutics

Precautions and Contraindications

Sucralfate's action is topical; there are no specific precautions or contraindications. It is Pregnancy Category B. Its safety and efficacy have not been established in children.

Misoprostol must be used with caution in renal impairment. Its half-life, maximum concentration, and the area under the curve (AUC) double with renal insufficiency. No routine dosage adjustments have been recommended, but dosage may need to be reduced if the usual dose is not tolerated. In older adults (older than 64 years), the AUC for the acid metabolite of misoprostol is increased. The cause may be decreased renal functioning associated with aging, and recommendations are the same as for renal impairment.

Misoprostol is Pregnancy Category X. It may cause abortion, premature birth, or birth defects. Uterine rupture has been reported in women who were administered misoprostol to induce labor. It should not be administered to pregnant women to treat NSAID-induced ulcers. Patients should be warned of the abortifacient properties of the drug and be advised not to give it to others (www.drugs.com). Misoprostol is metabolized in the mother to misoprostol acid that is excreted in breast milk. Caution is advised when administered to a nursing woman.

Safety and efficacy in children younger than 18 years have not been established.

Adverse Drug Reactions

Adverse reactions in clinical trials with sucralfate were minor and rarely led to discontinuance of the drug. Constipation, the most frequent complaint, occurs in only 2% of patients. Other adverse reactions, including dizziness and gastric discomfort, occurred in less than 0.5% of patients.

Adverse reactions with misoprostol were largely GI or gynecological. Diarrhea is the most common complaint (13% to 40% of patients). Abdominal pain, nausea, and flatulence occur in small numbers of patients and are difficult to separate from the symptoms of the disorder for which the drug was prescribed. Postmenopausal bleeding, spotting (0.7%), cramps (0.6%), hypermenorrhea (0.5%), menstrual disorder (0.3%), and dysmenorrhea (0.1%) occur in women. Reactions related to pregnancy were discussed previously.

Drug Interactions

Sucralfate may decrease the absorption of several drugs when given concurrently or prior to their administration (Table 20-8). Separating the administration of the interacting drug by at least 2 hours and giving the interacting drug first can often solve the problem. Sucralfate and antacids should be separated by at least 2 hours.

The only drug of concern with misoprostol is the potential for increased diarrhea risk with magnesium-based antacids. Food can decrease maximum plasma concentrations, but this has little clinical significance.

Clinical Use and Dosing

Prophylaxis and Treatment of Duodenal Ulcers Associated With NSAID Use

NSAIDs inhibit prostaglandin synthesis and damage the mucosal lining of the stomach, which may result in ulcer formation. The first choice is to discontinue the NSAID. Misoprostol is approved by the FDA for prophylaxis or treatment of duodenal ulcers that are due to use of NSAIDs for those

Table 20–8 ▦ **Drug Interactions: Cytoprotective Agents**

Drug	Interacting Drug	Possible Effect	Implications
Misoprostol	Magnesium-based antacids	Increased risk for diarrhea	Choose different antacid
	Food	Maximum plasma concentrations of acid metabolite are diminished when taken with food	Little clinical significance, but best taken on empty stomach
Sucralfate	Aluminum-based antacids	Increased constipation risk; increase in total body burden of aluminum	Choose different antacid
	Anticoagulants	Decrease in effect of warfarin	Avoid concurrent use
	Digoxin	Reduced serum levels of digoxin; reduced effects	Avoid concurrent use
	Hydantoins	Absorption may be decreased	Separate administration by 2 h and give hydantoin first
	Ketoconazole, quinolones	Bioavailability decreased	Separate administration by 2 h and give drugs first
	Quinidine	Reduced serum levels of quinidine; reduced effects	Separate administration by 2 h and give quinidine first

patients who must continue NSAID use. Dosage is 200 mcg 4 times a day with food (Table 20-9). If this dose cannot be tolerated, 100 mcg can be used. Misoprostol should be taken with meals and at bedtime. The drug is taken for the duration of NSAID therapy.

Because misoprostol commonly causes a dose-dependent diarrhea and other GI symptoms, and because its stimulant effect on the uterus contraindicates its use for women with childbearing potential, its use as prophylaxis is reserved for those with high risk for and little tolerance of the GI hazards of NSAIDs.

In a *Cochrane Review* of the literature regarding prevention of NSAID-induced gastroduodenal ulcers, misoprostol significantly reduced the risk of endoscopic ulcers. In gastric ulcers, 800 mg/day of misoprostol was more effective than 400 mg/day but not in duodenal ulcers (Rostom et al, 2002).

Treatment of Duodenal Ulcers From Other Causes

Sucralfate can be used for short-term (up to 8 weeks) treatment of active duodenal ulcer. Dosage is 1 g 4 times a day on an empty stomach, 1 hour before meals and at bedtime. Healing usually occurs within 2 weeks. Maintenance therapy after the ulcer has healed is 1 g twice a day. Sucralfate has off-labeled uses in treating gastric and esophageal ulcers, with the same dosing schedule. It appears to have some advantage over antacids and H$_2$RAs in stress ulcer prophylaxis.

Although more effective than placebo, misoprostol is less effective than H$_2$RAs or PPIs for treatment of duodenal ulcers from other causes. In doses greater than 400 mcg/day, it has an off-labeled use for treatment of duodenal ulcers not responsive to H$_2$RAs.

Rational Drug Selection

Drug selection is based on indications cited previously (see Table 20-9). Sucralfate is preferred over misoprostol for treatment of active duodenal ulcers not caused by NSAIDs. Sucralfate is also the cytoprotective drug of choice for women of childbearing age.

Monitoring

No specific monitoring parameters exist for these drugs. Monitoring should relate to the disease process being treated. Women of childbearing age should have a negative pregnancy test before misoprostol is prescribed to them.

Patient Education

Administration

Patients should be taught to take the drug exactly as prescribed. Sucralfate is taken on an empty stomach; misoprostol with food. Patients should not take antacids while taking sucralfate. Advise the patient to continue the therapy even if feeling better. Sucralfate is given for 4 to 8 weeks to ensure ulcer healing; misoprostol is given for the duration of NSAID therapy. Missed doses should be taken as soon as remembered unless it is almost time for the next dose. Doses should not be doubled. Women of childbearing age should have a negative pregnancy test and start misoprostol on day 2 or 3 of their menstrual period.

Adverse Reactions

Increased fluid intake, dietary bulk, and exercise may reduce the incidence of constipation associated with sucralfate. Diarrhea may occur with misoprostol. If it continues for more than 1 week, the health-care provider should be notified. The patient should also report onset of black, tarry stools or severe abdominal pain, which may indicate treatment failure and the onset of GI bleeding.

Women of childbearing age should be informed that misoprostol will cause spontaneous abortion. The drug should not be prescribed until contraceptive therapy is established and the patient has a negative serum pregnancy test within 2 weeks of starting therapy. If pregnancy is suspected, the drug should be immediately stopped and the health-care provider notified so that pregnancy testing can be performed.

Lifestyle Management

Lifestyle management related to peptic ulcers is discussed in Chapter 35.

ANTIEMETICS

Nausea and vomiting are common complaints in primary care and have a multitude of causes. Treatment is often nonpharmacological, but antiemetics may also be used to provide symptom relief and prevent fluid and electrolyte disturbances. This section discusses drugs used for these purposes.

Drug classes with antiemetic properties commonly used include antihistamines, phenothiazines, sedative hypnotics, cannabinoids, 5-HT$_3$ receptor antagonists, anticholinergics,

Table 20–9 ⊗ **Dosage Schedule: Cytoprotective Agents**

Drug	Indication	Dosage Forms	Dosage Schedule
Misoprostol Cytotec	Prophylaxis and treatment of duodenal ulcers due to NSAID use	Tablets: 100, 200 mcg	200 mcg qid with food. Last dose usually at bedtime. Taken for duration of NSAID therapy. If this dose is not tolerated, 100 mcg qid may be used.
Sucralfate Carafate	Active duodenal ulcer Maintenance after healing of duodenal ulcer	Tablets: 1 g Suspension: 1 g/10 mL	1 g qid taken 1 h before meals and at bedtime 1 g bid taken on empty stomach

and a substance P/neurokinin 1 (NK1) receptor antagonist. The antihistamines most commonly used for these antiemetic properties are dimenhydrinate (Dramamine), diphenhydramine (Benadryl), hydroxyzine (Vistaril), and meclizine (Antivert). The phenothiazines include prochlorperazine (Compazine), perphenazine, and promethazine (Phenergan). The cannabinoid dronabinol (Marinol) is used for nausea and vomiting associated with cancer. The 5-HT$_3$ receptor antagonists include palonosetron (Aloxi), dolasetron mesylate (Anzemet), granisetron (Kytril, Sancuso), and ondansetron (Zofran). Scopolamine (Transderm Scop) is an anticholinergic. Aprepitant (Emend) is a substance P/neurokinin 1 (NK1) receptor antagonist. A miscellaneous antiemetic not from the previous classes of drugs is trimethobenzamide (Tigan). Each of these drugs is discussed in this section.

Pharmacodynamics

Antihistamines that possess significant antiemetic activity have strong anticholinergic effects as well as histamine $_1$-blocking effects. Blockade of histamine $_1$ receptors results in decreased exocrine gland secretion (e.g., salivary and lacrimal). First-generation antihistamines with strong anticholinergic properties bind to central cholinergic receptors and produce antiemetic effects, decreasing nausea and vomiting. They are especially helpful in the nausea associated with motion sickness because of their depression of conduction in the vestibulocerebellar pathway. The antiemetic drugs in this class are dimenhydrinate, diphenhydramine, hydroxyzine, and meclizine.

Phenothiazines block dopamine receptors in the chemoreceptor trigger zone (CTZ). They also bind to and block cholinergic, alpha$_1$-adrenergic, and histamine$_1$ receptors. Although all phenothiazines have these actions to some degree, their use as antiemetics is limited by their sedating and extrapyramidal effects. The antiemetic drugs in this class are prochlorperazine and promethazine. They are less sedating and have antiemetic effects at lower doses than some other phenothiazines. Metoclopramide also blocks dopamine receptors and has been used as an antiemetic. Its main use, however, is as a prokinetic, and it is discussed in that section of this chapter.

Cannabinoids work in the CNS similar to cannabis (marijuana) to prevent nausea and vomiting associated with cancer chemotherapy and as an appetite stimulant, especially in HIV patients.

The 5-HT$_3$ receptor antagonists block serotonin both peripherally on vagal nerve terminals and centrally in the CTZ. Chemotherapy causes the release of serotonin from the enterochromaffin cells; pretreatment with a 5-HT$_3$ receptor antagonist decreases emesis.

Transdermal scopolamine is a belladonna alkaloid anticholinergic that acts as a competitive inhibitor of muscarinic receptors in the parasympathetic nervous system. Scopolamine may also work to block cholinergic transmission from the reticular center to the vomiting center in the brain. Anticholinergics also decrease secretion of saliva and decrease gastrointestinal motility.

Aprepitant (Emend) is a highly selective antagonist of substance P/neurokinin 1 (NK1) receptors. Aprepitant crosses the blood–brain barrier and occupies the NK$_1$ receptors. It has no affinity for 5-HT$_3$ or dopamine receptors. Aprepitant augments the activity of the 5-HT $_3$ receptor antagonists such as ondansetron and the corticosteroid dexamethasone to prevent nausea and vomiting in patients receiving chemotherapy.

Trimethobenzamide inhibits emetic stimulation of the CTZ.

Pharmacokinetics

Absorption and Distribution

All of the antiemetic drugs (except for transdermal scopolamine) are well absorbed after oral administration (Table 20-10). Oral liquid formulations provide the most reliable absorption. The antihistamines, phenothiazines, 5-HT $_3$ receptor antagonists, and aprepitant come in IV form. Prochlorperazine, promethazine, and trimethobenzamide have formulations for administration by the rectal route. The IM and rectal routes are commonly used when vomiting is present. Scopolamine is available as a transdermal patch and is well absorbed through the skin behind the ear.

Distribution of antihistamines is not clearly known, but phenothiazines are widely distributed, cross the blood–brain barrier and placenta, and enter breast milk. As a result, they are associated with more adverse reactions. Scopolamine crosses the blood–brain barrier and the placenta. Aprepitant crosses the blood–brain barrier in humans, and in animal studies it crosses the placenta.

Metabolism and Excretion

Dimenhydrinate, diphenhydramine, and hydroxyzine are extensively metabolized by the liver and eliminated in feces by biliary excretion. The cannabinoid dronabinol undergoes extensive first-pass hepatic metabolism and is eliminated as active and inactive metabolite in the feces and urine; as well, the 5-HT$_3$ receptor antagonists undergo extensive first-pass metabolism and are eliminated in the urine and feces. Trimethobenzamide is metabolized by the liver and is excreted in urine. The phenothiazines are metabolized by the liver into active compounds that persist for prolonged periods. Phenothiazines are eliminated half by the kidney in urine and half through enterohepatic circulation. The fetus, infants, and older adults have decreased ability to metabolize and excrete the phenothiazines. Scopolomine is extensively metabolized with less than 5% of active drug excreted in the urine. Aprepitant is extensively metabolized primarily by CYP 3A4 into seven weakly active metabolites. Aprepitant is not renally excreted; it is primarily eliminated via metabolism.

Pharmacotherapeutics

Precautions and Contraindications

The drug class determines the precautions and contraindications. Antihistamines have anticholinergic properties and

Table 20–10 ⚏ Pharmacokinetics: Selected Antiemetics

Drug	Onset	Peak	Duration	Protein Binding	Half-Life	Elimination
Aprepitant						
		3 h	24 h	95%	9–13 h

IM	15–35 m	UK	2–3 h	UK	UK	

ER = extended release; PR = per rectum; UK = unknown.

have precautions and contraindications similar to anticholinergics. Cautious use in narrow-angle glaucoma, seizure disorders, pyloric obstruction, hyperthyroidism, cardiovascular disease, and prostatic hypertrophy is in order. Because they are metabolized so extensively by the liver, they are contraindicated in severe liver disease. Cautious use is also suggested for older adults, and dosage reductions may be required.

Dimenhydrinate and diphenhydramine are Pregnancy Category B, and they are safe for use in children. Meclizine is also Pregnancy Category B. Safety and efficacy of meclizine has not been established in children less than 12 years or during lactation. Hydroxyzine is Pregnancy Category C but has been used safely during labor. Safety in lactation and in children has not been established, but it has been used for both, and children's doses are published.

Phenothiazines produce extrapyramidal reactions and are contraindicated in Parkinson's disease. They are also contraindicated in narrow-angle glaucoma, bone marrow depression, and severe cardiovascular or hepatic disease because of their serious adverse reactions. Cautious use is suggested in respiratory impairment caused by acute pulmonary infection or chronic respiratory disorders, such as severe asthma or emphysema. "Silent pneumonia" may develop in these patients when they are treated with phenothiazines. Because these drugs suppress the cough reflex, aspiration of vomitus is possible, and they should be used cautiously where aspiration is a risk. Although all of these points are important to consider, they are less likely to be a problem in very short-term use as an antiemetic.

The phenothiazines are Pregnancy Category C. Children of all ages are more prone to develop extrapyramidal reactions. Prochlorperazine should be avoided in children younger than age 5 years due to high incidence of extrapyramidal reactions. Promethazine is contraindicated in children younger than 2 years of age due to severe and potentially fatal respiratory depression. Promethazine is also associated with respiratory depression and sudden death in children 2 years of age or older and should be used with caution and at the lowest effective dose.

Dronabinol contains cannabinoid and sesame oil and should not be used by anyone sensitive to these ingredients.

Dronabinol should be used with caution in patients with a history of seizure disorder because it may lower the seizure threshold. Patients with cardiac disorders should be monitored for hypotension, possible hypertension, syncope, or tachycardia. Dronabinol has a high potential for abuse. Dronabinol is Pregnancy Category C.

The 5-HT$_3$ receptor antagonists may mask progressive ileus. Zofran ODT disintegrating tablets contain aspartame and should be used with caution in patients with phenylketonuria. Dolasetron, granisetron, and palonosetron are Pregnancy Category B.

Anticholinergics such as transdermal scopolomaine should be used cautiously in patients with open-angle glaucoma or gastrointestinal or bladder neck obstruction and is contraindicated in narrow-angle glaucoma. Transdermal scopolamine should be used cautiously in the elderly due to the increased likelihood of CNS effects. Transdermal scopolamine is Pregnancy Category C and is not approved for use in children.

Aprepitant is contraindicated in patients who are hypersensitive to any component of the product. Aprepitant inhibits CYP 3A4, and patients taking medications concurrently that are metabolized by CYP 3A4 may have elevated plasma concentrations leading to significant adverse effects (Table 20-11). Aprepitant is Pregnancy Category C and is not approved for use in children.

Table 20–11 ▦ Drug Interactions: Selected Antiemetics

Drug	Interacting Drug	Possible Effect	Implications
Aprepitant	Dexamethasone	Increased plasma dexamethasone levels	Decrease dexamethasone dose by 50% when coadministering
	Methylprednisolone	Increased methylprednisolone levels	Decrease IV methylprednisolone dose by 25% and oral methylprednisolone level by 50%
	CYP 2C9 substrates (warfarin, tolbutamide)	May result in lower plasma concentrations of drugs metabolized by CYP 2C9	Warfarin: monitor INR levels Tolbutamide: monitor for adverse effects
	Oral contraceptive containing ethinyl estradiol and norgestimate or norethindrone	May reduce efficacy of hormonal contraceptives	Use alternative or back-up method for birth control
	Benzodiazepines (alprazolam, midazolam, triazolam)	Increased plasma concentrations of benzodiazepine	Dosage adjustment may be necessary if IV benzodiazepines are given concurrently
	Ketoconazole	Increased ketoconazole levels 5-fold	Avoid concurrent use
	Rifampin	Decreased aprepitant levels	Avoid concurrent use
	Diltiazem	Increased diltiazem and aprepitant levels	Monitor for adverse effects
	Paroxetine	Decreased paroxetine levels	Monitor if coadministering
Dimenhydrinate, diphenhydramine, hydroxyzine, meclizine	Alcohol, other antihistamines, opioids, sedative hypnotics, other CNS depressants	Additive CNS depression	Avoid concurrent use or warn patient of drowsiness and its consequences
	Aminoglycosides, ethacrynic acid, other ototoxic drugs	May mask indications of ototoxicity of these drugs	Avoid concurrent use

Continued

Table 20–11 ⬚ **Drug Interactions: Selected Antiemetics—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
	Tricyclic antidepressants (TCAs), monoamine oxidase inhibitors, quinidine, and other drugs with anticholinergic properties	Additive anticholinergic effects	Avoid concurrent use or provide patient education about ways to reduce or treat anticholinergic effects
	Azole antifungals	Plasma levels (including metabolites) may be increased	Choose different antiemetic
	Macrolide antibiotics	Plasma levels (including metabolites) may be increased	Choose different antiemetic
	Serotonin reuptake inhibitors	Plasma levels (including metabolites) may be increased	Choose different antiemetic
Perphenazine	CYP 2D6 inhibitors tricyclic antidepressants and selective serotonin reuptake inhibitors	Concomitant administration of other drugs that inhibit the activity of P450 2D6 may acutely increase plasma concentrations	Close monitoring and dosage reduction may be necessary
Prochlorperazine, promethazine	Antihypertensives, nitrates, and acute ingestion of alcohol	Additive hypotensive effects	Avoid concurrent administration or monitor blood pressure closely
	Alcohol, antihistamines, antidepressants, opioids, sedative hypnotics, and other CNS depressants	Additive CNS depression May increase TCA serum levels	Avoid concurrent administration or warn about drowsiness and its risks; select different antiemetic or antidepressant other than TCA
	Antihistamines, antidepressants, atropine, haloperidol, other phenothiazines, and other drugs with anticholinergic properties	Additive anticholinergic effects	Avoid concurrent use or provide patient education about ways to reduce or treat anticholinergic effects
	Lithium	Lithium increases risk of extrapyramidal symptom (EPS) reactions; prochlorperazine may mask indications of lithium toxicity	Avoid concurrent use
	Antithyroid agents	Increased risk for agranulocytosis	Choose different antiemetic
	Antacids	Concurrent administration may decrease absorption	Separate administration or give antiemetic by IM or rectal route
Scopolamine	CNS sedatives	Increased sedation	Use concurrently with care
Trimethobenzamide	Alcohol, antihistamines, antidepressants, opioids, sedative hypnotics, and other CNS depressants	Additive CNS depression	Avoid concurrent use or warn patient of drowsiness and its consequences
Dronabinol	Alcohol, benzodiazepines, barbiturates, CNS depressants	Additive CNS depression	Write for smallest practical amount of dronabinol
	Tricyclic antidepressants (amitriptyline, amoxapine, desipramine,)	Additive tachycardia, hypertension, drowsiness	Avoid concurrent administration if possible
	Theophylline	antagonizes	
Dolasetron	Drugs that prolong QT interval		
Ondansetron	Potent inducers of CYP3A4 (i.e., phenytoin, carbamazepine, and rifampicin)	Clearance of ondansetron was significantly increased and ondansetron blood concentrations were decreased	No dosage adjustment necessary
	Apomorphine	Increased apomorphine levels	Avoid concomitant use
	P-glycoprotein inhibitors	Ondansetron levels increased	

Adverse Drug Reactions

The most common adverse reactions for antihistamines are drowsiness and the common anticholinergic effects of dry mouth, blurred vision, and urinary retention. Paradoxical excitation may occur in children. Pain at the injection site occurs in IM injections.

Phenothiazines produce drowsiness as well, but they also produce serious adverse reactions that sometimes occur even with short-term use and low doses. These reactions include extrapyramidal reactions such as dystonia, akathisia, and tardive dyskinesia. Other serious concerns are their ability to mask acute symptoms of surgical and neurological conditions and the potential for agranulocytosis 4 to 10 weeks after initiation of therapy.

Promethazine has been known to cause fatal respiratory depression in children younger than 2 years of age and has a Black-Box Warning regarding its use in children. In children older than age 2 years, the lowest effective dose should be used and coadministration of respiratory depressants should be avoided.

Other adverse reactions are associated with the anticholinergic effects of phenothiazines and include dry mouth, dry eyes, blurred vision, constipation, and urinary retention. They also discolor urine pink to reddish brown, and patients should be told that this reaction does not indicate hematuria.

The cannabinoid dronabinol may cause euphoria, depression, dizziness, paranoid thoughts, somnolence, and abnormal thoughts. Cardiac effects include palpitations, tachycardia, and hypotension. Seizures and seizure-like activity have been reported in patients receiving Marinol capsules in post-marketing surveillance.

The 5-HT$_3$ receptor antagonists have the common side effects of constipation, headache, fatigue, dizziness, and diarrhea. Less common but concerning are rare cases of tachycardia, bradycardia, hypotension, and QT prolongation.

The most frequently reported adverse effect of transdermal scopolamine is dry mouth. Some patients experience drowsiness, blurred vision, and dilated pupils. Patients have reported a withdrawal syndrome that occurs 24 hours or more after the patch has been removed, including symptoms of dizziness, nausea, vomiting, and headache.

Patients taking aprepitant for highly emetogenic chemotherapy reported greater fatigue (17.8% versus 11.8%), dizziness (6.6% versus 4.4%), and hiccups (10.8% versus 5.6%) than patients receiving standard therapy. Patients taking aprepitant were slightly more likely to experience elevated ALT/AST and BUN than patients receiving standard antiemetic therapy during clinical trials.

Drug Interactions

Antihistamines and phenothiazines have additive CNS depression with other drugs that produce CNS depression and additive anticholinergic effects with other drugs that have anticholinergic effects or adverse reactions.

Phenothiazines also have additive hypotensive effects with antihypertensive agents or acute ingestion of alcohol. Concurrent administration of lithium increases the risk for extrapyramidal reactions, and phenothiazines may mask the signs of lithium toxicity. Antithyroid agents increase the risk for agranulocytosis.

The cannabinoid dronabinol interacts with other CNS depressants, causing additive CNS depression with benzodiazepines, barbiturates, alcohol, opioids, antihistamines, muscle relaxants, and other CNS depressants. Dronabinol has been studied and administered with cytotoxic agents, anti-infective agents, sedatives, or opioid analgesics without significant adverse effects.

Aprepitant is an inducer of CYP 3A4 and can increase plasma concentrations of drugs that are metabolized via CYP 3A4, including hormonal contraceptives and some chemotherapy agents. Concurrent use of aprepitant and pimozide, terfenadine, astemizole, or cisapride is contraindicated due to potentially life-threatening reactions. These and additional drug interactions are listed in Table 20-11.

Clinical Use and Dosing

The only clinical use presented here is to treat nausea and vomiting. Table 20-12 shows the dosing schedules for each of the drugs for this purpose. Other uses for these drugs are discussed in Chapter 16.

Rational Drug Selection

Treatment of Nausea and Vomiting Due to Drugs or Gastroenteritis

Nausea and vomiting as an adverse effect of medication or gastroenteritis often improve with treatment using an antiemetic. Because of their low side-effect profile and tolerance, the 5-HT$_3$ receptor antagonists are being used extensively to treat nausea and vomiting. The phenothiazines are also a good choice for initial and short-term treatment of nausea, except in children. Trimethobenzamide is also effective. The antihistamines can also be used and, because they have less serious adverse reactions, are better for longer-term applications. All are available in a variety of dosage forms so that they need not be taken orally by a patient who is nauseated. Dronabinol is approved only for use in chemotherapy-associated nausea and vomiting and appetite stimulation. Aprepitant is approved for post-operative nausea and vomiting and in conjunction with other antiemetic agents for prevention of acute and delayed nausea and vomiting associated with initial and repeated doses of emetogenic cancer chemotherapy.

Motion Sickness

Antihistamines are useful for this indication because they act on the vestibular system and the CTZ to help control the nausea and vomiting associated with vestibular dysfunction. They also provide rapid onset of action and have a prolonged effect. Dimenhydrinate and meclizine are the most commonly used. Meclizine is also used to treat vertigo. The phenothiazines are not effective for motion sickness or vestibular disease because their site of action does not involve the vestibular system. Transdermal scopolamine is indicated for prevention of nausea and vomiting associated with motion

Table 20–12 Dosage Schedule: Selected Antiemetics

Drug	Indications	Dosage Form	Dosage Schedule	Notes
Aprepitant Emend	Prevention of chemotherapy-induced nausea and vomiting Prevention of post-operative nausea and vomiting	Capsules: 40, 80, 125 mg	Prevention of chemotherapy-induced nausea and vomiting: Day 1: 125 mg PO Day 2: 80 mg PO Day 3: 80 mg PO Post-operative nausea and vomiting: 40 mg PO within 3 h of anesthesia	For chemotherapy-induced nausea and vomiting, patients are coadministered dexamethasone 12 mg day 1 and 8 mg days 2–4
Dimenhydrinate Dramamine Generic	Antiemetic	Tablets: 50 mg Chewable tablets: 50 mg Liquid: 12.5 mg/5 mL	*Children >12 yr and adults:* 50 mg PO/IM or 25 mg ER capsules q4h; not to exceed 400 mg/d; PR = 50–100 mg q6–8h	For motion sickness, give dose 1–2 h prior to departure or ER dose 12 h prior to departure
Dramamine Gravol		Chewable tablets: 50 mg Liquid: 12.5 mg/5 mL Quick-dissolve tablets: 15 mg Liquid: 15 mg/5 mL	*Children 6–12 yr:* 25–50 mg (PO/IM) q6–8h; not to exceed 150 mg/d *Children 2 to 5 yrs:* 12.5–25 mg (PO/IM) q 6–8 h, maximum dose 75 mg/day	Use calibrated measuring device when giving liquid doses
Gravol Generic		Rectal suppositories: 25, 50, 100 mg	*Children 8–12 yr:* PR = 25–50 mg q8–12 h *Children 6–8 yr:* 12.5–25 PR q8–12 h *Children 2–6 yr:* Up to 12.5–25 mg q6–8 h; not to exceed 75 mg/d	
Diphenhydramine Benadryl Generic	Antiemetic	Soft gels: 25 mg Tablets: 25 mg	*Adults:* 25–50 mg q6h PO; 10–50 mg q2–3h IM; not to exceed 300 mg/d	For motion sickness, give dose 1–2 h prior to departure or ER dose 12 h prior to departure
		Chewable tablets: 12.5 mg	*Children >20 lb (9.1 kg):* 12.5–25 mg 3–4 times daily (5 mg/kg) not to exceed 300 mg/d	
		Liquid: 6.25 mg/ 5mL	*Children:* 1–1.5 mg/kg q4–6h PO; not to exceed 300 mg/d	Use calibrated measuring device when giving liquid doses.
		Injection: 50 mg/mL	IM = 1.25 mg/kg qid; not to exceed 300 mg/d	Give IM into deep, well-developed muscle; avoid SC administration
Hydroxyzine Atarax Vistaril	Antiemetic	Tablets: 10, 25, 50 mg Tablets: 100 mg Capsules: 25, 50, 100 mg Injection: 25 mg/mL, 50 mg/mL	*Children >12 yr and adults:* 25–100 mg PO/IM tid or qid	Tablets may be crushed and capsules opened and administered with food or fluid for patients with difficulty in swallowing
		Syrup: 10 mg/5 mL	*Children 6–12 yr:* 12.5–25 mg PO/IM q6h *Children <6 yr:* 12.5 mg q6h (General calculation for children: 0.5 mg/kg q6h)	Give IM into deep, well-developed muscle using Z track. Do not use deltoid. Injection is painful. Rotate sites frequently. Avoid SC or IV administration.
Meclizine Dramamine Less Drowsy Antivert Generic	Motion sickness	Tablets: 12.5, 25, 50 mg Chewable tablets: 25 mg Capsules: 25 mg	*Children >12 yr and adults:* 25–50 mg	Take 1 h prior to travel. May repeat dose every 24 h for duration of journey

Table 20–12 ⚕ **Dosage Schedule: Selected Antiemetics—cont'd**

Drug	Indications	Dosage Form	Dosage Schedule	Notes
	Vertigo		Adults: 25–100 mg daily in divided doses	
	Nausea and vomiting in pregnancy		Lowest dose that relieves nausea	Pregnancy Category B
Prochlorperazine Compazine Generic	Antiemetic	Tablets: 5, 10, 25 mg Spansules (SR): 10, 15, 30 mg Syrup: 5 mg/5 mL Injection: 5 mg/mL Suppositories: 2.5, 5, 25 mg	*Children >12 yr and adults:* 5–10 mg PO/IM tid or qid; not to exceed 40 mg/d *Children 19–39 kg:* 2.5 mg PO/PR tid or 5 mg bid; not to exceed 15 mg/d *Children 15-18 kg:* 2.5 mg PO/PR bid or tid; not to exceed 10 mg/d *Children >2 yr or 10-14 kg:* 2.5 mg PO/PR qd or bid; not to exceed 7.5 mg/d	Do not crush or chew ER capsules. Administer with food or milk or a full glass of water to minimize GI distress. Dilute syrup in citrus or chocolate-flavored drinks. Give IM into deep, well-developed muscle. Keep patient recumbent for at least 30 min following injection to avoid hypotensive effects. Do not use in pediatric patients under 2 yr of age or under 20 lb.
Promethazine Phenergan Generic	Antiemetic	Tablets: 12.5, 25, 50 mg Syrup: 6.25 mg/5 mL Suppositories: 12.5, 25, 50 mg Injection: 25 mg/mL, 50 mg/mL	*Adults:* 25 mg PO/IM/PR q4h *Children >2 yr:* 0.25–0.5 mg/kg q4–6h PO/IM/PR. Do not exceed 25 mg/dose.	For motion sickness, give dose 1–2 h prior to departure. Administer with food, water, or milk to minimize GI distress. Tablets may be crushed and mixed with food or fluids for patients with difficulty in swallowing. Use calibrated measuring device when giving liquid doses. Give IM into deep, well-developed muscle; SC administration may cause tissue necrosis. Do not administer to children <2 yr. Use with extreme caution in children using the lowest, most-effective dose.
Trimethobenzamide Tigan Generic	Antiemetic	Capsules: 100, 250, 300 mg Injection: 100 mg/mL	*Adults:* 300 mg PO tid/qid; IM = 200 mg tid/qid *Children:* 15–20 mg/kg/day PO divided tid/qid OR *Children > 40 kg:* 300 mg tid/qid *Children 15–40 kg:* 100–200 mg PO tid/qid or 15 mg/kg/d in 3–4 divided doses *Children <15 kg:* 100 mg PR tid/qid	Capsules can be opened and contents mixed with food or fluid for patients with difficulty in swallowing. Inject deep into well-developed muscle to minimize tissue irritation.
Dronabinol Marinol	Refractory nausea and vomiting associated with cancer chemotherapy	Capsules: 2.5 mg, 5 mg, 10 mg	*Adults and children:* 5 mg/m^2 1–3 h before chemotherapy. Then every 2–4 h after chemo. May increase as needed by increments of 2.5 mg/m^2 to a max of 15 mg/m^2	Individualize the dosing

Continued

Table 20–12 ✖ **Dosage Schedule: Selected Antiemetics—cont'd**

Drug	Indications	Dosage Form	Dosage Schedule	Notes
	Anorexia associated with weight loss in patients with AIDS		*Adults:* 2.5 mg bid before lunch and supper; dosage can be reduced to 2.5 qhs	
Dolasetron Anzemet	Prevention of nausea and vomiting after chemotherapy or surgery	Tablets: 50, 100 mg Injection solution: 20 mg/mL	*Children ≥16 yr and adults:* 100 mg within 1 h before chemotherapy or 2 h before surgery *Children 2 yr–16 yr:* 1.8 mg within 1 h of chemotherapy or 1.2 mg within 2 h before surgery	Dolasetron injection solution may be diluted in apple juice and taken orally. This solution is stable for 2 h.
Ondansetron Zofran Generic	Prevention of nausea and vomiting associated with chemotherapy Post-operative nausea and vomiting Gastroenteritis	Tablets: 4, 8 mg ODT (disintegrating tab): 4, 8 mg Solution: 4 mg/5 mL	*Adults:* 24 mg administered 30 min before the start of chemotherapy or 8 mg tid *Children 4–11 yr:* 4 mg tid *Infants and children < 40 kg:* 0.1 mg/kg/dose before induction of anesthesia *Children > 12 yr:* 4 mg *Adults:* 16 mg PO 1 h before induction of anesthesia, OR 4 mg IV *Infants and children 6 mo to 10 yr:* 8–15 kg: 2 mg/dose × 1 15–30 kg: 4 mg/dose × 1 > 30 kg: 8 mg/dose × 1	Routine use of ondasetron is not recommended in most cases of acute gastroenteritis.
Scopolamine Transderm Scop	Prevention of nausea and vomiting associated with motion sickness	Transdermal patch: 1.5 mg	*Adults:* Apply patch to hairless area behind one ear and leave in place for 3 days	Transdermal patch is programmed to deliver 1 mg over 3 days.

ER = extended release; PR = per rectum.

sickness in adults and is commonly used in patients who are cruising in large or small ships.

Vomiting Due to Gastroparesis

For this indication, prokinetic drugs are best. They are discussed later in this chapter.

Monitoring

When antiemetic drugs are used for a single dose or very short-term, no specific monitoring is required beyond that associated with the disease process and the potential fluid and electrolyte shifts that may result from vomiting. If treatment is needed for longer than a few days, the following monitoring parameters are suggested. Promethazine has been associated with bone marrow depression. A complete blood count (CBC) prior to initiation of therapy is appropriate. Pheno - thiazines have also been associated with blood dyscrasias that tend to occur between week 4 and week 10 of therapy. A CBC may be done prior to initiation and after 4 weeks of therapy.

Patient Education

Administration

These drugs should be taken as prescribed (Table 20-12). Each of them has special considerations related to administration,

which are presented in Table 20-12. All of the drugs used to treat motion sickness should be taken 1 to 2 hours prior to departure, except for extended-release dimenhydrinate, which is taken 12 hours before departure. For all liquid formulations, a calibrated measuring device should be used to attain an accurate dose. All injections should be administered deep into well-developed muscle, avoiding the deltoid and subcutaneous (SC) injections. A Z-track method of injection should also be used for hydroxyzine. All tablets except extended-release ones can be crushed or mixed with food, water, or milk to minimize GI distress and for patients who have difficulty with swallowing. Capsules can be opened and emptied to allow mixing for the same reasons. Transdermal scopolamine is applied to the hairless area behind one ear at least 4 hours before the antiemetic effect is needed and may be left in place for up to 3 days. If therapy is required for longer than 3 days, the patch should be removed and a new patch placed behind the other ear.

Adverse Reactions

Single-dose or short-term use have relatively few adverse reactions. All are associated with drowsiness, dry mouth, dry eyes, constipation, and urinary retention. Phenothiazines turn the urine pink to reddish brown. Patients need to be told that this effect does not constitute hematuria.

Longer-term administration of phenothiazines is not recommended because of potentially serious adverse reactions. Patients should be told the indications of dystonia, akathisia, and tardive dyskinesia and to stop the drug and report these immediately.

Phenergan should not be administered with other respiratory depressants in children.

Dronabinol (Marinol) may cause euphoria and behavior changes. Patients should not drive until they know how they will respond to the medication.

Scopolamine may cause dry mouth and, less frequently, drowsiness. Patients should wash their hands with soap and water after handling transdermal scopolamine (Transderm Scop) patches to avoid getting medication in their eyes. Temporary blurring of vision and pupil dilation may occur if unwashed hands come in contact with the eyes.

Lifestyle Management

Nausea and vomiting are often self-limiting disorders. Before drug therapy begins, unless there is clear indication of fluid or electrolyte disturbances, nonpharmacological interventions can be tried. Resting the GI tract for a brief time (8 hours) by taking only clear liquids in small amounts is often helpful. Clear liquids are those that can be held up to light and seen through. For infants, ORS (discussed in the Antidiarrheals section) such as Pedialyte may be used instead of other clear liquids. Formula and milk should be withheld for these 8 hours. For breastfed babies, continue breastfeeding, but nurse on only one side at each feeding during the first 8 hours. Older children and adults can take any clear liquid and require ORS only if they appear dehydrated. Remember, this treatment does not mean as much clear liquid as the patient can hold. Start with small amounts and gradually increase the intake.

After 8 hours without vomiting, start with bland food such as saltine crackers, honey on white bread, bland soup, rice, or mashed potatoes. For babies, start with applesauce, strained bananas, and rice cereal. If the baby takes only formula, give 1 or 2 oz less than usual with each feeding. Breastfed babies can return to regular breastfeeding after 1 hour without vomiting. Most patients will be back on a regular diet within 24 hours.

EMETICS

Poisoning is a serious problem in the United States, despite extensive prevention programs. According to the American Association of Poison Control Centers, 2.3 million poisoning cases are documented each year (Bronstein, Spyker, Cantilena, Rumack, & Dart, 2012). In the past, vomiting to remove a poison was advised in some circumstances. However, problems occurred with use of emetics, so they are no longer recommended. Poisoning is now treated with antidotes or gastric lavage. For this reason, emetics are not discussed in this book.

HISTAMINE$_2$ RECEPTOR ANTAGONISTS

Histamine$_2$ blockers (also known as histamine$_2$ antagonists [H$_2$RAs]) inhibit acid secretion by gastric parietal cells through a reversible blockade of histamine at histamine$_2$ receptors. They are used to reduce gastric acid in patients who are temporarily not taking anything by mouth and for prophylaxis and management of duodenal and gastric ulcers and GERD. They are also used to treat heartburn, acid indigestion, and "sour stomach."

Pharmacodynamics

Gastric parietal cells have three receptors that can be stimulated to cause the parietal cell to produce H$^+$: acetylcholine, gastrin, and histamine$_2$. H$_2$RAs are reversible competitive blockers of histamine at histamine$_2$ receptors. They are highly selective, do not affect histamine$_1$ receptors, and are not anticholinergic agents. They are potent inhibitors of all phases of gastric acid secretion, including that caused by muscarinic agonists and gastrin. Fasting and nocturnal secretions and those stimulated by food, insulin, caffeine, pentagastrin, and betazole are all inhibited. Because they do not inhibit acetylcholine, they reduce gastric acid secretion by only 35% to 50%.

The volume and hydrogen ion concentration of gastric juice, gastric emptying, and the lower esophageal sphincter pressure are all affected to varying degrees by different drugs in this class. Cimetidine (Tagamet), ranitidine (Zantac), and famotidine (Pepcid) have no effect on gastric emptying. Cimetidine and famotidine have no effect on lower esophageal sphincter pressure. Ranitidine, nizatidine (Axid), and famotidine have little or no effect on fasting or postprandial serum gastrin. Ranitidine does not affect pepsin secretion or pentagastrin-stimulated intrinsic factor secretion.

Ranitidine is 5 to 12 times more potent and famotidine is 30 to 60 times more potent than cimetidine in controlling gastric acid secretion, but there is no clear evidence that greater potency has any clinical advantage. Treatment failures have occurred with each of these drugs, and it is doubtful that treatment failure with one drug in the class can be corrected by changing drugs within the class.

Pharmacokinetics

Absorption and Distribution

All drugs in the class are well absorbed following oral administration (Table 20-13). The absorption of cimetidine, famotidine, and ranitidine may be decreased by antacids but is unaffected by food. The absorption of nizatidine is decreased by 10% by aluminum and magnesium hydroxides. With food, AUC and maximum concentration of nizatidine increases by 10%. Cimetidine and ranitidine also have IM routes of absorption. All agents enter breast milk and cerebrospinal fluid.

Metabolism and Excretion

All agents are metabolized to differing degrees by the CYP450 enzyme system of the liver and excreted in differing percentages as unchanged drug in the urine. Nizatidine has at least one metabolite that has histamine-blocking activity. All others are metabolized to inactive compounds.

Table 20–13 Pharmacokinetics: Histamine$_2$ Blockers

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Metabolized	Elimination
Cimetidine	30 min	45–90 min	4–5 h	13%–25%	60%–70%	2 h	30%–40%	48% unchanged in urine
Famotidine	60 min	1–4 h	1–4 h	15%–20%	40%–45%	2.5–3.5 h	30%–35%	25%–30% unchanged in urine
Nizatidine	60 min	0.5–3 h	UK	35%	>90%	1–2 h	<18%	60% unchanged in urine, <6% in feces
Ranitidine	60 min	1–3 h	1–3 h	15%	50%–60%	2–3 h	<10%	30%–35% unchanged in urine

UK = unknown.

Pharmacotherapeutics

Precautions and Contraindications

Renal impairment requires cautious use of the H$_2$RAs and dosage adjustments. Patients with renal impairment are more subject to the CNS adverse reactions. Older adults may have reduced renal function, and these drugs should be used cautiously with this age group. Cimetidine seems to have the most problems with decreased renal clearance, and ranitidine the fewest.

Hepatocellular injury may occur with nizatidine, as evidenced by elevated liver enzymes (alanine transaminase [ALT], aspartate aminotransferase [AST], or alkaline phosphatase). These abnormalities are reversible with discontinuation of the drug. Because of this risk, it should not be used for patients with a history of liver disease.

Occasional reversible hepatitis or hepatocellular disorders have occurred with ranitidine. It is contraindicated for patients with a history of liver disease.

H$_2$RAs are Pregnancy Category B; however, there are no adequate and well-controlled studies of these agents in pregnant women. They should be used only when the potential benefits outweigh the potential risks to the fetus.

These drugs vary in their excretion in breast milk. Cimetidine is excreted in breast milk in milk:plasma ratios of 5:1 to 12:1. The potential daily dose to the infant is 6 mg; nursing should be avoided. Famotidine is excreted in the breast milk of rats. It is not known whether it is excreted in human breast milk. The decision to discontinue the drug is made based on the need of the mother for the drug. Nizatidine is excreted in breast milk in a concentration of 0.1% of the oral dose in proportion to plasma concentrations. Once again, the decision to discontinue the drug is made based on the need of the mother for the drug. Ranitidine is excreted in breast milk with milk:plasma ratios of 1:1 to 6.7:1. Exercise caution when giving to a nursing mother.

There has been extensive study of the H$_2$RAs in the past few years as a part of the Best Pharmaceuticals for Children Act. The safety and efficacy of ranitidine have been established in children aged 1 month to 16 years. Famotidine is labeled safe for infants and children as young as neonates, although children younger than 1 year have experienced agitation that stopped when famotidine was stopped (FDA, 2010).

Adverse Drug Reactions

All of these drugs have similar adverse reaction profiles. Cimetidine appears to have the greatest degree of antiandrogenic reactions (e.g., gynecomastia and impotence). Reversible CNS adverse reactions (e.g., mental confusion, agitation, psychosis, depression, and disorientation) have also occurred with this drug.

Hematological adverse reactions include agranulocytosis, granulocytopenia, thrombocytopenia, and aplastic anemia. These reactions are rare but should be monitored. Other less common adverse drug reactions include drowsiness, dizziness, constipation or diarrhea, and nausea. Adverse drug reactions related to liver function are discussed in the Precautions and Contraindications section.

Drug Interactions

Many of the drug interactions with this class of drugs are related to their metabolism by the CYPP450 enzyme system of the liver. Cimetidine is the most problematic because it uses several isoenzymes (CYP1A2, CYP2C9, and CYP2D6). Any drug metabolized extensively by these isoenzymes will have its metabolism inhibited by cimetidine, with a risk for increased plasma levels and toxicity for that drug. Famotidine, nizatidine, and ranitidine have less effect on the CYP system and use a narrower number of isoenzymes in their metabolism. Although they still have drug interactions, they are fewer than with cimetidine. Table 20-14 provides a list of drug interactions for the various histamine$_2$ blockers.

Clinical Use and Dosing

Gastroesophageal Reflux Disease

Histamine$_2$ receptor antagonists are available OTC and are a popular self-treatment for heartburn and GERD. They are most effective if used as on-demand therapy for relief of GERD symptoms (Hershcovici & Fass, 2011). Owing to development of tachyphylaxis, H$_2$RAs are not recommended for first-line continuous treatment of GERD, but a dose before bed may help patients on PPIs with nighttime reflux (Katz, Gerson, & Vela, 2013). If no esophageal erosive disease is present, H$_2$RAs may be used as maintenance therapy after PPI treatment (Katz et al, 2013). Once-daily dosing of H$_2$RAs is not effective in treating GERD.

Table 20–14 ⚏ **Drug Interactions: Histamine₂ Blockers**

Drug	Interacting Drug	Possible Effect	Implications
Cimetidine	Benzodiazepines, caffeine, calcium channel blockers, carbamazepine, labetalol, metoprolol, metronidazole, pentoxifylline, propafenone, propranolol, quinidine, qui-nine, sulfonylureas, tacrine, theophylline, triamterene, tricyclic antidepressants, valproic acid, warfarin*	Decreased hepatic metabolism of these drugs	Select different histamine₂ blocker Monitor drug levels of those with narrow therapeutic range or potential for cardiac rhythm disturbances
	Ferrous salts, indomethacin, ketoconazole, tetracyclines	Action of these drugs decreased because of decreased absorption	Avoid concurrent administration; separate doses or select different histamine₂ blocker
	Digoxin	Decreased serum digoxin concentra-tions during coadministration	Select different histamine₂ blocker
	Flecainide	Increased drug effects of flecainide	Select different histamine₂ blocker
	Narcotic analgesics	Toxic effects (e.g., respiratory depression) may be increased	Select different histamine₂ blocker
	Procainamide	Increased plasma levels of pro-cainamide and its cardioactive metabolite by decreasing renal tubular secretion	Select different histamine₂ blocker; raniti-dine was shown to have similar action in only one study, so best not to choose that drug
	Tocainide	Decreased drug effects of tocainide	Select different histamine₂ blocker
	Cigarette smoking	Smoking reverses cimetidine-induced inhibition of nocturnal gastric secretion, hindering ulcer healing	Avoid cigarette smoking
Famotidine	Ketoconazole	Action of drug decreased by reduced absorption	Separate administration by at least 1 h and give ketoconazole first
	Food	May increase bioavailability of famotidine	No clinical significance
Nizatidine	Salicylates	Increased serum salicylate levels when given to patients receiving high doses (3.9 g/d) of salicylate	Monitor salicylate levels or select different histamine₂ blocker
	Food	May increase bioavailability of nizatidine	No clinical significance
Ranitidine	Diazepam	Decreased drug effects of diazepam due to decreased drug absorption	Separate doses by at least 1 h and give diazepam first
	Sulfonylureas	Increased hypoglycemic effects of glipizide or glyburide	Dosage adjustments may be needed
	Warfarin	May interfere with warfarin clearance; data conflicting	Monitor PT/INR more closely; may need dosage adjustment
All histamine₂ blockers	Alcohol	May increase blood alcohol levels	Avoid use of alcohol
	Antacids, anticholinergics, metoclopramide	May decrease absorption of cimetidine, ranitidine; less effect on nizatidine and famotidine	Separate dose by at least 1 h for cimetidine and ranitidine; no special precautions needed for nizatidine and famotidine

INR = international normalized ratio; PT = prothrombin time.

*Although interactions with these drugs are not listed for other histamine₂ blockers, some effect is probable, even though it is not to the same extent.

Infants and children with GERD have also been successfully treated with histamine$_2$ blockers for several years with good response and few adverse reactions. The international consensus on the diagnosis and management of gastroesophageal reflux (GER) and GERD reached by the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) and European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) no longer recommends empiric treatment with H$_2$RAs in infants (Vandenplas et al, 2009). Dosing of histamine$_2$ blockers for infants and children is shown in Table 20-15. Once again, twice-daily dosing is required.

Table 20–15 ⊗ **Dosage Schedule: Histamine$_2$ Blockers**

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
Cimetidine Tagamet Tagamet HB 200	Short-term treatment of active duodenal ulcer	Tablets: 200, 300, 400, 800 mg Liquid: 300 mg/5 mL Injection: 300 mg/2 mL	*Adults:* 800 mg at bedtime or 300 mg qid with meals and at bedtime or 400 mg bid *Infants:* 10–20 mg/kg/d divided q 6 to 12 h *Children:* 20–40 mg/kg/d in 4 divided doses	*Adults:* 400 mg at bedtime; dosage not to exceed 2.4 g/d. In severe renal impairment, use 300 mg every 8–12 h. *Children:* 20 mg/kg/d; 10–15 mg/kg/d in renal impairment
	Duodenal ulcer prophylaxis		*Adults:* 800 mg at bedtime	Same
	Treatment of active benign gastric ulcer		*Adults:* 800 mg at bedtime or 300 mg qid with meals and at bedtime	800 mg at bedtime. In severe renal impairment, use 300 mg every 8–12 h. No information concerning usefulness of treatment periods >8 wk.
	GERD		*Adults:* 800 mg bid in morning and at bedtime or 400 mg qid with meals and at bedtime *Children:* 20–40 mg/kg/d in 4 divided doses	*Adults:* Same dose for up to 12 wk. Use >12 wk has not been established. May go as high as 600 mg qid if needed. In severe renal impairment, use 300 mg every 8–12 h.
	Pathological hypersecretory conditions		*Adults:* 300 mg to 600 mg qid with meals and at bedtime	*Children:* 20 mg/kg/d; 10–15 mg/kg/d if renal impairment Individualize dose. Do not exceed 2,400 mg/d. Continue as long as clinically indicated.
	Heartburn, indigestion, sour stomach		*Adults:* 200 mg (OTC) 30 min before a meal. Max 2 tablets/24 h.	Take up to 400 mg bid. Do not take maximum dose for more than 2 wk without consulting health-care provider.
Famotidine Pepcid Generic	Short-term treatment of active duodenal ulcer	Tablets: 10, 20, 40 mg Powder for oral suspension: 40 mg/5 mL when reconstituted Injection: 10 mg/mL	*Adults:* 40 mg/d at bedtime or ≤20 mg bid (in morning and at bedtime) *Children:* 1–2 mg/kg/d in 1 or 2 divided doses	*Adults:* 20 mg at bedtime for up to 8 wk. Most heal in 4 wk. If CCr <10 mL/min, give 20 mg at bedtime or increase dosing interval to 36–48 h. *Children:* Same dose for up to 8 wk. Most heal in 4 wk.
	Duodenal ulcer prophylaxis		*Adults:* 20 mg at bedtime	Same

Table 20–15 ⊗ Dosage Schedule: Histamine₂ Blockers—cont'd

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
	Treatment of benign active gastric ulcer		*Adults:* 40 mg at bedtime	Same dose. If CCr <10 mL/min, give 20 mg at bedtime or increase dosing interval to 36–48 h. No data to support treatment beyond 8 wk.
	GERD		*Adults:* 20 mg bid (in morning and at bedtime)	*Adults:* 20 mg for up to 6 wk. If erosive disease, 20–40 mg bid for up to 12 wk.
			Children: 1–2 mg/kg/d in 1 or 2 divided doses	*Children:* Same dose. Treatment trial for 2–4 wk.
Pepcid Complete	Heartburn, acid indigestion, and sour stomach	Chewable tablet: Famotidine 10 mg, calcium carbonate 800 mg, magnesium hydroxide 165 mg	*Adults:* Relief: 10 mg (1 tablet) with water Prophylaxis: 10 mg 1 h prior to meal that is expected to cause symptoms *Adults and children >12 yr:* Chew and swallow 1 tablet prn; do not exceed 2 tablets in 24 h.	Can be used up to bid for <2 wk
Nizatidine Axid	Short-term treatment of active duodenal ulcer	Capsule: 150, 300 mg Solution: 15 mg/ mL	*Adults:* 300 mg at bedtime or 150 mg bid (in morning and at bedtime) *Infants 6 mo to Children 11 yr:* 5–10 mg/kg/d divided bid	300 mg at bedtime. If CCr 20–50 mL/min, give 150 mg at bedtime. If CCr <20 mL/min, give 150 mg every 2 or 3 d.
	Maintenance of healed duodenal ulcer		*Adults:* 150 mg at bedtime	150 mg at bedtime
	GERD		*Adults and children >12 yr:* 150 mg bid (in morning and at bedtime)	150 mg bid
Ranitidine Zantac Generic	Short-term treatment of active duodenal ulcer	Tablets: 75, 150, 300 mg Effervescent tablets: 150 mg Geldose: capsules: 150 mg Syrup: 15 mg/mL Efferdose: granules: 150 mg	*Adults:* 100–150 mg bid (in morning and at bedtime) or 300 mg at bedtime *Infants and children <16 yr:* 4–8 mg/kg/day, max 300 mg/day	150 mg at bedtime. If CCr <50 mL/min, give 150 mg at bedtime.
	Duodenal ulcer prophylaxis		*Adults:* 150 mg at bedtime	150 mg at bedtime
	Treatment of benign active gastric ulcer		*Adults:* 150 mg bid (in morning and at bedtime)	150 mg at bedtime
	GERD		*Adults:* 150 mg bid (in morning and at bedtime); if erosive disease, give 150 mg qid *Infants and children < 6 yr:* 4–10 mg/kg/d, max 300 mg/d	*Adults:* 150 mg bid. If CCr <50 mL/min, give 150 mg at bedtime. If erosive disease, give 150 mg bid.
	Pathologic hypersecretory conditions Heartburn, acid indigestion, and sour stomach		*Children:* 2–4 mg/kg/d in 2 divided doses *Adults:* 150 mg bid (in morning and at bedtime) *Adults:* Relief: 75 mg up to bid	*Children:* 2 mg/kg/d in 2 divided doses Individualize dose; doses up to 6 g/d have been used Can be used up to bid for <2 wk

GERD = gastroesophageal reflux disease.
   For all children <12 years of age, consultation with pediatric specialist is advised.

A more detailed discussion of the management of GERD is found in Chapter 35.

Peptic Ulcer Disease

With the advent of the discovery that the cause of PUD is usually an infection rather than excessive acid due to stress, diet, smoking, alcohol consumption, and NSAIDs, the treatment pattern has changed. Most patients will have tried an OTC H_2RA before they present with peptic ulcer symptoms. There is no treatment protocol that includes histamine$_2$ blockers when eradication of *H. pylori* as the source of the ulcer is required. Continued acid suppression may be accomplished with H_2RAs after the peptic ulcer has healed. A more detailed discussion of the management of PUD is found in Chapter 35.

Heartburn, Acid Indigestion, and "Sour Stomach"

Relief of symptoms may be provided by OTC use of H_2RAs. However, it is important for patients to be informed about the potential for drug interactions.

All Uses

Regardless of the reason for which the H_2RA is prescribed, consideration of renal function is important in determining dosage. In the presence of renal impairment, dosage intervals need to be increased. For cimetidine, the interval is increased if the renal impairment is severe; for famotidine, it is increased if creatinine clearance (CCr) is less than 10 mL/min; and for nizatidine and ranitidine, if CCr is less than 50 mL/min.

Rational Drug Selection

No specific H_2RA is preferred over another for effectiveness. Choice is based on cost and whether the patient is taking other drugs that might have interactions with the specific H_2RA.

Cost

Generic formulations are always less expensive than brand names. OTC drugs are usually less expensive than prescriptions, but because their dose is lower, the cost difference is lost in the increased number of pills required.

Other Drugs

Cimetidine has the most drug interaction potential. Other histamine$_2$ blockers have fewer listed drug interactions.

Monitoring

Because of the potential for hepatocellular damage, patients who require higher doses or more than short-term use of this class of drugs should have laboratory testing of liver function prior to initiation of therapy and at regular intervals throughout therapy.

Renal impairment influences drug dosing for all drugs in this class. Patients who require higher doses or more than short-term therapy or for whom renal impairment is a likely risk (e.g., older adults) should have renal function assessment done prior to initiation of therapy.

Patient Education

Administration

Instruct patients to take the drug as prescribed for the full course of therapy, even if they are feeling better. If a dose is missed, it should be taken as soon as remembered but not if it is almost time for the next dose. They should not double doses.

H_2RA should be taken with meals or immediately afterward and at bedtime to achieve the best effects. Doses taken once daily are best taken at bedtime. Oral suspensions are shaken prior to administration, and unused portions are discarded after 30 days. The foil is removed from ranitidine effervescent tablets or granules, and they are dissolved in 6 to 8 oz of water before they are taken. The available dosage forms of H_2RAs are found in Table 20-15.

If the patient is also taking antacids or other drugs whose interaction with H_2RA produces interference with absorption, the drugs' administration should be separated by at least 30 minutes to 1 hour. Sucralfate should be taken 2 hours after the H_2RA.

Patients taking OTC preparations are not to take the maximum doses continuously for more than 2 weeks without consulting their health-care provider. A diagnostic work-up is in order under these circumstances.

Adverse Reactions

H_2RA may cause drowsiness or dizziness. Caution patients to avoid driving or other activities requiring alertness until their response to the drug is known.

For male patients taking cimetidine, warn about the potential for gynecomastia and impotence. Because other drugs in the class are less likely to cause these problems, a different drug may be selected.

Advise patients to report the onset of black, tarry stools. They are not adverse reactions to the drug but may indicate GI bleeding. Sore throat, diarrhea, rash, confusion, or hallucinations should also be reported promptly. These adverse reactions may require dosage alteration or discontinuation of the drug. Increasing the fluid and fiber in the diet may minimize constipation.

Lifestyle Management

Smoking interferes with the absorption of H_2RA and increases gastric acid secretion. Advise the patient to stop smoking. Alcohol and products containing aspirin or NSAIDs and some foods may also increase gastric acid secretion; they should be avoided. Other lifestyle modifications are discussed in Chapter 35.

PROKINETICS

Prokinetic drugs, also known as gastrointestinal stimulants, stimulate the motility of the GI tract without stimulating gastric, biliary, or pancreatic secretions. These drugs are used in the management of a wide range of disorders in which reduced GI motility is a problem, including gastroparesis associated with diabetes mellitus, GERD, and emesis associated

with cancer chemotherapy. Only one drug, metoclopramide (Reglan, Metalov ODT), remains in this class since the removal of cisapride (Propulsid) from the market in 2004; metoclopramide will be discussed in this section.

Pharmacodynamics

Metoclopramide stimulates motility in the upper GI tract. Its mode of action is unclear but appears to be related to sensitizing tissues to the action of acetylcholine. The action does not depend on an intact vagal innervation system, but anticholinergic drugs can reverse the action. This drug increases the tone and amplitude of gastric contractions, relaxes the pyloric sphincter and duodenal bulb, and increases peristalsis of the duodenum and jejunum, resulting in accelerated gastric emptying and increased speed of gastric transit. It has almost no effect on the colon or gallbladder, nor does it stimulate gastric, biliary, or pancreatic secretions. For patients with GERD secondary to decreased lower esophageal sphincter pressure (LESP), metoclopramide produces dose-related increases in LESP. These effects begin at doses as low as 5 mg and continue through 20 mg doses.

Metoclopramide is a dopamine receptor antagonist in the CNS, including the chemoreceptor trigger zone leading to prevention of emesis (Taketomo et al, 2012). Metoclopramide has actions similar to the phenothiazines and other dopamine antagonists and produces sedation and may cause tardive dyskinesia or EPS. It also induces release of prolactin and transiently increases circulating aldosterone levels.

Pharmacokinetics

Absorption and Distribution

Metoclopramide is well absorbed after oral administration (Table 20-16) and has an injectable formulation. It has low protein binding and high bioavailability.

Metoclopramide is widely distributed throughout body tissues, crosses the blood–brain barrier and the placenta, and enters breast milk in concentrations greater than in plasma.

Metabolism and Excretion

Metoclopramide is partially metabolized by the liver. Because it is excreted in urine, clearance is affected by renal function. In patients whose creatinine clearance is less than 40 mL/min, the recommended dose is cut in half.

Pharmacotherapeutics

Precautions and Contraindications

Metoclopramide has a Black-Box Warning because of the risk of developing tardive dyskinesia. The risk for tardive dyskinesia increases with the length of treatment. Metoclopramide should be discontinued if patients develop signs of movement disorder. Treatment should not exceed 12 weeks, except in rare cases.

Metoclopramide is contraindicated in the presence of disorders in which stimulation of GI motility might be dangerous (GI hemorrhage, mechanical obstruction, new surgery on the GI tract, or perforation). Its dopamine-associated activity affects the CNS, and the drug is used cautiously with patients who have a history of depression. Depression with symptoms ranging from mild to severe, including suicide ideation, have been reported. Caution for patients who are at risk for EPS is also required. Metoclopramide is contraindicated in patients with known hypersensitivity to the drug and patients with pheochromocytoma, because the drug may cause a hypertensive crisis. Because metoclopramide is excreted primarily through the kidneys, it should be used with caution for patients with renal impairment. Dosage adjustments are mentioned above. It undergoes minimal hepatic metabolism and is safe to administer to patients with impaired hepatic function as long as their renal function is normal.

Metoclopramide is Pregnancy Category B; however, there are no adequate and well-controlled studies in pregnant women. Case reports to date have not been associated with fetal harm, but the drug should be prescribed only when the benefits clearly outweigh the risks to the fetus.

Metoclopramide is excreted in breast milk and concentrates at about twice the plasma level at 2 hours after taking the dose. However, in a mother taking 30 mg/day, the infant would receive less than 45 mg/day, which is still much less than the recommended maximum dose for infants. Exercise caution when giving to a nursing mother, but recognize that there appears to be little, if any, risk to the infant.

The safety and effectiveness of metoclopramide have not been established in infants and children. Caution should be used in neonates due to decreased clearance of metoclopramide and are more susceptible to methemoglobinemia. Movement disorders and EPS are more frequent in children than in adults taking metoclopramide.

Adverse Drug Reactions

The most serious adverse reaction are EPS, including acute dystonic reactions and the development of tardive dyskinesia

Table 20–16 Pharmacokinetics: Prokinetic Agents

	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Metoclopramide	30–60 m	1–2 h	1–2 h	30%	65%–95%	2.5–5 h	85% in urine after
PO IM	10–15 m	1–2 h	1–2 h	30%	65%–95%	2.5–5 h	72 h (25% as unchanged drug); clearance affected by renal function

and parkinsonian-like symptoms. Children and young adults more frequently develop EPS with metoclopromide use. Metoclopromide should be discontinued in any patient exhibiting movement disorders. There have been rare reports of neuroleptic malignant syndrome in patients taking metoclopramide. Other adverse reactions associated with metoclopramide include depression, dizziness, diarrhea, and hypoglycemia in patients with diabetes. Less common adverse reactions include galactorrhea, amenorrhea, gynecomastia, impotence secondary to hyperprolactinemia, and fluid retention secondary to transient elevations in aldosterone. Approximately 20% to 30% of all patients taking this drug experience some adverse reaction. The incidence correlates with the dose and duration of therapy.

Drug Interactions

Drug interactions with metoclopramide are largely related to its cholinergic and dopaminergic activities. Additive CNS depression occurs with other CNS depressants, and increased risk of EPS occurs with other drugs that have the potential for EPS. Drugs with anticholinergic effects reverse the action of metoclopramide, and the reverse is also true. There is a potential for hypertensive crisis if administered with MAOIs. Table 20-17 provides a more detailed list of these drug interactions.

Clinical Use and Dosing

Gastroesophageal Reflux Disease

The principal effect of metoclopramide in the management of GERD is on symptoms of postprandial and daytime heartburn. For adults, if symptoms occur throughout the day, a dose of 10 mg taken 30 minutes prior to each meal and at bedtime is recommended (Table 20-18). When symptoms are confined to specific situations, such as after the evening meal, a single 10 to 20 mg dose 30 minutes prior to that meal or at bedtime is effective in preventing the symptoms.

Occasionally, patients who are more sensitive to the therapeutic dose (e.g., older adults) require only 5 mg per dose. Neonatal dosing of metoclopramide (oral or IV) for GERD is 0.1 to 0.15 mg/kg/dose every 6 hours; avoid doses greater than 0.15 mg/kg/dose. Metoclopramide doses for gastroesophageal reflux in infants and children are 0.4 to 0.8 mg/kg/day divided in four doses (30 minutes prior to each meal). For patients whose CCr is less than 40 mL/min, doses are reduced (see above).

Nausea and Vomiting

Metoclopramide's action in the chemoreceptor trigger zone prevents nausea and vomiting. Post-operative nausea and vomiting in children 14 years of age or younger may be treated with 0.1 to 0.2 mg/kg IV metoclopramide with a maximum dose of 10 mg. Adults and children older than age 14 years are dosed at 10 mg every 6 to 8 hours to treat post-operative nausea and vomiting. Chemotherapy-induced emesis in adults and children is treated with 1 to 2 mg/kg/dose every 2 to 4 hours, with a maximum of 5 doses per day. If higher doses are used, such as with chemotherapy, the patient should be pretreated with diphenhydramine to prevent EPS (Taketomo et al, 2012).

Diabetic Gastroparesis

Metoclopramide has an indication for treatment of diabetic gastroparesis. Dosage is 10 mg 30 minutes before meals and

Table 20–17 ⠿ Drug Interactions: Prokinetic Agents

Drug	Interacting Drug	Possible Effect	Implications
Metoclopramide	Alcohol, antidepressants, antihistamines, opioids, and sedative hypnotics	Additive CNS depression; increases rate of absorption of alcohol	Avoid concurrent use or warn of potential CNS depression
	Haloperidol, phenothiazines, other drugs with EPS effects	Increased risk of extrapyramidal reactions	Avoid concurrent use; select different prokinetic
	Anticholinergics and opioids	Effects of metoclopramide on GL motility may antagonize these drugs	If not used therapeutically, avoid concurrent use
	Cimetidine	Reduced bioavailability of cimetidine	Select different histamine$_2$ blocker
	Digoxin	Decreased absorption, plasma levels, and therapeutic effects	Capsules, elixir, and tablets with high dissolution rate are least affected; use these formulations if both drugs must be given
	Levodopa	These drugs have opposite effects on dopamine receptors: bioavailability of levodopa increased; effects of metoclopramide decreased	Avoid concurrent use; metoclopramide is relatively contraindicated for patients with Parkinson's disease
	Monoamine oxidase inhibitors (MAOIs)	Metoclopramide releases catecholamines that may produce hypertension in patients taking MAOIs	Use cautiously concurrently, if at all; monitor blood pressure closely

Drug	Indication	Available Dosage	Dosage Schedule	Notes
Metoclopramide Reglan Generic	GERD	Tablets: 5 mg Tablets: 10 mg Syrup: 5 mg/5 mL Injection: 5 mg/mL	*Adults:* Treatment: 10–15 mg qid (30 min before meals and at bedtime) Prophylaxis: 20 mg at bedtime *Children:* 0.4–0.8 mg/kg/d in 4 divided doses (30 min before meals and at bedtime)	Some patients respond to doses as low as 5 mg. Dose not to exceed 0.5 mg/kg/d. Therapy not to exceed 8 wk. Patients with CCr <40 mL/min, initiate therapy with half the recommended dose.
	Diabetic gastroparesis		*Adults:* 10 mg qid (30 min before meals and at bedtime)	

GERD = gastroesophageal reflux disease.

at bedtime for 2 to 8 weeks. The route of administration is based on the severity of symptoms. If only the earliest manifestation of gastroparesis is present, oral administration is adequate. If the symptoms are more severe, parenteral therapy with 10 mg IV over 1 to 2 minutes for up to 10 days may be needed before oral therapy can be initiated. Rectal formulations can be made by a pharmacist to avoid the IV route. The suppositories each contain 25 mg of metoclopramide in polyethylene glycol. One suppository is administered 30 to 60 minutes before each meal and at bedtime. After symptoms are resolved (no more than 8 weeks of therapy), the drug is stopped and reinstituted at the earliest indications of symptom return.

Diabetics often experience renal impairment. Because metoclopramide is excreted principally by the kidney, those patients with CCr below 40 mL/min should have their therapy initiated at approximately half the recommended dosage. Depending on clinical efficacy and safety considerations, the dosage may be increased or decreased as appropriate.

Rational Drug Selection

Efficacy

Metoclopramide has demonstrated limited symptomatic improvement and endoscopically demonstrated esophageal healing for patients with GERD. Given its significantly higher cost and increased adverse effects, it is difficult to justify its use in place of H$_2$RAs or PPIs.

Length of Therapy

Metoclopramide is not used for management of GERD if treatment must be long-term. With longer than 8 weeks of therapy, there is a much higher risk for adverse reactions, including EPS.

Concomitant Diseases

Metoclopramide should be used cautiously for patients with diseases that place them at risk for EPS disorders or for patients taking drugs that place them at risk for these

disorders. Other considerations based on concomitant disorders are discussed in the Precautions and Contraindications section.

Monitoring

Because of the need to adjust dosage in the presence of renal impairment, renal function should be assessed before therapy with metoclopramide is begun. Patients should be educated about and monitored for movement disorders or EPS. No other monitoring is required except that for the disease process being treated.

Patient Education

Administration

Advise the patient to take the drug exactly as prescribed (see Table 20-18). Metoclopramide is taken 30 minutes before each meal and at bedtime. If a dose is missed, it should be taken as soon as the patient remembers unless it is almost time for the next dose. Patients should not double doses or exceed the recommended dose.

Adverse Reactions

Metoclopramide may cause drowsiness. Caution patients to avoid driving or other activities that require alertness until their response to the drug is known. Concurrent use of other CNS depressants, including alcohol, makes this problem worse and causes additive CNS depression.

Warn patients taking metoclopramide to notify their health-care provider immediately if involuntary movement of the eyes, face, or limbs occurs, which may be EPS-related. Depression may occur, and any change in mood should be reported to their providers.

Lifestyle Management

Lifestyle modifications are tried before any drug in the management of both GERD and diabetic gastroparesis. First, patients should try to avoid alcohol, NSAIDs, large meals, fatty foods, chocolate, caffeine, citrus, and food or fluid intake within 3 hours of going to bed at night. They should also

attempt smoking cessation, weight loss, and sleeping with the head of the bed elevated. These modifications are discussed in more detail in Chapter 35.

PROTON PUMP INHIBITORS

PPIs are antisecretory drugs used to treat gastric conditions characterized by hyperacidity. They are used for erosive gastritis, GERD, and Zollinger–Ellison syndrome and as part of a multidrug regimen for short-term treatment of active PUD, especially duodenal ulcers caused by *H. pylori.*

Pharmacodynamics

PPIs do not exhibit anticholinergic or histamine $_2$-blockade properties but suppress gastric acid secretion These drugs reduce H^+ secretion by inhibition of the $H^+/K^+/ATPase$ enzyme system at the secretory surface of the parietal cell itself to block the final step in H^+ secretion. The effect is dose-related and inhibits basal and stimulated acid secretion regardless of the stimulus. They reduce gastric acid by more than 90% and frequently produce achlorhydria. Serum gastrin levels increase parallel with inhibition of the acid secretion. The decrease in acid secretion lasts for up to 72 hours after each dose. Gastric acid secretion begins within 3 to 5 days after the drug is discontinued and returns to pretreatment levels within 1 to 2 weeks with omeprazole (Prilosec), 4 weeks with esomeprazole (Nexium) and lansoprazole (Prevacid), or 3 months with pantoprazole (Protonix).

   Normal physiological effects related to suppression of gastric acid secretion result in decreased blood flow to the antrum, pylorus, and duodenal bulb. Increased serum pepsinogen levels and decreased pepsin activity also occur. As with other drugs that increase gastric pH, related increases in nitrate-reducing bacteria and elevation of nitrate concentration in gastric juice occur in patients with gastric ulcer. Compensatory increases in serum gastrin levels develop initially, but no further increase occurs with continued treatment, and there are no apparent ill effects from this increase.

Pharmacokinetics

Absorption and Distribution

All of the PPIs are acid labile and so most are formulated as enteric-coated tablets or granules (Table 20-19). Absorption is rapid and begins after the granules leave the stomach and reach the less acidic duodenum. Peak plasma concentrations are approximately proportional, but because of a saturable first-pass effect, omeprazole has a greater-than-linear response when given in doses above 40 mg. Esomeprazole peak increases proportionally when the dose is increased, and there is a three-fold increase in the AUC from 20 to 40 mg. The AUC is decreased by 43% to 53% after food intake compared to fasting conditions for this drug. Esomeprazole should be taken at least 1 hour before meals.

   The peak and AUC of lansoprazole are diminished by 50% to 70% if the drug is given after food as opposed to the fasting state. It should be given on an empty stomach. When pantoprazole is given with food, absorption may be delayed by 2 hours or longer. Taking rabeprazole (Aciphex) with a

On The Horizon   ILAPRAZOLE

Ilaprazole is a proton pump inhibitor developed by Il-Yang Pharmaceutical (Korea) and is approved for use in Korea and China. It has completed phase II trials in the United States.

Table 20–19 ⊞ **Pharmacokinetics: Proton Pump Inhibitors**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Esomeprazole	UK	1.5 h	UK	97%	64% (single dose); 90% (multiple doses)	1–1.5 h	80% in urine as metabolite; <1% unchanged drug
Lansoprazole	1 h	1.7 h	>24 h	97%	>80%	1.5 h; increases to 3.2–7.2 h in hepatic impairment	33% in urine; remainder in feces
Omeprazole	1 h	0.5–3.5 h	>72 h	95%	30%–40%; increases to 100% in hepatic impairment	30–60 min; increases to 3 h in hepatic impairment	77% in urine; remainder in feces
Pantoprazole	UK	2.5 h	>24 h	98%	77%	1 h	71% in urine as metabolite; 18% in feces
Rabeprazole	<1 h	2–5 h	UK	96.3%	52%	1–2 h	90% in urine as metabolites; 10% in feces
Dexlansoprazole		4–5 h		96.1%		1–2 h	50.7% is excreted in the urine and 47.6% in the feces

high-fat meal may delay its absorption by up to 4 hours. In each case, the peak and AUC are not altered.

All drugs are distributed to the parietal cells of the stomach. They all cross the placenta. Omeprazole has been measured in human breast milk; the other PPIs have been found in breast milk in animal studies.

Metabolism and Excretion

These drugs are extensively metabolized by CYP450 2C19 and CYP450 3A4, and several metabolites have been identified that appear to have little or no antisecretory activity. Omeprazole is metabolized by the CYP450 system and may interact with other drugs also metabolized by this system. Lansoprazole and dexlansoprazole are metabolized by the CYP450 3A4 and CYP450 2C19 isoenzyme systems; however, they do not have clinically significant drug interactions related to this metabolic site.

In patients with varying degrees of hepatic disease, the mean plasma half-life of each of these drugs increases from a low of 3 hours with omeprazole to a high of 9 hours for pantoprazole. The plasma elimination half-life of these drugs does not reflect the duration of suppression of gastric acid secretion, apparently because of prolonged binding to the parietal $H^+/K^+/ATPase$ enzyme.

Little unchanged drug is excreted in the urine, but 33% to 90% of the metabolites is excreted in the urine. The rest is excreted in feces. A significant biliary excretion route is implied, especially for omeprazole and lansoprazole. Older adults have somewhat decreased elimination rates of all of these drugs, perhaps related to the decreased renal function associated with aging.

Pharmacotherapeutics

Precautions and Contraindications

The only true contraindication to the PPIs are hypersensitivity to the ingredients. The PPIs are extensively metabolized in the liver; therefore, they should be used cautiously in patients with hepatic dysfunction and in the elderly. No dosage adjustments are recommended for these patients, however.

Omeprazole is Pregnancy Category C. Multiple studies have followed women exposed to omeprazole during pregnancy and found no increase in congenital malformations, perinatal mortality, or morbidity (Arnon et al, 2003; Matok et al, 2012). Guidelines for treatment of GERD state, "PPIs are safe in pregnant patients if clinically indicated" (Katz et al, 2013). Lansoprazole, esomeprazole, pantoprazole, and rabeprazole are Pregnancy Category B, but there have been no adequate and well-controlled studies in pregnant women for these drugs, either. Use in pregnancy only if the potential benefits outweigh the potential risks to the fetus.

Omeprazole is excreted in low levels in human breast milk and the other drugs in this class have been found in breast milk in animal studies. Omeprazole (20 mg/day), esomeprazole (20 mg/day), or pantoprazole (40 mg/day) do not cause any adverse effects in breastfed infants (LactMed, 2013).

There is little information on the use of lansoprazole, dexlansoprazole, or rabeprazole during lactation (LactMed, 2013). The decision to discontinue the drug or discontinue nursing should take into account the importance of the drug to the mother.

The safety and efficacy of pantoprazole and rabeprazole have not been established in children younger than age 12 years. Esomeprazole, omeprazole, and lansoprazole have been found safe and efficacious for short-term treatment of GERD and erosive esophagitis in pediatric patients and are FDA-approved for use in children as young as 1 year of age. There have been no large-scale long-term safety studies of PPI use in growing children, but there is a concern for increased respiratory and gastrointestinal infections found in a few small studies (Tjon, Pe, Soscia, & Mahant, 2013).

Adverse Drug Reactions

These drugs are generally well tolerated when used for short-term treatment, and the adverse reactions that did occur in more than 1% of patients in clinical trials included dizziness, drowsiness, abdominal pain, constipation, diarrhea, and flatulence. It is difficult to determine if the GI-related symptoms were associated with the disease or the drug.

PPIs have now been on the market long enough to have a large body of long-term safety data. In an extensive review of the literature to determine the long-term safety of PPIs, Ali, Roberts, and Tierney (2009) suggest the combined body of knowledge raises concerns. There is evidence for significant nutrient deficiencies in patients taking PPIs long-term. Iron, vitamin B_{12}, and calcium all need an acid environment for optimal absorption. The PPIs are so effective in reducing acid production that patients are at risk for iron deficiency anemia, vitamin B_{12} deficiency, and calcium deficiency (Ali et al, 2009; Lodato et al, 2010). Patients on long-term PPIs may be at risk for osteoporosis and increased hip fractures, especially when combined with other risk factors for fracture such as age and female gender (Ali et al, 2009; Corley, Kubo, Zhao, & Quesenberry, 2010; Lodato et al, 2010; Thomson, Sauve, Kassam, & Kamitakahara, 2010).

Stomach acid provides a natural defense against microbial pathogens. Patients on long-term PPI therapy have an increased risk of *Clostridium difficile*, salmonella, and camphylobacter infections (Ali et al, 2009). Short-term use of PPIs increases the risk of pneumonia (Katz et al, 2013).

There are cellular level changes that occur with long-term PPI therapy, including hyperplasia of enterochromaffin-like cells, leading to a concern about the development of gastric cancers (Ali et al, 2009; Lodato et al, 2010; Vandenplas et al, 2009). Atrophic gastritis has been noted in patients taking omeprazole long-term, and chronic atrophic gastritis is a risk factor for developing gastric carcinoid tumors (Lodato et al, 2010). In spite of these cellular changes, at this time there is not strong evidence for the development of gastric cancers from long-term PPI use (Lodato et al, 2010; Thomson et al, 2010; Brunner, Athmann, & Schneider, 2012).

Drug Interactions

Drug interactions with PPIs relate to their use of the CYP450 enzyme system for metabolism and the change in bioavailability of concurrently administered drugs requiring an acid environment for absorption. PPIs may decrease the effects of atazanavir, indinavir, and nelfinavir, and coadministration is not recommended. All PPIs may interfere with absorption of drugs given orally that depend on an acidic gastric pH to be effective. These drugs include ketoconazole, esters of ampicillin, digoxin, and iron salts. Increased monitoring of INR is required if warfarin is administered with PPIs.

Clopidogrel (Plavix) has a Black-Box Warning regarding poor metabolizers of CYP2C19 and concurrent administration of medications that interfere with CYP2C19. Coadministration of clopidogrel and omeprazole has been shown to decrease the active metabolite of clopidogrel by 46%, leading to decreased effectiveness. Clinically, a decrease in the antiplatelet effect of clopidogrel may lead to increased clot formation. The FDA issued a warning in November 2009 to avoid concurrent use of PPIs and clopidogrel, followed by a labeling update for clopidogrel in December 2011 that recommends avoiding concomitant use with the PPIs omeprazole or esomeprazole due to reduced antiplatelet activity of clopidogrel caused by impaired CYP2C19 function (FDA, 2012). The American College of Gastroenterology GERD guidelines continue to recommend using PPIs with clopidogrel due to lack of clinical data to support that concomitant use increases cardiovascular events (Katz et al, 2013). Given the conflicting expert opinion, choose a PPI with less CYP2C19 activity (dexlansoprazole, lansoprazole, and pantoprazole) and monitor patients carefully who are taking clopidrogrel with any PPI. These and other interactions are shown in Table 20-19.

Clinical Use and Dosing

Duodenal and Gastric Ulcers

Treatment for patients with uncomplicated gastric ulcers includes testing and treating for *H. pylori* and acid-suppressive therapy with PPIs. Lansoprazole, omeprazole, esomeprazole, and rabeprazole are used for treatment of active duodenal ulcer and active benign gastric ulcer. The once-daily dose is taken before a meal, preferably in the morning (Table 20-20). Treatment is for 12 weeks.

Table 20–20 ⊞ **Drug Interactions: Proton Pump Inhibitors**

Drug	Interacting Drug	Possible Effect	Implications
Esomeprazole	Benzodiazepines	Oxidative metabolism of BDZ decreased Reduced clearance and increased half-life	Reduce dose of BDZ or increase dose interval
	Clarithromycin	Increased concentrations of both drugs	No action required
Lansoprazole	Theophylline	10% increase in theophylline clearance	Additional titration of theophylline dosage may be required
Omeprazole	Clarithromycin	Coadministration may result in increased plasma levels of both drugs	This combination is among the FDA-approved treatment options for *H.pylori* eradication
	Benzodiazepines, phenytoin	103% increase in diazepam half-life; 15% reduced clearance of phenytoin	Use lansoprazole or select a treatment regimen that does not require a proton pump inhibitor if the interacting drugs must be given
	Sulfonylureas	Concurrent use may increase serum sulfonylurea concentration, increasing hypoglycemic effects	No specific action beyond monitoring blood glucose
Rabeprazole	Clarithromycin	Increased concentrations of both drugs	No action required; may be part of *H. pylori* protocol
All PPIs	Sucralfate	Decreased absorption of proton pump inhibitor	Take proton pump inhibitor 30 min prior to sucralfate
	Ketoconazole, esters of ampicillin, digoxin, iron salts	Proton pump inhibitors decrease absorption of these drugs	Avoid concurrent administration; for digoxin, monitor serum levels closely
	Azole antifungals (itraconazole, ketoconazole, etc.)	Bioavailability of azole decreased due to high gastric pH interference with tablet dissolving	Avoid concomitant administration
	Digoxin	Increased serum digoxin levels	Magnitude of change may not be clinically significant, but need to monitor
	Salicylates	Enteric-coated salicylates may dissolve more rapidly, increasing gastric adverse response	Separate administration by at least one h and give salicylate first
	Warfarin	Prolonged elimination of warfarin; increased INR	Increase monitoring frequency

More than 90% of duodenal ulcers and 80% of gastric ulcers are thought to be related to infection with *H. pylori.* Multiple treatment regimens are available for *H. pylori* eradication; triple regimens combine a PPI with two antibiotics for 14 days and the quadruple regimen combines a PPI with two antibiotics and bismuth subsalicylate (Lew, 2009). Acid suppression by the PPI in conjunction with the antimicrobial helps alleviate the ulcer-related symptoms, heals gastric mucosal inflammation, and may enhance the efficacy of the antimicrobial agent against *H. pylori* at the mucosal surface. Eradication of *H. pylori* significantly affects healing and recurrence rates. The recurrence rate of peptic ulcers is 6% to 15% for patients taking antimicrobial therapy versus 80% recurrence for those on conventional anti-secretory therapy (Chey & Wong, 2007). Chapter 35 discusses the treatment of peptic ulcer disease in depth and Table 35-6 discusses triple and quadruple therapy for gastric ulcers. Any of the PPIs can be used in these protocols. See Table 20-20.

Gastroesophageal Reflux Disease

For most patients, GERD is treated with stepped therapy. The steps are based on symptom relief and degree of esophageal damage. Either the step-up approach or the step-down approach may be used. There is evidence supporting both and the provider may select either. Regardless of the approach chosen, lifestyle modifications occur throughout therapy. They are discussed in detail in Chapter 35.

GERD treatment begins with lifestyle modifications and OTC antacids or H₂RAs, which patients have often tried before seeking care from a provider. The American College of Gastroenterology GERD guidelines recommend 8 weeks of PPIs for symptom relief and healing of erosive esophagitis associated with GERD (Katz et al, 2013). Standard once-a-day therapy is started and tailored to symptom relief. If night-time symptoms are an issue, dosing can be adjusted or twice-a-day dosing can be used for the traditional PPIs. Another option would be to add an H₂RA before bed to address night-time symptoms (Katz et al, 2013).

Failure to achieve symptom relief after 3 months or the presence of symptoms that suggest complications should be referred to a gastroenterologist. PPIs may mask the symptoms of gastric cancers, and the provider should keep this in mind. The presence of alarm symptoms (dysphagia, painful swallowing, noncardiac chest pain, weight loss, hematemesis, and choking) suggests endoscopy as part of the initial evaluation.

All PPIs are approved for the treatment of GERD. The once-daily dosing is taken 30 to 60 minutes before breakfast. The length of therapy is 8 weeks. In the rare patient whose healing does not occur by then, an additional 4 weeks may be needed. Nonresponsive patients require referral to a gastroenterology specialist. Patients may need long-term intermittent therapy for GERD. Dosage schedules for GERD are found in Table 20-21.

Table 20–21 ⚙ **Dosage Schedule: Proton Pump Inhibitors**

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
Esomeprazole Nexium	GERD with erosive esophagitis	Capsules: delayed-release: 20, 40 mg Granules for suspension: 10, 20, 40 mg/packet	*Adolescents and adults:* 20 or 40 mg daily for 4–8 wk. Maintenance: 20 mg daily for 4 wk. *Children:* <20 kg: 10 mg daily for 8 wk; >20 kg: 10–20 mg daily for 8 wk	20 mg/d
	Symptomatic GERD *H. pylori* eradication/ prevent duodenal ulcer		*Adults:* 20 mg daily for 8 wk *Children 1–11 yr:* 10 mg daily for 8 wk Triple therapy: Esomperazole 40 mg daily + amoxicillin 1 g bid + clarithromycin 500 mg bid for 7–10 d	
Lansoprazole Prevacid	Duodenal ulcer *H.pylori* eradication/ prevent duodenal ulcer	Capsules, delayed-release: 15, 30 mg Tablet: 15, 30 mg Suspension: 3 mg/mL	*Children 12 yr and adults:* 15 mg qd for 4 wk *H. pylori:* Triple therapy: Lansoprazole 30 mg bid + amoxicillin 1 g bid + clarithromycin 500 mg tid for 10 d Double therapy: Lansoprazole 30 mg tid + amoxicillin 1 g tid for 14 d	15 mg qd
	Benign gastric ulcer		30 mg daily for <8 wk	
	Erosive esophagitis		30 mg daily for <8 wk	15 mg qd
	Hypersecretory disorders		60 mg daily	Up to 90 mg bid; doses >120 mg/d must be divided
	Erosive esophagitis		*Adults:* 30 mg once daily for up to 8 wk *Children 12–17 yr and adults:* 30 mg once daily for up to 8 wk *Children 1–11 yr:* ≤30 kg: 15 mg daily for up to 12 wk >30 kg: 30 mg daily for up to 12 wk	If not healed, repeat dose for additional 8 wk Increase to 30 mg bid in patients who remain symptomatic after 2 wk of therapy

Continued

Table 20–21 ✖ Dosage Schedule: Proton Pump Inhibitors—cont'd

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
	Gastric ulcer associated with NSAID therapy		*Adults:* 30 mg daily for up to 8 wk	15 mg/d for up to 12 wk
	GERD	Prevacid OTC: Capsules, delayed-release: 15 mg	*Children 12–17 yr and adults:* 15 mg daily for up to 8 wk *Children 1–11 yr:* ≤30 kg: 15 mg daily for up to 12 wk >30 kg: 30 mg daily for up to 12 wk	
Omeprazole Prilosec Generic	Duodenal ulcer	Capsules, delayed-release: 10, 20, 40 mg Granules for suspension: 2.5, 10 mg/packet	*Adults:* 20 mg daily for 4–8 wk *Infants and children:* 15–30 kg: 10 mg bid, >30 kg: 20 mg bid *H. pylori:* Triple therapy: Omeprazole 20 mg bid + clarithromycin 500 mg bid + amoxicillin 1 g bid for 10 d Double therapy: Omeprazole 40 daily + clarithromycin 500 mg tid for 14 d; then omeprazole 20 mg daily for 14 additional d	
	Benign gastric ulcer		40 mg daily for 4–8 wk	
	Erosive esophagitis		20 mg daily for 4–8 wk	20 mg qid
	GERD		*Children 2–18 yr:* ≤20 kg: 10 mg daily for 4–8 wk >20 kg: 20 mg daily for 4–8 wk	Note: On a per kg basis doses are higher for children than adults.
	Hypersecretory disorders		*Adolescents > 16 yr and adults:* 60 mg daily	Up to 120 mg tid; doses >80 mg/d must be divided
Pantoprazole Protonix	Symptomatic GERD	Tablets: delayed-release: 20 40 mg Granules for suspension: 40 mg/packet	20–40 mg daily for 7–10 d	20 mg/d
	GERD with erosive esophagitis		40 mg daily for up to 8 wk	40 mg/d If not healed, repeat same dose for additional 8 wk
	Hypersecretory disorders		Individualized. 40 mg bid; may treat for up to 2 yr	Doses up to 240 mg/d have been used
Rabeprazole Aciphex	Duodenal ulcers	Tablets, delayed-release: 20 mg	*Adults and adolescents >12 yr:* 20 mg daily after the morning meal for up to 4 wk	If not healed, repeat dose for 4 wk
	GERD		*Adults and adolescents >12 yr:* 20 mg daily for 4 wk	If symptoms, repeat dose for 4 wk
	Erosive esophagitis		20 mg daily for 4–8 wk	If not healed, repeat dose for 4 wk
	H. pylori eradication/ prevent duodenal ulcer		Triple therapy: Rabeprazole 20 mg bid + amoxicillin 1 g bid + clarithromycin 500 mg bid for 7 d	
	Hypersecretory disorders		Individualized: 60 mg daily; may treat for up to 1 yr	Dose up to 100 mg/d or 60 mg bid have been used
Dexlansoprazole Dexilant Kapidex	Erosive esophagitis	Delayed-release capsules: 30, 60 mg 60 mg capsule	Treatment: 60 mg daily for 8 wk Maintenance for healed EE: 30 mg daily for up to 6 mo	Moderate hepatic dysfunction: 30 mg/d Not recommended for children <18 yr
	GERD		30 mg daily for 4 wk	

Further discussion of multidrug treatment for *H. pylori* is found in Chapter 34.

Hypersecretory Conditions (Including Zollinger–Ellison Syndrome)

All PPIs can be used to treat hypersecretory conditions such as Zollinger–Ellison syndrome. These disorders usually require higher dosing than does GERD or PUD and vary depending on the drug used. Some patients with Zollinger–Ellison syndrome have been treated continuously for more than 5 years.

Rational Drug Selection

Drug Interactions

For patients taking drugs metabolized by the CYP450 system, lansoprazole is the best choice. Although all PPIs are metabolized by CYP450 enzymes, lansoprazole appears to have no clinically significant drug interactions with warfarin or other drugs metabolized by CYP450. All the PPIs interact with atazanavir equally.

Difficulty in Swallowing

For patients with difficulty in swallowing, omeprazole, esomeprazole, and lansoprazole capsules can be opened and the intact granules sprinkled on 1 tablespoon of applesauce and swallowed immediately. Patients should not chew or crush the granules. Lansoprazole comes as a quick-dissolve tablet (Prevacid SoluTab) or as granules for suspension (Prevacid for Oral Suspension) that are mixed in 30 mL of water. Omeprazole (Prilosec for Delayed-Release Oral Suspension) comes as granules for suspension that are mixed with water and left to thicken for 2 to 3 minutes before administration. Pantoprazole (Protonix) comes as granules for delayed-release suspension that are mixed in applesauce or apple juice. The instructions for rabeprazole specifically state not to crush the tablet. All the PPIs have an enteric coating, even the granules; therefore, none of them should be crushed or chewed.

Patients being tube fed require a formulation that will not clog the tube. Omeprazole capsules or granules may be used with these patients. An omeprazole capsule may be opened and mixed with an acidic juice or omeprazole granules may be mixed with water in a catheter-tip syringe and administered after waiting 2 to 3 minutes for the mixture to thicken. Pantoprazole granules are emptied into the barrel of a syringe and 10 mL of apple juice is added; additional apple juice may be needed to rinse the syringe of granules. Lansoprazole granules for suspension or quick-dissolve tablets should not be used for nasogastric feedings. A lansoprazole capsule may be opened and mixed with 40 mL of apple, cranberry, grape, orange, tomato, or V-8 juice and administered via nasogastric tube.

H. Pylori Treatment

To increase adherence, choose the least complex regimen with the fewest adverse reactions that still has a high eradication rate. Chapter 35 has more discussion of this treatment.

Monitoring

The only monitoring relates to the disease process being treated. However, patients taking proton pump inhibitors to treat ulcers should be tested for _H. pylori_ infection. Patients taking PPIs should stop therapy for 2 weeks before undergoing urea breath testing to diagnose this infection or be tested via stool antigen testing. PPIs alone rarely eradicate _H. pylori_ infection, but they can suppress it so that testing during antisecretory therapy may lead to false-negative results.

Patient Education

Administration

Patients should take the drug exactly as prescribed, even if they are feeling better. If a dose is missed, it should be taken as soon as the patient remembers it, unless it is almost time for the next dose. Patients should not double up on doses. All of these drugs are taken before a meal. Drugs taken once daily are preferably taken in the morning. These drugs may safely be taken with antacids. Patients who have difficulty swallowing should be instructed not to chew or crush tablets or granules. Patients or caregivers should have clear instructions on how to administer PPIs to those with swallowing problems or tube feedings.

Adverse Reactions

PPIs may occasionally cause drowsiness or dizziness. Patients should avoid activities that require mental alertness until their response to the drug is known. Advise patients to promptly report to their health-care provider the onset of black, tarry stool; diarrhea; abdominal pain; or persistent headache, which may indicate progression of the disease or adverse drug effects.

Lifestyle Management

Lifestyle modifications are always attempted before drugs are used to treat GERD. They are also often used prior to treatment of the other indications for PPIs. These modifications are discussed in more detail in Chapter 35.

LAXATIVES

Constipation is a common affliction caused by everything from lack of sufficient fluids, fiber, and exercise to serious GI diseases to iatrogenic causes secondary to adverse reactions to drugs. It is among the most frequent reasons for self-medication and is particularly troublesome to older adults.

Treatment often takes the form of laxative use. More than $500 million is spent annually in the United States on laxatives. The pathophysiology of constipation varies with its cause, and the action of the drug chosen to treat the constipation must also vary to match the cause. In light of these differences, six main classes of drugs are used to promote evacuation of the bowel: stimulants, osmotics, bulk-producing laxatives, lubricants, surfactants, and hyperosmolar laxatives. Each class is discussed in this section. Because each laxative has several brand names, only the generic name is used.

A newer treatment for opioid-induced constipation is methylnaltrexone (Relistor), a mu-opioid receptor antagonist.

Pharmacodynamics

Stimulants

The stimulant laxatives have a direct action on intestinal mucosa by stimulating the myenteric plexus. Stimulants facilitate the release of prostaglandins and increase cyclic adenosine monophosphate (cAMP) concentration. This increase in cAMP increases the secretion of electrolytes and stimulates peristalsis. Drugs in the stimulant class include cascara, senna, bisacodyl, and castor oil.

The stimulants are used most often for treatment of constipation associated with reduced mobility, constipating drugs, reduced motility, neurogenic bowel secondary to spinal cord injury, and irritable bowel syndrome. They are also used to prepare the bowel for radiological or surgical procedures.

Osmotics

The class of osmotics exerts its effects mainly by drawing water into the intestinal lumen to increase intraluminal pressure. These drugs are hypertonic salt-based solutions that cause the diffusion of fluid from the plasma into the intestine to dilute the solution to an isotonic state. The magnesium salts also cause an increase in the release of cholecystokinin by the duodenum. Sulfate salts are considered the most powerful. Drugs in this class include magnesium hydroxide, magnesium citrate, sodium phosphate, polyethylene glycol electrolyte solution, and polyethylene glycol (PEG) 3350.

Polyethylene glycol electrolyte solution is used to cleanse the entire GI tract for diagnostic purposes, to flush poisons from the system, and to remove parasites. PEG 3350 powder is used for constipation.

Bulk-Producing Laxatives

The bulk-producing laxatives are the safest and most physiological because their action is similar to that achieved by increasing fiber in the diet. They do not hinder absorption of nutrients and are less likely to be habit-forming. The bulk-producing laxatives consist of natural and semisynthetic polysaccharides and cellulose. When combined with water in the intestine, they produce mechanical distention resulting in an increase in peristalsis. Drugs in this class include psyllium, methylcellulose, and polycarbophil.

The bulk-producing laxatives may be used for long-term management of simple, chronic constipation, especially if it is related to low fiber intake in the diet. They are also useful in situations in which straining at stool is to be avoided and in the management of chronic, watery diarrhea.

Lubricants

Mineral oil is the main ingredient in lubricant laxatives. Its action is to retard colonic absorption of fecal water and soften the stool. It does not stimulate peristalsis. It is used to soften stool associated with fecal impaction. Mineral oil also lubricates the intestine to facilitate the passage of stool. Major concerns with the use of mineral oil are that it may decrease absorption of fat-soluble vitamins, and there is concern for aspiration in children younger than 4 years of age if given orally.

Surfactants

Surfactants are often referred to as "stool softeners" because they reduce the surface tension of the oil–water interface on the stool and facilitate admixture of fat and water into the stool, producing an emollient action. Drugs in this class are the docusate compounds: docusate sodium, docusate calcium, and docusate potassium.

Surfactants are most beneficial when feces are hard or dry, in anorectal conditions in which passage for firm stool is painful, and in situations when straining at stool is to be avoided. Docusate sodium can be safely administered to all ages from infants to the elderly.

Hyperosmolar Laxatives

Hyperosmolar laxatives are often listed as "miscellaneous," but they share a similar mechanism of action. Glycerin produces local irritation and, as a hyperosmotic compound, draws water from the extravascular spaces into the lumen of the intestine, resulting in more liquid stool. Lactulose is a hyperosmotic disaccharide. In the colon, resident bacteria transform the drug into lactic acid and acetic and formic acids. These acids exert an osmotic effect by drawing water from the extravascular spaces into the intestinal lumen.

Glycerin is used to treat fecal impaction and patients with neurogenic bowel, in which the bowel is filled with feces that cannot be evacuated. Lactulose is used to treat chronic constipation in older adults, but it also is the only laxative used to treat hepatic encephalopathy. It lowers the pH of the colon, which in turn inhibits the diffusion of ammonia across colonic membranes.

Chloride Channel Activators

Lubiprostone (Amitiza) acts by activating CIC-2 chloride channels in the gastrointestinal epithelial lining, producing chloride-rich secretions that soften the stool and increase gastrointestinal motility. Lubiprostone does not affect serum sodium or potassium concentrations. Lubiprostone is used to treat chronic idiopathic constipation, irritable bowel syndrome with constipation in women aged 18 years or older, and chronic opioid-induced constipation in adults with chronic noncancer pain.

Opioid-Receptor Antagonists

Methylnaltrexone works as an antagonist to the mu-receptor in the GI track and treats the constipation patients experience when taking opioids. Methylnaltrexone does not cross the blood–brain barrier; therefore, it does not affect the kappa receptor analgesic effect of opioids.

Pharmacokinetics

Absorption and Distribution

Absorption is highly variable between classes, from no absorption for the bulk-forming laxatives to 3% or less for all other classes except the magnesium salts, of which up to 30% may be absorbed (Table 20-22). Magnesium salts are widely

Table 20–22 ⬍ **Pharmacokinetics: Selected Laxatives**

Drug Class	Onset	Peak	Site of Action	Elimination
Stimulants	6–10 h 0.25–1 h bisacodyl PR 2–6 h castor oil	UK	Colon Colon Small intestine	Mostly in feces
Osmotics (magnesium salts)	0.5–3 h	UK	Small and large intestine	Primarily in urine
Bulk-forming	12–24 h	2–3 d	Small and large intestine	In feces
Lubricants	6–8 h PO 2–15 min PR	UK	Colon Colon	In feces
Surfactants	24–48 h PO 2–15 min PR	UK	Small and large intestine	Small amount absorbed is eliminated in bile
Hyperosmolar	0.25–0.5 h glycerin 24–48 h lactulose	UK UK	Colon Colon	UK Small amount absorbed is excreted unchanged in urine

PR = per rectum; UK = unknown.

distributed, cross the placenta, and enter breast milk. Small amounts of metabolites of bisacodyl have been found in breast milk. The remaining drugs in each class have no distribution, with their action being localized in the intestine. Methylnaltrexone is administered subcutaneous and peaks in 30 minutes.

Metabolism and Excretion

Locally acting drugs have no specific metabolism and are excreted in feces. The liver metabolizes small amounts of bisacodyl. Glycerin is 80% metabolized by the liver and 10% to 20% by the kidney. Magnesium salts are metabolized by the liver and excreted primarily by the kidney.

Methylnaltrexone is metabolized in the liver into five metabolites including o methyl-6-naltrexol isomers and methylnaltrexone sulfate. The half-life of methylnaltrexone is 8 hours and it is renally excreted.

Pharmacotherapeutics

Precautions and Contraindications

Precautions and contraindications vary by class of laxative, but all share the contraindication of use in the presence of nausea, vomiting, or undiagnosed abdominal pain or if bowel obstruction is suspected or diagnosed. Other precautions and contraindications are specific to a class or a drug.

Stimulants

Bisacodyl is to be used with caution in the presence of severe cardiovascular disease. The extract of cascara sagrada contains alcohol and should be avoided by people with alcohol intolerance.

Castor oil is contraindicated in pregnancy because it has been associated with induction of uterine contractions. Cascara derivatives are Pregnancy Category C. Bisacodyl is safe to use in pregnancy and is listed as Pregnancy Category B.

Cascara sagrada is excreted in breast milk and may increase the incidence of diarrhea in the nursing infant.

Osmotics

Magnesium hydroxide is contraindicated in the presence of any degree of renal insufficiency because the kidney may be unable to excrete excessive magnesium ions. Hypermagnesemia, hypocalcemia, and heart block also contraindicate their use. Because large quantities of polyethylene glycol electrolyte solution must be taken, these salts are used cautiously for patients with diminished gag reflex unless it is being administered by nasogastric tube. Osmotics should be avoided in patients with bowel obstruction or ileus.

Magnesium hydroxide is Pregnancy Category B. Polyethylene glycol electrolyte solution is Pregnancy Category C, as is PEG 3350 (Miralax).

PEG 3350 should not be used in children younger than 4 years of age. The use of polyethylene glycol electrolyte solution to treat constipation in children is contraindicated because of concerns about electrolyte disturbance.

Bulk-Forming Laxatives

Bulk-forming laxatives are used with caution for patients with a narrowed esophageal or intestinal lumen. Some dosage forms contain sugar or salt and should be avoided by patients who must restrict these substances. Bulk-forming laxatives should be avoided in patients who are impacted. Bulk-forming agents are not given a specific pregnancy category but have been safely used during pregnancy.

Lubricants

Lipid pneumonia has occurred in patients who aspirated mineral oil. The very young, older adults, people with dysphagia, and debilitated patients are at highest risk.

Although no specific pregnancy category is listed for mineral oil, it should be avoided during pregnancy because chronic use decreases the absorption of fat-soluble vitamins and causes hypoprothrombinemia in the newborn.

Surfactants

Docusate compounds have no specific contraindications or precautions. They have not been given a specific pregnancy category but have been safely used during pregnancy.

Hyperosmolar Agents

Hyperosmolar agents are used with caution in the presence of volume depletion. Older adults are especially at risk for dehydration. Hyperglycemia has been noted in some patients taking lactulose, and it is used with caution in the presence of diabetes mellitus.

Glycerin is Pregnancy Category C; lactulose is Pregnancy Category B. It is not known if lactulose is excreted in breast milk.

Sodium Channel Activators

Nausea is the most common adverse effect of lubiprosone, with 29% of patients in clinical trials experiencing nausea that may be relieved by administration with food (Sucampo Pharma Americas, 2013). Dyspnea has been reported in patients taking 24 mcg twice daily, with the onset of chest tightness and shortness of breath 30 to 60 minutes after taking the first dose. The dyspnea generally resolves after a few hours but may recur with subsequent doses; some patients have discontinued treatment due to dyspnea (Sucampo Pharma Americas, 2013). Diarrhea occurred in 13% of patients during clinical trials.

Lubiprosone is Pregnancy Category C. There are no adequate, well-controlled studies of lubiprosone in pregnant women. There was a dose-dependent fetal loss noted in guinea pig studies of lubiprosone.

Opioid-Receptor Antagonists

Methylnaltrexone may cause opioid withdrawal particularly if the blood–brain barrier is disturbed. Patients should be monitored closely. Patients with constipation are at risk for bowel rupture and methylnaltrexone should be used with care and the patient monitored for severe abdominal pain.

Precautions for All Laxatives

Other general laxative precautions include the following:

1. Abuse and dependency: Chronic use of laxatives, particularly stimulants, may lead to laxative dependency, which in turn may result in fluid and electrolyte imbalances, steatorrhea, osteomalacia, and vitamin and mineral deficiencies. The "laxative abuse syndrome" is most commonly seen in women with depression, personality disorders, or anorexia nervosa. Cathartic colon can also result. The pathology resembles ulcerative colitis.
2. Tartrazine sensitivity: Some of these products contain tartrazine, which may cause allergic types of reactions, including asthma, in susceptible individuals. Although the incidence of this sensitivity in the general population is low, it is frequently seen in patients who also have aspirin sensitivity.

Adverse Drug Reactions

Adverse drug reactions are most commonly extensions of the drug's action and include excessive bowel activity, cramping, flatulence, and bloating. Perianal irritation may also develop. Allergic reactions such as urticaria, dermatitis, rhinitis, and bronchospasm have occurred when patients accidentally inhaled bulk-forming laxatives. Phenolphthalein may cause a skin hypersensitivity characterized by a fixed drug eruption. Discontinue the drug if this occurs.

In clinical trials of methylnaltrexone 21% of patients reported abdominal pain versus 9% of those taking a placebo. Other adverse effects of methylnaltrexone that occurred more frequently than placebo were nausea (9% versus 6% taking placebo), diarrhea (6% versus 4%), and hyperhidrosis (6% versus 1%).

Drug Interactions

Because most laxatives have local activity and limited absorption, few drug interactions occur. Methylnaltrexone should not be taken with other opioid antagonists because of the potential for additive effects. Table 20-23 lists drug interactions with laxatives.

Clinical Use and Dosing

All laxatives are used to treat constipation or to prepare the bowel for a procedure. Specific uses for each class are discussed in the Pharmacodynamics section. Table 20-24 lists the dosing schedules for each indication.

Rational Drug Selection

The choice of drug to treat constipation depends on the severity of the constipation, the reason for it, and the speed with which resolution is needed. Drugs are used only after the reason for the constipation has been corrected if possible (stop or decrease the dose of the drug that induced the constipation). Indications for the use of each class of drug are presented in the Pharmacodynamics section.

Rapid Response and Short Term

Stimulants are the drug of choice when rapid response is needed. All are equally effective. They should be used only for the short term. Safer drugs can be used for long-term management when speed is not the main issue. The choice of drug depends largely on cost.

Osmotic laxatives work quickly as well. Magnesium hydroxide produces evacuation in 6 to 8 hours and is generally administered before bedtime. PEG 3350 produces a bowel movement in 1 to 3 days. Docusate sodium is the preferred surfactant.

Slower Response and Long Term

Bulk-forming laxatives are the drug of choice when rapid response is not needed and long-term management with the least adverse reactions is desired. They are especially suited to older adults. The choice of product depends upon the patient's acceptance of texture and taste. Lactulose can be used if the bulk-forming laxatives do not work or are not well tolerated. It works well in older adults and children.

Table 20–23 ✦ Drug Interactions: Selected Laxatives

Drug	Interacting Drug	Possible Effect	Implications
All laxatives	Other orally administered drugs	May decrease absorption of other orally administered drugs because of increased motility and decreased transit time	Separate administration by at least 1 h
Bisacodyl	Antacids, histamine$_2$ blockers, proton pump inhibitors	May remove enteric coating of tablets	Separate administration or select different laxative
Lactulose	Antimicrobials	Concurrent use may decrease effectiveness of lactulose used in hepatic encephalopathy	If concurrent use cannot be avoided, dosage adjustments of lactulose may be required
	Antacids	May decrease the effect of lactulose on colon pH	Separate doses by at least 1 h
Magnesium salts	Fluoroquinolones, nitrofurantoin, tetracycline	May decrease absorption of these drugs	Avoid concurrent administration
Mineral oil	Docusate compounds	Concurrent use may increase mineral oil absorption	Avoid concurrent use
	Foods	May decrease absorption of vitamins A, D, E, K	
Psyllium	Digoxin, salicylates, warfarin	May decrease absorption of these drugs	Separate administration by at least 1 h and give drug before psyllium

Table 20–24 ✦ Dosage Schedule: Selected Laxatives

Drug	Indication	Dosage Form	Dose	Notes
Bisacodyl Dulcolax	Constipation	Tablets: 5 mg Suppositories: 10 mg	*Children >12 yr and adults:* Tablets: 10–15 mg once daily PR: 10 mg once daily *Children 2–11 yr:* Tablets: 5 mg (0.3 mg/kg) once daily PR: 5 mg once daily *Children <2 yr:* PR: 5 mg single dose	Up to 30 mg have been used as preparation for bowel procedure
Cascara sagrada	Constipation	Tablets: 325 mg	*Children >12 yr and adults:* Tablets: 300 mg–1 g once daily Extract tablet: 200–400 mg daily	Tablets and liquids come in combinations with docusate and milk of magnesia
Castor oil Generic	Constipation	Oil	*Children >12 yr and adults:* 15–60 mL in a single dose *Children 2–11 yr:* 5–15 mL in a single dose	
Docusate calcium Surfak	Constipation	Capsules: 50, 240 mg	*Calcium* *Adults:* 240 mg once daily *Children >6 yr:* 50–150 mg once daily	
Docusate potassium (Diocto-K, Dialose, Kasof)		Capsules: 100, 240 mg	*Potassium* *Adults:* 100–300 mg once daily *Children >6 yr:* 100 mg once daily at bedtime	
Docusate sodium (Colace)		Capsules: 50, 100 mg Syrup: 60 mg/15 mL Liquid: 150 mg/15 mL	*Sodium* *Children >12 yr and adults:* 50–500 mg once daily *Children 6–11 yr:* 40–120 mg once daily *Children 3–6 yr:* 20–60 mg once daily *Children <3 yr:* 10–40 mg Suppository: *Adults:* 50–100 mg or 1 suppository	
Glycerin PR	Constipation	Suppositories: Adult, Pediatric	*Children >6 yr and adults:* 2–3 g as suppository or 5–15 mg as enema *Children <6 yr:* 1–1.7 g as a suppository or 2–5 mL as enema	

Continued

Table 20–24 ⊗ Dosage Schedule: Selected Laxatives—cont'd

Drug	Indication	Dosage Form	Dose	Notes
Lactulose (Cephulac, Chronulac, Enulose) Generic	Constipation	Syrup: 10 g lactulose/ 15 mL	*Adults:* 15–30 mL once daily *Children:* 7.5 mL once daily	May use up to 60 mg/d; unlabeled use
	Hepatic encephalopathy		*Adults:* 30–45 mL tid–qid *Children and adolescents:* 40–90 mL daily in divided doses *Infants:* 2.5–10 mL daily in divided doses	May be given q1–2 h initially; goal is 2–3 soft stools/d; discontinue if diarrhea develops
Magnesium salts Epsom salts Magnesium hydroxide Milk of magnesia Magnesium citrate	Constipation	Granules: 40 mEq Mg^{2+} per 5g Chewable tablets: 300 and 600 mg Liquid: 80 mEq Mg^{2+} per 30 mL Liquid: 77 mEq Mg^{2+} per 100 mL	*Hydroxide (milk of magnesia)* *Children >12 yr and adults:* 30–60 mL once daily (in concentrate: 10–20 mL once daily) *Children 6–11 yr:* 15–30 mL in single or divided doses *Children 2–5 yr:* 5–15 mg in divided doses	
	Bowel prep or bowel cleanout if impacted		*Citrate* *Children >12 yr and adults:* 240 mL *Children 6–11 yr:* 100 mL	
Polyethylene glycol/ electrolyte solution (Colyte, GoLYTEly)	Bowel prep	In oral solution or powder for oral solution	*Adults:* 240 mL every 10 min (up to 4 L) until fecal discharge is clear with no solid material *Children:* 25–40 mg/kg/h until fecal discharge is clear with no solid material	Tastes salty, making it difficult to take. Ice it. May suck on hard candy or breath mints to make more palatable.
PEG 3350 (Miralax)	Constipation	Powder for solution: 17 g/dose	*Adults:* oral 17 g daily *Children >4 yr:* 0.7–1.5 g/kg daily, do not exceed 17 g	Mix with 4 to 8 oz of beverage
Psyllium (Fiberall, Konsyl, Metamucil)	Constipation	Powder: 3.4 g psyllium/5 mL, 6 g psyllium/5 mL Wafers: 1.7 g psyllium, 3.4 g psyllium Effervescent powder: 3.4 g/5 mL	*Adults:* 1–2 tsp/packet/wafer (3–6 g psyllium) in or with a full glass of liquid bid–tid *Children >6 yr:* 1 tsp/packet/wafer (1.5–3 g psyllium) in or with ½–1 glass of liquid bid–tid	Up to 30 g/d in divided doses Up to 15 g/d in divided doses
Senna (Senokot, Fletcher's Castoria)	Constipation	Tablets: 187 mg Granules: 326 mg Syrup: 218 mg/5 mL Liquid: 33.3 mg/mL	*Children >12 yr and adults:* 360 mg–2 g at bedtime *Children 6–11 yr:* 50% of adult dose *Children 1–5 yr:* 33% of adult dose Rectal: *Children >12 yr and adults:* 30 mg qid–bid	Fletcher's Castoria lists a children's dose of 10–15 mL (6–15 yr) and 5–10 mL (2–5 yr)

PR = per rectum.

Special Indications

Polyethylene glycol electrolyte solution is the best drug for cleansing the bowel in preparation for radiological or surgical procedures. It is very effective and does not produce electrolyte disturbances.

Lactulose is effective in reducing ammonia levels in the blood and brain with patients who have hepatic encephalopathy. It prevents absorption of ammonia from the intestine and produces diarrhea that flushes the ammonia out. Dietary adjustments to reduce ammonia production are simultaneously implemented.

Lubiprostone is indicated for the treatment of constipation associated with irritable bowel syndrome in women aged 18 years or older or chronic idiopathic constipation. It may also be used for opioid-induced constipation in patients with chronic noncancer pain. Methylnaltrexone is indicated for constipation associated with chronic opioid use.

Pregnancy

For pregnant women, bulk-forming laxatives and surfactants are safe and effective for regular use throughout pregnancy and for lactating women. Magnesium hydroxide is Pregnancy

Category B and can be used intermittently. Lubiprostone should not be prescribed for pregnant women unless the risk outweighs the benefit.

CLINICAL PEARL

Polyethylene Glycol/Electrolyte Solution
The taste of polyethylene glycol/electrolyte solution is quite salty, and many patients find it difficult to consume the required volume in the required amount of time. Place the container of solution in ice in a basin. Do not pour it over ice, which will melt and increase the volume the patient must consume. Have the patient drink 240 mL of fluid each 10 minutes and give a Tic-Tac or similar small mint-flavored hard candy to suck on between glasses of the drug. This reduces the salty taste in the mouth and makes the drug more palatable.

The Precautions and Contraindications section lists the pregnancy categories for other drugs, including those that should not be used during pregnancy.

Monitoring

In general, the monitoring for patients taking laxatives for more than 6 months includes laboratory assessment of fluid and electrolyte status, especially potassium and in the case of magnesium hydroxide use, magnesium level. For patients taking lactulose for hepatic encephalopathy, the overall management of this disorder requires careful monitoring because it is a serious disease with a high potential for complications. Monitoring includes serum electrolytes for hypokalemia and hypernatremia. For older adults taking lactulose for more than 6 months to manage their constipation, laboratory assessment of potassium, chloride, and carbon dioxide should be done periodically or with any indication of fluid or electrolyte disturbance.

Patient Education

Laxatives should not be taken in the presence of nausea, vomiting, or abdominal pain. These symptoms may indicate serious disorders that may be the cause of the constipation and that require a work-up. Patients should not take a laxative but instead contact their health-care provider.

Administration

Rapid-acting laxatives are best taken in the morning; slower-acting ones are best taken at bedtime. Taking a laxative on an empty stomach and with a full glass of water will produce more rapid results. Do not crush or chew enteric-coated tablets. Liquids can be given with fruit juice. For infants, taking liquids with fruit juice may mask any unpleasant taste. Suspensions are shaken before they are taken. Effervescent tablets are dissolved in a full glass of water before they are taken.

Suppositories are usually given close to the time that a bowel movement is desired. Lubricate them with a water-soluble lubricant and insert far enough into the rectum to pass the internal rectal sphincter. Encourage the patient to retain the suppository for 15 to 30 minutes before expelling.

Some liquid laxatives have special storage requirements and manufacturers' recommendations should be followed.

Adverse Reactions

The most common adverse drug reactions are excessive bowel activity, cramping, flatulence, and bloating. Perianal irritation may also occur. Allergic reactions such as a rash, rhinitis, and bronchospasm have occurred when patients accidentally inhaled bulk-forming laxatives. Be careful when pouring the powder to avoid this possibility. Phenolphthalein may cause a skin hypersensitivity rash. Advise the patient to notify the health-care provider if this occurs. The drug is discontinued and a different laxative chosen if the need for a laxative continues. Teach patients the indications of a fluid or electrolyte disturbance and have them report these symptoms promptly.

Lifestyle Management

Prevention is the key with regard to constipation. Lifestyle management should be a major focus. Stress the need for adequate fluids, fiber, and exercise. Laxatives are last-resort and temporary measures. They are not intended for long-term management in most cases.

Misconceptions about bowel function should be corrected. Different people have different bowel patterns, all of which may be normal and not signal pathology. Stressing this point is especially important for older adults, who were often taught in their youth that maintenance of health depended on having one bowel movement every day.

Constipation in children may be a control issue or signal pathology. Discuss this topic with the parents. A trial of a laxative concurrently with behavior modification is appropriate, but the child needs to be monitored for the need for referral for a GI work-up.

DRUGS AFFECTING THE ENDOCRINE SYSTEM

Marylou Robinson • Kathy Shaw

BISPHOSPHONATES

Bone is dynamic tissue that undergoes a continuous process of resorption (osteoclastic activity) and formation (osteoblastic activity) throughout life. Under normal physiological states, the two processes are about equal. Skeletal mass is usually maximal at about age 35 and declines in women after age 40 and men after age 50. The rate of decline becomes most rapid in women within 2 years of menopause, with one-third to one-half of all bone that will be lost going during the first 5 years after menopause.

The cycle of bone remodeling takes longer to complete and the rate of mineralization slows with aging. As the life expectancy of women reaches the mid-80s, osteopenia in perimenopausal women takes on epidemic proportions (50%), especially among white and Asian women in industrial societies (International Osteoporosis Foundation [IOF], 2012). Men experience bone loss as well, but at later ages and slower rates than women. Initial bone mass is also about 30% higher in men than it is in women, so the loss is less disabling (McCance & Huether, 2014). The femoral neck and lumbar vertebrae lose the most. Cortical (compact) bone, which is 80% of the skeleton, is lost less rapidly than is cancellous (spongy) bone. Bone loss is related to smoking, calcium deficiency, magnesium deficiency, vitamin D deficiency, high-protein intake, excess phosphorus intake, overly vigorous exercise, certain prescription and over-the-counter (OTC) drugs, alcohol intake, and reduced physical activity. There are 5,500 osteoporosis-related fractures in the United States daily, of which 80% are in women (IOF, 2012). Chapters 38 and 48 discuss this concern as it relates to women's health.

In addition to normal aging, pathophysiological conditions can also alter the balance between resorption and formation. Even a minor imbalance can have devastating effects. For example, if bone resorption exceeds formation by only 2% per year, in 20 years 40% of skeletal mass will be lost. Malignancy, syndromes of ectopic calcification, and Paget's disease are examples of pathological conditions associated with altered bone remodeling.

Longitudinal reevaluation of the risks versus benefits of osteoporosis prevention is shifting the primary clinical use of bone remodeling drugs toward those patients with the highest risk of fracture development. FRAX (Fracture Risk Assessment Tool) scores estimate the 10-year probability for major bone fractures of the hip, wrist, and shoulder. Revised guidelines using FRAX scores and BMD (bone mass density) T scores of less than 2.5 are the major focus of any prefracture treatment. Those patients with BMD T scores between –1.0 and –2.5 with other factors that increase fracture risk to more than 20% in 10 years are also considered for drug interventions. There is no consensus as to how often BMD is measured after the start of therapy, though 2 years is the time line most often cited (Rosen & Drezner, 2012).

The IOF (2012) estimates that only 17% of patients who have sustained an osteoporotic fracture get bone support medications even after a second fracture. Men are less likely to be treated than women and less likely to be screened for the disease. Concerns about the rare, atypical fractures and osteonecrosis should be mitigated by considering the reported incidents are about 10 per 10,000 patients, or 0.1%; however, some experts believe the incidences are underreported (Hellier & Ross, 2012). This said, the very low incidence rate of these rare events should not overshadow the benefit gained from therapy (Black et al, 2010; U.S. Food and Drug Administration [FDA], 2010a; Rizzoli et al, 2011).

Pharmacodynamics

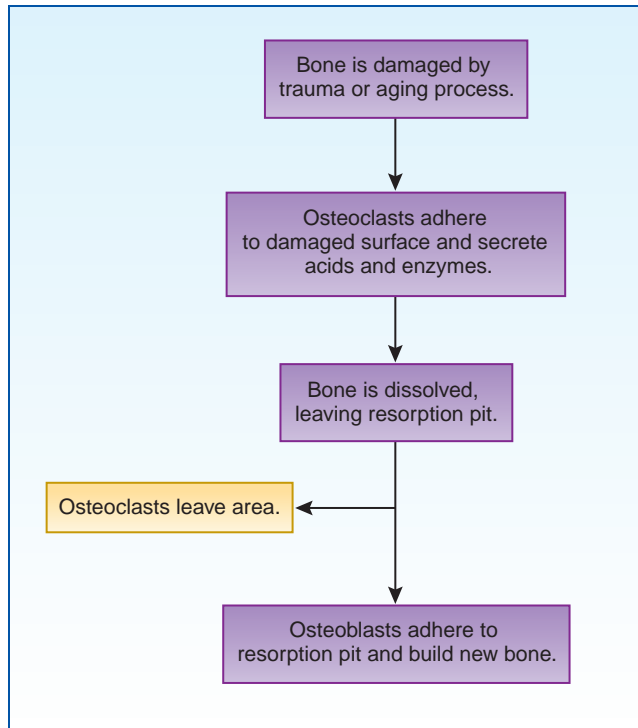
The remodeling cycle is initiated by osteoclastic activity. In response to microfractures and other damage associated with normal wear and tear, osteoclasts are drawn to the damaged area of the trabecula, attach to its surface, and resorb the damaged and surrounding bone, creating a resorption pit (Fig. 21-1). Resorption is accomplished by


Figure 21–1. Bone remodeling. Damaged bone sections are removed by osteoclasts that use pseudopods to attach to bone surface. Bone is dissolved, leaving a resorption pit. The osteoclasts then leave the site of damage. Osteoblasts enter the resorption pit and build new bone. The process takes 4 to 5 months.

pseudopodia, which attach tightly to the bone surface and secrete acids and enzymes that dissolve bone. The osteoclasts then leave the area and osteoblasts move in, line up to cover the surface of the pit, and form new bone. RANKL, one component of the TNF-associated ligands and receptors, facilitates osteoclast formation. The newest monoclonal antibody approaches to modifying bone remodeling (like demosumab) reduces RANKL action. These meds are covered further in Chapter 38.

Several medication groups, including estrogens, SERMS, and parathyroid hormone agents, can be used to support bone health. Bisphosphonates remain the most commonly used agents and are the focus of this section.

Bisphosphonates adhere tightly to bone and, by inhibiting osteoclastic activity, are potent inhibitors of both normal and abnormal bone resorption. Among this group of drugs, etidronate (Didronel) reduces both bone resorption and bone formation because formation is coupled with resorption. Pamidronate (Aredia) and risedronate (Actonel) inhibit bone resorption without inhibiting bone formation and mineralization. Alendronate (Fosamax) is a highly selective inhibitor of bone resorption and is 100 to 500 times more potent than the other drugs. It does not interfere with osteoclast recruitment or attachment, but it does inhibit osteoclastic activity. Tiludronate (Skelid) inhibits osteoclastic activity through two different mechanisms. It inhibits protein-tyrosine-phosphatase, resulting in detachment of osteoclasts from the bone surface, and it inhibits the osteoclastic proton pump.

Zoledronic acid (Zometa) inhibits osteoclastic activity and induces osteoclast apoptosis. It also inhibits the increased osteoclastic activity and skeletal calcium release induced by various stimulatory factors released by tumors. Ibandronate (Boniva) inhibits osteoclast activity and reduces bone resorption and turnover based on its affinity for hydroxyapatite, which is part of the mineral matrix of the bone. All reduce vertebral fractures, only aldendronate, risedronate, and zoledronic acid have demonstrated nonvertebral fracture reductions; it cannot be assumed the others can achieve the same endpoint (*Drug Facts and Comparisons* [*DF & C*], 2011). Aledronate, risedronate, and zolendronic acid have been studied in men, but transferability of results with other medications is considered a safe assumption. Because pamidronate and zoledronic acid are available only for parenteral use, they are not discussed in detail except to alert the primary care provider about monitoring the drug and its place in the total treatment regimen of the patient.

Pharmacokinetics

Absorption and Distribution

All oral bisphosphonates potentially cause esophagitis and gastric irritation. Absorption and bioavailability of oral doses are significantly reduced by the presence of food in the gut or other preparations containing divalent cations. To enhance absorption, the patient takes the drug with 8 oz of water. No other food or drink should be ingested, and the patient must remain upright for at least half an hour (1 hour with ibandronate). Table 21-1 shows the effect of food, coffee, and juice on bioavailability.

These drugs are all mainly distributed to bone. Their terminal half-life in bone is exceedingly long, varying from more than 10 years for alendronate to more than 90 days for etidronate. The half-life of risedronate is much shorter, at 480 hours; ibandronate is 220 hours; zoledronic acid is 167 hours; and tiludronate is 150 hours, but these times are thought to represent the dissociation of the drug from the bone surface, rather than its time within the bone. Their volumes of distribution exclusive of bone vary significantly from 90 L/kg for ibandronate to 1.3 L/kg for etidronate.

Most bisphosphonates are Pregnancy Category C. Pamidronate and zoledronic acid are Category D. *Drug Facts and Comparisons* (2011) states that fetal anomalies have occurred in animal studies. There are no adequate and well-controlled studies in pregnant women. Bisphosphonates should be prescribed only when they are clearly needed and the benefits to the mother outweigh the potential hazards to the fetus. All bisphosphonates are used with extreme caution during breastfeeding; zoledronic acid binds to bone for long periods so is never used in lactating mothers.

Safety and efficacy in children have not been fully established, but children have been treated with etidronate (Pregnancy Category B) at doses recommended for adults to prevent heterotopic ossifications or soft tissue calcifications. The epiphyseal changes that occurred were reversible with discontinuation of the drug. In children with low bone

Table 21–1 ⬛ **Pharmacokinetics: Bisphosphonates**

Drug	Onset of Effect	Peak	Duration	Bioavailability (With/Without Food)	Steady-State V_d Exclusive of Bone	Half-Life Normal Renal (Function)	Elimination
Alendronate	1 mo	3–6 mo	7 mo (following after discontinuation of the drug)	0.7% in females; 0.59% in males. Reduced 40% when taken with food; 60% with coffee or juice.	28 L/kg or more	10 yr (in bone)	50% in urine
Etidronate	1 mo	UK	1 yr (following after discontinuation of the drug)	1%; reduced when taken with food or juice	1.37 L/kg	More than 90 d (in bone	Absorbed dose: 50% in urine; unabsorbed dose: in feces
Ibandronate	UK	0.5–2 h	Up to 1 mo	0.6% absorbed; less with food	90 L	10–60 h	50%–60% urine; unabsorbed in feces
Risedronate	Days	1 h	16 mo (following after discontinuance of drug)	0.63%; reduced by 55% when taken with food	6.3 L/kg	Terminal half-life 480 h	50% absorbed drug in urine; rest in feces
Tiludronate	UK	2 h	UK	6%; reduced when taken with food	1–4.6 mg/L	150 h	60% in urine

UK = unknown; V_d = volume/density.

density due to malabsorption syndromes such as cystic fibrosis, alendronate was shown to increase BMD to normal levels after only 1 year of therapy; the impact was greatest in children who also achieved puberty during the clinical trial (Bianchi et al., 2013).

Metabolism and Excretion

There is no evidence that any of the bisphosphonates are systemically metabolized. Drug that is not distributed to bone is largely excreted in the urine. Because of the fairly exclusive renal excretion and the high volumes of distribution exclusive of bone, these drugs are not recommended for patients with moderate to severe renal impairment (serum creatinine greater than 4.9; creatinine clearance (CCr) less than 30 to 35 mL/min). Dosage adjustments may be necessary if the drug must be given (FDA, 2011a).

Pharmacotherapeutics

Precautions and Contraindications

There are no absolute contraindications except uncorrected hypocalcemia, documented Barrett's esophagus, and renal insufficiency (*DF&C,* 2011; FDA, 2010a, 2011a). Cautious use is recommended for patients with gastrointestinal (GI) disorders. The risk for severe esophageal adverse reactions is greater in patients who lie down after taking these drugs or who fail to swallow them with a full glass (8 oz) of water. Etidronate has been withheld from patients with enterocolitis because diarrhea has occurred in some patients, particularly at high doses.

Etidronate has also been associated with fractures in patients with Paget's disease when they are given high doses or when therapy lasted longer than 6 months. These patients must be carefully monitored with x-rays and laboratory work to assess for these lesions. The development of a rare form of subtrochanteric femur fracture in non-Paget's patients using bisphosphonates is under close scrutiny and has contributed to movement away from osteopenia prevention care to only osteoporosis therapy (FDA, 2010a). The personal and economic impact of a patient sustaining a preventable hip fracture overshadows these risks (Black et al., 2010; Rizzoli et al., 2011).

IV formulations are associated with higher renal toxicity risk, especially with rapid infusion. Checking serum creatinine prior to every dose is required. Forcing fluids before and after infusion is also recommended (FDA, 2011).

Adverse Drug Reactions

An adverse drug reaction for all bisphosphonates is musculoskeletal pain. It is more common for patients with Paget's disease and in those taking risedronate and higher doses of etidronate. Musculoskeletal pain occurred in about 6% of patients taking alendronate and ibandronate.

Rare reports of osteonecrosis of the jaw have been associated with active dental disease or invasive procedures, especially in cancer patients, but it can occur without dental issues in those receiving frequent high IV doses. Earlier onset is associated with the IV forms of bisphosphonates, but oral medications may also carry the risk after 3 years of use (Fleisha et al, 2013; Zhang, Saag, & Curtis, 2011). If elective dental procedures are planned, drug cessation for 3 months pre- and

post-procedure may decrease the risk, but there is no evidence to support this plan (*DF & C* , 2011; McClung et al., 2013; Ruggiero et al, 2009).

Some concerns have arisen about increased risk of atrial fibrillation. A systematic review has shown a 27% increased risk to develop the rhythm, but no associated increase in stroke or cardiovascular related deaths (Sharma et al, 2013). Risk is increased with both oral and IV drug forms. Recommendations to halt use have not been made in those with pre-treatment atrial fib or for those at risk for other reasons (FDA, 2011; Institute for Clinical Systems Improvement [ICSI], 2011; Kim, Kim, Cadarette, & Solomon, 2010).

Drug Interactions

Because of these drugs' adverse reactions on the GI tract, drug interactions are most common with other drugs that also affect the GI tract. Histamine$_2$ blocking agents double alendronate bioavailability, but the impact is unknown (*DF & C*, 2011). Calcium supplements and antacids interfere with bisphosphonate absorption when taken within 1 hour of each other. The risk of GI bleeding is increased when aspirin and NSAIDs are concomitantly taken. Aspirin may decrease the bioavailability of tiludronate by up to 50% when taken 2 hours after the tiludronate. Although

indomethacin increases the bioavailability of tiludronate by 2- to 4-fold, the bioavailability is not significantly altered by diclofenac; therefore, each NSAID must be considered individually. Table 21-2 presents these and other drug interactions.

Concurrent use of bisphosphonates and other drugs known to build bone density, such as estrogens and SERMs, prove to have additive bone density, but fracture reduction potential is unknown. The safety of combination therapy appears to be the same as the use of each drug separately (*DF & C*, 2011). It is reserved for extreme cases where one drug is inadequate.

Clinical Use and Dosing

Osteoporosis

Clinical trial data support the use of bisphosphonates for prevention and treatment of osteoporosis and its risk for fractures in men and postmenopausal women, especially vertebral fractures. The best trials have been done with alendronate, risedronate, and zoledronic acid with hip fracture reductions (ICSI, 2011) and have received FDA approval for this indication. Ibandronate is considered a second-line drug (Watts et al, 2010). Ibandronate and zoledronic acid come in an IV form and alendronate has an oral solution (Binosto) for those patients unable to take tablets. Among

Table 21–2 ▦ **Drug and Food Interactions: Bisphosphonates**

Drug	Interacting Drugs and Food	Possible Effect	Implications
Alendronate	Ranitidine, aspirin, NSAIDs	Bioavailability doubled Increases risk of GI bleeding with doses more than 10 mg/d	Clinical significance unknown Avoid concurrent use
	Any food	Bioavailability decreased by 40%	Take 30 min or more before any food intake
	Coffee, orange juice	Bioavailability decreased by 60%	Take 30 min or more before intake
Etidronate	Warfarin	INR may increase when added to regimen that includes warfarin	Increase INR monitoring
Ibandronate	Ca^{++}, aluminum, Mg^{++}, and iron products Food and milk products	Decreased absorption	Take 60 min prior to food or mineral products
Risedronate	Any food	Bioavailability decreased	Take 30 min or more before any food intake
Tiludronate	Aspirin	Tiludronate bioavailability decreased by up to 50% when aspirin taken 2 h after the tiludronate	Avoid concurrent use or give aspirin more than 2 h after tiludronate
	Indomethacin	Increases tiludronate bioavailability 2- to 4-fold	Clinical significance unknown
	Any food	Bioavailability decreased by 90%	Take after overnight fast and 4 h before standard breakfast
Zoledronic acid	Concurrent use loop diuretics or aminoglycosides	Increases hypocalcemia risk	Check Ca^{++} levels before
All bisphosphonates	Calcium supplements, antacids	Interferes with bisphosphonate absorption Bioavailability may be decreased by 60% when given within 1 h	Take most bisphosphonates at least 30 min before; ibandronate requires 1 h before

these alternative forms, only the zoledronic acid shows evidence of hip fracture reduction.

Practitioners should consider prophylactic use of bisphosphonates in patients with early osteopenia related to long-term use of medications that contribute to bone loss, such as thyroid hormone, aromatase inhibitors, and glucocorticoids (Watts et al, 2010). The use of proton-pump inhibitors (PPI) and serontonin-receptor inhibitors (SSRIs) are newly linked with significant bone loss at a level equal to that of glucocorticoids (Adachi, 2013).

It is recommended that all adults taking more than 7.5 mg of prednisone or its equivalent for more than 3 weeks be given alendronate or risedronate (*DF &C,* 2011; Watts et al, 2010). In very high-risk patients, a maximum 2-year use of teriparatide (Forteo), a parathyroid hormone, may be more efficacious (ICSI, 2011). The bone mass benefit disappears after teriparatide discontinuance, a decline not seen with the

bisphosphonates for 5 years. Concerns about a cancer link (osteosarcoma) need to be considered with the use of teriparatide. There is currently an ongoing 15-year surveillance study of post-marketing incidence of osteosarcoma in patients taking teriparatide which started in 2003, with no pattern indicative of causal association at the 7-year mark in the study (Andrews et al, 2012).

Initial doses for prevention of bone loss for alendronate and risedronate are 5 mg/day or 35 mg/week. For treatment of existing osteoporosis, the dose of alendronate doubles to 10 mg/day or 70 mg/week, and the dose of risedronate increases to 75 mg for 2 consecutive days or 150 mg once a month. Therapy with 10 mg daily can increase bone density by up to 10% after 3 years and can decrease vertebral and hip fractures by 50% (Table 21-3). Use for more than 4 years is currently under review concerning its efficacy or safety. A "drug holiday" for up to 3 years may be considered for lower-risk

Table 21–3 ⊗ Dosage Schedule: Selected Bisphosphonates

Drug	Indication	Dosage Forms	Initial Dose	Maintenance Dose
Alendronate	Osteoporosis: men, post-menopausal women, glucocorticoid-induced	Tablets: 5, 10, 35, 40, 70 mg Oral solution: 70 mg	Prevention: 5 mg/d or 35 mg/wk Treatment: 10 mg/d or 70 mg/wk	5 mg/d or 35 mg/wk 10 mg/d or 70 mg/wk Renal parameters: CCr 35–60: no dosage adjustment CCr 35: use not recommended
	Paget's disease		40 mg/d for 6 mo	Re-treat if needed with same dose only after 6 mo post-treatment evaluation Renal dose as above
Etidronate (Didronel)	Paget's disease	Tablets: 200. 400 mg	5 mg/kg/d	5–10 mg/kg/d not to exceed 6 mo or 11–20 mg/kg/d not to exceed 3 mo; re-treat if needed with same dose only after 3–6 mo post-treatment evaluation Renal dose: serum creatinine 2.5–4.9, reduce dose Creatinine more than 5: use not recommended
	Heterotropic ossification: hip replacement		20 mg/kg/d for 1 mo pre-operatively	20 mg/kg/d for 3 mo post-operatively Renal dose as above
	Spinal cord injury		20 mg/kg/d for 2 wk	10 mg/kg/d for 10 wk Renal dose as above
Ibandronate (Boniva)	Osteoporosis prevention and treatment	Tablets: 150 mg 1 mg/mL prefilled syringe for IV is brand only	2.5 mg daily or 150 mg monthly; IV 3 mg over 30 sec bolus	Same Renal dose: CCr <30 contraindicated
Pamidronate (Aredia)	Paget's disease	Powder for injection 30 mg and 90 mg; injection 3, 6, 9 mg	30 mg IV over 4 hon 3 consec days	Evaluate in 6–9 mo if repeated dose required
Risedronate (Actonel)	Osteoporosis prevention and treatment: men, postmenopausal women, and glucocorticoid-induced osteoporosis	Tablets: 5, 30, 35, 75, 150 mg	5 mg/d or 35 mg/wk or 75 mg on two consecutive dates monthly or 150 mg/mo	Not to exceed 10 mg/kg/d for 6 mo or 11–20 mg/kg/d for 3 mo Renal dose: CCr less than 30: use not recommended

Table 21–3 🔗 Dosage Schedule: Selected Bisphosphonates—cont'd

Drug	Indication	Dosage Forms	Initial Dose	Maintenance Dose
	Paget's disease		30 mg/d for 2 mo	Re-treat if needed with same dose only after 2 mo post-treatment evaluation Renal dose: as above
Tiludronate (Skelid)	Paget's disease	Tablet: 240 mg in foil strips of 56	Two 240 mg tabs give 400 mg of actual medication	400 mg/d for 3 mo; re-treat if needed with same dose only after 3 mo post-treatment evaluation Renal dose: CCr less than 30: use not recommended
Zoledronic acid (Reclast and Zometa)	Osteoporosis Paget's disease Treatment and prevention	5 mg/100 mL IV dose	5 mg IV infusion yearly	Renal dose: If serum Cr greater than 4.5, consider risks

patients; higher-risk patients are encouraged to remain on therapy due to a better risk versus harm profile (McClure, et al, 2013).

The initial and maintenance dosage of ibandronate for both prevention and treatment is one 2.5 mg tablet taken daily or one 150 mg tablet taken once monthly on the same date of each month. The IV dose is 3 mg given over 30 seconds and repeated every 3 months, a schedule that must be closely maintained for best results. Another IV osteoporosis treatment and fracture prevention medication is zoledronic acid (5 mg), which is taken only yearly. The 4 mg dosing is typically reserved for monthly cancer metastasis prevention and treatment.

Although its labeled use is for treatment of Paget's disease, etidronate has been prescribed off-label to treat post-menopausal osteoporosis and prevent further bone loss in early postmenopausal women. Dosage is 400 mg daily for 14 days, followed by 76 days of elemental calcium, 500 mg daily. This drug also has an off-labeled use in the treatment of glucocorticoid-induced bone loss in postmenopausal women. Dosage is 400 mg daily for 1 month and then 400 mg daily for 2 weeks every third month, plus calcium and ergocalciferol. None of the major guidelines mentions etidronate for this indication.

The antiresorptive property of raloxifene (a SERM) as a bone supplement is less dramatic. Post menopausal estrogen replacement is covered elsewhere. The combination of estrogens with an atypical SERM, bazedoxifene (Duavee), is a limited impact medication for bone health. (See Chap. 38.) The RANKL drugs such as teriparatide have some cancer concerns that are dose and treatment duration dependent (Forteo Package Insert, 2012). Alternative agents such as phytoestrogens, synthetic isoflavones, natural progesterone cream, magnesium, vitamin K, and eicosapentaenoic acid have also been subjected to limited randomized clinical trials. Findings from these trials have been inconsistent in their support of these alternative agents (Whelen, Jurgens, Bowles, & Doyle, 2009). Fluoride is of no help (Grey et al, 2013). Vitamin D alone is not an effective alternative.

The costs for bisphosphonates are high for the branded and IV-delivered products. The advent of generic tablets has significantly changed prices from several hundred dollars a month to about a hundred dollars per month. The lowest cost drug tends to be aldendronate generic.

Paget's Disease *(Osteitis Deformans)*

All bisphosphonates are used to treat Paget's disease when the alkaline phosphatase is at least twice the upper limit of normal. They may also be used for those who are asymptomatic or at risk for future complications from their disease. Symptomatic Paget's disease is best treated with etidronate. Editronate slows accelerated bone turnover in pagetic lesions and, to a lesser extent, in normal bone. This reduced turnover is accompanied by symptomatic improvement, including less bone pain and decreased bone fractures. The initial dose is 5 to 10 mg/kg daily for up to, but not exceeding, 6 months, or 11 to 20 mg/kg daily, not to exceed 3 months. The higher doses are reserved for times when lower doses are ineffective or when there is an overriding need for suppression of increased bone turnover. Doses greater than 20 mg/kg daily are not recommended. Retreatment for relapse is acceptable only after more than 90 drug-free days and when there is evidence of active disease. Dosage is the same as for initial treatment.

Treatment with alendronate using doses of 40 mg daily for 6 months has produced highly significant decreases in serum alkaline phosphatase as well as in urinary markers of bone collagen degradation (*DF & C,* 2011). Retreatment may be considered after a 6-month post-treatment evaluation period. Risedronate treatment is 30 mg daily for 2 months. In patients with this treatment protocol, bone turnover returned to normal in a majority of the patients and no evidence of new fractures was found (*DF & C,* 2011). Retreatment requires a post-treatment evaluation time of 2 months. Tiludronate treatment is 400 mg daily for 3 months. Patients on this protocol had a reduction toward normal in the rate of bone turnover and a reduced number of osteoclasts. Retreatment occurs only after a 3-month post-treatment evaluation. Pamidronate IV is useful in patients with moderate to

severe Paget's disease. For all of these drugs, indications for retreatment are evidence of active disease or failure to normalize alkaline phosphatase levels.

Patients with Paget's disease benefit from supplemental calcium and vitamin D if their dietary intake is not adequate. Consideration must be given to spacing the administration of the calcium supplement and the bisphosphonate to prevent reduction in bioavailability.

Heterotopic Ossification

When heterotopic ossification is a complication of total hip replacement, etidronate may be used at 20 mg/kg daily for 1 month pre-operatively and 20 mg/kg daily for 3 months post-operatively. Etidronate is also used when heterotopic ossification occurs secondary to spinal cord injury. The dosage then is 20 mg/kg daily for 2 weeks, followed by 10 mg/kg daily for 10 weeks, begun as soon as possible after the injury and prior to evidence of heterotopic ossification.

Other uses of bisphosphonates to treat the hypercalcemia of malignancy are with parenteral dosage forms and are usually reserved for use by specialists. These uses are not discussed here.

Rational Drug Selection

Alendronate, ibandronate, risedonrate, and zoledronic acid are approved by the FDA for prevention and treatment of osteoporosis in postmenopausal women, but some health-care providers have used etidronate. There have been no randomized, controlled studies comparing the FDA-approved drugs with etidronate, but the same bone mineral density has not been achieved by cyclic use of etidronate as has been achieved by the use of the other drugs. In addition, 3- to 4-year studies of etidronate are inconclusive with regard to fracture prevention.

For the treatment of Paget's disease, bisphosphonates may be used, but ibandronate does not have approval for this indication. Etidronate has been used longer for this indication and has midrange adverse drug reactions. Clinical trials reported in *Drug Facts and Comparisons* (2011), however, showed increased efficacy of alendronate over etidronate in suppression of alkaline phosphatase, with a response rate of 85% for alendronate as compared with 30% for etidronate and 0% for placebo. In addition, alendronate produced mild, transient, and asymptomatic decreases in serum calcium and phosphate as compared with etidronate. *Drug Facts and Comparisons* also reported a positive-controlled study conducted in Europe, with treatment groups taking 400 mg/day of tiludronate versus 400 mg/day of etidronate for 6 months. Tiludronate was more efficacious than etidronate in that trial. Risedronate has the highest adverse drug reaction profile. With consideration of all these factors, the drugs of choice appear to be alendronate and tiludronate.

Monitoring

Before beginning treatment, rule out common treatable disorders that can also cause low bone density. These include hyperparathyroidism, vitamin D deficiency, hyperthyroidism, and renal disease. Tests for these disorders are serum calcium and albumin, 25-hydroxy vitamin D, thyroid-stimulating hormone (TSH), and serum creatinine levels, respectively. Serum creatinine levels are drawn prior to initiating therapy. Dosage alterations or contraindications to using specific bisphosphonates occur with serum creatinine levels above 2.5 mg/dL. Because bisphosphonates inhibit intestinal calcium transport, careful monitoring of serum calcium should be done during therapy. Phosphate, magnesium, and potassium should also be monitored because these electrolytes may be altered by bisphosphonate administration.

Elevation of alkaline phosphatase is a major indicator of Paget's disease and its reduction is an indicator of the efficacy of treatment. Alkaline phosphatase should be monitored prior to initiating therapy, at the end of each cycle of therapy, and prior to initiating any retreatment.

Measurement of bone mineral density is the most accurate predictor of fracture risk and the efficacy of these drugs. Each 10% change below peak bone mass is associated with a doubling of the fracture risk for patients with osteoporosis. Dual-energy x-ray absorptiometry (DEXA) is the gold standard by which bone mineral density and therapy are monitored. Initial evaluation with DEXA can also suggest when a disease process other than aging is the probable cause of the bone loss. Once therapy has been established, DEXA is repeated 1 to 2 years later to determine progress. Whether to repeat DEXA again at later dates is controversial (Watts et al, 2010). The use of DEXA and other bone risk factors are also covered in Chapter 38.

Patient Education

Administration

The oral drugs should be taken first thing in the morning, at least 30 minutes prior to other medications, beverages, or food (60 min for ibandronate). Etidronate and tiludronate should be taken 2 hours before any food. Alendronate, ibandronate, risedronate, and tiludronate should be taken with 8 oz of plain water. Mineral water, coffee, orange juice, and other beverages greatly reduce absorption. If supplemental calcium or antacids are taken, the bisphosphonate must be administered at least 1 hour before these other drugs. If a daily dose is missed, that dose should be skipped and the patient should resume taking the drug the next morning. For ibandronate, if the once-monthly dose is missed, and the next scheduled dose is more than 7 days away, the patient should take one 150 mg tablet in the morning following the date that it is remembered and then return to the every month dosing on the original schedule. Double doses should not be taken nor should the patient take doses later in the day. Remaining upright for at least 30 minutes after taking the oral medications (60 min for ibandronate) facilitates passage out of the stomach and minimizes the risk for esophageal irritation. The IV forms of zoledronic acid and ibandronate can be taken without regard for food but must be administered by health-care professionals.

Adverse Reactions

GI distress and dyspepsia are the most common adverse reactions. If needed, aluminum- or magnesium-containing

antacids may be taken more than 2 hours after the bisphos-phonate. If diarrhea occurs with etidronate, the health-care provider may divide the dose throughout the day to control the diarrhea. Female patients should advise their health-care provider if pregnancy is planned or suspected or if they are breastfeeding. The drug may have to be changed or stopped.

Lifestyle Management

The patient should eat a balanced diet with adequate amounts of calcium and vitamin D. Supplemental calcium and vitamin D are typically needed. Regular exercise is beneficial for cardiovascular fitness as well as preserving bone mass. Behaviors such as smoking and alcohol intake that increase the risk of osteoporosis should be reduced or stopped. Because relapse is not uncommon, keeping follow-up appointments to monitor progress, even after the drug is discontinued, is important.

HYPOTHALAMIC AND PITUITARY HORMONES

A combination of neural and endocrine systems located in the hypothalamus and the pituitary gland mediates control of metabolism, growth, and certain aspects of reproduction. The hormones involved in these hypothalamus-pituitary-hormone axes are adrenocorticotropic hormone, corticotropin-releasing hormone, follicle-stimulating hormone, growth hormone, growth hormone–binding protein, growth hormone–releasing hormone, gonadotropin-releasing hormone, insulin-like growth factor 1, luteinizing hormone, luteinizing hormone–releasing factor, prolactin-releasing factor, prolactin, somatotropin-releasing factor, thyrotropin-releasing hormone, and thyroid-stimulating hormone.

The reproductive hormones are covered in Chapter 22, the corticosteroid-related hormones are covered in Chapter 25, and the thyroid-related hormones are discussed later in this chapter. This section discusses the growth-hormone axis. Drugs affecting this axis are prescribed by specialists; the role of the primary care provider is largely to monitor the drug and its place in the total treatment regimen of the patient. The predominant use is in children with short stature; however, some adults with pan-pituitary failure may also benefit (Molitch, Clemmons, Malozowski, Merriam, & Vance, 2011).

Pharmacodynamics

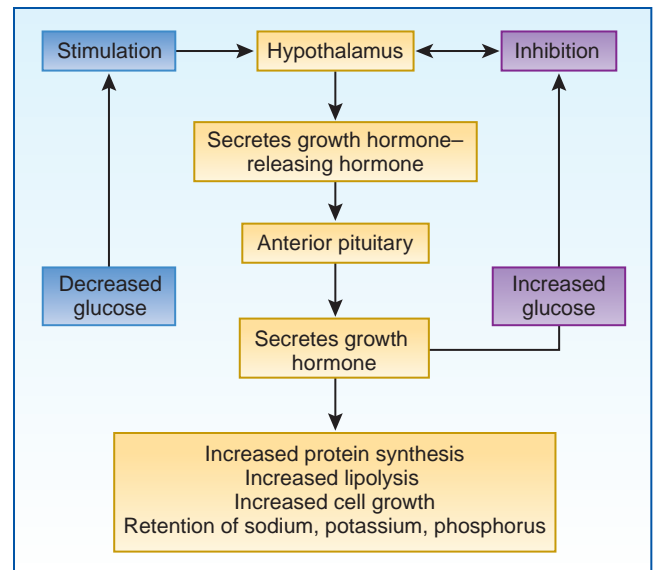
The hypothalamus-pituitary–growth hormone axis (Fig. 21-2) begins with growth hormone–releasing hormone (GHRH), which is secreted by the hypothalamus in response to decreased serum glucose levels in the body (hypoglycemia stimulates secretion, and hyperglycemia inhibits it). GHRH then binds to receptors in the anterior pituitary, resulting in the secretion by that gland of growth hormone (GH) (also called somatotropin). GH is a single peptide that attaches to receptors that allow it to pass through the cell membrane. Once inside cells, GH fosters protein synthesis, fat breakdown, and tissue growth. GH also causes hyperglycemia by decreasing glucose utilization by cells and increasing the rate by which


Figure 21–2. Hypothalamus-pituitary–growth hormone axis.

glycogen is broken down into glucose. Both GHRH and GH have now been synthesized by recombinant DNA technology and are available in drug form. They produce the same actions as the natural hormones.

The primary role of GHRH is as a diagnostic tool for evaluation of children of short stature in order to assess for dysfunction of the hypothalamus or the pituitary. It will not be discussed further.

Administration of synthetic GH somatropin (191 amino acids) and somatrem (somatropin plus the amino acid methionine), results in an initial insulin-like effect, with increased tissue uptake of both glucose and amino acids and decreased lipolysis. Within a few hours, there is a peripheral insulin antagonistic effect, with impaired glucose uptake and increased lipolysis. These drugs also stimulate synthesis of somatomedins in the growth plate cartilage and the liver, resulting in increased linear, organ, and skeletal growth and increased cellular protein synthesis. Children with GH deficiency sometimes experience hypoglycemia that is improved by administration of these drugs. Patients may also experience reduction in fat stores, increased lean muscle mass, and decreased mean cholesterol levels. Conflicting results are reported for adult patients (Molitch et al, 2011). Tesamorelin (Egrifta—a synthetic growth hormone–releasing factor) has been approved by the FDA to treat the lipodystrophy of HIV patients (FDA, 2010c). Reduction of wasting and cachexia are desired effects when used in AIDS patients (Serostim somatropin [rDNA origin] only) (FDA, 2003).

In cases of overabundance of growth axis hormones (acromegaly), pituitary surgical interventions are primary interventions, but the recurrence rate sometimes requires the use of somatostatin analogues such as octreotide or lancreotide (Katznelson et al, 2011). These GH suppressant agents are also used in GI bleeds and cases of severe diarrhea in AIDS patients. The benefit of using GH for AIDS wasting

is reversed if the analogues are also used. These high-cost parenteral medications are not further discussed in this chapter. The supplemental use of dopamine agonists like cabergoline is also not covered.

Pharmacokinetics

Absorption and Distribution

Somatrem and somatropin are both well absorbed after subcutaneous (SC) or intramuscular (IM) administration (Table 21-4). They tend to localize to highly perfused organs, such as the liver and kidney. The area under the curve (AUC) of the two drugs is similar and does not vary based on the injection type or site.

Metabolism and Excretion

Circulating hormone has a half-life of about 20 to 25 minutes and is predominantly cleared by the liver. In the kidney, both drugs are filtered by the glomerulus, reabsorbed in the proximal tubule, and broken down within the renal cells into amino acids that return to the circulation. The total mean half-life of both drugs from administration to elimination is 3.8 to 4.9 hours. Active blood levels persist for up to 36 hours. This factor is the basis for every-other-day treatment plans; however, daily dosing produces more consistent growth (Rogel, 2012).There is a reduction in hormone clearance in patients with hepatic or renal dysfunction.

Pharmacotherapeutics

Precautions and Contraindications

Growth hormone supplements are generally contraindicated in patients with closed epiphyses and those with evidence of active tumor growth. GH is used cautiously in patients with intracranial tumors because it can increase the tumor growth. Patients with coexisting adrenocorticotropic hormone deficiency may experience increased symptoms of this disorder. Serum levels of inorganic phosphorus, alkaline phosphatase, and parathyroid hormone may increase with GH therapy. Changes in thyroid hormone levels have also occurred. This makes management of thyroid disorders more difficult. In addition, untreated hypothyroidism prevents optimal response to GH therapy.

Insulin resistance may be induced by GH. The drugs are used cautiously with diabetic patients and those with glucose intolerance or risk of metabolic syndrome. The potential lipid benefits may make the risk worthwhile. The safety and efficacy of synthetic GH have not been established in pregnancy and lactation. They are Pregnancy Category C and should be used only if clearly needed.

Adverse Drug Reactions

Approximately 30% to 40% of patients on somatrem and 2% to 4.7% of patients on somatropin develop persistent antibodies, making them less likely to respond to the drug. Other adverse reactions are rare and include pain at the injection site, hyperglycemia, hypothyroidism, and edema secondary to retained sodium. Rare instances of death have been reported (FDA, 2011). Evidence is not available on longer-term issues of carbohydrate, protein, and fat metabolism.

Drug Interactions

Glucocorticoid therapy and estrogens may inhibit the growth-promoting effect of GH. Anticonvulsants may have more severe side effects. Insulin may lose its effectiveness.

Clinical Use and Dosing

Growth Failure Associated With Chronic Renal Insufficiency

Growth hormone is used to treat children with growth failure up to the time of renal transplantation (National Institute for Health and Clinical Excellence [NICE], 2010). The dosages used are higher than normal due to a relative hormone resistance. Use after transplantation is typically restricted to children 2 standard deviations below the mean for their gender if they have not experienced epiphyseal closure. Growth hormone is known to increase the side effects of cyclosporine, so it is typically evaluated 1 year after transplant for continued use. To optimize therapy for patients receiving hemodialysis, injections are given at night, just prior to going to sleep, or at least 3 to 4 hours after dialysis to prevent hematoma formation caused by the heparin. Patients undergoing chronic cycling peritoneal dialysis (CCPD) receive their injections in the morning after they have completed dialysis. Patients undergoing chronic ambulatory peritoneal dialysis (CAPD) receive their injections in the evening at the time of the overnight exchange.

Long-Term Treatment of Growth Failure in Children Who Lack Adequate Endogenous GH

Somatrem and all forms of somatropin (except Serostim) have been used for this indication. Dosing is started at 40 mcg/kg day and titrated to individual patient response. Younger children respond better than prepubertal adolescents. Doses in excess of 0.3 mg/kg have resulted in risks of known effects of excess human GH. Dosage of the various

Table 21–4 ⊞ Pharmacokinetics: Growth Hormones

Drug	Onset of Effect	Peak (Drug in Plasma)	Duration (Drug in Plasma)	Bioavailability	Half-Life (Normal Renal Function)	Elimination
Somatrem, somatropin	Within 3 mo	7.5 h	36 h	75% (SC) 63% (IM)	3.8 h (SC) 4.9 h (IM)	By liver and kidney

forms of somatropin varies by manufacturer; selected forms shown in Table 21-5. Nocturnal administration is based on expert opinion to mimic native GH secretion patterns, not on evidence establishing circadian efficacy (Rogel, 2012).

Turner's Syndrome

Somatropin is approved for long-term treatment of short stature associated with Turner's syndrome. Specific dosing scheduling is individualized. A relative hormone resistance

Table 21–5 ⊗ Dosage Schedule: Selected Growth Hormones

Drug*	Indication	Dosage Form	Initial Dose	Maintenance Dose
Somatropin (Nutropin and Nutropin AQ)	Growth failure related to chronic renal failure	Powder: 5 mg and 10 mg vial Depot: 13.5, 18, and 22.5 mg AQ: 10 mg vial	Not more than 0.0006 mg/kg daily	0.35 mg/kg/wk (see note in text regarding hemodialysis and transplant)
Somatrem (Protropin)	Growth failure due to inadequate endogenous growth hormone (kids)	Powder for injection: 5 mg per vial, 10 mg per vial	0.1 mg/kg	0.1–0.3 mg/kg 3 times/wk; not to exceed 0.3 mg/kg
Somatropin (Gentropin)	Growth failure due to inadequate endoge-nous growth hormone	10 mg (30 IU) in 3mL cartridges	*Children:* 0.07 mg/kg/d *Adults:* 0.3 mg/d	*Children:* 0.16–0.24 mg/kg/wk in equal doses divided into 6–7 injections *Adults:* Increase every 1–2 mo by 0.15 mg/d
	Turner's syndrome		0.375 mg/kg in divided 6–7 doses per wk	
Somatropin (Humatrope)	Growth failure due to inadequate en-dogenous growth hormone or somatropin deficiency	Powder for injection: 5, 6, or 24 mg In vial with 5 mL of diluents In cartridge with prefilled syringe and diluent	*Children:* 0.18 mg/kg/wk *Adults:* 0.006 mg/kg/d	*Children :* 0.18–0.3 mg/kg/wk di-vided into equal doses, given on 3 alternate days or 6 d/wk *Adults:* 0.006 mg/kg/d
Somatropin (Norditropin)	Growth failure due to inadequate endoge-nous growth hormone	Powder for injection: 4 and 8 mg Injection: 5, 10, and 15 mg/ 1.5 mL In vials with diluents or cartridges	0.024 mg/kg	0.024–0.034 mg/kg, given 6–7 times weekly
Somatropin (Nutropin)	Growth failure due to inadequate endogenous growth hormone	Powder for injection: 5 and 10 mg vial in cartons of 2 vials with 10 mL multidose vial of diluent Depot: 13.5,18, and 22.5 mg in single-use vials with 1.5 mL diluent and needles AQ: 10 mg multidose vial	0.3 mg/kg	0.3 mg/kg/wk
Somatropin (Accretropin)	Growth failure due to inadequate endogenous growth hormone	15 IU/mL vial	0.18mg/kg in divided doses	Up to 0.3mg/kg divided over 6–7 times/wk
	Turner's syndrome		0.36 mg/kg in divided doses given 6–7 times/wk	
Somatropin (Saizen)	Growth failure due to inadequate endogenous growth hormone	Powder: 5 and 8.8 mg vials Easy Click System: 8.8 mg drug + 1 cartridge diluent	*Children:* 0.18 mg/kg/wk in equal divided doses in 3 alternate or 6 times/wk or daily dosing *Adults:* 0.2 mg/day	*Adults:* increase every 1–2 months by increments of 0.1–0.2 mg/d Max of 0.01 kg/d

Table 21–5 ⊗ **Dosage Schedule: Selected Growth Hormones—cont'd**

Drug*	Indication	Dosage Form	Initial Dose	Maintenance Dose
Somatropin (Serostim)	Treatment of HIV patients with wasting and cachexia	4, 5, or 6 mg vial needing to mix with sterile water for injection	*Adults:* 0.1 mg/daily at bedtime	*Adults:* Increase up to 6 mg total

Many additional formulations available with unique dosing patterns.

is common, requiring higher doses to obtain growth. Traditionally, introduction of estrogen to stimulate puberty has been delayed as long as possible for best terminal height achievement. Small studies introducing very-low-dose estrogen around normal menarche indicate improved outcomes. This might influence practice in the future in combination with the known positive effects of estrogen on other body systems (Ross et al, 2011).

Somatropin Deficiency

Patients must meet strict criteria before growth hormone is prescribed by the endocrinology team. For children, the recommended weekly dose of Humatrope is 0.18 mg/kg, divided into equal doses and given either on 3 alternate days or 6 times per week SC. For adults, the recommended SC dose is started at 0.006 mg/kg given daily and increased to a maximum of 0.0125 mg/kg daily, based on patient response. Practitioners are cautioned to reference the dosing schedules of each individual brand, as they all vary. This is not an independent primary care decision.

Rational Drug Selection

Choice of drug is based on indication and multiple variables considered by the endocrinology team. Costs are significant and coordination with patient assistance and prior authorization of insurance programs is typically needed. There are no evidence-based indications growth hormone will stop aging (Molitch et al, 2011). Inappropriate use is akin to anabolic steroid abuse. It results in similar issues of insulin resistance, fluid resistance, liver damage, and organ hypertrophy.

Monitoring

Prior to initiating and throughout therapy, hepatic and renal function studies are done. Patients with thyroid dysfunction, diabetes mellitus, or glucose intolerance have their disease processes more carefully monitored, as discussed in the Precautions and Contraindications section.

Growth responses are not linearly associated with dosing. A target height goal is set at the 75th percentile for other children of similar parental heritage or at a calculated genetic target height calculated from the parents (Box 21-1). Monitoring of bone age by x-ray is done to evaluate growth and to determine epiphyseal closure (typically age 14 or 15 in girls, 15 or 16 in boys). The schedule for this assessment is determined by the endocrinology team and may be influenced by IGF-1–level monitoring and Tanner stages. Dosing is typically

---

BOX 21–1 CALCULATING TARGET HEIGHT GOAL

The average expected growth with hormone therapy can be estimated. For girls, subtract 13 cm from the father's height and average this number with the mother's height. For boys, add 13 cm to the mother's height and average the sum with the father's height (Albert, 2012). Conversion from inches to cm is achieved by using the formula 1 in. = 2.54 cm. A mother who is 65 in. tall would be 165.1 cm. A father who is 68 in. tall would be 172.72 cm. For their daughter, the calculation would be 172.72 – 13 cm, or 159.72, which averaged with the mother's 165.1 cm would yield a 162.41 cm expected height.

---

halted when growth is less than 2 cm over the previous year (NICE, 2010). The majority of children do not need dosing into adulthood. They should be monitored for increasing alkaline phosphate, hypertension, and acromegalic changes (in adults), which are indicative of excessive dosing. Abuse of all of these drug formulations exists for illegal athletic performance enhancement and non-FDA-approved antiaging properties. Excessive requests for refills should be monitored.

Patient Education

These drugs are usually injected at home by a family member or self-administered. Education is directed to both the patient and the person who will administer the drug. Information about proper use and disposal of needles and syringes and cautions against reuse of needles is important. Consistent dosing yields consistent results; however, stopping the drug for financial or supply considerations does not induce any major adverse issues. Caution that one drug dosing is not the same as another and reconstitution requirements differ between brands.

Administration

These drugs have specific reconstitution and storage requirements. Storage for all of them is at temperatures from 2°C to 8°C (36°F to 46°F). They are not to be frozen. Each brand has a specific reconstitution formula. Reconstituted vials are stable in refrigeration for 14 to 28 days, depending on the brand (except for Serostim, which is stable for only 24 hours). Newer formulations do not always require reconstitution.

There are multiple studies currently in progress studying the short- and long-term effects of growth horomone in children and adults. Sustained, related, once-weekly injections of growth hormone currently in clinical trials portend sustained growth without impaired bone maturation.

The techniques for injection and site selection must be taught to the patient or caregiver. The dosage schedule must be reviewed because it can vary on a weekly basis. A calendar marked with the days of the week when the drug is to be given and the appropriate dose may be helpful to children assuming self-management of their therapy.

Adverse Reactions

Adverse reactions are typically minimal. Patients and their parents should be taught to report persistent pain at the injection site and edema. Because of the potential for hyperglycemia, patients should also be taught the signs and symptoms of this disorder and what to do should it occur. Growing pains are to be anticipated. Development of cancer requires discontinuation. Growth of pseudo-tumor cerebrii has been reported, so headache and neurological changes must be evaluated.

Lifestyle Management

Emphasize the need for regular follow-up visits with the endocrinology team to ensure appropriate growth rate, laboratory work, and determination of bone age by x-ray. Bone health nutrition tips to include active exercise with calcium and vitamin D supplementation also applies to this population.

EXOCRINE PANCREATIC ENZYMES

The exocrine functions of the pancreas are related to secretion of enzymes into the gut for digestion. Disorders that decrease pancreatic function impair the production and secretion of these enzymes and, therefore, impair digestion. Two major disorders that are characterized by decreased pancreatic functioning are cystic fibrosis and pancreatitis. Some bariatric procedures may also induce need for enzymatic supplementation. Pancreatic cancer and short bowel syndrome patients may also benefit. The prescriber is cautioned that pancreatic endocrine insufficiency can coexist with pancreatic exocrine issues.

Cystic fibrosis (CF) affects approximately 30,000 people in the United States (Cystic Fibrosis Foundation, 2014). Once a disease of childhood, improved and aggressive management has resulted in survival into adulthood and middle age with approximately half of CF patients over age 18 years. Initially, this disorder is an obstructive lung disease, but plugging of the pancreatic ducts eventually results in pancreatic insufficiency, with resultant malabsorption of protein, fat, and carbohydrates. This potentially results in failure to thrive and growth impairment as well.

Acute pancreatitis and chronic pancreatitis are both characterized by inflammation that results in swelling and obstruction of the pancreatic ducts. This obstruction leads not only to activated enzymes digesting the pancreas itself but also to failure of the enzymes to reach the duodenum; thus, the same malabsorption problems as occur in CF. Only bariatric surgery patients exhibiting malabsorption issues need enzyme supplementation.

Pharmacodynamics

The enzymes secreted by the exocrine pancreas are trypsinogen (protein digestion), chymotrypsin (protein digestion), amylase (carbohydrate digestion), and lipase (fat digestion). These enzymes are secreted into the bowel distal to the stomach. Pancrelipase contains principally lipase with some amylase and protease. This drug family substitutes for pancreatic enzymes and hydrolyzes fats to glycerol and fatty acids, changes proteins into peptides and amino acids, and converts starch into dextrins and sugars.

Pharmacokinetics

Absorption and Distribution

These agents exert most of their effects in the duodenum and upper jejunum with limited if any systemic distribution. Because they are inactivated by gastric acid pH of 4 or less and pepsin secretion, problems in drug delivery by the oral route may occur. Enteric coating may prevent destruction or inactivation by gastric acid but inhibits enzyme delivery to the duodenum. For this reason, it is important to synchronize the delivery of the drug with gastric emptying; therefore, the drug is taken immediately before or with a meal. Current FDA-approved products are not formally approved for use with GI tubes but are being tested. Safe, long-term experience with earlier formulations did not reveal any particular issue of concern (FDA, 2012).

Metabolism and Excretion

There is limited if any systemic distribution. There is no metabolism or excretion beyond that which would normally occur in the body with the natural secretion of these enzymes.

Pharmacotherapeutics

Precautions and Contraindications

Pancrelipase is derived from a porcine source. The enzymes increase uric acid levels, which may be an issue for those with gout or renal impairment. Pancreatin products are not FDA-approved at this time. They are derived from porcine, bovine, or vegetable sources, depending on the brand that patients might purchase internationally on the Internet. These drugs are contraindicated during acute exacerbations of chronic pancreatitis. During this time, patients receive nothing by mouth in order to rest the GI tract and have no need for these

enzymes. The presence of these enzymes would exacerbate the pancreatic disorder.

It is not known whether these drugs can cause fetal harm when administered to a pregnant woman. Most are considered Pregnancy Category C. Because there are no well-controlled studies on pregnant women, supplements should be given only if the benefit to the mother outweighs any risk to the fetus. It is also not known whether these drugs are excreted in breast milk and so should be used cautiously by nursing mothers.

Adverse Drug Reactions

High doses have been associated with GI symptoms, such as nausea, cramping, abdominal pain, diarrhea, and colonic strictures. One brand (Viokase) must be administered with a proton pump inhibitor (PPI) to help protect the gastric lining.

Irritation of the skin and mucous membranes occurs less commonly. Powder from inside capsules spilled on the hands may cause local irritation or irritate the nasal mucosa and respiratory tract. Inhalation of airborne powder can precipitate an asthma attack.

Drug and Food Interactions

Calcium- and magnesium-based antacids will decrease the effectiveness of the enzymes (Table 21-6). The ability of oral iron to increase serum iron levels may be reduced by concomitant administration. Alkaline foods destroy the coating of enteric-coated products, resulting in destruction of the enzymes by gastric acids.

Clinical Use and Dosing

Enzyme Replacement in Patients With Deficient Exocrine Pancreatic Secretions, Cystic Fibrosis, Chronic Pancreatitis, Pancreatic Insufficiency and Steatorrhea of Malabsorption Syndromes, and Post-Gastrectomy

The dosing and schedule for cystic fibrosis is the same for each of the FDA-approved enzymes. Adult dosing for pancreatic insufficiency is individualized and based on stool output and consistency. Although each drug is specified in lipase, protease, and amylase units, the drugs are prescribed in units of lipase. Infants under 1 year initiate therapy with 3,000 units of lipase per bottle or breast feed (Table 21-7). Some brands do not have infant dosing because dose formulations are

Table 21–6 ▦ Drug and Food Interactions: Pancreatic Enzymes

Drug	Interacting Drug	Possible Effect	Implications
Pancreatin, pancrelipase	Calcium carbonate, magnesium hydroxide	Decreases effectiveness of pancreatin and pancrelipase	Avoid concurrent administration
	Oral iron	Decreases the serum iron response	Avoid concurrent administration
	Alkaline foods	Destroys coating on enteric-coated products	Give enzymes first and separate administration by at least 1 h

not small enough to accurately dose infants. Capsules must be opened and sprinkled directly into the infant's mouth or on applesauce; the medication cannot be dissolved in milk or formula. Children 1 to 4 years old initiate therapy with 4,000 to 8,000 units of lipase sprinkled on acidic foods such as applesauce or commercially prepared bananas or pears. Several brands have dosage forms that can deliver this dose. Initial doses for children over 4 are listed the same as for adults because actual dosing is titrated to stool response. There are no studies using weight as an outcome, only this subjective steatorrhea response (Fieker, Philpott, & Armand, 2011).

Post-Pancreatectomy and Ductal Obstructions Caused by Cancer of the Pancreas or Common Bile Duct

The dosing and schedule for these indications starts with low values and can be taken at 2-hour intervals. In severe

deficiencies, the dose may be increased to a larger number of units of lipase with meals. The frequency of administration may be increased to hourly intervals unless nausea, cramps, or diarrhea occurs.

Rational Drug Selection

Cost

Historically, there have been many available dosages and brands of these drugs. Now with only six FDA-approved products, costs have become unpredictable as insurance companies adjust to FDA recommendations. Cash prices for one approved med (ZenPop) runs around $140.00 for a month's supply. Traditionally, pancrealipase drugs with higher lipase units are more expensive but are about as expensive as it would be to take enough of the lower-dose tablets to gain the higher dose. Given this fact, the dose per unit of lipase is about the same across brands. Many formulas available

online have not completed the newest FDA approval process (FDA, 2010). The Cystic Fibrosis Foundation (CFF) only endorses FDA-approved medications (CFF, 2009). Table 21-7 reflects only the FDA-approved meds as of this publication.

Brand

It is important to remember that the various brands are not bioequivalent. Each drug varies in the number of units of lipase, protease, and amylase present. When it is necessary to change brands to obtain a more rational dosing amount, the health-care provider should monitor the effect of the new drug on endpoints. Treatment failures have been reported in CF patients when brand-name products were replaced by a generic or when one product was switched for another (*DF & C,* 2011). Variability in manufacturing standards and bioavailability prompted the FDA to require all pancreatic enzymes to apply for approval from the FDA or to be eventually removed from the market (FDA, 2012).

Monitoring

Assessment of the efficacy of pancreatic enzyme replacement and the dosage of drug required is accomplished by determining which dose minimizes steatorrhea and maintains good nutritional status. The assessment of the endpoints in children is aided by charting growth curves. Other data include skinfold thickness, arm muscle circumference, and laboratory values such as albumin, cholesterol, glucose, hemoglobin, hematocrit, transferrin, and electrolytes. Because these drugs may produce elevated uric acid levels, serum and urine are tested for uric acid at regular intervals. Stools are monitored for fat content (steatorrhea), and the patient is told to report foul-smelling and frothy stools.

CF patients are originally diagnosed using a fecal elastase test to determine the need for pancreatic enzyme replacement. This test is not a quantitative measure; therefore, it is not used to monitor enzyme effect (CFF, 2009). In infants, fecal fat up to 15% of of total fat intake is normal, but this drops to less than 7% in childhood (CFF, 2009). Because fat malabsorption pathologies can render patients at risk for deficiencies in the fat soluble vitamins (A, C, E, and K), suspicion of hypovitaminosis and osteopenia should trigger monitoring of these key factors.

Patient Education

Administration

All doses are taken immediately before or with meals or snacks with a fatty component. Fruit, hard candy, fruit juice-like drinks, tea or coffee, or popsicles do not require enzymes (CFF, 2009). Capsules may be opened and sprinkled on food. Capsules with enteric-coated beads should not be chewed. They may be sprinkled on soft acidic food that is not hot and that can be swallowed without chewing, such as applesauce or gelatin. Swallow immediately because the proteolytic enzymes may irritate the mucosa. Following with a glass of water or juice or eating immediately after taking the drug helps to ensure that the medication is swallowed and does

not remain in contact with the mouth and esophagus for long periods. Pancrelipase is destroyed by acid. Proton pump inhibitors, sodium bicarbonate, or aluminum-based antacids may be used with preparations without enteric coating to neutralize gastric pH. Calcium- and magnesium-based antacids should not be used for this purpose because they interfere with drug action. Enteric-coated beads are designed to withstand the acid pH of the stomach. Enteric-coated formulations should not be mixed with alkaline food or the coating will be destroyed.

Adverse Reactions

Adverse reactions are usually GI in nature. The lowest effective dose should be used to minimize nausea, stomach cramps, abdominal pain, or diarrhea. Dosages or brands may need to be changed if symptoms persist. Washing off powder in contact with the skin is the only treatment required for any irritation. The dust of finely powdered concentrates may irritate the nasal mucosa and respiratory tract. Super-sensitive patients may need to mask during dose preparation.

Lifestyle Management

Pancreatic enzyme replacement is only part of the treatment regimen. It will not be successful without adherence to the rest of the treatment regimen. Dietary recommendations depend on the reason enzyme replacement is needed, but generally the diet is high calorie, high protein, and low fat. For children with CF, the diet is high calorie, high protein, and high fat. The dosage of the enzyme replacement is based on fat content of the diet, so the amount of fat in each meal should be fairly consistent. Small, frequent meals are often better tolerated than three large meals, especially when the reason for the enzyme replacement is CF, post-operative gastrectomy, or bariatric procedure. Use the same brand consistently. Enzymes should not be refrigerated, nor stored in hot places, and must be checked for expiration dates. The lid should be replaced tightly to avoid air and humidity interactions as needed.

ENDOCRINE PANCREATIC HORMONES (INSULIN)

Insulin is a small protein molecule secreted by the beta cells of the pancreas. It is essential to the utilization of glucose by all body cells. Disorders of insulin secretion and utilization are found in diabetes mellitus, and the primary use of insulin as a drug is the treatment for this disorder.

Type 1 diabetes accounts for 5% to 10% of total diabetes and results from an autoimmune destruction of the beta cells of the islet of Langerhans leading to complete insulin deficiency. Before hyperglycemia occurs, 80% to 90% of the function of insulin-secreting beta cells must be lost. Beta cell abnormalities are present long before the acute clinical onset of type 1 diabetes. Regardless of the cause, the pathology is probably disequilibrium between the relative excess production of glucagon by the pancreatic A cells and the lack of

insulin produced by the B cells. Treatment requires insulin replacement. If the disease progresses without treatment, diabetic ketoacidosis (DKA), weight loss, muscle wasting, and death may occur. Chapter 33 discusses the treatment of both type 1 and type 2 diabetes, including the use of insulin. Figure 33-1 depicts the pathological cause of the various symptoms of type 1 diabetes.

Pharmacodynamics

Insulin is normally released from pancreatic beta cells at a constant low basal rate with intermittent bursts in response to a variety of stimuli, including stress, vagal activity, and high blood glucose levels. Figure 21-3 shows one mechanism for the stimulation of insulin release from beta cells. Once the insulin has arrived at an insulin-sensitive cell, it is bound to specialized receptors that are found on the cell membrane. These receptors foster changes within the cell membrane that result in translocation of certain proteins, such as glucose transporters, from sequestered sites within the cell to the cell surface. Once on the cell surface, the transporter facilitates the intake of glucose by the cell. Several hormonal agents such as corticosteroids lower the affinity of the insulin receptor, and others such as GH increase this affinity. Insulin promotes the storage of fat as well as glucose and influences cell growth and metabolic functions in a wide variety of tissues.

Action on Glucose Transporters

The GLUT 1 insulin transporter is found in all tissue, especially in red blood cells and in the brain. It is associated with basal uptake of glucose and transport of glucose across the blood–brain barrier. The GLUT 2 transporter is found in the beta cells of the pancreas and in the liver, kidney, and gut. It regulates insulin release and glucose homeostasis. Defects in this receptor are thought to contribute to the reduced insulin secretion seen in type 2 diabetes. The GLUT 3 transporter is located in the brain, kidney, and placenta and is related to uptake of glucose in neurons and some other tissues. The GLUT 4 transporter is located in muscle and adipose tissue. It is the transporter most associated with lowering blood glucose (BG) levels and is the primary influence in glucose uptake, especially during exercise. It is also the one most associated with insulin resistance in type 2 diabetes. GLUT 5 transporters are found in the gut and the kidney. They are associated with intestinal absorption of fructose.

The total number of insulin receptors can be suppressed by such factors as obesity and long-standing hyperglycemia. This may explain why weight loss can be a significant factor in diabetes management.

Action on the Liver

Insulin acts on the liver to increase storage of glucose as glycogen and resets the liver after food intake by reversing the amount of catabolic activity. Insulin also decreases urea production, protein catabolism, and cyclic adenosine monophosphate (cAMP) in the liver; promotes triglyceride synthesis; and increases potassium and phosphate uptake by the liver.

Action on Muscle Cells

Insulin promotes protein synthesis by increasing amino acid transport and by stimulating ribosomal activity. It also promotes glycogen synthesis to replace glycogen stores used during muscle activity.

Action on Adipose Tissue

Finally, insulin reduces the circulation of free fatty acids and promotes the storage of triglycerides in adipose tissue. This process is accomplished, in part, by suppression of cAMP production and dephosphorylation of the lipases in fat cells.

Administration of insulin acts on each of these receptors to produce the same effect as the naturally occurring hormone. Although it is given largely to control blood glucose (BG) in patients with diabetes, that is not its only effect on the body.

Pharmacokinetics
Absorption and Distribution

Insulin is absorbed from SC or IM injection sites because it would be destroyed by proteolytic enzymes in the stomach if given orally. The absorption rate is determined by type of insulin, injection site, and volume injected. Inhaled forms are faster onset than the most rapid standard forms due to the capillary network of the lung. Insulin may also be given via IV and goes directly into circulation without the need for absorption. Insulin preparations are divided into types based on onset, duration, and peak intensity of action and whether inhaled or parenteral. Table 21-8 presents each type. Because human insulin has a more rapid onset and shorter duration of action than pork or beef insulin, and because it is less antigenic, it has replaced animal insulin. Injection sites in the abdomen have as much as 50% more absorption than the arm, followed by the thighs and buttocks.

Types of Insulin

Rapid-Acting (RAI)

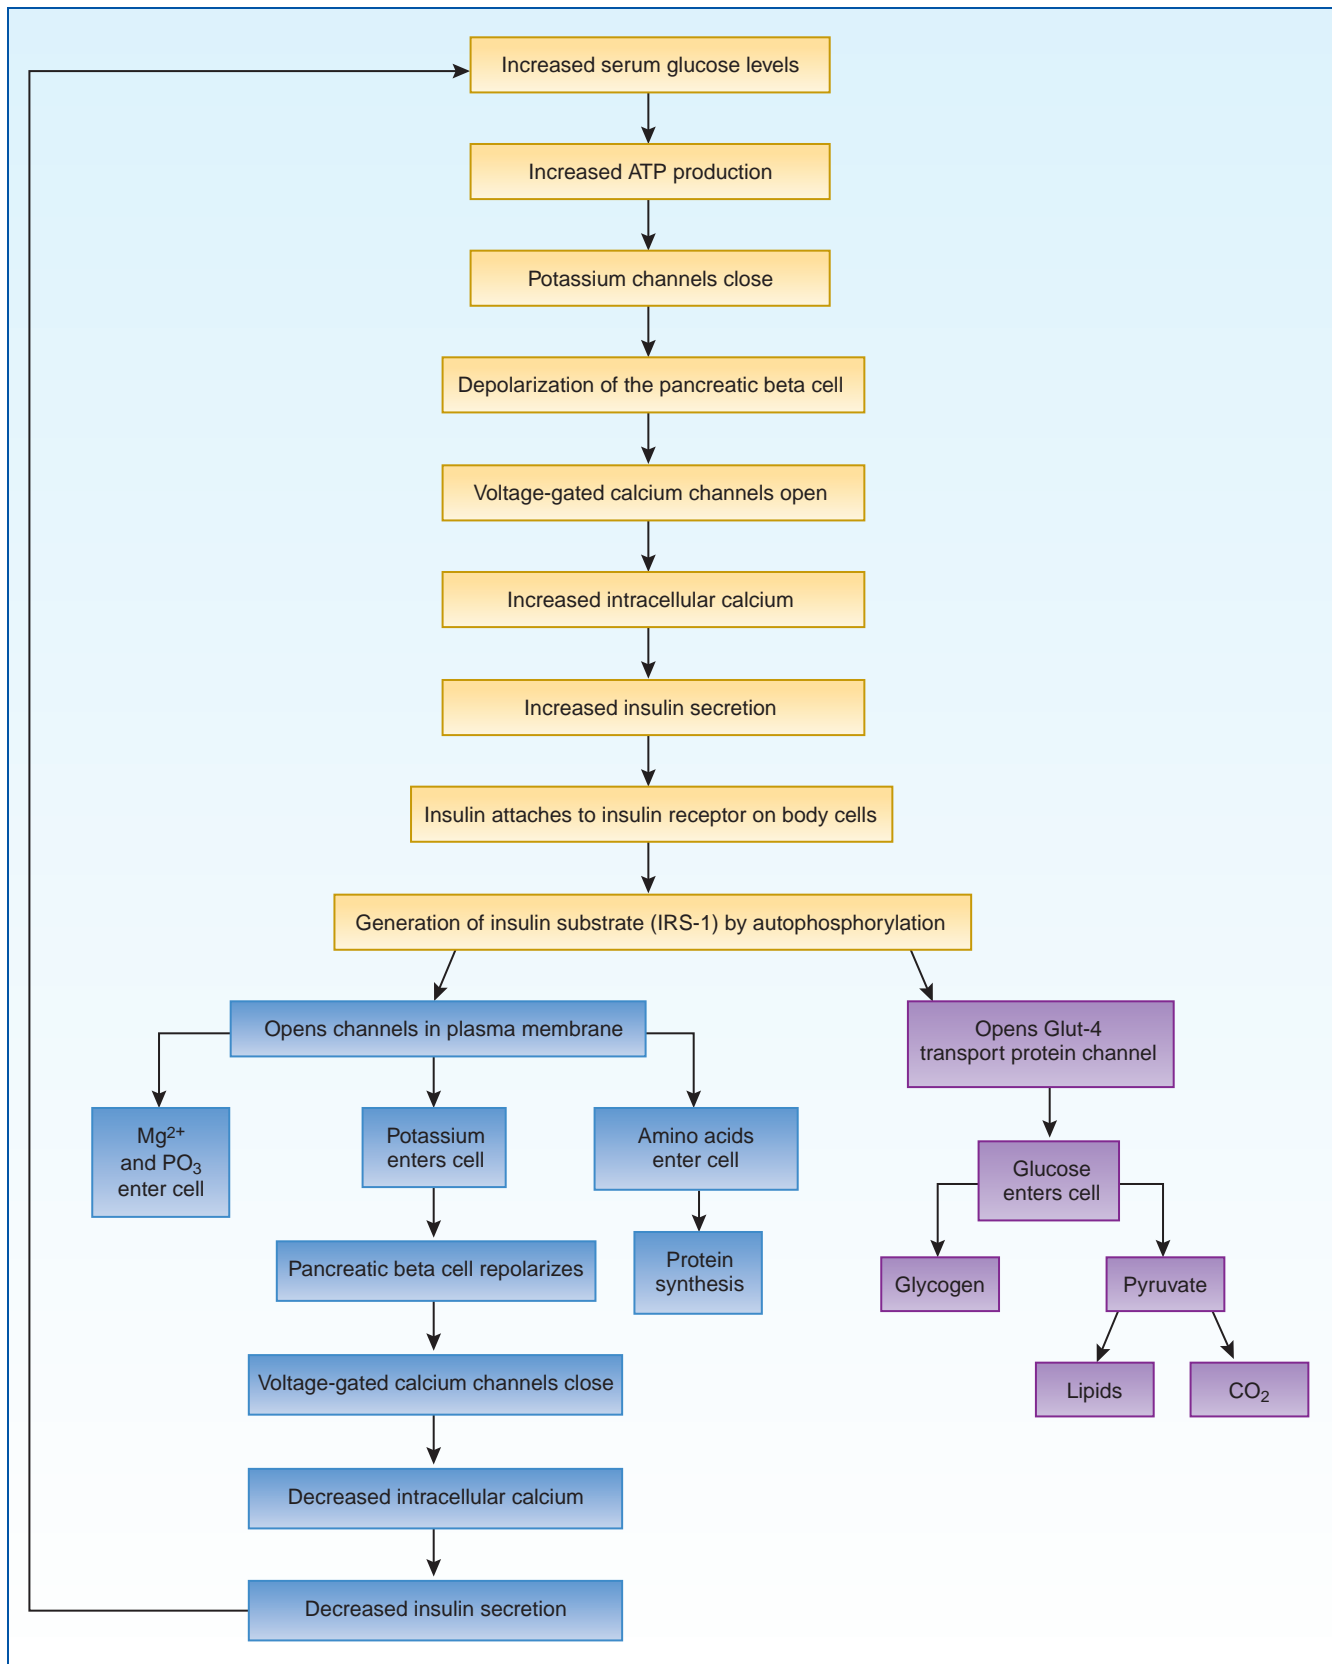
Lispro is an insulin analogue produced by recombinant DNA technology. It is created by reversing two amino acids on the insulin B chain. This rapid-acting insulin (RAI) has the same method of binding to insulin receptors, the same circulating half-life, and the same immunogenicity as regular insulin. Its onset of action, however, is much shorter—15 minutes—and it reaches its peak within 1 hour. Clinical trials have demonstrated that the optimal time for preprandial injection of this insulin is 15 minutes rather than the 30-minute interval used for regular insulin. The duration of action of this insulin is not increased with a larger dose. It is compatible with neutral protamine Hagedorn (NPH). Insulin aspart, homologous with regular human insulin except for one amino acid, has a rapid onset of action similar to that of insulin lispro. Insulin glulisine is created by replacing lysine and glutamic acid on the insulin B chain. Its profile is similar to that of lispro. The RAIs are used as bolus doses to correct hyperglycemia or to cover food eaten at meals, specifically carbohydrate (CHO).


Figure 21–3. Mechanism of insulin release from beta cells.

Table 21–8 ⬛ **Pharmacokinetics: Insulins**

	Onset (m)	Peak (h)	Duration (h)*	Elimination	Compatibility
Rapid-Acting					
Insulin aspart	0–15	0.5–2	3–5	Urine	NPH
Insulin glulisine	0–15	0.5–2	3–5	Urine	NPH
Lispro	0–15	0.5-1.5	3–5	Urine	NPH
Short-Acting Regular	30–60	2–3	3–7	Very little unchanged insulin is excreted in the urine	NPH
Regular U-500	30-45	2-4	8–24 hr*	Same	Not recommended
Intermediate-Acting NPH	30–60	4–10	10–16	Very little unchanged insulin is excreted in the urine	Regular, Glulisine, Lipro, Aspart
Long-Acting Insulin glargine	60	—	24	Urine	No other insulin
Insulin detemir	60	—	Up to 24	Urine	No other insulin
Inhaled Inhaled Human Insulin (Afrezza)	0-12**	1	2-3	Urine	N/A

*Duration of U 500 dependent on volume injected.

  **Afrezza has rapid absoption, but its actual onset of action is not faster than regular.

Short-Acting (SAI)

Regular insulin is a short-acting insulin (SAI) whose effect appears within 30 minutes of injection and generally lasts for 8 to 12 hours. The clinically significant duration of action is slightly less, at 4 to 6 hours. It is used as bolus insulin to correct hyperglycemia or to cover food eaten at meals.

Intermediate-Acting (IAI)

Neutral protamine Hagedorn (NPH) or isophane is an intermediate-acting insulin. The onset of action is delayed by combining the insulin with protamine. After SC injection, proteolytic enzymes degrade the protamine in NPH to permit absorption of the insulin. Its onset of action is 1 to 1.5 hours, and its duration is 12 to 24 hours, although the duration is usually no longer than 16 hours in actual clinical effect. NPH is used as basal insulin in both types 1 and 2 diabetes.

Long-Acting (LAI)

Insulin glargine is created by substituting glycine and arginine for other amino acids in human insulin. It has a unique AUC profile that has no pronounced peak, as small amounts of insulin are released slowly, resulting in a constant concentration/time profile over 24 hours. This profile has resulted in improved glycemic control in large, diverse populations with long-standing type 2 diabetes. White and colleagues (2009) found greater reductions in glucose variability for insulin glargine when compared with NPH insulin. Because variability in blood glucose has been associated with an increased incidence of diabetic complications, this is an important finding (Kilpatrick, Rigby, & Atkin, 2008; Marfella et al, 2009).

Insulin detemir is an insulin analogue that differs from human insulin by a single amino acid deletion and the acylation of myristic acid to the B terminus of the molecule. These changes prolong absorption from the subcutaneous depot, resulting in a more prolonged, less peaked absorption compared to that of NPH insulin. It has a pharmacokinetic profile similar to insulin. Insulin is widely distributed to most body tissues.

Both LAIs are used in types 1 and 2 as basal insulin and are typically given at bedtime, although they can be given at other times of the day.

On The Horizon INSULIN DEGLUDEC

The ultra–long-acting basal insulin analogue degludec (Tresiba) has been placed on a more extended roll-out by Novo-Nordisk in the United States. It is used for both type 1 and type 2 patients, especially those who need to overcome nocturnal hypoglycemia. The 42 hour action time may allow a staggered administration plan. Due to limited post-marketing experience, it is not fully described in this edition.

There are many drugs currently in the pipeline to treat DM. Insulin degludec (Tresiba) has a longer duration of action than insulin glargine. Insulin degludec/liraglutide (Xultopy) is an insulin/GLP-1 agonist combination in phase 3 trials. Other diabetes drugs in phase III trials include exenatice subcutaneous implant (ITCA 650, Intarcia Therapeutics); semaglutide (Novo Nordisk) is a once-weekly GLP-1 analog; omariglipin (Merck) is a once-weekly DPP-4 inhibitor similar to once daily Januvia; Oral-Lyn (Generex) is an investigational liquid regular recombinant human insulin that is delivered to the buccal mucosa using a trademarked RapidMist device; and insulin peglispro (Eli Lilly) is a new long-acting basal insulin.

Lixisenatide (Lyxumia), a once-daily prandial GLP-1 receptor agonist approved in Europe, was denied FDA approval in June 2014 due to pronounced after meal hypoglycemia.

Inhaled Insulin

A new inhaled human insulin (Afrezza Inhalation Powder) was approved by the FDA in 2014. It is the most rapid acting of any type of insulin. It has a short time to peak (12 to 15 minutes) with a short duration of action (2 to 3 hours). This short duration of action is thought to be one reason why this forumulation has less weight gain impact than other forms of insulin. It is given with meals. It has no indication for treating diabetic emergencies. If it is used in Type I DM, a long-acting insulin must also be part of the therapeutic plan.

Metabolism and Excretion

Insulin is metabolized by the liver, the kidney, and muscle cells. Almost all of it is metabolized, and a very small amount is excreted unchanged in the urine. For inhaled insulin, 39% is excreted in the urine and 7% is swallowed and not absorbed in the intestines.

Pharmacotherapeutics

Precautions and Contraindications

The only contraindications to insulin are hypoglycemia and hypersensitivity to any of the ingredients in the product. Human insulin derived by recombinant DNA technology from *Escherichia coli* bacteria or yeast rarely poses hypersensitivity problems.

Some studies with human insulin have shown increased circulating levels of insulin in patients with renal failure (*DF & C,* 2011). Because renal insufficiency and failure are common complications of diabetes, careful glucose monitoring and dose adjustments are needed for patients with renal dysfunction.

Studies have also shown increased circulating levels of insulin in patients with hepatic function impairment. Hepatic failure is uncommon in diabetes, but careful glucose monitoring and dose adjustments are needed for these patients as well.

Pregnancy requires careful diabetes management. Human insulin does not cross the placenta and is the drug of choice for pregnant women and those considering pregnancy. Most insulin is Pregnancy Category B; however, insulin aspart, insulin glargine, insulin glulisine, insulin detemir, and inhaled insulin formulations have not been studied in pregnant women and use during pregnancy is on a risk/benefit basis. They are listed as Pregnancy Category C. Although human insulin is excreted in breast milk, because it is given by injection, it is not absorbed intact by the breastfeeding infant. Inadequate or excessive insulin treatment of mothers with diabetes, however, reduces milk production. It is not known if insulin aspart, insulin glargine, insulin glulisine, and insulin detemir are excreted in breast milk and so caution should be exercised in administering these drugs to nursing mothers. In rat studies 10% of inhaled insulin (Afrezza) is measured in breast milk. Insulin can be used safely in infants and children.

Hypothyroidism may delay insulin turnover, requiring less insulin to treat diabetes. Hyperthyroidism may cause an increase in the renal clearance of insulin. Patients with either of these concurrent diseases require more frequent monitoring of glucose levels than other patients with diabetes when insulin management is required.

Insulin resistance, a suboptimal response of insulin-sensitive tissues to insulin (especially in the liver, muscle, and adipose tissue) occurs in patients with type 2 diabetes. The result is an increased rate of endogenous glucose production secondary to increased glucagon levels because liver cells do not receive feedback messages about the amount of insulin being secreted or the amount of glucose already in the bloodstream. Type 2 diabetes is also associated with down-regulation of insulin receptors in skeletal muscle, resulting in insulin resistance. Patients who have this problem may require more than 1.5 units/kg/day in the absence of ketoacidosis or acute infection. Patients who may exhibit this resistance include obese patients; patients with acanthosis nigricans, ketoacidosis, or endocrinopathies; and patients with insulin receptor defects who may need to have their diabetes managed by an endocrinologist. They typically need to use a concentrated form of insulin U-500, to keep volumes of injections down.

Adverse Drug Reactions

Two life-threatening adverse reactions are central to patient management with insulin: hypoglycemia and diabetic ketoacidosis. One is associated with too much insulin or not enough food and the other with too little insulin. Bronchospasm can occur with inhaled insulin especially in those with COPD and asthma. Spirometry is indicated at baseline and 6 months, then annually for all patients, even if not symptomatic. Inhaled insulin should not be prescribed to a patient with lung cancer or a history of lung cancer.

Hypoglycemia

Hypoglycemia may result from an excessive insulin dose, excessive work or exercise without eating, food that is not

absorbed in the usual manner because of a postponed or omitted meal, not eating enough food, or an illness that results in vomiting or diarrhea. It may also be associated with concurrent administration of another drug that increases the hypoglycemic effects of insulin. Alcohol is especially risky in this regard because it not only induces hypoglycemia but also masks the signs and symptoms of the disorder. Table 21-9 shows these drug interactions. Signs and symptoms of hypoglycemia include decreased levels of consciousness, hunger, diaphoresis, weakness, dizziness, and tachycardia. The peak of action for each type of insulin is the most likely time for a hypoglycemic reaction. This is especially important when more than one type of insulin is being used and the peaks of the different types of insulin coincide. It also occurs when a change in dose occurs or when a provider "over-corrects" a reported high sugar value.

Hypoglycemia is defined as BG less than 70 mg/dL. The treatment that should be used is known as "The Rule of 15": when symptoms occur, consume 15 gr of fast-acting carbohydrate (CHO), wait 15 minutes, and check BG. Examples of fast-acting CHO are 4 oz juice, 8 oz milk, one-half can of a regular soft drink, 1 tbsp honey, or four to five hard or soft candies. Commercial glucose tablets and gel may also be used. It is important to emphasize chocolate candy is not effective in treating hypoglycemia due to the fat content, which delays glucose absorption. A snack or small meal should be eaten within a few hours of the hypoglycemic episode. Adjustments in insulin dosage, meal patterns, or exercise may be needed to prevent further episodes. More severe episodes, with coma, seizure activity, or neurological impairment, require treatment with IM or SC glucagon or concentrated IV glucose.

Diabetic Ketoacidosis (DKA)

Diabetic ketoacidosis (DKA) may result from stress, illness, infection, or insulin omission. It may also develop slowly after a long period of adequate control of BG. Children with undiagnosed type 1 diabetes may present with DKA at the time of diagnosis. Signs and symptoms of DKA include drowsiness, dim vision, and Kussmaul respiration. Indications of hyperglycemia that may precede DKA and give warning of its impending occurrence include polyuria, polydipsia, polyphagia, weight loss and fatigue, vomiting, dehydration, ketone odor to the breath, and abdominal pain. Treatment requires hospitalization and is directed at the acid–base and fluid imbalances that result, as well as the elevated BG. IV fluids, correction of the acidosis and hypotension, and low-dose regular insulin by SC or IV are required. There is no role for U-500 or inhaled insulin with DKA.

Drug Interactions

Many drugs either decrease or increase the effects of insulin because of their effects on BG. Table 21-9 shows these interactions. Beta blockers are especially problematic because they can increase insulin resistance, producing hyperglycemia, but can also mask most of the signs and symptoms of hypoglycemia. The one indication of hypoglycemia that beta blockers do not mask is diaphoresis, and people with diabetes who must take beta blockers for a concurrent disease or condition should be taught to test their blood sugar level whenever they experience diaphoresis. Inhaled insulin has he same potential drug interactions as injectable insulin, something most patients do not anticipate because it is perceived as not being "injected" into the body.

Clinical Use and Dosing

Type 1 Diabetes Mellitus

Patients with type 1 diabetes mellitus do not produce insulin, therefore they must receive insulin replacement. A wide variety of regimens are used in this treatment, including regular insulin delivered only via insulin pump, split-mix regimens, and intensive insulin therapy. Mixtures of SAI and IAI or SAI or RAI and LAI are given in multiple doses from 2 to 4 times daily (see Table 21-10). Table 33-6 discusses in more detail the various insulin regimens that are used for management of type 1 diabetes mellitus. Now inhaled insulin can be part of the plan.

Table 21–9 ⠿ Drug Interactions With Insulin

Interacting Drug	Possible Effects	Implications
Acetazolamide, AIDS antivirals, asparaginase, calcitonin, corticosteroids, cyclophosphamide, dextrothyroxine, diazoxide, diltiazem, dobutamide, epinephrine, estrogens, ethacrynic acid, isoniazid, lithium carbonate, morphine sulfate, niacin, phenothiazines, phenytoin, nicotine, thiazide diuretics, thyroid hormones	Decreases hypoglycemic effect of insulin, including inhaled forms	Close monitoring of blood glucose levels is required if concurrent administration
Alcohol, anabolic steroids, beta-adrenergic blockers,* chloroquine, guanethidine, lithium carbonate, monoamine oxidase inhibitors, mebendazole, octreotide, pentamidine, phenylbutazone, pyridoxine, salicylates, sulfinpyrazone, sulfonamides, tetracyclines	Increases hypoglycemic effect of insulin, including inhaled forms	Close monitoring of blood glucose levels is required if concurrent administration

*Cardioselective beta-adrenergic blockers (those affecting only or mainly beta$_1$ receptors) are less likely to affect insulin's hypoglycemic effect and may be acceptable alternatives for patients who must take beta-adrenergic blockers.

Table 21–10 ⊗ Dosage Schedule: Insulin

Drug	Dosage Form	Schedule	Initial Dose	Comments
Insulin aspart* (Novolog) and Insulin glulisine (Apidra)	Vial Disposable pen Cartridge	Use in combination with IA or LA due to rapid onset and short duration. *Start meal within 5–10 min of injection.* Also used in pumps.	50%–70% of TDD requirement as aspart. Remainder as IA or LA insulin.	May need increased basal insulin or more total daily insulin to prevent premeal hyperglycemia
Insulin lispro* (Humalog)	Vial Disposable pen Cartridge U 100	Use in combination with IA or LA insulin due to rapid onset and short duration of action. Also used in pumps.	50%–70% of TDD before meals. Remainder as IA given 2/3 in morning and 1/3 in evening or as LA given in morning.	Draw lispro into the syringe first if mixing with IA insulin. Inject immediately after mixing. Concentrations higher, duration shorter if given in abdomen
Regular (Humulin, Novolin)	Vial Cartridge U 100	Used in combination with IA or LA insulin due to short onset and short duration of action	50%–70% of TDD as regular given 30–60 min before meals. Remainder as IA given 2/3 in morning and 1/3 in evening or as LA given in morning.	Also comes in U 500 for patients who need high doses. See Chap. 33 for more information
NPH (Lilly) (Novolog)	Lilly: Vial Disposable pen Novolog: Vial Cartridge	Often used in combination with RA or SA insulin 2:1 ratio in a.m., 1:1 ratio in p.m. If using for basal: Start with 6–10 units or 0.1–0.2 unit/kg body weight/d at breakfast or HS to initiate therapy.	Give twice daily with 2/3 of daily dose in morning and 1/3 in evening. Same protocol with 70/30 or 50/50.	See text related to mixing
		With oral agent for type 2 patients who cannot control with oral agent and lifestyle modifications alone	10 units of NPH at bedtime with oral agent in morning	Individualized
Insulin glargine (Lantus)	Vial, disposable pen	Use as single dose (once daily) at bedtime. May be given at other times of day. RA can be given at meals.	Glargine to = 50% of TDD at bedtime, then split remainder of TDD with RAI at breakfast and evening meal.	Calculate total daily insulin requirement at 0.3 units /kg/d
		As single dose at bedtime given with 70/30 mixed insulin	Glargine to = 50% of TDD at bedtime; 70/30 mixed insulin at bedtime and morning for remainder of TDD	
		As single dose with oral agent	As single dose in morning with oral agent	See text for notes on use
Insulin detemir (Levemir)	Vial, disposable pen	Use as single dose (once daily) at bedtime. Given with RAI at meals.	Detemir to = 50% TDD at bedtime, then split remainder of TDD insulin dose with RAI at meal times. Initiate at 0.1–0.2 units/kg in the evening.	Calculate TDD at 0.3–0.5 Units/kg/d
		As a single dose with oral agent Twice daily	0.1–0.2 units/kg or 10 units	Dosage adjusted to achieve glycemic goals
Human Inhaled Insulin (Afrezza)	Single use cartridge 4 or 8 units each.	As a single dose with meals or as needed	Can be adjunct to injectable; multiple cartridges required in multiples of 4 or 8 units	Typically reserved for those with severe fear of needles
Humulin or Novolin 70/30	Vial, disposable pen 70% Isophane suspension 30% Regular			

Table 21–10 ⊗ **Dosage Schedule: Insulin—cont'd**

Drug	Dosage Form	Schedule	Initial Dose	Comments
Humulin 50/50	Vial 50% Isophane suspension 30% Regular			
Humalog Mix 50/50	Vial, disposable pen 50% Lispro Protamine Suspension (IA) 50% Humalog			
Humalog Mix 75/25	75% Lispro Protamine Suspension (IA) 25% Humalog Vial, disposable pen, cartridge			
Novolog Mix 70/30	70% Aspart Protamine Suspension (IA) 30% Novolog Vial, disposable pen, cartridge			

RA = rapid-acting; IA = intermediate-acing; LA = long-acting.

 NOTE: Usual daily insulin requirement is 0.6–0.8 U/kg/d for adults and 0.8–1.2 U/kg/d for children during rapid growth. For drugs with*, daily insulin requirement is 0.05–1 U/kg/d. These do not represent all possible combinations or scheduling protocols.

Type 2 Diabetes Mellitus

Patients with type 2 diabetes produce insulin, but they may not produce enough to meet the body's needs. They also have insulin receptor defects, insulin resistance, and altered hepatic glucose metabolism. Insulin is prescribed when the disease process cannot be adequately controlled by diet, exercise, weight reduction, and oral agents. Chapter 33 and Table 33-6 discusses in more detail insulin regimens used for the management of type 2 diabetes mellitus. Insulin may be used alone or in conjunction with oral agents, and several regimens may be used, as in type 1.

Dosing

Average insulin doses are 0.6 to 0.8 units/kg/d. Starting doses are 0.3 to 0.5 units/kg/d. Obese patients may require more than 100 units per day. Volumes approaching 200 units per injection triggers a switch to the concentrated U-500 formulation. How the doses are dispersed throughout the day depends on the pharmacokinetics of the type of insulin used. For example, for twice-daily dosing for IAI and SAI, two-thirds of the total daily dose is given in the morning and one-third in the evening in most cases. One way to give insulin glargine is to calculate the daily dose of insulin at 0.3 units/kg/d and start bedtime glargine at 50% of the total dose and split the remaining 50% with short-acting insulin before meals. In type 2, LAI can be initiated at a dose of approximately 0.1 unit/kg/d while simultaneously starting an oral agent. A third possibility is to calculate the daily dose of insulin at 0.3 units/kg/d and use premixed 70/30 insulin with two-thirds of the total daily dose in the morning and one-third of the dose in the evening. Basal plus meal time dosing regimens are becoming more populuar. Inhaled insulin in 4 or 8 unit inhalations is used with meals. Table 33-6 lists the commonly used insulin regimens. The use of a sliding scale with regular insulin is no longer used for long-term management; however, it may be used for short-term management in an acute care setting.

 If persons with type 1 or type 2 diabetes mellitus who are on insulin are NPO (i.e., for a procedure), it is advisable to schedule the procedure in the morning to avoid disruption of the insulin regimen. BG levels should be monitored before, during, and after the procedure. Persons with type 1 diabetes require insulin even when NPO because ketosis can occur within 12 to 24 hours. For either type 1 or 2, one-half of IAI can be administered on the morning of the procedure. For patient on bedtime glargine or detemir, the usual dose can be given the night before or the dose can be reduced from 20% to 50%, depending on the level of glycemic control. RAI and SAI should not be given unless the BG level is greater than 200, and if that is the case, insulin is given in small doses of 1 to 4 units to achieve a BG level less than 200 mg/dL (Duncan, 2012; Inzucchi, 2011).

> ### CLINICAL PEARL
>
> For patients on insulin pumps, be attentive to daylight saving time changes. Many pump computers are not GPS enabled or time zone adjusting. This is not an issue with basal insulin provision, but could be significant for rapid-acting forms. Verify date and time settings during appointments (Aldasouqui & Reed, 2014).

Mixing

Mixing insulin is common practice in diabetic regimens, but not all insulin is compatible. LAI insulin cannot be mixed with other insulin, which requires an additional injection. It is recommended that when mixing two different types of insulin to always draw clear insulin into the syringe first. Patients will have a consistent response if the method of mixing is standardized. "Clear to cloudy" is a good way to remember and teach this. Do not suggest mixing of U-500 insulin with other types due to the confusing variance of mixing insulin in units and TB syringe measurements in mL.

All premixed formulations of insulin (70/30 Novolin, 70/30 Humulin, and 50/50 Humulin) contain NPH (the first number) and regular (SAI) or aspart or lispro (RAI) (the second number). These premixed insulins remain stable at room temperature for 1 month or for 3 months under refrigeration. NPH and regular insulin mixed in plastic or glass syringes may be stored for 1 week at room temperature and 14 days if refrigerated. RAIs can be mixed with NPH immediately before injection without affecting its rapid absorption. Regardless of the insulin mixture used, the patient should standardize the interval between mixing the insulins and injecting them.

Switching Insulins

Every insulin has unique characteristics and neither brand of insulin nor type of syringe nor needle should be changed without monitoring by the health-care provider. The provider may want, however, to switch from an insulin formulation that has peaks in its action to one that does not. If changing from a treatment regimen with an IAI to a regimen with LAI, the amount and timing of the RAI or oral antihyperglycemic may need to be adjusted. This is especially true for patients who have developed insulin antibodies and require high doses of insulin. In one clinical study with insulin-naïve patients with type 2 diabetes and already being treated with oral antihyperglycemic agents, insulin glargine was started at 10 units once daily and subsequently adjusted based on the patient's response to a total daily dose between 2 units and 100 units. In other clinical studies, when patients were switched from once-daily NPH to once-daily insulin glargine, the initial dose was usually not changed. If the change was from twice-daily NPH to insulin glargine, to avoid hypoglycemia the initial dose of insulin glargine was reduced by 20% and then adjusted based on patient response (*DF & C,* 2011). Regardless of the drugs

involved in the switch, careful monitoring of BG is required during the transition period. Monitoring for respiratory issues is required if inhaled insulin is added to a regimen. A one to one substitution of inhaled units with short-acting SQ units is a common switch; rounding up to the closest 4 or 8 unit cartridge dosing is required.

Switching patients to U-500 insulin because they take large doses of U-100 insulin is not a simple division of dose by 5. Due to the significant risks of using concentrated insulin, providers who are not fully familiar with dosing this medication are advised to consult with an expert endocrinologist or Certified Diabetes Educator. See Chapter 33 for specifics of switching.

Hyperkalemia

IV infusions of glucose and insulin produce a shift of potassium into cells and lower serum potassium levels. This treatment is usually reserved for hospitalized patients with very high potassium levels or those at risk for cardiac arrhythmias.

Severe Ketoacidosis or Diabetic Coma

Regular insulin given IV is used for rapid effect in severe ketoacidosis or diabetic coma. Because there is a high risk for inducing hyperosmolar coma with this therapy, these patients are also hospitalized.

Pregnancy

For treatment of gestational diabetes and management of patients with diabetes who become pregnant, insulin is usually the drug of choice. Most oral hypoglycemic agents are contraindicated in pregnancy; the exceptions are metformin and glyburide. Any of the insulin treatment regimens may be used during pregnancy. Special care must be taken to avoid hypoglycemic episodes. Coordination with a provider versed in obstetrical implications is strongly suggested. Inhaled insulin is Category C.

Rational Drug Selection

Level of Intensity of Control

Results of the Diabetes Control and Complications Trial (DCCT, 1993) indicate that BG levels closer to target range can significantly reduce the risk of complications associated with diabetes. This trial conclusively demonstrated, in patients with type 1 diabetes, that the risk for development or progression of retinopathy was reduced by 76%, for nephropathy by 50%, for neuropathy by 60%, and for cardiovascular disease by 35%. These benefits were observed with an average Hb A1c of less than 7%. This has been further supported in other studies (Kilpatrick et al, 2008; Marfella et al, 2009). The American Diabetic Association [ADA], Canadian Diabetic Association, and the European Association for the Study of Diabetes [EASD] recommend that A1C levels of less than 7% are desirable for most patients with diabetes. More latitude is recommended for senior patients as the risk of hypoglycemia has many more consequences for elders than adults.

The reduction in risk in the DCCT correlated continuously with reduction in Hb A1c. This relationship implies that complete normalization of glycemic levels may prevent complications. These benefits have also been demonstrated for patients with type 2 diabetes. DCCT patients on tight control used combinations of SAI and IAI given 3 to 4 times per day. Those on intensive insulin therapy used LAI at night and RAI before each meal or more frequently, based on self-monitored glucose measurements. A third group used an insulin pump.

Presence of Complications Such as Retinopathy and Neuropathy

Patients with complications such as retinopathy and neuropathy may find it difficult to draw up their own insulin. Premixed insulin may assist with this problem. Choice of insulin is based on the commercial availability of premixed insulin or those that can be safely stored for some time after mixing. To ensure safety in patients with visual or dexterity problems, pens that click to indicate number of units, magnifiers, and other aids should be considered.

Type 2 Diabetes Mellitus Unable to Control

About 28% of patients with type 2 diabetes use some form of insulin to control blood glucose levels and limit complication risks (Agency for Healthcare Research and Quality [AHRQ], 2008). Because type 2 diabetes is a chronic disease, most patients will need insulin when oral agents fail.

Patients with type 2 diabetes who are not controlled on oral agents and have postprandial hyperglycemia may benefit from an RAI added immediately prior to meals. Patients who have fasting hyperglycemia may have bedtime NPH added. If they have overall poor control, intensive insulin therapy or the split-mix regimen is used. Initially, therapy is started with the use of once- or twice-daily injections of either IAI or LAI.

A systematic review of 45 research studies comparing the newer premixed insulins and the newer insulin analogues with other diabetic medicines for type 2 diabetes (AHRQ, 2008) have indicated risks and benefits for each choice:

- The premixed insulin analogues are better at lowering Hb A1c and preprandial blood glucose than are the oral antihyperglycemic agents; however, they have more risk for hypoglycemia.
- The premixed insulin analogues and the newer premixed insulins are associated with less weight gain than all of the oral antihyperglycemic agents except metformin and the gliptins.
- Long-acting insulin analogues appear to be more effective than premixed insulin analogues in lowering fasting blood glucose levels, but the reverse is true for lowering blood glucose levels after a meal with high sugar content.
- The newer premixed insulins are better at lowering Hb A1c and postprandial glucose than long-acting insulin; however, they carry a higher risk for hypoglycemia.

- Cost is a major factor with all the newer insulin analogues, regardless of formulation; they are more expensive than either regular or NPH insulin. Inhaled insulins are cost consistent with the newer agents.

The number of times the drug must be administered (complexity) was not discussed in this article, but the more complex the regimen, the greater is the risk for nonadherence. These data are further supported by other studies (Buse et al, 2009; Umpierrez et al, 2009). Chapter 33 provides more information on dosing.

Monitoring

Two categories of monitoring are needed for persons with diabetes: (1) BG within target range and (2) signs of complications.

Control of Blood Glucose

For patients with type 1 and 2 diabetes, the goals of therapy are preprandial BG levels of 70 to 130 mg/dL, postprandial BG levels less than 180 mg/dL, bedtime glucose levels of 100 to 140 mg/dL, and Hb A1c levels of less than 7% (ADA, 2012). See Table 33-7 for recommendations. Patients with comorbid diseases, the very young, older adults, and others with unusual conditions or circumstances may warrant different treatment goals. Every 1% change in Hb A1c equals a change in BG of about 30 mg/dL. Hb A1c values can be increased by iron-deficiency anemia, alcohol use, and lead toxicity and can be decreased by chronic blood loss, chronic renal failure, and pregnancy when performed by some techniques. These potential confounding variables should be considered in assessing changes in Hb A1c levels.

Pre- and postprandial and/or bedtime BG levels can be assessed by self-monitoring blood glucose (SMBG). All patients on insulin therapy should be taught and routinely assessed for accurate SMBG. The frequency and pattern of SMBG should be based on level of control, episodes of both hypo- and hyperglycemia, medication regimen, activity, and meal patterns. Both SMBG and Hb A1c should be monitored; the SMBG reflects day-to-day control and trends, while the Hb A1c reflects the average BG level over a period of 90 to 120 days. Current recommendations for patients with type 1 diabetes are quarterly Hb A1c levels, and at least every 6 months for patients with type 2 diabetes if treatment goals are being met (ADA, 2012). More frequent testing is needed every 3 months if treatment goals are not being met or if therapy has changed. Chapter 33 includes more discussion of this monitoring.

Signs of Complications

Acute Complications

Acute complications include DKA in patients with type 1 and hyperosmolar hyperglycemic nonketotic syndrome (HHNKS) in patients with type 2. All patients with diabetes may experience hypoglycemic episodes; therefore, all patients with diabetes who are on medication should be taught how to prevent, monitor, and treat hypoglycemia.

Chronic Complications

The most common chronic complications of diabetes are nephropathy, retinopathy, peripheral and GI neuropathies, hypertension, cardiovascular disease, and dyslipidemia. Progressive weight gain also occurs. Providers need to be aware of the physical examination and laboratory evaluations that are appropriate to determine the degree of glycemic control and associated complications and risks. Pharmacological therapies are discussed in the ADA clinical practice recommendations that are updated and published annually.

Patient Education

Administration

The number, type, and amount of daily insulin administrations depend on numerous factors, including BG, diet, and activity levels. The provider must work with the patient to establish the diet-exercise-insulin-glucose monitoring regimen with active patient participation.

Patients and/or caregivers should be educated on the onset, peak, and duration of the type of insulin being used. See Table 21-8. For insulin suspensions such as NPH, ensure uniform dispersion of insulin by rolling the vial gently between the hands until the color is even. Avoid vigorous shaking, which produces air bubbles or foam. Lispro and regular insulins are clear solutions and do not require dispersion of suspended particles. Do not use them if they are cloudy, discolored, or unusually viscous, which may indicate loss of potency.

Vials of insulin not in use should be refrigerated in temperatures from 36°F to 46°F. Extreme temperatures (greater than 86°F or less than 28°F) and excessive agitation should be avoided to prevent loss of potency, clumping, frosting, or precipitation. Insulin in use may be kept at a room temperature lower than 86°F. Most insulin, including premixed types, is stable at room temperature for 1 month and for 3 months if refrigerated between 2°C and 8°C (36°F to 46°F). Mixtures involving lispro that patients mix themselves must be given immediately after they are mixed. Regular and NPH are stable for 7 days at room temperature and 14 days if refrigerated. Patients should be taught storage requirements for their specific insulin.

Parenteral insulin is available in either disposable or reusable pens. Disposable pens are prefilled with insulin and are discarded when empty. They should be stored in the refrigerator before use, then stored at room temperature once opened. Reusable pens have cartridges that are purchased separately. While the cartridges can be stored in the refrigerator prior to use, the reusable pens should not be put in the refrigerator at any time. Either type of pen requires a special pen needle. Some pens come in half-unit dosages and others in whole-unit dosages. The amount of insulin delivered at one time depends on the pen and ranges from 30 to 80 units.

The patient must be taught the technique for drawing up the correct dose, SC injection, site selection and rotation, disposal of syringes, and mixing if required. Only insulin syringes should be used to draw up U-100 insulin dosages. U-500 insulin uses a standard 1cc tuberculin (TB) syringe. Sites should be rotated, but because the abdomen, arm, and leg have different absorption rates, rotation should occur within one general area (e.g., the abdomen). As a general rule, do not administer within 1 inch of the same site for 1 month. Exercise increases the rate of absorption from injection sites and increases glucose recycling, both of which may result in increased risk for hypoglycemia if the dose of insulin is unchanged. Exercise should be planned and consistent within a treatment regimen.

When different types of insulin are mixed, always draw clear insulin into the syringe first. The order of mixing and the procedure used, including the model or brand of syringe and needle, should not be changed from dose to dose. Patients stabilized on a mixture of insulins should have a consistent response if the procedure is the same each time. Premixed insulin is available commercially and may be used if the type and concentration mix fit the patient. Some formulations cannot be mixed.

Different brands of insulin are not bioequivalent. The patient should not change brands without first consulting the provider, who will arrange for close monitoring if the change is appropriate.

Inhaled insulin comes in single dose cartridges, placed into a special inhaler. Only one inhalation is required to deliver the full dose from the cartridge. The delivery system is much less cumbersome than the original forumulation (Exubura) that was removed from the market by the manufacturer. Afrezza is easier to deliver, but requires hand and breath coordination akin to other inhaled medications. No special oral care after inhalation is required. Baseline spirometry is recommended for all patients before starting inhaled insulin, at 6 months and annually, regardless of respiratory symptoms.

Adverse Reactions

Common adverse drug reactions are related to altered insulin effects. Hypoglycemia can be life-threatening and has a higher risk of occurrence as the intensity of therapy increases. The patient should be taught the signs and symptoms of hypoglycemia and the appropriate treatment for it, based on whether it is mild, moderate, or severe. Decreased food intake, skipping meals, and increased activity may decrease insulin requirements and increase the risk for hypoglycemia.

Alcohol intake is especially dangerous for patients with diabetes. The effect of alcohol on BG is dependent on the amount ingested and the relationship to food intake. Alcohol is not metabolized to glucose and inhibits gluconeogenesis. If it is ingested without food, hypoglycemia can result, even at levels that do not exceed mild intoxication. Not only can it cause hypoglycemia but it also can mask the signs and symptoms of the disorder. For patients using insulin, no more than two alcoholic beverages a day for men, one per day for women, are recommended with and in addition to

the regular meal plan. One alcoholic beverage equals 12 oz beer, 5 oz wine, or 1.5 oz distilled spirits. The calories from this alcohol must be calculated as part of the total caloric intake and substituted as one alcoholic beverage that equals two fat exchanges. Reduction of or abstinence from alcohol is preferable.

Hyperglycemia is less immediately life-threatening than hypoglycemia but is an indication of poor BG control and may be life-threatening if it is high enough to produce ketosis and/or hyperosmolar state. Patients should be taught to recognize early indications of hyperglycemia and the treatment.

Site reactions and lipodystrophy are skin issues that can generate future problems if not limited at the first sign of development. Progression to an infection and/or issues with dosage absorption will contribute to glucose imbalances. For inhaled insulin, an adverse reaction can be cough and sore throat. For respiratory patients with COPD or asthma, and for indviduals who are sensitive to particles in the air with reactive airways, this form of insulin is not recommended.

Lifestyle Modification

Management of type 1 or type 2 diabetes involves diet, exercise, weight control, stress management, SMBG, administration of medication, and preventive care. Patient teaching related to management of diabetes is discussed in Chapter 33 .

ORAL AGENTS

Ninety percent of patients with diabetes mellitus have type 2 diabetes. The main physiological alteration in type 2 diabetes is insulin resistance, a suboptimal response of insulin-sensitive tissues (especially in the liver, muscle, and adipose tissue) to insulin. The result is four primary alterations in glucose metabolism: (1) insufficient production of endogenous insulin by the beta cells of the pancreas, (2) tissue insensitivity to insulin, (3) impaired response of the beta cells to BG levels, and (4) excessive production of glucose by the liver secondary to increased glucagon levels. Glucagon-like peptide 1 (GLP-1), an incretin hormone released by the intestine throughout the day and increased in response to a meal, stimulates insulin secretion by the beta cells and suppresses glucagon secretion. GLP-1 levels are decreased in type 2 diabetes.

These patients do not have an absence of insulin secretion, although some may eventually develop absence of insulin. If the pancreas is the major organ involved in type 1diabetes, the liver and the incretin hormone system are the major organs in type 2. Patients with type 2 have few and nonspecific pancreatic changes. Many years of compensatory hyperinsulinemia may occur before the onset of clinical symptoms of diabetes. Eventually, the beta cell responsiveness to glucose stimulus diminishes and hyperglycemia prevails.

Adipose tissue also does not take up glucose in response to insulin, resulting in obesity. Increased visceral fat shows an inverse relationship with insulin. Because the link between obesity and type 2 diabetes is firmly established, oral hypoglycemic agents and other oral antihyperglycemic agents should be considered in relation to their tendency to contribute to weight gain, to their being weight neutral, or to contribute to weight loss.

Because there is endogenous insulin production in type 2, insulin may not be required initially but may be required later in the disease process or during acute illness or stress. Oral hypoglycemic agents and other oral antihyperglycemic agents are effective in addressing one or more of the metabolic defects in type 2 diabetes; insulin is added during episodes when glycemic control is not possible with oral agents alone.

BIGUANIDES

The biguanides are oral antihyperglycemic drugs used in the treatment of type 2 diabetes mellitus. To date, metformin (Glucophage) is the only drug in this class used clinically. Because its actions directly address the major pathological defects in type 2 diabetes, it is first-line therapy in adults and children older than 10 years of age. Monotherapy with metformin is effective as initial drug therapy. If monotherapy with metformin is not effective, it is used as combination therapy with a variety of drugs from other antihyperglycemic agent classes or insulin. It is commonly used with significant effect for those with "pre-diabetes" or glucose intolerance; however, this is not an FDA-approved indication.

Pharmacodynamics

Metformin increases peripheral glucose uptake and utilization (insulin sensitivity), decreases hepatic glucose production, and decreases intestinal absorption of glucose. Together, these actions address the primary pathological defects of type 2 diabetes to improve glucose tolerance and lower both basal and postprandial plasma glucose levels. Metformin does not stimulate insulin release from the pancreatic beta cells, nor does it produce hypoglycemia except in specific circumstances. Metformin does not cause hyperinsulinemia. Metformin also does not cause weight gain; often patients lose weight. Because obesity is a major factor in the pathogenesis of type 2 diabetes, this is an important drug action. Metformin also inhibits platelet aggregation and reduces blood viscosity. This property is a factor in its use in metabolic syndrome, which is discussed below.

The magnitude of decline in FPG (fasting plasma glucose) concentrations with metformin therapy is directly proportional to the level of fasting hyperglycemia. Patients with higher BG levels experience a greater percentage of decrease in BG and A1C levels than those with lower BG levels. This is a significant factor because those with higher BG levels for longer periods of time have more complications. African Americans with diabetes tend to have higher BG

levels; the recent study that metformin may work almost twice as well in this population than in whites is very good news indeed.

Metformin also has a modestly favorable impact on lipids because of its actions in the liver. In clinical studies, metformin alone lowered mean fasting serum triglycerides by 16%, total cholesterol by 5%, and low-density lipids (LDL) by 8%, and increased high-density lipids (HDL) by 2%. The same was true when metformin was combined with a sulfonylurea or other antihyperglycemic, but the magnitude of the changes was less for the combination (*DF & C*, 2011).

Pharmacokinetics

Absorption and Distribution

Metformin is 50% to 60% absorbed after oral administration under fasting conditions. The extended-release form of the drug has a different absorption profile from the immediate-release form (Table 21-11). Food decreases the extent and slightly delays the absorption in the immediate-release form, with an approximately 40% decrease in C_{max} and a 25% decrease in AUC. It is not known if these are clinically relevant. The extent of absorption from the extended-release form (Fortamet) was increased by approximately 60% when given with food. Glumetza must be administered immediately after a meal to maximize absorption. The rate and extent of absorption with metformin solution is comparable with that of the tablets under fasting or fed conditions (*DF & C*, 2011). Absorption is not linearly related to dose. The higher the dose the patient takes, the lower the percentage that is absorbed. Increased doses do not result in proportionally increased amounts of drug in the body.

Metformin is negligibly bound to plasma proteins. Plasma half-life is 6.2 hours, but the half-life in the blood is

Table 21–11 Pharmacokinetics: Selected Antihyperglycemic Agents

Drug	Onset*	Peak*	Duration*	Protein Binding	Bioavailability	Half-Life	Excretion
Metformin IR and solution	Days	1–8 h	UK	Minimal	50%–60% if taken fasting; nonlinear; reduced by food intake	6.2 h (plasma) 17.6 h (blood)	100% excreted unchanged in urine
Metformin ER (Fortamet, Glumetza)	Days	3–10 h	UK	Minimal	Increased by 60% with food for Fortamet and Glumetza	UK	In urine
Acarbose (Precose)	0.5–1 h	1 h	2–3 h		Less than 2% in plasma	2 h	51% in feces as unabsorbed drug; 34% in urine
Miglitol (Glyset)	0.5–1 h	2 h	3h		100% in extracellular fluids at 25 mg; 50%–70% at higher doses	Normal renal function: 2 h; renal impairment: CCr <25: 4 h	95% in urine as unchanged drug
Nateglinide (Starlix)	20 min	1 h	4 h	98%	73%	1.5 h	83% in urine; 10% in feces
Pioglitazone (Actos)	UA	2–4 h	UA		99%	3–7 h	15%–30% in urine
Repaglinide (Prandin)	0.5 h	1 h	1.4 h		100%	1–1.4 h	90% in feces; 8% in urine
Rosiglitazone (Avandia)	UA	1–3 h	UA		99%	3–4 h	64% in urine; 23% in feces
Sitagliptin (Januvia) (B)	UK	1–4 h	24 h	38%	87%	12.4 h	87% in urine; 13% in feces
Linagliptin Tradjenta (B)	UK	1.5 h	UA	75%–99%	30%	12 h	Enterohepatic 80%, urine 5%
Alogliptin Nesina (B)	UK	1–2 h	UA	20%	100%	21 h	Urine 76%; feces 13%

Table 21–11 ✚ **Pharmacokinetics: Selected Antihyperglycemic Agents—cont'd**

Drug	Onset*	Peak*	Duration*	Protein Binding	Bioavailability	Half-Life	Excretion
Saxagliptin (Onglyza) (B)	UK	2 h	12–24 h	UK	75%	2.2–3.8 h	70% in urine
Exenatide (Byetta) (B)	UK	2.1 h	10 h	UK	UK	2.4 h	Mainly in urine
Liraglutide (Victoza)(B)	UK	9–12 h	UK	UK	51%	11–15 h	As metabolites in urine and feces
Pramlintide (Symlin)(B)	UK	19–21 min	UK	40%	30%–40%	48 min	As metabolites in urine
Canagliflozin (Invokana)(B)	Within 24 h	1–2 h	UA	99%	65%	10–13 h dose-dependent	Feces 41%, metabolites in urine 31%
Dapagliflozin (Farxiga) (B)	UA	2h	UA	91%	78%	12.9 h	75% urine; 21% feces
Empagliflozin (Jardiance) (B)	UA	1.5h	UA	86.2%	UA	10-19h	41% urine; 55% feces

UA = data unavailable; UK = unknown.
　*Of antihyperglycemic effect.

17.6 hours, suggesting that RBCs may be a compartment of distribution. The apparent volume of distribution is very high and averages 654 L following single doses of 850 mg.

Metabolism and Excretion

There is no hepatic metabolism for metformin, and it is excreted unchanged in the urine. There is no biliary excretion. Renal clearance is 3.5 times that of CCr, indicating that renal tubular secretion is the major route of elimination. Data suggest a trend toward higher C_{max} and AUC values for Glumetza in Asian subjects when compared with white, Hispanic, and African American subjects. This difference does not appear to be clinically significant.

Pharmacotherapeutics

Precautions and Contraindications

There are two major contraindications to metformin use: (1) renal disease or dysfunction and (2) metabolic acidosis.Current standards state males with serum creatinine levels 1.5 or higher, females with levels 1.4 or higher, and patients of either gender with abnormal CCr rates should not receive metformin because of its heavy dependence on renal function for elimination. The ADA is recommending using eGFR above 30 mL/min as the cut point, which is moderate kidney disease. This is would allow many more DM patients to use this effective medication under cautious supervision (Inzucchi, Lipska, Mayo, Bailey, & McGuire, 2014). The FDA has yet to respond to the ADA recommendation. Patients with acute or chronic metabolic

acidosis and patients at high risk for lactic acidosis because of tissue hypoperfusion or hypoxia (e.g., severe dehydration, heart failure, respiratory failure, and chronic alcoholism with severe liver damage) also should not receive this drug when being managed solely by primary care providers.

Lactic acidosis is a rare, but serious, complication that can occur with metformin because of its accumulation during treatment. When it occurs, it is fatal 50% of the time. The risk for lactic acidosis increases in the presence of renal and hepatic dysfunction, making the interaction of these two contraindications more serious than either one alone. Metformin also should not be used for patients with clinical and laboratory evidence of hepatic disease.

Cautious use is suggested with patients over age 80 due to the probability of decreased renal function. Limited data suggest that total plasma clearance is decreased and half-life is prolonged in healthy older adults as compared with healthy young subjects (*DF & C*, 2011). These data suggest that the change in pharmacokinetics is primarily accounted for by change in renal function. For older adults, CCr should be tested before beginning therapy and at least annually during therapy.

Metformin should also be temporarily withheld 48 hours before to 48 hours after undergoing radiological studies that involve an iodine-based contrast medium because such materials may result in altered renal function and have been associated with lactic acidosis in patients receiving metformin. Metformin should be reinstituted only after renal function has been reevaluated and found to be normal. It should also be temporarily withheld from patients undergoing surgical

procedures in which fluid will be withheld because of the risk for dehydration and hypoperfusion that may result in lactic acidosis. The time frame for withholding the drug is the same.

A decrease in vitamin B_{12} levels to subnormal without clinical manifestations has been observed in about 7% of patients receiving metformin. This decrease is probably due to interference with vitamin B_{12} absorption from the intrinsic factor–vitamin B_{12} complex. Patients with or at risk for anemia associated with altered vitamin B_{12} utilization should have the disorder treated and under control before beginning metformin therapy. The low levels may be the reason why some studies have found a dementia link with the medication.

There is evidence that metformin increases the risk of developing low TSH levels. This occurs more frequently within the first 6 months of use. This does not occur in persons with normal thyroid function, but is increased 55% for those with hypothyroid issues (Duntas, Orgiazzi, & Brabant, 2011). Metformin is listed as Pregnancy Category B, and has been studied for safety during pregnancy, but its use during pregnancy requires obstetric or endocrinology consultation (Feig & Moses, 2011; Kumar & Kahn, 2012). Studies in rats indicate that metformin is excreted in breast milk in levels approximately the same as in the plasma. Similar studies have not been conducted in nursing mothers. Because the potential for hypoglycemia in nursing infants may exist, decide whether the patient should discontinue nursing or discontinue metformin based on the importance of the drug to the mother.

Use of metformin in 10- to 16-year-old children is supported by evidence from adequate and well-controlled clinical trials with children of this age with type 2 diabetes; the trials demonstrated a similar response in glycemic control and adverse reactions to those seen in adults. Studies in children younger than 10 years have not been conducted.

African Americans, a group that is at higher risk of diabetes and faster onset of complications, appear to be more responsive to metformin than European Americans. There is a clinically important average decrease in Hb A1c levels when the two groups are compared (Williams et. al, 2014); the minority group has more benefit.

Adverse Drug Reactions

The most common adverse reaction involves GI disturbances (e.g., abdominal bloating, diarrhea, nausea, vomiting, and an unpleasant metallic taste). These adverse reactions are usually transient and resolve in about 2 weeks without a change in dose. They may be reduced by initiating therapy with a low dose and titrating the dose slowly.

Lactic acidosis is rare. Hypoglycemia is also rare unless there is a concurrent reduction in caloric intake, an increase in strenuous exercise not compensated for with increased caloric intake, or concurrent use of another glucose-lowering drug or alcohol. Older adults, debilitated and malnourished patients, and those with adrenal or pituitary insufficiency are also at increased risk for hypoglycemia. It is safe in most populations.

Drug Interactions

There are many drug interactions with metformin (Table 21-12). Carbonic anhydrase inhibitors may increase the risk for lactic acidosis and should be used cautiously. Cationic drugs that are eliminated by renal secretion (e.g., amiloride, digoxin, morphine, procainamide, quinidine, ranitidine, triamterene, trimethoprim, and vancomycin) may compete with metformin for its elimination pathway. Dosage adjustments may be needed in metformin or the interacting drugs. Cimetidine increases the peak metformin plasma level by 60%, with an increase of 40% in its AUC. Furosemide increases these levels by 15% without any significant change in renal clearance. Both of these

Table 21–12 ▦ Drug Interactions With Metformin

Interacting Drug	Possible Effects	Implications
Alcohol	Potentiates the effect of metformin on lactate metabolism	Warn patients against excessive alcohol intake while taking metformin
Amiloride, digoxin, morphine, procainamide, quinidine, ranitidine, triamterene, trimethoprim, vancomycin	May compete for elimination pathway	Dosage adjustments may be needed for metformin or interacting drug
Beta-adrenergic blockers	May mask signs and symptoms of hypoglycemia	Does not affect diaphoresis as indicator of hypoglycemia; teach patient to check blood glucose level if experiencing diaphoresis
Cimetidine, furosemide	Increases plasma levels of metformin without concurrent increase in renal excretion	Dosage adjustments of metformin may be needed
Iodine-based contrast media	May affect renal function and increase the risk for lactic acidosis	Withhold metformin for 48 h before and after procedure in which contrast is used
Nifedipine	Enhances absorption of metformin and may increase effects	Dosage adjustments of metformin may be needed

drugs may increase the effects of metformin because of these alterations. Dosage adjustment for metformin may be necessary. Alcohol should be avoided when metformin is used.

Clinical Use and Dosing

Type 2 Diabetes Mellitus

Metformin is indicated as monotherapy and in multidrug therapy for patients with type 2 diabetes who cannot achieve adequate BG control on healthy eating, increased activity, and weight loss. It is the first-line drug therapy for patients with type 2 diabetes (ADA, 2012). The Hb A1c reduction commonly achieved with this drug alone is approximately 1.5% (Nathan et al, 2006). It is especially useful for obese patients because it is not associated with weight gain and may produce some weight loss. Its positive effect on lipids creates a clear advantage for patients with hyperlipidemia.

The pharmacodynamics of metformin are different from those of sulfonylureas so that the two drugs taken together potentiate each other's actions. In clinical trials, both the fasting and the postprandial BG levels of patients decreased by 20% to 30%. Because this drop is so dramatic, it is important to monitor BG levels closely when metformin is added to the treatment regimen of a drug that can produce hypoglycemia.

Metformin is available in intermediate- and extended-release formulations and in an oral solution of 500 mg/5 mL. Begin therapy with 500 mg bid with the morning and evening meal or 850 mg bid with the morning and evening meal for adults (Table 21-13). For children, the starting dose is 500 mg bid with the morning and evening meals. The dose is increased in increments of 500 mg at weekly intervals for both adults and children or 850 mg every other week for adults. The most common adverse reactions are GI disturbances. If they occur, the starting dose can be lowered or

Table 21–13 ⚕ Dosage Schedule: Selected Metformin Formulations

Drug	Initial Dose	Dosage Form	Maintenance Dose	Maximum Dose
Metformin IR (G) Glucophage IR (B) Riomet 500 mg/5 mL solution (B)	*Adults ≥17 yr:* Initial: 500 mg twice daily **or** 850 mg once daily; titrate in increments of 500 mg weekly or 850 mg every other week; may also titrate from 500 mg twice a day to 850 mg twice a day after 2 wk *Children 10 to 16 yrs:* 500 mg twice daily, dosage increases weekly, in increments of 500 mg/day, up to a maximum of 2000 mg/day	500, 850, 1,000 mg tablets		Maximum dose 2,550 mg *Children 10–16 yr:* 2,000 mg
Extended-Release				
Metformin ER (G), Glucophage XR (B), Fortamet (B), Glumetza (B)	*Adults and children >17 yr:* Fortamet: Initial: 500–1,000 mg once daily; dosage may be increased by 500 mg weekly Glucophage XR: Initial: 500 mg once daily; dosage may be increased by 500 mg weekly Glumetza: Initial: 1,000 mg once daily; dosage may be increased by 500 mg weekly	500 mg or 1,000 mg tablets		Maximum dose: 2,500 mg once daily for Fortamet Maximum dose: 2,000 mg daily for both Glucophage XR and Glumetza
Combination Drugs				
Glipizide/ metformin (G), Metaglip (B)	2.5 mg/250 mg glipizide/metformin daily with food **If FPG = 280–320 mg/dL:** 2.5/500 mg every 12 h Titrate every 2 wk to no more than 10/2,000 mg per day in divided doses **Second-line treatment if not controlled on metformin and/or sulfonylurea:** 2.5/ 500 mg or 5/500 mg every 12 h with food Titrate to no more than 20/2,000 mg daily in divided doses **Older adults:** Use conservatively; do not titrate to max dose	2.5 mg/500 mg tablets 5 mg/500 mg tablets		20 mg glipizide/ 2,000 mg metformin
Glyburide/ metformin (G), Glucovance (B)	1.25 mg/250 mg once daily or every 12 h Titrate up in 2 wk intervals **Older adults:** 1.25 mg/250 mg daily or every 12 h; use conservative dosing. Assess renal function if using in adults >80 yr; do not titrate to max dose	1.25 mg/250 mg 2.5 mg/500 mg 5 mg/500 mg		20/2,000 mg daily

IR = immediate release; ER = extended release.

the current dose can be held at that level and not increased. The symptoms will most likely resolve in about 2 weeks, at which time the dosage can be increased again until target BG levels are reached. The maximum dose recommended is 2,550 mg/d for adults or 2,000 mg/d for children. The maximum dose should be divided and given 3 times daily to reduce GI reactions.

Conversion of Immediate-Release Formulation to Extended-Release Formulation

Clinical trials have shown that patients treated with the immediate-release (IR) formulation of metformin who were switched to the extended-release (ER) formulation could safely be transferred with the same total daily dose. Close monitoring of glucose levels is recommended during the transition; the understanding that metformin typically does not cause hypoglycemia does not apply to this transition period.

Concomitant Metformin and Sulfonylurea Therapy in Adults

If a patient is not responsive to metformin monotherapy after 3 months, addition of another drug, including insulin, should be considered (see Table 33-3). There are combination formulations that include metformin plus glipizide (Metaglip) and metformin plus glyburide (Glucovance). These combination drugs are administered similarly to metformin IR and carry the precautions/contraindications, adverse effects, and drug interactions of both drugs. If a patient has not met BG and Hb A1c targets by 3 months of combination therapy, consider adding a third drug to the regimen. This patient may benefit from referral to an endocrinologist.

Concomitant Metformin and Thiazolidinediones

Thiazolidinediones can also be added to a treatment regimen when the patient has not achieved BG targets on metformin alone or in combination with other drugs. The starting dose is based on the patient's current regimen of each of the drugs. The starting doses of these drugs are discussed in their section below. There are combination formulations that include metformin plus pioglitazone (ActoPlus Met and ActoPlus Met XR) and metformin plus rosiglitazone (Avandamet). The same issues related to administration and combining that are stated with sulfonylureas apply, as does the information about achieving target Hb A1c goals.

Concomitant Metformin and Meglitinides

These drugs can be added to a treatment regimen when the patient has not achieved BG targets on metformin alone or in combination with other drugs. The starting dose is based on the patient's current regimen of each of the drugs. The starting doses of these drugs are discussed in their section below. There is a combination formulation of metformin plus repaglinde (PrandiMet). The same data apply to the combination as stated above.

Concomitant Metformin and Gliptins

All of the gliptins have been approved for this combination. The starting doses of these drugs are discussed in their section below. There is a combination formulation of sitagliptin plus metformin (Janumet). It is given twice daily with meals with a gradual dose escalation to reduce the adverse GI reaction caused by metformin (*DF & C*, 2011; Reynolds, 2009). This combination is purported to have fewer hypoglycemic risks than the combination of a glypizide (Metaglip) and metformin but is under scrutiny for worsening renal impairment (most likely the impact of the sitagliptin) and pancreatitis (Olansky, 2010).

Concomitant Metformin and Insulin Therapy

Initiate metformin IR or ER at 500 mg once daily in patients on insulin therapy. For patients who do not respond adequately, increase the dose of metformin by 500 mg daily after 1 week and by 500 mg daily every week thereafter until adequate glycemic control is achieved. The maximum daily dose is the same as for metformin alone for both adults and children. The insulin dose should then be decreased by 10% to 25% when the fasting blood glucose (FBG) decreases to less than 120 mg/dL.

Concomitant Metformin and SGLT2 medications

There is no long-term experience with this combination of medications. At least one combination tablet is on the market as of this time, dapagliflozin/metforminin extended release (Xigduo XR). As with any other combination tablet, it may be prudent to start one, then the other to determine tolerance prior to ordering a combination tablet. The side effects of both medications are important to monitor; therefore, lactic acidosis, renal response, and genital infections become important things to monitor. The starting dose would be consistent with the current dosing of each medication and increased to a max of 10 mg of the SGLT2 and 2,000 mg of the metformin. The duplication of hypoglycemic effect increases the risk of hypoglycemia if it is started without an initial trial period of dual prescriptions. It is taken in the a.m. with food to reduce the GI side effects. This medication cannot be crushed.

Metabolic Syndrome

Metformin inhibits platelet aggregation and decreases blood viscosity. It is recommended along with angiotensin converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) and statins in the treatment of insulin resistance syndromes including metabolic syndrome (Bloomgarden, 2003). Other chapters have more discussion of this syndrome, which includes obesity, hypertension, hyperlipidemia, and insulin resistance.

Prevention of Conversion of Prediabetes to Diabetes

The Diabetes Prevention Program Research Group (2002) tested metformin and lifestyle modifications as methods for preventing the conversion of prediabetes to type 2 diabetes. This group also found that both of these interventions were cost-effective across subjects regardless of age,

ethnicity, or gender and affordable in routine clinical practice. Because prevention of movement from prediabetes to diabetes is a primary goal of treatment directed at children who may develop type 2 diabetes, metformin has become first-line therapy for this indication. This is discussed further in Chapter 33. Table 21-13 lists the available dosage forms of metformin, including the ER and oral solution formulations.

Monitoring

Before initiating therapy and at least annually thereafter, assess renal function. Assessment is by serum creatinine and CCr initially and then by serum creatinine annually. For patients with increased risk for developing altered renal function, the assessment should be made more often. Patients who have been previously well controlled on metformin who are no longer controlled or who develop illnesses that place them at risk for metabolic acidosis should be assessed for evidence of ketoacidosis or lactic acidosis. Assessment includes serum electrolytes and ketones, BG, and, if indicated, blood pH and lactate levels. Lactic acidosis is characterized by elevated blood lactate levels (greater than 5 mmol/L), decreased blood pH, and electrolyte disturbances with an increased anion gap. Because impaired hepatic function may significantly decrease the ability to clear lactate, liver function studies should be done before therapy is initiated.

> ### ● CLINICAL PEARL ●
>
> When **metformin** is added to a **sulfonylurea**, the increased sensitivity to **insulin** caused by **metformin** results in less need for the insulin secretion generated by the **sulfonylurea**. If the BG level drops too much, the dose of the **sulfonylurea** should be reduced.

Response to metformin therapy is assessed by daily to weekly monitoring of fasting and postprandial BG and by monitoring Hb A1c every 3 months or monitoring fructosamine every 2 months. During initial therapy and with each incremental increase, FBG is used to evaluate response. After the patient is stabilized on a specific dose, monitoring with FBG and A1C levels every 6 months is sufficient.

Some patients with inadequate vitamin B_{12} or calcium intake or absorption may be predisposed to developing subnormal vitamin B_{12} levels. Assessment for this problem is done by red blood cell indices drawn at initiation of therapy and every 2 to 3 years thereafter.

Patient Education

Administration

Patients are taught to take the drug at the same time each day exactly as prescribed. The tablets should be swallowed whole and not cut, crushed, or chewed. Because the titrating doses will change weekly or every other week, a card or calendar is helpful to remind patients of the schedule. If a dose of metformin is missed, it is taken as soon as it is remembered unless it is about time for the next dose. Doses should not be doubled. If a dose of the ER drug is missed, patients resume taking the drug according to schedule.

Adverse Reactions

The most common adverse reactions are GI disturbances. If they occur, they may be reduced by taking the drug with food rather than before the meal. The provider should be notified of GI disturbances so that the dose may be kept at the current level until they resolve. Even with the same dose, GI disturbances will usually resolve in about 2 weeks. If the GI disturbances include vomiting or diarrhea or the patient develops a fever, the drug is stopped. Dehydration may result and presents a risk for the patient to develop lactic acidosis and decreased renal function. Patients are taught the signs and symptoms of lactic acidosis (e.g., chills, dizziness, low blood pressure, muscle pain, sleepiness, trouble breathing, slow heart rate, and weakness) and to report them immediately.

A patient who is to undergo a procedure with an iodine-based contrast medium or surgery in which fluid will be withheld should be temporarily taken off metformin; the provider should be notified if one of these procedures is anticipated.

SULFONYLUREAS

The first class of oral drugs developed to manage patients with type 2 diabetes mellitus was the sulfonylureas. They are true oral hypoglycemics and are useful only for patients with some endogenous insulin secretion. Owing to the risk for hypoglycemia and their limited action on insulin resistance, their use should be used in combination therapy.

Pharmacodynamics

Sulfonylureas cause an increase in endogenous insulin secretion by the beta cells of the pancreas related to increased cAMP generation. They may improve the binding between insulin and insulin receptors or increase the number of receptors, thereby having a limited ability to improve insulin utilization by the tissues. Hypoglycemic effects appear to be due to increased endogenous insulin production and to improved beta cell sensitivity to BG levels or suppression of glucose release by the liver. Sulfonylureas also potentiate the effect of antidiuretic hormone and may produce a mild diuresis. They appear to be similar to metformin in lowering Hb A1c levels by about 1.5% (Nathan et al, 2009). The glucose-lowering effect of these drugs is rapid compared to some other antihyperglycemic agents, but the maintenance of glycemic targets over time is not as effective as monotherapy with metformin (Nathan et al, 2009).

Pharmacokinetics

Absorption and Distribution

All sulfonylureas are well absorbed after oral administration and all except glipizide (Glucotrol) can be taken with food

(Table 21-14). Absorption of glipizide is delayed by the presence of food in the gut. Tolbutamide, glyburide, and glipizide are more effective when taken 30 minutes prior to a meal. Tolazamide (Tolinase) is absorbed more slowly than the other sulfonylureas.

Although the mechanisms of action are similar for all sulfonylureas, the first and second generations differ in absorption. Second-generation compounds are more nonpolar and lipophilic. Therapeutically effective doses and serum concentrations are lower because of their intrinsic potency and ability to cross plasma membranes. All sulfonylureas are highly bound to plasma proteins, especially albumin, but the first-generation binding is ionic, whereas the second-generation binding is not. Because they have ionic bonds, first-generation drugs are more likely to be displaced from their binding sites by drugs that competitively bind to proteins (e.g., warfarin, phenylbutazone). Displacement would result in a greater hypoglycemic effect and may account for the increased risk for hypoglycemia found with first-generation drugs.

Chlorpropamide and tolbutamide enter breast milk. Glyburide (DiaBeta) reaches high concentrations in bile and crosses the placenta.

Metabolism and Excretion

All sulfonylureas are metabolized in the liver to active or inactive metabolites. The hypoglycemic effects of these drugs may be prolonged by severe liver disease because of reduced metabolism. Differences exist among the sulfonylureas in the duration of hypoglycemic effects, in part because of their metabolism. Tolbutamide is short-acting because it is rapidly metabolized to an inactive metabolite by the liver. Tolazamide has two active metabolites that are less potent than the parent compound.

All sulfonylureas are excreted primarily in the urine; first generation are excreted 100% and second generation has both urine and feces elimination routes. Glyburide is excreted as metabolites in bile and urine, approximately 50% by each route. The renal elimination of chlorpropamide may be sensitive to changes in urine pH, with urinary alkalinization

Table 21–14 ⚏ **Pharmacokinetics: Sulfonylureas**

Drug	Onset (h)	Peak (h)	Duration (h)	Protein Binding	Half-Life (h)	Metabolism	Elimination
First-Generation							
Chlorpropamide	1	3–6	25–60	99%	36 (prolonged by renal disease)	80% metabolized in liver; activity unknown	Excreted 100% in urine; renal elimination may be hastened by increased urine pH
Tolazamide	4–6	1–6	12–24	99%	7	Metabolized in liver to several mildly active metabolites	Excreted 100% in urine
Tolbutamide	1	4–6	6–12	99%	4.5–6.5	Oxidized in liver to inactive metabolites	Excreted 100% in urine
Second-Generation							
Glipizide	1–1.5	1–2	10–16	99%	2–4	Metabolized in liver to inactive metabolites	Excreted 80%–85% in urine
Glyburide				99%		Metabolized in liver to weakly active metabolites	Excreted as metabolites in bile and urine, approximately 50% by each route
Nonmicronized	2–4		24		10		
Micronized	1	1.5–3	24		4		
Glimepiride	2	2–3	24	99.5%	5	Completely metabolized by liver	Excreted 60% in urine and 40% in feces

UK = unknown.

hastening its excretion. The half-life of this drug is prolonged in renal disease.

Pharmacotherapeutics

Precautions and Contraindications

All sulfonylureas are contraindicated for patients with hypersensitivity to the drugs or the compounds in which they are mixed. Cross-sensitivity may occur with other sulfonamides, including thiazide diuretics.

Sulfonylureas are listed as Pregnancy Category C (glyburide is Pregnancy Category B). Abnormal BG levels during pregnancy may be associated with a higher incidence of congenital abnormalities; thus insulin has been the drug of choice. All sulfonylureas except glyburide are teratogenic in animals. There are no adequate studies in pregnant women. Prolonged severe hypoglycemia has occurred in neonates born to mothers on a sulfonylurea at the time of delivery. If these drugs must be used during pregnancy, discontinue use 2 to 4 weeks before the expected delivery date.

Chlorpropamide and tolbutamide are known to enter breast milk; it is not known if other sulfonylureas are also excreted in breast milk. Because of the potential for hypoglycemic reactions in nursing infants, sulfonylureas are contraindicated in nursing mothers. The safety and efficacy of these drugs in children have not been established; however, with the increased incidence of type 2 diabetes in children, studies may be conducted to address the possible use of these drugs in children.

Other conditions in which sulfonylureas should not be used include type 1 diabetes; DKA or diabetic coma; and uncontrolled infection, burns, or trauma. Patients with adrenal or pituitary insufficiency are especially susceptible to hypoglycemia, and sulfonylureas should be used cautiously and patients monitored more frequently if they have these comorbid conditions. Severe hepatic impairment may cause inadequate hepatic release of glucose in response to hypoglycemia. Renal impairment may cause decreased elimination, leading to accumulation of these drugs and resulting in hypoglycemia. All sulfonylureas should be used with extreme caution for patients with hepatic or renal impairment, and liver and renal function should be monitored frequently if they must be used.

Older adults and debilitated patients are particularly susceptible to the hypoglycemic action of sulfonylureas, and the signs and symptoms of hypoglycemia may be difficult to recognize. Long-acting agents should be avoided, and short-acting agents should be used with caution in these patients.

All sulfonylureas carry a warning that states that the administration of oral hypoglycemic drugs has been reported to be associated with increased cardiovascular mortality as compared to treatment with diet alone or diet plus insulin. This warning is based on the study conducted by the University Group Diabetes Program (1970). Patients who were treated for 5 to 8 years with diet plus tolbutamide had a rate of cardiovascular mortality approximately 2.5 times that of patients treated with diet alone despite ongoing analyses of the study-identified limitations. Although only one drug in the sulfonylurea class was shown to produce this problem, this warning was extended to the entire drug class because of the close similarities in mode of action and chemical structure of drugs within the class. These concerns were not substantiated by the UK Prospective Diabetes Study (UKPDS) or Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE) studies (Nathan et al, 2009), but the warning remains.

Adverse Drug Reactions

All sulfonylureas may produce severe hypoglycemia. Second-generation drugs are less likely than first-generation drugs to cause this adverse reaction. Hypoglycemia may be difficult to recognize in patients who are concurrently taking beta blockers because these drugs mask the signs and symptoms of hypoglycemia, with the exception of diaphoresis. Hypoglycemia is also more likely when caloric intake is reduced, after severe or prolonged exercise, when alcohol is consumed, or when more than one glucose-lowering agent is used.

Weight gain is common following the initiation of sulfonylurea therapy. The increased insulin secretion generated by sulfonylureas has been associated with weight gain and hyperinsulinemia. Combination with metformin (Glucophage) reduces these adverse effects.

Gastrointestinal disturbances (nausea, epigastric fullness, and heartburn) are the most common adverse reactions. They tend to be dose-related and disappear when the dose is reduced. Diarrhea has been associated with glipizide use; taste alteration has been associated with tolbutamide use. Cholestatic jaundice is rare but requires discontinuation of the drug.

Dermatological reactions include rashes, pruritus, erythema, and urticaria. These tend to be transient and may disappear despite continued use of the drug. Photosensitivity can also occur, and patients should use sunblock and wear clothing when exposed to sunlight.

Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has occurred after administration of sulfonylureas, especially with patients who also have congestive heart failure or hepatic cirrhosis. These drugs stimulate ADH release, augmenting hypothalamic-pituitary release of ADH. The result is excessive water retention and dilutional hyponatremia. Glipizide, tolazamide, and glyburide are mildly diuretic.

Hemolytic anemia, agranulocytosis, leukopenia, and thrombocytopenia have occurred but are rare. Patients should have initial and annual complete blood counts done.

Drug Interactions

Sulfonylureas interact with a large number of drugs that either increase or decrease their hypoglycemic effect (Table 21-15). Alcohol interacts with these drugs to produce a disulfiram-like syndrome, characterized by facial flushing and occasional breathlessness but without the nausea, vomiting, and

Table 21–15 ▦ Drug Interactions: Sulfonylureas

Drug	Interacting Drug	Possible Effect	Implications
All sulfonylureas	Androgens, anticoagulants,* chloramphenicol, fluconazole, gemfibrozil, histamine₂ blockers, magnesium salts, methyldopa, MAO inhibitors, NSAIDs (except diclofenac), phenylbutazone, probenecid, salicylates, sulfonamides, tricyclic antidepressants, urinary acidifiers	Enhance the hypoglycemic effect of the sulfonylurea	Avoid concurrent administration or monitor blood glucose levels closely if drug must be given
All sulfonylureas	Beta-adrenergic blockers, cholestyramine, diazoxide, hydantoins, rifampin, thiazide diuretics, urinary alkalinizers	Decrease the hypoglycemic effect of the sulfonylurea	Avoid concurrent administration or monitor blood glucose levels closely
Glimepiride*	In addition to drugs with all sulfonylureas: corticosteroids, phenothiazines, thyroid products, estrogens, oral contraceptives, nicotinic acid, sympathomimetics, and isoniazid	May cause loss of glucose control because these drugs can cause hyperglycemia	If concurrently administered, monitor closely for loss of glucose control; when they are withdrawn, monitor closely for hypoglycemia

The changes in prothrombin time/international normalized ratio (PT/INR) were so small that they are unlikely to be clinically significant.

*Concurrent administration of glimepiride and warfarin did not alter the pharmacokinetic properties of warfarin.

hypotension seen in a true alcohol–disulfram reaction. This reaction occurs in about 33% of patients concurrently ingesting alcohol and chlorpropamide. It is uncertain whether this reaction occurs with glyburide and glipizide.

Clinical Use and Dosing

Type 2 Diabetes Mellitus

Both first- and second-generation sulfonylureas are used to treat type 2 diabetes. They are effective as second-line therapy with patients who have previously used diet, exercise, weight control, and metformin. Equivalent therapeutic doses vary from 1 mg to 1,000 mg, depending on the drug. Micronized glyburide 3 mg tablets provide serum concentrations that are not bioequivalent to those from the conventional formulation group. When transferring patients from any sulfonylurea to micronized glyburide, the dose must be retitrated. Although all the drugs are listed as once-daily doses, many of the drugs work equally well when the daily dose is divided and given twice, especially when higher doses are required. The dose is highly individualized, based on BG readings (Table 21-16). Start with the lowest dose and increase every 4 to 7 days, based on glucose control. In general, one-half the maximum dose is usually the maximally efficient dose for glucose control. If the BG level goal is not achieved on one-half the maximum dose, consider adding a drug from a different class.

Table 21–16 ✂ Dosage Schedule: Sulfonylureas

Drug	Initial Dose	Dosage Form	Maintenance Dose	Maximum Dose
First-Generation				
Chlorpropamide	Moderately severe, middle-aged stable adults: 250 mg	100 and 250 mg tablets	250 mg/d before morning meal	750 mg/d
	Older adults: 100–125 mg Severe disease: 250 mg		100–250 mg/d before morning meal 500 mg/d before morning meal	
Tolazamide	100 mg	100, 250, and 500 mg tablets	If FPG less than 200 mg/dL, give 100 mg/d before morning meal. If FPG more than 200 mg/dL, give 250 mg/d before morning meal. If patient malnourished, underweight, or elderly, give 100 mg/d before morning meal.	1,000 mg/d

Table 21–16 ⊗ **Dosage Schedule: Sulfonylureas—cont'd**

Drug	Initial Dose	Dosage Form	Maintenance Dose	Maximum Dose
			If more than 500 mg/d, divide dose and give bid before morning and evening meal.	
Tolbutamide (Orinase)	1,000 mg	500 mg	500–2,000 mg/d; divide dose and give bid before morning and evening meal	2,000 mg/d
Second-Generation				
Glipizide (Glucotrol, Glucotrol XL) (B)	5 mg Older adults, liver disease: 2.5 mg	5 and 10 mg tablets	Doses more than 15 mg/day: divide and give bid before morning and evening meal; adjust doses in 2.5–5 mg increments several days apart	40 mg/d
Glyburide				
Glyburide (DiaBeta, Micronase) (Generic available in both micronized and nonmicronized formulations)	2.5 mg	Tablets: 1.25, 2.5, 5 mg Micronized tablets: 1.5, 3, 6 mg	1.25–20 mg/d before morning meal. Dose more than 10 mg/d: divide and give bid; adjust dose in increments of 2.5 mg at weekly intervals	12 mg/d for micronized; 20 mg/d for nonmicronized
Glynase (micronized formulation)	1.5 mg		0.75–6 mg/d before morning meal. Dose more than 10 mg/d: divide and give bid before morning and evening meal; adjust dose in increments of 1.5 mg at weekly intervals	12 mg/d
Glimepiride (Amaryl) (G)	1 mg	1, 2, and 4 mg tablets	1–4 mg/d before morning meal. After reaching 2 mg dose, increase in increments of no more than 2 mg at 1–2 wk intervals.	8 mg/d

Rational Drug Selection

Age

Glyburide should be avoided in older adults because of the risk for severe hypoglycemia in this age group (Kirkman et al, 2012). Sulfonylureas in general may cause problems with hypoglycemia in older adults; they are not currently approved for use in children.

Concurrent Disease

In the presence of renal impairment, glipizide and tolbutamide are reasonable choices because they are oxidized in the liver to inactive metabolites. Glyburide is also a reasonable choice because 50% of it is excreted in bile, which gives an alternative route for excretion. Tolazamide is also safe to use with creatinine clearance (CCr) less than 30 mL/min.

Taking Multiple Medications

Second-generation sulfonylureas are best to minimize potential drug interactions and for patients who are taking multiple medications. Second-generation sulfonylureas also have the advantage of once-daily administration, thereby reducing the complexity of the drug regimen and improving adherence. Among this group of drugs, glimepiride binds to different insulin receptors than do other sulfonylureas and may be effective when others are not. It is also associated with a lower incidence of hypoglycemic reactions.

◉ CLINICAL PEARL ◉

Tolazamide has the added advantage that it may be crushed and put down a nasogastric tube or sprinkled on applesauce or other soft food for patients who have difficulty in swallowing tablets.

Monitoring

Hb A1c is the preferred tool for monitoring long-term glycemic control. Glycated albumin (fructosamine) is also sometimes used for monitoring, although it is not recommended as a substitute for A1C except in situations such as hemolytic anemia in which Hb A1c cannot be used. It indicates the average BG for the past 1 to 3 weeks and is used to assess short-term control. The minimum goal for fructosamine levels is 325 mmol or less, with a goal for intensive therapy of 287 mmol or less. All decreases in these monitoring parameters are beneficial, even if the goal is not met. SMBG should be performed and monitored for daily BG changes and adequacy of control.

Patient Education

Administration

Patients are taught to take the medication exactly as prescribed, at the same time each day, preferably before or with

the morning meal. All sulfonylureas except glipizide may be taken with food. Glipizide must be taken 30 minutes before a meal to prevent a reduction in absorption. If a dose is missed, instruct the patient to take it as soon as remembered unless the timing of the dose will produce a risk for hypoglycemia. Doses should not be taken if the patient is unable to eat.

Adverse Reactions

The most common adverse reactions are gastrointestinal. If GI upset is a problem, notify the health-care provider. The dose may be divided and given twice daily to reduce this adverse effect. The most serious potential adverse reaction is hypoglycemia. Teach the patient the signs and symptoms of hypoglycemia and how to treat it. Caution the patient to avoid concurrent administration of other drugs without first discussing them with the health-care provider. Many drugs increase or decrease the effectiveness of sulfonylureas and can produce hypoglycemia or hyperglycemia. This is especially a problem with alcohol because it both produces hypoglycemia and masks the indications of this adverse reaction. Alcohol may also produce a disulfram-like reaction when combined with some sulfonylureas.

Because these drugs may produce alterations in red and white blood cell and platelet formation, patients should notify their provider promptly if they experience sore throat, rash, or unusual bruising or bleeding. Sulfonylureas may also produce an antidiuretic effect, and patients should promptly report unusual weight gain, swelling of the ankles, drowsiness, or shortness of breath.

ALPHA-GLUCOSIDASE INHIBITORS

The alpha-glucosidase inhibitors are oral antihyperglycemic drugs used in the treatment of type 2 diabetes mellitus. The action of this class has proved to reduce BG both as added therapy for patients who cannot achieve control on diet alone and as added therapy for patients whose BG cannot be controlled by lifestyle modifications and other oral antihyperglycemic agents. These drugs are not typically given as monotherapy; they are adjunct to other therapy for type 2 diabetes. In Asia, it is used as initial, mono therapy and is being considered as a metformin substitute if someone cannot take that drug (Yang et al, 2014).

Pharmacodynamics

Alpha-glucosidase inhibitors do not act directly on any of the defects in metabolism seen in type 2 diabetes mellitus. They competitively inhibit the absorption of complex carbohydrates (CHO) from the small bowel. Their chemical structure is a pseudo-tetrasaccharide that binds to alpha glucosidase. Because this structure is so similar to the CHO molecule, digestive enzyme activity is partially diverted from CHO digestion while it is trying to digest the alpha-glucosidase inhibitor. This effectively delays the digestion of CHO and permits CHOs that would normally have been digested in the upper small bowel to move farther down in the bowel. The lower parts of the bowel have the necessary enzymes to digest this CHO, but, because they are not normally active in this process, enzyme induction is required. The process of induction takes weeks to months, and during this time patients may experience intestinal flatus and abdominal distention. Alpha-glucosidase inhibitors have no inhibitory activity against lactase and do not induce lactose intolerance.

Alpha-glucosidase inhibitors lower BG levels after meals. The higher that the postprandial BG level is, the larger the reduction will be that this drug can provide. As a consequence of plasma glucose reduction, they also reduce glycosylated hemoglobin levels. The mean reduction in Hb A1c is 0.77%, postprandial BG reduction is approximately 50 mg/dL, and fasting BG reduction is 20 mg/dL (*DF & C*, 2011).

Unlike other classes of antihyperglycemic agents, they do not enhance pancreatic beta cell secretion of insulin and so do not produce hypoglycemia. Like metformin, they are not associated with weight gain, and they diminish the weight-increasing effects of sulfonylureas when given in combination with them. Their activity is effective on any CHO food intake, including liquid diets taken via nasogastric tube.

Pharmacokinetics

Absorption and Distribution

Less than 2% of acarbose is systemically absorbed as an active drug. The remainder is active in the GI tract with no systemic distribution. Miglitol is completely absorbed in the GI tract at 25 mg doses, and 50% to 70% is absorbed at higher doses. Its volume of distribution of 0.18 is consistent with distribution primarily into extracellular fluids.

Metabolism and Excretion

Acarbose and miglitol are metabolized exclusively by intestinal bacteria and digestive enzymes. The minimal amount of drug absorbed is excreted by the kidneys. The plasma elimination half-life of both drugs is about 2 hours, so drug accumulation does not occur with 3-times-daily dosing. The mean steady-state AUC and maximum concentration of this drug were 1.5 times higher in older adults taking acarbose, but this was neither statistically nor clinically significant. This change was not seen with miglitol.

Pharmacotherapeutics

Precautions and Contraindications

Alpha-glucosidase inhibitors should not be used for patients with bowel diseases such as inflammatory bowel disease, bowel obstruction or risk factors for it, chronic intestinal disease associated with marked digestive disorders, or conditions that may deteriorate as a result of increased gas in the intestine.

Plasma concentrations of alpha-glucosidase inhibitors were 5 times higher in patients with severe renal impairment (CCr less than 25 mL/min); however, dosage adjustments to compensate for this are not possible because the drugs act

locally (*DF & C*, 2011). Long-term studies with diabetes patients with renal impairment have not been conducted. Therefore, treatment with these drugs is not recommended for these patients.

The safety of alpha-glucosidase inhibitors in pregnant women has not been established. Although they are listed as Pregnancy Category B, they should not be used in pregnancy unless clearly needed. As previously discussed with other oral agents, insulin is the drug of choice for pregnant diabetics. In a study, a small amount of acarbose was excreted in the breast milk of rats. It is not known if it is excreted in human breast milk, and it should not be used in lactating women. Miglitol is excreted in human breast milk to a small degree. Total excretion in breast milk accounts for 0.02% of a 100 mg maternal dose. Although the levels in breast milk are exceedingly low, it also should not be used for lactating women.

Safety and efficacy in children have not been established for either drug.

Adverse Drug Reactions

GI symptoms are the most common adverse reactions seen with alpha-glucosidase inhibitors. Approximately 77% of patients taking acarbose and 41% of patients taking miglitol experience flatulence, the leading reason for discontinuance of the drug. Approximately 33% of patients taking acarbose and 29% of patients taking miglitol experience diarrhea, whereas 21% report abdominal pain while taking acarbose and 12% while taking miglitol. These adverse effects can be reduced by slow titration to maximal dose.

> ### ⊙ CLINICAL PEARL ⊙
>
> Starting the **alpha-glucosidase inhibitor** at 25 mg daily for 1 week and increasing the dose to 25 mg twice daily for 1 week and then to 25 mg 3 times daily for 1 week decreases the incidence of GI-adverse responses.

Because of their mechanism of action, alpha-glucosidase inhibitors alone do not cause hypoglycemia but may do so in combination with other drugs that lower BG, such as sulfonylureas and insulin. Treatment of this hypoglycemia cannot be accomplished with the usual ingestion of sucrose, fructose, or starches because alpha-glucosidase inhibitors delay the absorption of these disaccharides. Reversible increases in serum transaminases (alanine aminotransferase [ALT] and aspartate aminotranspeptidase [AST]) have occurred with doses of acarbose greater than 200 mg 3 times daily. Hepatic abnormalities improved or resolved with discontinuance of the drug. This laboratory change has not been reported with miglitol.

Drug Interactions

Acarbose may decrease serum digoxin levels. Drugs may enhance the hypoglycemic effects of acarbose and miglitol, such as neomycin, selective serotonin uptake inhibitors, salicylates, and MAO inhibitors; those that may diminish the hypoglycemic effects are somatropin, loop and thiazide diuretics, and corticosteroids (Access Pharmacy, 2013). Both acarbose and miglitol may have their therapeutic effects reduced by concurrent administration with digestive enzymes or intestinal absorbents (Table 21-17).

Clinical Use and Dosing

Management of type 2 diabetes mellitus is the only indication for these drugs. They are useful for patients with high postprandial BG levels. The initial dose of both drugs is 25 mg 3 times daily taken with the first bite of each meal. Taking the dose with the first bite is critical; a space between administration of the drug and ingestion of food decreases its effect, and no effect occurs if it is taken after a meal. The dose is increased in increments of 25 mg with each meal (75 mg/day) at 4- to 8-week intervals. The maintenance dose is usually 50 mg 3 times daily, although some patients may benefit from increasing the dose to 100 mg 3 times daily. If no further reduction in postprandial BG is achieved at the higher dose, consider reducing the dose to 50 mg 3 times daily (Table 21-18).

Because patients with low body weight are at higher risk for elevations in serum transaminase, the dose should not be higher than 50 mg 3 times daily for patients weighing less than 60 kg, and the 100 mg 3 times daily dose should be reserved for patients weighing more than 60 kg. The maximum dose is 100 mg 3 times daily.

Table 21–17 ⠿ Drug Interactions: Alpha-Glucosidase Inhibitors

Drug	Interacting Drug	Possible Effect	Implications
Acarbose, miglitol	Digoxin	Serum digoxin concentrations may be reduced with reduced therapeutic effect	Choose another antihyperglycemic drug
	Digestive enzymes and intestinal absorbents	Reduced effect of alpha-glucosidase inhibitor	Do not take concomitantly
Miglitol	Propranolol	Reduces bioavailability of propranolol by 40%	Avoid current use
	Ranitidine	Reduces bioavailability of ranitidine by 60%	Avoid current use

Table 21–18 ⚛ **Dosage Schedule: Alpha-Glucosidase Inhibitors**

Drug	Dosage Form	Initial Dose	Maintenance Dose	Maximum Dose
Acarbose (Precose) Meglitol (glyset)	25, 50, 100 mg tablets	*Wt > 60 kg* : 25 mg 3 times daily with the first bite of each meal for 4 wk *Wt < 60 kg:* 25 mg 3 times daily with the first bite of each meal for 4 wk *Poor GI tolerance:* 25 mg daily with first bite of evening meal for 2 wk	Weeks 5–8: 50 mg tid Weeks 9–12: 100 mg tid Weeks 5–8: 50 mg tid Weeks 3–4: 25 mg tid; Weeks 5–12: 25 mg tid Week 50 mg tid	100 mg tid 50 mg tid 50 mg tid

When given in combination with a sulfonylurea or insulin, hypoglycemia may occur. It is important to monitor BG levels closely when alpha-glucosidase inhibitors are added to the treatment regimen to avoid hypoglycemia. For treatment of mild–moderate hypoglycemia, oral glucose (dextrose) should be used instead of sucrose (cane sugar). For severe hypoglycemia, IV glucose or glucagon should be used.

Rational Drug Selection

Adverse Reactions

Elevated serum transaminase levels have been reported in long-term studies of acarbose, usually with doses up to 300 mg 3 times daily. These elevations appear to be dose-related and disappeared with maximum doses at 100 mg 3 times a day. There have been no reported hepatic adverse reactions and no reported changes in liver function tests with miglitol. The percentage of patients experiencing GI adverse effects in clinical trials is slightly lower with miglitol. Patients at risk for this adverse effect might be tried first on miglitol. During stress-related states, such as fever, trauma, infection, or surgery, treatment may need to be changed to insulin.

Monitoring

Before initiating therapy and at least annually thereafter, assess renal function. For patients with increased risk beyond their diabetes for developing altered renal function, the assessment timing should be related to the disease process that produces the added risk. Alpha-glucosidase inhibitors are not recommended for patients with renal impairment. Assessment of renal function includes serum electrolytes, blood urea nitrogen (BUN), and serum creatinine. A similar assessment is required related to hepatic function for patients taking acarbose. Because acarbose has been associated with reversible elevations in serum transaminase, these values should be assessed every 3 months for the first year.

Response to alpha-glucosidase inhibitor therapy is assessed by regular monitoring of fasting and postprandial BG. During initial therapy and with each incremental increase, FPG is used to evaluate response. After the patient is stabilized on a specific dose, monitoring with FPG and Hb A1c levels every 3 to 6 months is sufficient.

Patient Education

Administration

Patients are taught to take these drugs with the first bite of each meal. The need for this timing of administration must be stressed because taking it too soon reduces its effect and taking it after a meal has no effect.

Adverse Reactions

The most common adverse reactions are GI disturbances. These effects can be reduced or prevented by slow titration of the dose. Even without changing the dose, GI disturbances usually resolve in about 2 weeks.

🔵 **CLINICAL PEARL** 🔵

The delayed absorption of carbohydrates caused by **alpha-glucosidase inhibitors** results in less need for the insulin secretion generated by a **sulfonylurea**. If the BG level drops too much, the dose of the **sulfonylurea** should be reduced.

Hypoglycemia is less common than with other glucose-lowering drugs but may occur when alpha-glucosidase inhibitors are given with insulin, sulfonylureas, or repaglinide (Prandin). The usual treatment for hypoglycemia with sucrose, fructose, or starches does not resolve the problem for patients on alpha-glucosidase inhibitors because it interferes with the absorption of these carbohydrates. Treatment for mild to moderate hypoglycemia should be treated with glucose in the form of dextrose, not sucrose (table sugar, candy, cookies, etc.). Severe hypoglycemia may need to be treated with IV glucose or glucagon. Patients should wear identification that states they are taking an alpha-glucosidase inhibitor and the source of simple carbohydrate that should be used in case of hypoglycemia.

THIAZOLIDINEDIONES

The thiazolidinediones (TZDs) are oral antihyperglycemic drugs used in the treatment of type 2 diabetes. Their action lowers BG levels as monotherapy for patients who cannot achieve BG control with diet alone, and they are successful as added therapy for patients who cannot be controlled by lifestyle modifications or other antihyperglycemic agents. They are not part of initial therapy. Troglitazone (Rezulin), the first TZD, was approved in March 1997. It was removed from the market in 1999 because of the adverse reactions associated with liver damage. Pioglitazone (Actos) and rosiglitazone (Avandia) are the only TZDs on the U.S. market. TZDs are recommended in the current guidelines in two or

three drug combinations if glycemic targets are not met but should be used cautiously because of the potential for cardiovascular problems, especially with rosiglitazone. In 2011, the FDA imposed restrictions on prescribing rosiglitazone-containing drugs that required health-care providers and patients be enrolled in the Avandia-Rosiglitazone Medicines Access Program (REMS) (FDA, 2011). Two FDA panels met in 2013 to relinquish many of the restrictions placed on rosiglitazone after the "Rosiglitazone Evaluated for Cardiovascular Outcomes and Regulation of Glycemia in Diabetes" (RECORD) study reanalysis (Medscape 2013). This remains controversial due to reports of severe cardiovascular (CV) compromise in some patients.

Pharmacodynamics

TZDs improve glycemic control by improving insulin sensitivity, a major pathological problem with type 2 diabetes. They are effective only in type 2 diabetes because they depend on the presence of insulin for their action. They are highly selective activators of the peroxisome proliferator-activated receptor gamma, a nuclear receptor that regulates gene transcription, resulting in expression of proteins that improve insulin action in the cell. This action leads to increased utilization of available insulin by the liver and muscle cells and also in adipose tissue. In addition, these drugs reduce hepatic glucose production. Taken together, these actions improve glucose tolerance and lower both basal and postprandial plasma glucose levels. Unlike the sulfonylureas, TZDs do not produce hypoglycemia, except in special situations, and do not cause hyperinsulinemia because they do not stimulate insulin release from the pancreatic beta cells. Like metformin, they have a modest impact on lipids because of their actions in the liver.

Pharmacokinetics

Absorption and Distribution

Pioglitazone and rosiglitazone are rapidly absorbed after oral administration. Food does not alter the extent of absorption, but it does delay the time until peak concentration is reached. Both drugs are extensively bound to plasma proteins, with a mean volume of distribution (V_d) ranging from 0.63 L/kg for pioglitazone to 17.6 L/kg for rosiglitazone. This difference in V_d might be a factor in drug choice for patients with high extracellular fluid levels.

Metabolism and Excretion

Both drugs are highly metabolized by the liver into metabolites, and pioglitazone has at least two active metabolites. Hepatic function impairment increased C_{max} for both drugs and AUC levels for rosiglitazone. The pioglitazone site of metabolism in the liver results in inhibition of the CYP450 2C8, 3A4, and 1A1 isoezymes. Drugs using these isoezymes are likely to have drug interactions. In vitro drug studies suggest that rosiglitazone does not inhibit any of the major CPY450 enzyme systems. It is predominantly metabolized by CYP450 2C8 and, to a lesser extent, 2C9.

Mean plasma elimination half-life ranges from 3 to 7 hours, with 23% of rosiglitazone and its metabolites recovered in the feces and 64% in the urine. Pioglitazone is excreted 15% to 30% in the urine.

> ### ◉ CLINICAL PEARL ◉
>
> When **thiazolidinediones** are added to a **sulfonylurea** in a diabetic regimen, the increased sensitivity to insulin caused by the **thiazolidinedione** results in less need for the **insulin** secretion generated by the **sulfonylurea**. If the BG level drops too much, the dose of the **sulfonylurea** should be reduced.

The mean pioglitazone C_{max} and AUC values are increased 20% and 60% in women. The mean oral clearance of rosiglitazone in women is 6% lower compared to men (*DF & C*, 2011).

Pharmacotherapeutics

Precautions and Contraindications

The metabolites of these drugs have been found in increased concentrations in patients with chronic liver disease. Serum transaminase levels must be checked at the start of therapy and frequently during therapy. These drugs should not be initiated in patients with ALT levels greater than 2.5 times the upper limit of normal. They should be discontinued if the patient develops jaundice or has laboratory measurements suggesting liver injury (e.g., ALT greater than 3 times the upper limit of normal).

An increase in plasma volume (fluid retention) with a resultant increase in body weight and decrease in hemoglobin of less than or equal to 1% with rosiglitazone and 2% to 4% with pioglitazone has been noted in some patients. In the United States, initiation of therapy is contraindicated in patients with NYHA class III or IV heart failure; in Canada, use is contraindicated in patients with any stage of heart failure (NYHA I, II, III, IV). A higher frequency of cardiovascular events has been noted in patients with NYHA class I or II heart failure treated with rosiglitazone. Use may also be associated with an increased risk of angina and myocarcial infarction (MI). Use with caution in patients at risk for cardiovascular events and monitor closely following the Black-Box Warning for cardiotoxicity (Access Pharmacy, 2013). The apparent risk for macular edema associated with pioglatizone use may more be a function of the typically higher BMI and resistant hyperglycemic status of patients on glitazone therapy rather than the medication itself (Fujimoto, 2013).

In premenopausal anovulatory patients with insulin resistance, TZD treatment may result in resumption of ovulation. This has been found to be useful in Polycystic Ovarian Syndrome patients. If pregnancy is not desired, a birth control method should be instituted prior to beginning therapy. There are no adequate and well-controlled studies of the use of pioglitazone or rosiglitazone in

pregnant women. Some animal studies have shown fetal death and growth retardation. These drugs are listed as Pregnancy Category C; TZDs should not be used during pregnancy unless the potential benefit clearly outweighs the risk. Insulin is the drug of choice for treatment of diabetes during pregnancy.

It is not known whether these drugs are excreted in human breast milk. They are secreted in the milk of lactating rats. Do not administer these drugs to lactating women. The safety and efficacy in children younger than 18 years have not been established.

Adverse Drug Reactions

TZDs are generally well tolerated, with the exception of cardiovascular effects, including weight gain (5%), hypertension (4%), heart failure (2% to 3% in patients receiving insulin), and myocardial ischemia (3%). Increases in total cholesterol, HDL cholesterol, LDL cholesterol, and weight gain occur in less than 10% of patients (Access Pharmacy, 2013).

Drug Interactions

Administration of pioglitazone with an oral contraceptive that contains ethinyl estradiol and norethindrone reduces the plasma concentrations of both components by 30%. These changes, added to the resumption of ovulation that occurs in some anovulatory women, could result in loss of contraception. A higher dose of oral contraceptive or an alternative birth control method may be needed.

Pioglitazone is metabolized by the CPY450 3A4 isoezyme system. Specific formal pharmacokinetic interaction studies have not been conducted with other drugs also metabolized by this system (e.g., erythromycin, calcium channel blockers, corticosteroids, cyclosporine, HMG-CoA reductase inhibitors). Until data are available, it is prudent to avoid these drug combinations or to carefully monitor patients concurrently taking pioglitazone and any of the drugs also metabolized by the CYP450 3A4 isoenzyme system. Table 21-19 presents drug interactions with thiazolidinediones.

Clinical Use and Dosing

The only approved indication for these drugs is as therapy for type 2 diabetes not controlled by diet alone or diet and an oral antihyperglycemic agent or insulin (Table 21-20).

Monotherapy

Clinical trials have been conducted to study the use of both pioglitazone and rosiglitazone as monotherapy for patients

Table 21–19 ⵘ Drug Interactions With Thiazolidinediones

Drug	Interacting Drug	Possible Effect	Implications
Pioglitazone	Oral contraceptives	Oral contraceptives with ethinyl estradiol and norethindrone show reduced plasma contraceptive components	May result in loss of contraception; consider higher dose of contraceptive or alternative method
	Atorvastatin	Concurrent use for 7 d shows an increase in serum concentrations of both drugs	Monitor BG closely
	Ketoconazole	Coadministration shows an increase in pioglitazone AUC and C_{max}. Ketoconazole significantly inhibits pioglitazone metabolism.	Avoid concurrent use. Select different antifungal agent. If both must be given, monitor glycemic control closely.
	Nifedipine	Concurrent use shows an increase in nifedipine-ER concentrations	Unknown clinical significance
Pioglitazone and rosiglitazone	Bile-acid sequestrants	Pharmacological effects of thiazolidinedione may be decreased; bile-acid sequestrant reduces absorption	Avoid concurrent use; separate doses by 4 h, giving thiazolidinedione first

Table 21–20 � Dosage Schedule: Thiazolidinediones

Drug	Initial Dose	Dosage Form	Maximum Dose	Maintenance Dose
Pioglitazone (Actos) Pioglitazone and metformin (ActoPlus Met) ActoPlus Met XR	15–30 mg daily	15, 30, 45 mg tablets 15 mg XR: 15, 30 mg tablets	45 mg/day	45 mg/d
Rosiglitazone (Avandia) Rosiglitzaone and metformin (Avandamet)	4 mg/d in single dose or in divided doses twice daily	2 and 4 mg tablets 1, 2, and 4 mg tablets	8 mg/day	Increase to 8 mg/d in single or divided doses. With insulin: Do not exceed 4 mg/d. Decrease insulin dose by 10%–25% if hypoglycemia or FBG <100 mg/dL

previously treated only with diet. The current Standards of Medical Care in Diabetes of the American Diabetes Association (2013), however, recommend that these drugs be used as adjunctive therapy when BG targets are not achieved by lifestyle modifications and metformin. Doses of 15 to 30 mg/d of pioglitazone were associated with decreased FPG by 39 mg/dL for the 15 mg dose and 58 mg/dL for the 30 mg dose. Hb A1c was reduced by 0.9% for the 15 mg dose and 1.3% for the 30 mg dose. The initial dose of pioglitazone may be either 15 mg or 30 mg and the dose may be increased in 15 mg increments to a maximum dose of 45 mg/d (Table 21-20). Because effectiveness of therapy is best evaluated by Hb A1c, it is recommended that the adequate time period for evaluation of drug effectiveness is 3 months unless glycemic control deteriorates.

Rosiglitazone in doses of 4 mg/d reduced FPG by 25.4% and A1C by 0.27%. Rosiglitazone is usually initiated at 4 mg/d as a single dose. If single-dose therapy is not effective, the dose may be divided into twice-daily dosing or increased incrementally to a maximum dose of 8 mg/d. As with pioglitazone, evaluation of adequacy of response requires 12 weeks of therapy.

Combination Therapy With Oral Agents

When used as added therapy to management with a sulfonylurea, initiate pioglitazone with either the 15 or 30 mg dose. For rosiglitazone, initiate therapy at 4 mg/d in single or divided doses. Continue the current dose of the sulfonylurea. If the response in terms of glycemic control is inadequate, increase the dose of the TZD at 8 to 12 weeks, not to exceed the maximum mg/d.

The pharmacodynamics of TZDs is different from that of sulfonylureas so that the two drugs taken together potentiate each other's actions. Both fasting and postprandial BG levels of patients decrease. It is important to monitor BG levels closely when TZDs are added to the treatment regimen to avoid hypoglycemia.

Combination Therapy With Insulin

For patients stabilized on insulin, continue the insulin dose while initiating the TZD. For pioglitazone, initiate the dose at 15 to 30 mg once daily. For rosiglitazone, initiate the dose at 4 mg once daily and do not increase this dose. For both drugs, decrease the insulin dose by 10% to 25% if the patient reports hypoglycemia or if the FBG decreases to less than 100 mg/dL. Further adjustments are individualized based on the glucose-lowering response (see Table 21-20).

Monitoring

Serum transaminase (ALT) levels must be checked at the start of therapy. TZDs are not started if the pretreatment serum ALT level is more than 2.5 times the upper limit of normal (ULN). Once therapy is started, ALT is checked every 2 months for the first 12 months and periodically thereafter. If the ALT increases to more than 1.5 to 2 times the ULN, liver function tests are done every week until levels return to normal. The drug is discontinued if the ALT level is more than 3 times the ULN. The cost of this amount of monitoring must be considered in the total cost of therapy with these drugs.

If any patient develops symptoms suggesting hepatic dysfunction, the decision whether to continue the therapy with pioglitazone or rosiglitazone is guided by clinical judgment pending laboratory evaluation. If jaundice is observed, therapy is discontinued.

Due to contradictory evidence on the cardiotoxicity of rosiglitazone, patients taking this drug should have their cardiac function evaluated on a regular basis. This evaluation should look for indications of myocardial ischemia and heart failure. Response to TZD therapy is also assessed by regular monitoring of FPG and A1C every 3 to 6 months. During initial therapy and with each incremental increase, FPG is used to evaluate response.

Patient Education

Administration

Pioglitazone is to be taken once daily in the morning. If it is missed, it can be taken as soon as remembered. If the dose is missed for the entire day, the dose should not be doubled the next day. Explain to the patient that pioglitazone helps to control hyperglycemia, but it does not cure diabetes. The therapy is long-term.

Rosiglitazone may be taken once daily or twice daily in divided doses. The dosing schedule should not be changed without consultation with the provider. If the dose is missed for the entire day, the dose should not be doubled the next day.

Adverse Reactions

TZDs are generally well tolerated and adverse reactions are rare. The one adverse reaction of concern is hepatocellular injury. Advise the patient to report immediately any signs of hepatic dysfunction such as nausea, vomiting, abdominal pain, fatigue, anorexia, jaundice, or dark urine. Explain to the patient that hepatic function must be carefully monitored and that it is essential to keep follow-up appointments for laboratory work.

Hypoglycemia is not a risk with monotherapy but may occur when TZDs are given with another glucose-lowering drug. The usual treatment for hypoglycemia with sucrose, fructose, or starches will resolve the problem.

Cardiac risk has been discussed. Patients should report immediately any chest pain, shortness of breath, peripheral edema, or indications of impending stroke.

Female patients using oral contraceptives for birth control and premenopausal anovulatory patients should be informed about the possible need to increase the dose of oral contraceptive or choose an alternative birth control method.

MEGLITINIDES

The meglitinides are phenylalanine derivatives that are short-acting insulin secretagogues; they act by stimulation of insulin secretion to lower postprandial BG levels. They do not directly affect fasting BG levels or any of the other defects in metabolism seen in type 2 diabetes mellitus. They are most useful in patients whose primary glucose alteration is

postprandial hyperglycemia and the amount of insulin released depends on existing BG levels. Current guidelines suggest these drugs be used as adjunct therapy. This section discusses the two drugs repaglinide (Prandin) and nateglinide (Starlix).

Pharmacodynamics

Meglitinides close ATP-dependent potassium channels in the beta cell membrane by binding at specific receptor sites. This potassium channel blockade depolarizes the beta cell and leads to an opening of calcium channels. The resultant influx of calcium increases the secretion of insulin. Because its time in the plasma is less than 2 hours, the effect is 4 hours with peak effect in 1 hour (Access Pharmacy, 2013). The ion channel mechanism is highly tissue selective, with low affinity for heart and skeletal muscle, which reduces the potential adverse effects on these tissues.

Pharmacokinetics

Absorption and Distribution

After oral administration, meglitinides are rapidly and completely absorbed from the GI tract. They are highly bound to albumin for distribution, primarily to beta cell membranes. Peak plasma levels occur within 1 hour. The presence of food in the gut does not affect AUC, but there is a delay in C_{max} and time to peak plasma concentration (T_{max}). Both drugs are taken 20 minutes before a meal.

Metabolism and Excretion

Both drugs are completely metabolized by oxidative biotransformation and direct conjugation with glucuronic acid. The CYP450 enzyme system, particularly 2C9 for nateglinide and 3A4 for repaglinide, is involved in their metabolism. The metabolites of nateglinide are less potent antihyperglycemic agents, but the metabolites of repaglinide do not contribute to any glucose-lowering effect.

This drug is rapidly eliminated from the plasma, with a half-life of 1 to 1.5 hours. Within 96 hours after administration of repaglinide and 6 hours of nateglinide, the drugs and their metabolites are recovered in the feces and in the urine. Table 21-11 depicts the pharmacokinetics of these drugs.

Pharmacotherapeutics

Precautions and Contraindications

These drugs should be used cautiously with patients who have hepatic impairment, and longer intervals between dosage adjustments should be used. Caution should be used in patients with severe renal impairment and adrenal/pituitary impairment because these drugs may exert more glucose-lowering effects.

Repaglinide and nateglinide are Pregnancy Category C. Nonteratogenic skeletal deformities occurred in test animals. There are no adequate and well-controlled trials in pregnant women. Meglitinides should not be used during pregnancy.

Both drugs are excreted in the breast milk of test animals. It is not known if they are excreted in human breast milk. Because the potential exists for hypoglycemia in nursing infants, the drugs should not be used with lactating women. No studies have been done to test the safety and efficacy of these drugs in children.

Adverse Drug Reactions

The risk for hypoglycemia with meglitinides is a concern, so appropriate patient selection should be used when prescribing. Patients with hepatic insufficiency, older adults, and debilitated and malnourished patients are at higher risk for hypoglycemia. The frequency of hypoglycemia is also greater for patients who have not been previously treated with oral hypoglycemic agents or whose A1C is less than 8%. Careful timing of administration with regard to meals lessens the likelihood of this adverse reaction. The risk for weight gain is similar to that of the sulfonylureas.

Drug Interactions

Because the CYP450 3A4 enzyme system is involved in the metabolism of repaglinide and both 2C9 (70%) and 3A4 (30%) in the metabolism of nateglinide, drugs that induce these isoezymes (e.g., rifampin, barbiturates, carbamazepine) may increase meglitinide metabolism (Table 21-21). These

Table 21–21 ⁂ **Drug Interactions With Meglitinides and Repaglinide**

Interacting Drug	Possible Effect	Implications
Drugs that induce CYP450 3A4	Increases metabolism and decreases effect of repaglinide and nateglinide	Closely monitor blood glucose levels and patient response
Drugs that induce CYP450 2C9	Increases metabolism and decreases the effect of nateglinide	Closely monitor blood glucose levels and patient response
Ketoconazole, miconazole, and potentially other "azoles"	Inhibits meglitinide metabolism and may increase risk for hypoglycemia	Closely monitor blood glucose levels and patient response Choose a different antifungal
Erythromycin and potentially other macrolides	Inhibits meglitinide metabolism and may increase risk for hypoglycemia	Closely monitor blood glucose levels and patient response Choose a different class of antimicrobial
Any drug that increases or decreases BG levels	May alter glycemic effects of meglitinide and increases risk for lack of control or hypoglycemia	Closely monitor blood glucose levels and patient response

isoezymes are among the most used widely by drugs for metabolism; other drug reactions may be found as these drugs are used.

Antifungal agents such as ketoconazole and miconazole and antimicrobial agents such as erythromycin inhibit repaglinide metabolism and may increase the risk for hypoglycemia by raising blood levels of the drug. Any drug that alters BG levels has the potential to alter the glycemic control effects of meglitinides. Meglitinides can potentiate the action of drugs that are highly protein bound by competing for their binding sites (e.g., NSAIDs, salicylates, sulfonamides, warfarin, beta-adrenergic blockers, and monoamine oxidase inhibitors). Table 21-21 shows drug interactions for the meglitinides.

Meglitinides should not be used in place of metformin monotherapy or if other insulin-stimulating drugs (sulfonylureas) have been used unsuccessfully. Using concurrently with sulfonylureas has no additional benefit and should not be prescribed (Access Pharmacy, 2013).

Clinical Use and Dosing

Monotherapy

For nateglitinide, the initial and maintenance dose is 120 mg 3 times/day, 1 to 30 minutes before each meal; if the patient is near target A1C (less than 7%), dosing may be started at 60 mg 3 times daily. For repaglinide, if A1C is less than 8% or not previously treated, the dose is 0.5 mg before each meal; if the A1C is greater than 8% or the patient is being switched from another oral agent, the initial dose is 1 to 2 mg 3 times/d (Access Pharmacy, 2013).

Combination Therapy

Meglitinides may be given in conjunction with metformin or TZDs. Meglitinides are not currently on the ADA treatment algorithm for type 2 diabetes, the primary reason being more frequent dosing and less glucose-lowering effectiveness than other drugs available (Inzucchi et al, 2012). When adding meglitinides to either metformin or TZD therapy, careful monitoring and dosing is necessary to prevent hypoglycemic episodes.

For Both Uses

Dosage changes are based on FPG and Hb A1c levels. With repaglinide, the preprandial dose should be doubled, up to 4 mg, until satisfactory response is achieved. The initial dose and the maintenance dose are the same for nateglinide. Allow at least 1 week to assess patient response before adjusting a dose. The maximum daily dose is 16 mg for repaglinide and 720 mg for nateglinide. No dosage adjustments are required based on age, race, or gender. Table 21-22 shows the dosage schedules for these drugs.

Monitoring

The monitoring required with the meglitinides is periodic monitoring of FPG and Hb A1c every 3 months. These values should be determined prior to initiation of therapy to determine baseline values and contribute to the decision about initial dose. Thereafter, they are used to monitor patient response.

Patient Education

Administration

Doses are always administered 0 to 30 minutes prior to each meal and should be omitted if meals are not eaten. If extra meals are eaten, extra doses should also be taken. Timing of the drug in relation to food is critical.

Adverse Reactions

The adverse effect associated with the meglitinides is hypoglycemia. Patients should be taught how to prevent, recognize, and treat hypoglycemia, as discussed earlier in the Patient Teaching sections on insulin and oral hypoglycemics.

Table 21–22 ⚕ Dosage Schedule: Meglitinides

Drug	Initial Dose	Dosage Form	Maximum Dose	Maintenance Dose
Nateglinide (Starlix)	60–120 mg taken 20–30 min before each meal	60 mg 120 mg tablets	720 mg/day	Same as initial dose.
Repaglinide (Prandin)	0.5–2 mg taken 30 min or less before each meal If A1c less than 8%, dose is 0.5 mg If A1c is 8% or more, dose is 1–2 mg	0.5, 1, and 2 mg tablets	16 mg/d	
Repaglinide and Metformin (Prandimet)	**On metformin alone:** 1 mg repaglinide/500 metformin twice daily with meals **On repaglinide:** Start with 500 mg metformin dose and titrate as GI side effects are tolerated.	1 mg/500 mg and 2 mg/500 mg tablets		Double preprandial dose up to 4 mg. Dose increases at 1 wk intervals. 10 mg repaglinide/2,500 metformin 2–3 times daily before meals. No more than 4 mg repaglinide/1,000 metformin per meal.

DIPEPTIDYL PEPTIDASE-4 INHIBITORS

The dipeptidyl peptidasase-4 inhibitors (DPP-4) are also known as gliptins. There are currently four approved for use in the United States: sitagliptin, saxagliptin, linagliptin, and alogliptin. Vildagliptin is not yet approved in the United States but is being used in other countries. All except linagliptin require considerations for renal dysfunction.

Newer insights into the pathogenesis of type 2 diabetes have created a bigger role for the incretin hormones. The action of gliptins is different from that of other antihyperglycemic agents because gliptins act on the incretin hormone system to have an indirect effect on increasing insulin production. Although the improvement in glycemic control is moderate and no more than with metformin, gliptins are well tolerated, have a low risk for hypoglycemia, are weight neutral, and can be given orally. These effects contrast with the common adverse effects of existing antidiabetic agents. Although they have been approved for monotherapy, gliptins are best used as add-on therapy in combination with metformin as second-line therapy. Long-term impact on CV and DM outcomes is yet to be determined.

Pharmacodynamics

Glucagon-like peptide (GLP-1) is an incretin hormone derived from the gut that stimulates glucose-dependent insulin secretion, enhances insulin gene transcription and insulin biosynthesis, enhances cellular transformation from pancreatic ductal tissues to beta cell tissue, increases beta cell mass by cellular neogenesis and proliferation, inhibits beta cell apoptosis, suppresses glucagon secretion, inhibits gastric emptying, and reduces appetite and food intake (Drucker & Nauck, 2006; Pande, 2009). The actions of this peptide address several defects found in type 2 diabetes. DM GLP-1 receptors have been found in the stomach, intestine, central nervous system, kidney, heart, and lungs (Pande, 2009) and are significantly reduced in type 2 diabetes. DPP-4 is a naturally occurring enzyme that inactivates GLP-1. The DPP-4 inhibitor drug class does not directly change this reduction in GLP-1 production but extends the action of any GLP-1 still present in the system by interfering with its rate of breakdown. This effect is akin to doubling the endogenous GLP-1 available in the system.

The DPP-4 inhibitors have demonstrated efficacy in reducing pre- and postprandial glucose levels, reducing A1C levels and promoting weight loss. Although gliptins enhance the activity of any residual GLP-1, they also reduce postprandial glucose concentration by stimulating insulin secretion and suppressing glucagon secretion but have no direct effect on insulin action to increase glucose utilization and so do not address cellular insulin resistance Though not as strong in their therapeutic impact on BG and Hb A1c reduction as the GLP-1 agonist group, the fact they are oral drugs is a strong factor for patients who do not wish to use injectable medications.

Pharmacokinetics

Absorption and Distribution

After oral administration, these drugs are rapidly absorbed from the GI tract. They can be taken with or without food. The volume of distribution of sitagliptin is approximately 198 L. Older adults have a greater volume of distribution of saxagliptin than do younger patients.

Metabolism and Excretion

DPP 4s are metabolized primarily in the small intestine and they are excreted through the urine unchanged. Decreased renal function results in reduced renal clearance, and doses should be adjusted accordingly. Table 21-11 shows the pharmacokinetics of these drugs.

Pharmacotherapeutics

Precautions and Contraindications

Because of their high dependence on the renal system for elimination, these drugs should be used cautiously with those with impaired renal function. A risk for toxicity exists for patients with end-stage renal disease and for those with moderate to severe renal impairment. Dosage adjustments for renal impairment are needed but less so for linagliptin. Older adults are more likely to have renal impairment; therefore kidney function should be considered for initial dosing and periodically monitored when these drugs are used in this population. Given that, for patients without severe renal impairment, the typical progression of microalbuinuria to proteinuria in DM appears to reverse after 2 years of saxagliptin use (Udell et al, 2014). This is probably a class effect. No other DM medication has demonstrated this outcome. The same secondary analysis of the SAVOR-TIMI 53 study also indicated saxagliptin did not increase CV risk in renal patients.

Gliptins are Pregnancy Category B; however, no well-controlled trials have been performed in humans related to pregnancy. These are relatively new drugs without long-term exposure to the pregnant population with diabetes. It is unknown if gliptins pass into breast milk and infant risk has not been determined. Caution should be used when these drugs are given to nursing mothers.

The safety and efficacy in children (under 18 years of age) have not been established. These drugs are not used in type 1 diabetes.

Adverse Drug Reactions

DPP-4 medications are typically well tolerated; much better tolerated than the GLP-1 class of medications. The most common adverse effects are edema (4%), headache (7%), and urinary tract infections (7%). Hypoglycemia can occur when used in combination with insulin secretagogues (15%) (Access Pharmacy, 2013). Cases of acute pancreatitis have been reported with the DPP-4 inhibitors. Use caution if the patient has a history of pancreatitis or is at greater risk. Reports of pancreatic metaplasia are being investigated because longitudinal

animal models are reporting pancreatic cellular changes even at exposures only double that for humans. Monitoring for pancreatic impact is part of the required post-marking studies currently underway. Saxagliptim has been linked to an increase in bone fractures, but there is no firm evidence that this is a drug or class effect.

Drug Interactions

Coadministration of gliptins with ACE inhibitors has been associated with increased risk of angioedema. Digoxin has an increase in concentration when coadministered with sitagliptin. Gliptins have limited hepatic metabolism with CYP 3A4 and CYP 2C8. Until there is more long-term experience with these drugs, other drugs that use these same isoenzyme systems should be monitored for potential interactions. Table 21-23 shows the drug interactions with these drugs.

Clinical Use and Dosing

Gliptins are indicated as monotherapy and in combination with or added to other antihyperglycemic drugs for the treatment of patients with type 2 diabetes who cannot achieve adequate BG control with diet, exercise, weight control, metformin, and other drugs. They are especially useful for obese

patients because they are not associated with weight gain. The current guidelines typically use these drugs as adjunctive therapy. They are preferred over GLP-1 medications in those who are injection averse.

Monotherapy

All of the gliptins have been approved for monotherapy. Sitagliptin is administered in a once-daily dose of 100 mg. Saxagliptin is administered once daily with dose ranges between 2.5 and 5 mg. Linagliptin dosage is 5 mg once daily. Dosages for both sitaglipitn and saxagliptin are reduced for decreased creatinine clearance (Access Pharmacy, 2013), but reductions are not necessary for linagliptin (Table 21-24).

Combination Therapy

All of the gliptins have been approved for use in combination with other antihyperglycemic agents. The current treatment algorithm recommends using DPP-4s in two-drug combinations with metformin or three-drug combinations with sulfonylureas, TZDs, or insulin. Saxagliptin, alogliptin, and sitagliptin come in combination formulations with metformin.

TZD combinations are associated with more adverse effects, such as weight gain and potential increased cardiovascular risk. The newest gliptin, alogliptin, comes in a combination formulation with pigliozone (Osani), which was

Table 21–23 ⚎ Drug Interactions With Dipeptidyl Peptidase-4 Inhibitors (Gliptins)

Drug	Interacting Drug	Possible Outcomes	Implications
Sitagliptin	Digoxin	AUC of digoxin increased 11%	Monitor patients receiving digoxin
Alogliptin/pioglitazone	Strong CYP2C8 inhibitors (i.e., Gemfibrozil)	Significantly increases AUC and half-life of pioglitazone	Maximum recommended dose of pioglitazone is 15 mg daily if used in combination with gemfibrozil or other strong CYP2C8 inhibitors
Linagliptin	Inducers of CYP3A4 or P-gp (e.g., rifampin)	Decreases linagliptin concentrations	For patients requiring use of such drugs, an alternative is strongly recommended
Saxtagliptin	CYP3A4/5 inhibitors Diltiazem Ketoconazole	Increases saxtagliptin peak concentration by 63%; AUC increases by 2-fold	Monitor

Table 21–24 ⚭ Dosage Schedule for Dipeptidyl Peptidase-4 Inhibitors (Gliptins)

Drug	Initial Dose	Dosage Form	Maintenance Dose	Maximum Dose
Sitagliptin	100 mg once daily	Tablets: 25, 50, 100 mg	100 mg once daily	200 mg total daily dose
Sitagliptin/ metformin (Janumet) (B) (Janumet XR)	**Inadequately controlled on metformin alone:** 100 mg/day sitagliptin plus current dose of metformin **Inadequately controlled on sitagliptin alone:** 1,000 mg/day metformin PO plus 100 mg/day PO sitagliptin	Tablets: 500 mg/50 mg 1,000 mg/50 mg Tablets, extended-release: 500 mg/50 mg 1,000 mg/50 mg 1,000 mg/100 mg		Not to exceed 2,000 mg metformin and 100 mg sitagliptin

Continued

Table 21–24 ⚷ **Dosage Schedule for Dipeptidyl Peptidase-4 Inhibitors (Gliptins)—cont'd**

Drug	Initial Dose	Dosage Form	Maintenance Dose	Maximum Dose
Alogliptin (G) Nesina (B)	25 mg daily **Renal impairment:** Moderate (CrCl ≥30 to <60 mL/min): 12.5 mg daily Severe (CrCl ≥15 to <30 mL/min) or ESRD (CrCl <15 mL/min) or requiring hemodialysis: 6.25 mg daily	12.5, 25, or 6.25 mg tablets		25 mg daily
Alogliptin/ pioglitazone (Oseni) (B)	**Adjunct to diet/exercise, metformin monotherapy:** 25/15 or 25/30 mg once daily **Already on pioglitazone:** 25 mg/ 15 mg, 25 mg/30 mg, or 25 mg/ 45 mg once daily **CHF:** 25/15 mg once daily	Tablets: 12.5 mg/15 mg 12.5 mg/30 mg 12.5 mg/45 mg 25 mg/15 mg 25 mg/30 mg 25 mg/45 mg		25/45 mg once daily based on response
Alogliptin/ metformin (Kazano) (B)	Starting dose based on current regimen. Take twice daily with food and gradually titrate to decrease GI side effects.	Tablets: 12.5/500 mg, 12.5/1,000 mg		25/2,000 mg daily
Linagliptin (G) Tradjenta (B)	5 mg daily; lower dose of insulin or secretagogues may be needed when used in combination	5 mg tablets	5 mg daily	5 mg daily
Linagliptin/ metformin Jentadueto (B)	**Not currently taking metformin:** 2.5 mg/500 mg twice daily **Already taking metformin:** Base dose on current metformin dose twice daily	Tablets: 2.5/500 mg, 2.5/850 mg 2.5/1,000 mg		2.5/1,000 mg twice daily
Saxaglitpin (G) Onglyza (B)	2.5–5 mg once daily **CrCl <50 mL/min:** 2.5 mg daily	2.5, 5 mg tablets	2.5–5 mg once daily	5 mg once daily

shown in four clinical trials involving more than 1,500 patients to produce additional A1C reductions of 0.4 to 0.6 percentage points over pioglitazone monotherapy and 0.4 to 0.9 percentage points over alogliptin alone. Because of the increased risk of heart failure, it has a Black-Box Warning. The FDA is also requiring pharmacovigilance related to liver abnormalities, pancreatitis, and allergic reactions (FDA, 2013). If a gliptin is used in combination with a sulfonylurea or insulin, the dose of insulin or secretagogue should be lowered to reduce the risk of hypoglycemia. The use of basal insulin affects fasting BG; the incretin agents improve both fasting sugars and postprandial readings.

Adding a DPP-4 to insulin therapy typically requires adjustment of the insulin dose. If possible, start the DPP-4 agent and then add the insulin once glycemic impact is known. The addition of a DPP-4 can stunt the additional body weight associated with insulin.

Rational Drug Selection

Age

Gliptins have been studied in the elderly population. Despite the concerns raised above about renal function, gliptins are effective and well-tolerated treatment options in elderly patients with type 2 diabetes. They demonstrate improvement in glycemic control similar to that of metformin, for example, with similar improvements in glycemic control and better GI tolerability (Schweizer, Dejager, & Bosi, 2009). Dosage adjustments may be made as needed for renal function.

Weight/Obesity

In two separate studies comparing a gliptin with a TZD, body weight decreased for the patients on the gliptin and increased for patients on the TZD alone (Blonde et al, 2009; Bolli, Dotta, Colin, Minic, & Goodman, 2009). Both gliptins and metformin are weight neutral, but have also been associated with weight loss! These drugs are appropriate for overweight patients with diabetes.

Cost

As is usually true for new classes of drugs that have required significant research and development costs, the gliptins are expensive. To date, there is not much variability among the drugs in terms of cost. Because they are expensive, insurance coverage might be an economic barricade. A whole-picture evaluation of treatment costs over time demonstrates that early and aggressive interventions reduce onset and intensity of complications. Reduction of such events is actually cost-effective; therefore, the argument against use of incretin therapy due to cost is starting to change.

Monitoring

Before initiating therapy and at least annually thereafter, assess renal function. Assessment is by serum creatinine and CCr initially and then by serum creatinine annually. Dosage adjustments are required based on creatinine clearance. For patients with increased risk of developing altered renal function, the assessment should be made more often.

Response to gliptin therapy is assessed by daily to weekly monitoring of FPG and postprandial BG and by monitoring Hb A1c every 3 months or monitoring fructosamine every 2 months. During initial therapy and with each incremental increase, FPG is used to evaluate response. After the patient is stabilized on a specific dose, monitoring with FPG and Hb A1c levels every 6 months is sufficient.

Patient Education

Administration

All gliptins are taken once daily in the morning. If the dose is missed, it should be taken as soon as remembered. If the dose is missed for the entire day, it should not be doubled the next day. It would be prudent to SMBG in the case of missed doses.

Adverse Reactions

Gliptins are generally well tolerated and adverse reactions occur in only a small percentage of those taking the drugs. Hypoglycemia is not anticipated with monotherapy but may occur when these drugs are combined with another glucose-lowering agent. The usual treatment for hypoglycemia is recommended. In clinical trials of alogliptin, pancreatitis (2%) and hypersensitivity (6%) were reported.

SELECTIVE SODIUM GLUCOSE CO-TRANSPORTER 2 (SGLT-2) INHIBITORS

Canagliflozin (Invokana), dapglifoxin (Farxiga), and empagliflozin (Jardiance) are novel inhibitors of renal SGLT-2, block the reabsorption of glucose in the kidneys, and promote excretion of excess glucose in the urine. Canagliflozin, the first drug in this class, was approved by the FDA in 2013, with requirements to continue five post-marketing studies, which include a cardiovascular outcomes study, and a pediatric safety and efficacy study which includes inquiry into any impact on renal and bone maturation. The other drugs in the class have the same requirements. These drugs are approved for use as monotherapy or in combination with other anti-hyperglycemic agents for adults with type 2 diabetes. They are not recommended for treatment of type 1 diabetes or DKA (FDA, 2013).

Pharmacodynamics

Inhibition of SGLT-2 lowers reabsorption of plasma glucose concentration in the kidneys, which results in increased urinary glucose excretion and reduction of plasma glucose in type 2 diabetes (Medscape Reference, 2013). SGLT-2 works in the proximal tubule to absorb about 90% of the glucose in the ultrafiltrate. This is comparable to around 200 to 250 calories a day. If blood glucose is high, then more is excreted in the urine. There is an osmotic fluid loss which can lead to intravascular volume depletion.

In a 52 week, phase III trial of patients with type 2 diabetes who were not controlled with metformin and sulfonylurea, adding canagliflozin improved glycemic control better than adding sitagliptin. Mean Hb A1c levels dropped by 1.03% with canagliflozin versus 0.66% with sitagliptin. Canagliflozin also resulted in weight loss and reductions in FPG and BP (Schernthaner et al, 2013). Similar outcomes were demonstrated with studies for efficacy of empagliflozin and dapagliflozin across gender, age, duration of disease, and baseline BMI average. Empaglifozin also inhibits other SGLT receptors; the impact on outcomes and comparison to other drugs in the class is unknown. This new class of drugs adds another option for therapy in type 2 diabetes for selected patients, although there are significant side effects for selected populations.

Pharmacokinetics

Absorption and Distribution

Canagliflozin binds 99% primarily to albumin and has a peak plasma time of 1 to 2 hours. Dapagliflozin is 91% protein bound and empaglifozin is 86.2% bound. Both peak within 1.5–2 hours. Empagliflozin has some decrease in circulation after a fatty meal, but this is considered not clinically significant.

Metabolism and Excretion

The major metabolic elimination pathway is O-glucuronidation for these drugs. The half-life of canagliflozin for the 100 mg dose is 10.6 hours and for a 300 mg dose it is 13.1 hours. Excretion is through feces as cangliflozin (41.5%), and 33% is excreted in urine, mainly as O-glucuronide metabolites. Dapagliflozin is similarly processed with 75% renally excreted and 21% in the feces. The half-life is 12.9 hours. Empagliflozin has a half-life of 10 to 19 hours. It is excreted 41% in the urine and 55% in the feces. None of the medications require dose adjustment with mild to moderate hepatic disease. (Child-Pugh class A or B). The drug class has not been studied extensively with advanced liver issues (Child-Pugh class C). Empagliflozin has data on Child-Pugh class C which demonstrates an increasing retention of medication in the system. Appropriate precautions extend to the whole drug class. See Table 21-11 for drug class pharmacokinetic information.

Pharmacotherapeutics

Precautions and Contraindications

SGLT-2 inhibitors are contraindicated in patients with severe renal impairment (eGFR less than 30 mL/min/1.73 m^2), end-stage renal disease, or who are on dialysis. Modification of the dose is suggested when eGFR less than 45mL/min/1.73.

Severe hypersensitivity reactions were reported in clinical trials, specifically in the form of generalized urticaria. These drugs are contraindicated in the treatment of DKA or type 1 diabetes.

SGLT-2 inhibitors can cause intravascular volume depletion and symptomatic hypotension. Urine volume increases about 300 mL on day one, but stabilizes to around 135 mL extra per day after day five. There is no change in electrolyte balance in normally functioning kidneys. Precaution should be used when the eGFR is less than 60 mL/min/1.73 m², in older adults, in those who have low systolic BP, or in those who are on diuretics or drugs that interfere with the renin-angiotensin-aldosterone system (RAS) such as ACE inhibitors and ARBs. Volume status should be assessed and monitored prior to and during treatment with these drugs, particularly if patients have one or more of these issues (Janssen Pharmaceuticals, 2013). This drug class increases serum creatinine and decreases eGFR in longer-term DM. Patients with hypovolemia are more susceptible to renal function impairment. Their renal function should be monitored frequently. Hyperkalemia can also occur in patients with moderate renal impairment who take potassium-sparing diuretics or drugs that alter RAS are more prone to hyperkalemia. Potassium should be monitored frequently after initiating treatment (Janssen Pharmaceuticals, 2013). If renal issues do not exist, there is no suggested decrease in dosing for elders, though the risk of falls related to hypovolemia should be considered.

Interestingly, the impact of SGLT-2 medications in early diagnosis DM patients may actually induce a form of renal protection (Cherney, et al, 2014). They cause a decrease in urine protein loss, and appear to reduce the damaging hyperfiltration associated with the disease. The "renal protective" effects of the ACE and ARB class actually drops over time; about 20% of patients still progress to renal disease due to hyperfiltration damage. The SGLT2 drugs do not increase potassium like the RAS active medications. More research is needed to determine if this drug class has a true renal protective role.

There is an increased risk of hypoglycemia when SGLT-2 medications are used with insulin and secretagogues; insulin or secretagogue doses should be lowered to avoid hypoglycemia (Medscape Reference, 2013). There is no impact on natural insulin secretion. The reduction of serum glucose by renal reabsorption blockade may trigger a need to adjust other medications.

SGLT-2 medications are Pregnancy Category C. Rat studies showed these medications may affect renal development and maturation in utero. Appropriate alternative therapies should be considered for pregnant women, especially during the second and third trimesters. These medications should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. It is unknown whether the drug can be excreted through human breast milk; therefore, breastfeeding women should not take them.

Adverse Drug Reactions

Genital fungal infections, urinary tract infections, and increased urination are the most commonly reported drug reactions. This is most likely linked to the 50 to 60 g of glucose now found in the urine. The most frequently reported side effect (greater than 10%) is female genital mycotic infections or male genital mycotic infections (4%). A dose-related increase in LDL-C can also occur. Volume depletion has been reported in adults older than 75 years (4.9% to 8.7%), eGFR less than 60/mL/min/1.73 m³ (4.7% to 8.1%), and in individuals using loop diuretics (3.2% to 8.8%) (MedScape Reference, 2013).

There are reports of bladder cancer, but too few cases for the FDA to take action. The provider must balance the small risk of cancer with the demonstrated positive impact on Hb A1c. Do not prescribe if there is a history of bladder cancer or high risk for cancer as there are other effective therapeutic choices available.

There is an increase in LDL cholesterol (2.5%) and a tendency toward intravascular volume contraction related to the osmotic diuretic impact of glucose in the urine; therefore, in patients with higher CV or DVT risk may not be the best choice of medication. There have been no studies on macrovascular risk changes in this class of drugs.

Drug Interactions

Canagliflozin should not be taken with pimizide. When digoxin was given with 300 mg of canagliflozin, there was an increase in the area AUC and C_{max} of digoxin. Monitor patients who are taking digoxin and canagliflozin concomitantly. Concurrent use with canagliflozin can increase the effect of ACE and ARB medications, aliskiren, aripiprazole, dofetilide, duloxetine, eplerenone, hypoglycemic agents, lomitapide, and potassium-sparing diuretics. The impact of canagliflozin may be reduced by systemic and inhaled steroids, danazol, fosphenytoin, loop and thiazide diurectics, luteinizing hormone releasing analogs, phenobarbital, phenytoin, rifampin, ritonavir, and somatropin. It may build up to toxic levels when given with androgens, barbiturates, low-molecular weight heparin, MAO inhibitors, hypoglycemic agents, hypotensive agents of lopitapide, pimozide, and potassium-sparing diuretics. Dapagliflozin is decreased in effectiveness when mixed with both systemic and inhaled steroids, danazol, loop and thiazide diuretics somatropin, and luteinizing hormone–releasing analogs. It may build up to toxic levels when given with androgens, barbiturates, MAO inhibitors, pegvisomant, salicylates, and SSRIs. Dapagliflozin can increase the effect of duloxetine, hypotensive agents, and hypoglycemic agents. Empagliflozin package inserts put an emphasis on interactions with diuretics and hypoglycemic agents (see Table 21-25 for interactions).

Canagliflozin AUC was decreased by 51% when coadministered with rifampin, a nonselective inducer of several UGT enzymes. If coadministering canagliflozin with UGT enzyme inducers (e.g., rifampin, phenytoin, phenobarbital, ritonavir), consider increasing the dose to 300 mg/d in patients tolerating 100 mg/d, who have eGFR greater than or equal to 60 mL/

Table 21–25 ⠿ Drug Interactions With SGLT-2 Drugs

Drug	Interacting Drug	Possible Outcomes	Implications
Canagliflozin Dapapagliflozin and empagliflozin	UGT enzyme inducers (Rifampin, phenytoin, phenobarbitol, ritonavir)	Decreased AUC Decreased efficacy	If UGT enzyme inducers and canagliflozin must be coadministered, consider increasing the dose if patients are currently tolerating and have an eGFR greater than 60 mL/min/1.73 m^2. Consider other antihyperglycemic therapy in patients with an eGFR of 45 to less than 60 mL/min/1.73 m^2 receiving concurrent therapy with a UGT inducer.
	Insulin and insulin secretogogues and any other other medication that causes hypoglycemia	Hypoglycemia increased when coadministered with SGLT-2 meds	Decrease dose of insulin or insulin secretogogue or the other medications, but maintain SGLT-2 unless at the higher dose.
	Antihypertensives	Intensified lowering of BP	Check specific interactions of larger impact: cangliflozin and ACE/ARB, aliskiren, lomitapide, and potassium-sparing diuretics, eplerenone.
Cangagliflozin and dapagliflozin	Systemic and inhaled steroids, danazol, loop and thiazide diuretics, leutinizing hormone-releasing analogues, somatropin	Effect of SGLT-2 medication is reduced	Try another medication group or consider increasing dose.
	Androgens, barbiturate, MAO Inhibitors	SGLT-2 medications are increased and may become toxic	Consider different drug classes or reduce dose of SGLT meds.
	Duloxetine	Effect of duloxetine is intensified	Reduce dose of duloxetine
Canagliflozin	Digoxin	Increased AUC 20% and mean peak drug concentration (C_{max}) of digoxin 36% when coadministered with Invokana 300 mg	Patients taking concomitant digoxin should be monitored appropriately
	Aripiprazole, dofetildide, lopitapide	Increase the effect of these meds	Coordinated possible dose reductions in these meds
	Low-molecular weight heparin, lopitapide, pimozide, and potassium-sparing diuretics	SGLT effect is increased	Consider not mixing or decreasing dose of SGLT
Dapagliflozin	Pegvisomat, salicylates, and SSRIs	SGLT effects increased to potential toxic level	Consider not mixing or decrdeasing dose of SGLT.

min/1.73 m^2 and require additional glycemic control. The other drugs are also UGT-mediated and have similar concerns. Decisions to increase any drug dosing should be coordinated with a specialist (Jannsen Pharmaceuticals, 2013).

Clinical Use and Dosing

Type 2 Diabetes

SGLT-2 drugs are indicated as an adjunct to diet and exercise in the treatment of adults with type 2 diabetes. Because the drugs are new on the market, they are just being included in the current standards of care. They can decrease Hb A1c by 1% and contribute to a 2–4 pound weight loss. Initial treatment with canagliflozin is initiated at 100 mg/d before the first

meal is eaten. Timing of food does not appear to clinically impact the dosing of the other SGLT-2 medications. If patients require additional glycemic control and are tolerating the initial doses, they can be increased if eGFR levels are adequate. Volume depletion should be corrected before initiating therapy with any SGLT-2 inhibitor (Table 21-26). Dapagliflozin is started at 5 mg and adjusted up to 10 mg depending on tolerance and efficacy. Empagliflozin starting dose is 10 mg, advancing to 25 mg based on tolerability and efficacy.

Monitoring

As stated previously, select individuals may need monitoring above what is indicated for management of diabetes, including

Table 21–26 ⊗ Dosing Schedule for SGLT2 Drugs

Drug	Initial Dose	Dosage Form	Maintenance Dose	Maximum Dose
Cangaflozin(B)	100 mg once daily taken before the first meal of the day. Dose should be limited to 100 mg once daily in patients who have an eGFR of 45–60 mL/min/1.73 m². Patients with eGFR < 45 mL/min/1.73 m² should not take canagliflozin.	100 and 300 mg tablets		300 mg once daily (eGFR of ≥60 mL/min/1.73 m²)
Dapagiltozin (Farixga) (B)	5 mg without regard to meals	5 and 10 mg tablets	Based on tolerability and efficacy	10 mg daily
Empagliflozin (Jardiance) (B)	Without regard to meals	10 and 25 mg tablets	See above	25 mg daily

renal function and electrolytes plus screening for genital mycotic infections. Urine dip sticks are expected to show positive for glucose, as this is an intended consequence of the medication. There an anticipated increase in hematocrit. Increases in both LDL lipids and serum inorganic phosphorus is possible.

Patient Education

Administration

Canagliflozin (Invokana) should be taken at the same time each day before the first meal; dapaglifloxin and empagliflozin can be taken without regard to meals. If a dose is missed of any drug in the class, it should be taken as soon as it is remembered, but if it is almost time for the next dose, the missed dose should be skipped and taken at the next regularly scheduled time. SMBG should be performed to assess if treatment goals are being met.

Adverse Reactions

Patients should be taught the signs and symptoms of dehydration (dizziness, hypotension, weakness) and genital yeast infections for both men and women (itching, redness/swelling of the genitals, thick white discharge). Most are minor and easily treated, but will recur.

Allergic reactions include rash, hives, and swelling of the face, lips, tongue, and throat that may cause difficulty in breathing or swallowing. The medication should be discontinued if this occurs. Emergency intervention may be required.

Hypoglycemia should be expected if other antihyperglycemics are being taken. The patient should be taught prevention, recognition of the signs and symptoms, and treatment using fast-acting CHO. Adjustment of concurrent medication dosages should be anticipated at the onset of SGLT-2 inhibitor introduction.

AMYLIN AGONISTS

Amylin agonists are a synthetic analogue of the beta cell hormone amylin for use as adjunct therapy in both types 1 and type 2 diabetes to help reduce blood glucose after eating. In type 1 diabetes, pramlintide is used for patients who use mealtime insulin therapy and have failed to achieve their glycemic target despite optimal insulin therapy. In type 2 diabetes, pramlintide is used for patients who use mealtime insulin therapy, with or without a concurrent sulfonylurea or metformin, and still have not achieved their glycemic target. Like the GLP-1 agonists, pramlintide lowers glucose by acting on glucagon secretion, slowing gastric emptying, and suppressing the appetite (Access Pharmacy, 2013). To date, there is only one drug in this class, pramlintide (Symlin). Currently, it is approved for use in the United States only as second-line therapy for those using insulin.

Pharmacodynamics

Amylin is co-located with insulin in secretory granules and co-secreted with insulin by pancreatic beta cells in response to food intake. Both amylin and insulin show similar fasting and postprandial patterns in healthy individuals. Amylin affects the rate of postprandial glucose by slowing gastric emptying; by suppressing glucagon secretion, which leads to decreased endogenous glucose output by the liver; and by centrally mediated modulation of appetite. Patients with type 1 and type 2 diabetes have dysfunctional beta cells, resulting in reduced secretion of both insulin and amylin in response to food.

Pramlintide acts as an amylin mimetic to modulate gastric emptying, prevent postprandial risk in plasma glucagons, and improve satiety, leading to decreased caloric intake and potential weight loss. In clinical studies, Hb A1c has decreased 0.5% to 0.7% and weight loss associated with this drug is about 1 to 1.5 kg over 6 months.

Pharmacokinetics

Absorption and Distribution

Pramlintide is slowly absorbed from injection sites in the abdomen or thigh. Injection into the arm results in higher

exposure to the drug with greater variability compared with injection into the abdomen or thigh. The drug does not bind extensively to plasma cells or albumin, so its pharmacokinetics is relatively insensitive to changes in binding sites.

Metabolism and Excretion

Pramlintide is metabolized primarily by the kidneys, and its primary metabolite (2-37 praline) has a similar half-life and is biologically active. AUC values are relatively constant with repeat dosing, indicating lack of bioaccumulation. Table 21-11 shows the pharmacokinetics of this drug.

Pharmacotherapeutics

Precautions and Contraindications

Confirmed diagnosis of gastroparesis or the required use of drugs to stimulate GI motility is contraindicated in using this drug. It should not be used in patients with a history of nausea (Access Pharmacy, 2013).

Although pramlintide alone does not cause hypoglycemia, it is coadministered with insulin, which increases the risk for hypoglycemia. Pramlintide should not be used in patients who have recurrent episodes of severe hypoglycemia or hypoglycemic unawareness. The insulin dose should be reduced by 50% to avoid hypoglycemia (Access Pharmacy, 2013).

Do not use in patients with poor compliance with insulin regimen and/or blood glucose monitoring or with recurrent episodes of hypoglycemia. A detailed history of glucose control, including Hb A1c, incidence of hypoglycemia, glucose monitoring, medication compliance, and baseline body weight should be obtained before initiating therapy. Use caution in patients with visual or dexterity impairment. Patients should use caution when driving or operating heavy machinery until effects on blood sugar are known (Access Pharmacy, 2013).

Older adults are prone to hypoglycemic unawareness, a reason to use the drug with caution in that population. No consistent age-related differences in drug activity have been shown in clinical studies with older adults, but, given its renal metabolism, it is prudent to use caution or closely monitor older adults on this drug. Studies of patients with moderate or severe renal impairment did not show increased exposure or decreased clearance of the drug, but caution seems prudent given its renal metabolism.

Pramlintide is Pregnancy Category C. No adequate and well-controlled studies have been conducted on pregnant women. Increases in congenital anomalies were observed in fetuses of rats treated with this drug, but no such changes were noted in rabbits. The potential risks to the fetus must be balanced with the needs of the mother for the drug when deciding to prescribe it.

Whether this drug is excreted in human milk is unknown. Administer to nursing women only if it is determined that the potential benefit outweighs the potential risk to the infant.

Adverse Drug Reactions

Pramlintide has a Black-Box Warning about the increased risk for severe hypoglycemia when this drug is used in conjunction with insulin. It should also be used cautiously with certain antihypertensives (beta blockers, etc.) that may mask the signs and symptoms of hypoglycemia.

Most adverse effects are GI disturbances. The incidence of nausea was higher at the beginning of treatment and decreased with time in most patients. The incidence and severity of nausea were reduced by gradual titration to the recommended dose.

Drug Interactions

Drug interactions are based largely on other drugs that increase or decrease the actions of pramlintide. Drugs that alter GI motility and orally administered drugs that depend on gastric emptying time for absorption interact because of pramlintide's slowing of gastric emptying. Anticholinergic effects of drugs may be enhanced by pramlintide. Drugs that affect BG levels and those with an adverse effect of hypoglycemia interact because of pramlintide's BG-lowering effects. Alcohol should be avoided because of the increased risk of hypoglycemia. Herbs such as garlic, chromium, and gymnema also increase the hypoglycemic effects. Table 21-27 shows these interactions.

Table 21–27 ▦ **Drug Interactions With GLP-1 and Amylin Agonists**

Drug	Interacting Drug	Possible Outcomes	Implications
Exenatide and liraglutide	Acetaminophen	Acetaminophen AUC and C_{max} decreased and T_{max} increased when coadministered	Give acetaminophen at least 1 h before or 4 h after exenatide
Exenatide and liraglutide	Digoxin	Coadministration of repeated doses of exenatide decreased digoxin C_{max} 17% and delayed T_{max} by about 2.5 h	Avoid concurrent use unless both are specifically needed. If so, monitor digoxin level and cardiac rhythm closely.
Exenatide	Lovastatin	Lovastatin AUC decreased by 40% and C_{max} by 28% and T_{max} delayed by 4 h when drugs coadministered	Give lovastatin at least 1 h before or 4 h after exenatide
Exenatide and liraglutide	Oral antibiotics and oral contraceptives	Slowed gastric emptying may reduce extent and rate of oral medications that require rapid GI absorption	Take these drugs at least 1 h before exenatide

Continued

Table 21–27 ▦ **Drug Interactions With GLP-1 and Amylin Agonists—cont'd**

Drug	Interacting Drug	Possible Outcomes	Implications
Exenatide	Warfarin	Exenatide may lead to increased INR and increased bleeding when coadministered with warfarin	Avoid concurrent use unless both are specifically needed. If so, monitor INR closely.
Albiglutide	Simvastatin	Levels of simvastatin 80 mg increased	Unknown clinical impact as 80 mg no longer prescribed.
Pramlintide	Drugs that alter GI motility (e.g., anticholinergics)	Pramlintide may increase the effects of drugs that slow gastric emptying	Patients using these drugs have not been studied. Avoid concurrent use at this time.
Pramlintide	Orally administered drugs (e.g., analgesics, antibiotics, contraceptives)	Pramlintide has potential to delay absorption if coadministered	Administer interacting drug at least 1 h prior to or 2 h after pramlintide injection.
Pramlintide	Acetaminophen	Acetaminophen C_{max} decreased 29% and T_{max} increased 48–72 min when coadministered or given within 2 h of pramlintide injection	Separate dosing by more than 2 h. Give acetaminophen prior to pramlintide.
Pramlintide	Sulfonylureas, ACE inhibitors, fibrates, fluoxetine, pentoxifylline, propoxyphene, salicylates, and sulfonamide antibiotics	Increase the blood glucose lowering effect and susceptibility to hypoglycemia	If must be given, monitor blood glucose levels closely, which may mean frequent blood glucose testing (AC, PC, HS) and teach patient signs and symptoms of hypoglycemia.
Pramlintide	All insulin	Unknown interaction	Do not mix. Must administer each separately.

Clinical Use and Dosing

Pramlintide is used in treating type 1 and type 2 diabetes, and dosage differs depending on the type of diabetes (Table 21-28). When initiating pramlintide, reduce current insulin dose (including rapidly and mixed-acting preparations) by 50% to avoid hypoglycemia. If pramlintide is discontinued for any reason, restart therapy with same initial titration protocol (Access Pharmacy, 2013).

Type 1 Diabetes Dosing

Initiate pramlintide at a dose of 15 mcg and titrate the dosage up in 15 mcg increments as tolerated every 3 days, to a 30 or 60 mcg maintenance dose. Pre- and postprandial blood glucose and bedtime glucose levels are monitored frequently. The dose of the pramlintide is then increased to the next increment when no clinically significant nausea has occurred for at least 3 days. If significant nausea persists at the 46 or 60 mcg dosage, reduce the dose back to 30 mcg. If the 30 mcg dosage is not tolerated, consider discontinuing the drug. After a maintenance dose of pramlintide is achieved, insulin doses may be adjusted to optimize glycemic control.

Type 2 Diabetes Dosing

Initiate pramlintide at 60 mcg immediately before meals. Monitor pre- and postprandial blood glucose and bedtime glucose levels frequently. Then increase the dose of the pramlintide to 120 mcg when no clinically significant nausea has occurred for 3 to 7 days. If significant nausea continues at the 120 mcg dose, decrease the dose to 60 mcg. Adjust the insulin dose to optimize glycemic control once the target dose of pramlintide is achieved and nausea has subsided.

Monitoring

The only monitoring required for this drug is that associated with the management of diabetes.

Patient Education

Administration

Pramlintide is administered by subcutaneous injection in the thigh or abdomen but not in the upper arm because of variability of absorption. It is given immediately before each major meal containing at least 250 kcal or at least 30 g of carbohydrate. Pramlintide cannot be mixed with any form of insulin; it is administered in a separate syringe from insulin. The injection site for pramlintide should be at least 2 inches away from the injection site for the insulin. The solution should be room temperature to avoid injection site reactions (Access Pharmacy, 2013). Inform patients that if a dose is missed, they should wait until the next meal and take the usual dose of pramlintide at that meal.

Table 21–28 � Dosage Schedule GLP-1 and Amylin Agonists

Drug	Initial Dose	Dosage Form	Maintenance Dose	Maximum Dose
Exenatide (Byetta) (B)	5 mcg SC every 12 h, 60 min before a.m. and p.m. meals at least 6 h apart; may increase to 10 mcg every 12 h after 1 mo	250 mcg/mL solution: 1.2 mL (5 mcg) and 2.4 mL (10 mcg) prefilled pens in 60 dose kits	5–10 mcg every 12 h	10 mcg every 12 h
Exenatide Bydureon (B) Extended release	2 mg SC once weekly May administer any time of day with or without meals	Injectable suspension 2 mg/vial; comes in a single-dose tray containing 1 vial of 2 mg exenatide, 1 vial connector, 1 prefilled diluent syringe	2 mg once weekly	2 mg once weekly
Pramlintide (Symlin) (B)	**Type 1:** 15 mcg SC before meals; increase by 15 mcg every 3 d. Reduce SA insulin dose by 50%. **Type 2:** 60 mcg SC before meals; increase to 120 mcg before meals in 3–7 d. Reduce SA insulin by 50%.	Injection solution: 0.6 mg/mL Pen injectors: 15, 30, 45, 60, 120 mcg/dose	Type 1: 30–60 mcg Type 2: 60–120 mcg	Type 1: 60 mcg Type 2: 120 mcg
Liraglutide (Victoza)	**Type 2:** 0.6 mg SC once daily without regard to meals	Prefilled pen that can deliver the 0.6, 1.2, or 1.8 mg doses	Based on glycemic response	1.8 mg daily
Albigutide (Tanzeum)	**Type 2:** 30 mg SC weekly without regard to meals	Pen that needs reconstitution. Wait 15–30 min to ensure all in solution.	Takes 4–5 wk for steady state and decision to advance dose	50 mg weekly;
Dulaglutide (Trulicity)	**Type 2:** 0.75 mg SC weekly	Single use pen that needs refrigeration; room temp no more than 14 d.	Takes 2–4 wk for steady state.	1.5 mg SQ weekly

Pramlintide is available in 5 mL vials and in a multidose prefilled pen for injection. Patients should confirm they are using the correct pen injector to deliver their prescribed dose. A package insert provides instructions for using the pen injector. Needles are not included with the pen and must be purchased separately. If drawing from a multidose vial, patients should be taught to convert to mL, not units, as the confusion could result in a 6-fold overdosage (Fig. 21-4).

Pramlintide Dose in Micrograms	Amount to Draw Up in a U-100 Insulin Syringe
15	2.5
30	5
45	7.5
60	10
120	20

Figure 21–4. Conversion of mcg to units for injecting pramlintide.

Adverse Reactions

Patients on the drug should check BG levels before and after every meal and at bedtime. Because this drug is taken with insulin, patients have an increased risk for severe hypoglycemic reactions. Hypoglycemic reactions should be reported to the provider so that dosage adjustments can be made if needed. Patients should be taught the signs and symptoms of hypoglycemia, prevention, and how to treat using 15 g of fast-acting CHO. In case of severe hypoglycemia and the inability to swallow, the patient should have glucagon available and someone who is knowledgeable in administering it.

GLUCAGON-LIKE PEPTIDE AGONISTS

Another class of drugs that acts on the incretin system is the glucagon-like peptide-1 agonists (GLP-1 or incretin mimetics). Drugs approved for use in this class include exenatide (immediate- and extended-release), liraglutide, dulaglutide, and albiglutide. Glucagon-like peptide-1 is a naturally occurring

peptide produced in the small intestine that potentiates glucose-stimulated insulin secretion,Although the gliptins support endogenous GLP activity indirectly, GLP-1 agonists directly bind to the GLP-1 receptor in the pancreatic beta cell and act as an incretin mimetic. Improvement in glycemic control with a reduction in A1C of 0.5% to 1.7% has been demonstrated when GLP-1 is added to other antihyperglycemic agents. A real positive attribute is that these drugs have a low risk for hypoglycemia , but some patients are hesitant to start them because they are given by injection. That objection is less intense when weekly dosing schedules are allowed with exenatide and albigutide. GLP-1 are recommended in a two-step therapy for patients on metformin, and in a three-drug approach with metformin and a sulfonylurea, or TZD, or insulin (Inzucchi et al, 2012).

Incretin mimetics require a GLP-1 receptor in the gut to act. Part of the newly recognized pathological processes in DM is the loss of receptor numbers. When compared to the DPP-4 inhibitors, this class of drugs promotes satiety and weight loss more. It appears incretin mimetics contribute to reduction of systolic pressures and lower triglycerides. These effects are not as strong in the DPP-4 medications. The extended-release formulations have better fasting BG control than the short-acting ones.

Pharmacodynamics

The role of GLP-1 in the incretin system was discussed in a previous section. Exenatide is a homologue of the human GLP-1 sequence, but it has a longer circulating half-life. It binds avidly with the GLP-1 receptor on the pancreatic beta cell to augment glucose-mediated insulin release. It also enhances other antihyperglycemic actions of the incretins, such as moderating glucagon secretion and lowering glucagon concentrations during periods of hyperglycemia. This latter effect leads to decreased hepatic glucose output and decreased insulin demand. Each of these effects occurs only in the presence of increased glucose and subsides as BG concentrations decrease and approach euglycemia. GLP-1 agonists improve glycemic control by reducing fasting and postprandial glucose concentrations. They also slow gastric emptying and reduce appetite, making them either weight neutral or promoting weight loss, a significant factor in type 2 diabetes. Exenatide is associated with weight loss of 2 to 3 kg over 6 months (Nathan et al, 2009); the extended-release formulation produces up to a 5 kg weight loss over the same period.

Pharmacokinetics

Absorption and Distribution

Exenatide is slowly absorbed following subcutaneous injection, reaching median peak plasma concentrations in 2.1 hours. Liraglutide reaches peak concentration later, at 9 to 12 hours. Absorption is similar for both drugs, whether given in the upper arm, abdomen, or thigh. Steady state of the extended-release formulations of this drug class takes 2 to 4 weeks for dulaglutide and 4 to 5 weeks for the others. They have half-lives of 2 to 3 days for dulaglutide and 4 to 7 days for the other extended-release forms. Increasing doses, therefore, is delayed until full glycemic impact is achieved.

Metabolism and Excretion

The metabolic fate of exenatide is not clear, but it is excreted predominantly by glomerular filtration with subsequent proteolytic degradation. Liraglutide is metabolized to a number of minor metabolites, which are excreted in both urine and feces. Albigutide and dulaglutide are cleared much like natural albumin. Table 21-11 presents pharmacokinetic information on these drugs.

Pharmacotherapeutics

Precautions and Contraindications

Patients with severe GI disease (e.g., ulcerative colitis, Crohn's disease) should not use these drugs because of their effects on gastric emptying. Pancreatitis has been reported in patients treated with these drugs. Patients should report persistent, severe abdominal pain, which may be accompanied by vomiting; these are hallmark symptoms of pancreatitis. C cell thyroid tumors or hyperplasia have been associated with several of the medications when used in animals and humans; it carries a boxed warning. Patients should be assessed appropriately and counseled on this risk as well as those with a family history of medullary thyroid tumor and other endocrine neoplasia (Access Pharmacy, 2013).

GLP-1s are not recommended for use in those with moderate renal impairment or end-stage renal disease. Cases of acute renal failure and exacerbation of chronic renal failure have been reported, possibly due to the GI side effects that may cause dehydration (Access Pharmacy, 2013). Increases in LFTs have been noted on occasion, but appear to be linked to prior gallbladder and/or liver disease.

These drugs are listed as Pregnancy Category C based on studies in pregnant laboratory animals. No studies have been conducted on pregnant women. It is not known if these drugs are excreted in breast milk. The decision whether to discontinue either breastfeeding or the drug should take into account the drug's importance to the mother.

Adverse Drug Reactions

This class of medications has been associated with a relatively high frequency of GI disturbances, with 8% to 45% of treated patients experiencing one or more episodes of nausea, vomiting, or diarrhea (Access Pharmacy, 2013). These adverse reactions tend to subside over time; the extended-release formulations have a more transient nausea profile, and liraglutide has fewer reports of GI distress when compared with twice-daily exenatide. Dulaglutide at the highest doses may have 21% nausea rate. Consult with an endocrinologist if antiemetic use is considered to get over this initial-phase problem. Slower, lower-dose titration may also

be helpful. Because many DM patients have a reduced satiety reflex, the slow down of gastric motility and sensation of fullness maybe reported as nausea.

Reports of pancreatic duct metaplasia are being investigated by the FDA for the entire class. Patients with new nodules or changes in thyroid function tests should be evaluated by an endocrinologist. There is the possibility of site reactions with any injectable medication. They appear to be infrequent and self-limiting.

Drug Interactions

The major interactions for these drugs relate to their action in slowing gastric emptying. Separating the administration of the interacting drug and the incretin mimetic will usually resolve the problem. The International Normalized Ratio (INR) increases and the risk of bleeding also increases when exenatide is coadministered with warfarin; these two drugs should not be used concurrently. Serum concentration of oral contraceptives is decreased by exenatide. Neither of these interactions are documented for albigutide. The effect of simvastatin is reduced when taken with albigutide. Table 21-27 lists the interactions.

Clinical Use and Dosing

This drug class is not typically used in DM type I. None of these drugs has been approved for monotherapy to treat type 2 diabetes but are being used off-label even in prediabetic patients. They typically are adjunctive therapies for patients already taking other drugs. All are administered subcutaneously. Regardless of the other antidiabetic drugs being taken, the initial dose of immediate-release exenatide is 5 mcg subcutaneously twice daily 60 minutes before morning and evening meals (or the two main meals of the day, approximately 6 or more hours apart). Based on clinical response, the dose of exenatide can be increased to 10 mcg twice daily after 1 month of therapy. Liraglutide is started as 0.6 mg/d for 1 week and 1.2 mg daily thereafter. It can be increased to 1.8 mg daily if tolerated. If more than 3 days are missed, return to a previous dose level is indicated to reduce GI distress.

Extended-release exenatide is administered 2 mg once a week. If a dose is missed or a different day dosing schedule is desired, the patient should wait no more than 3 days to administer the next dose. Liraglutide is administered once daily, initiating treatment at 0.6 mg for 1 week, then increasing to 1.2 mg daily. It may be increased to 1.8 mg if the target is not reached on 1.2 mg/d. Albigutide is started at 30 mg and advanced to 50 mg weekly depending on glycemic response. Due to its extended half-life, some patients may be stable on biweekly dosing (see Table 21-26).

Some patients do not respond to GLP-1 medications or have a reduction in effects over time. The hypothesis is that they have genetic antibody responses to the molecules or develop those antibodies over time. Antibody development against one drug may be overcome by switching to another one in the same class.

Combination Therapy

When added to metformin or TZD therapy, the current dose of metformin or TZD can be continued. Dosage adjustment is not required because the risk of hypoglycemia is low. When added to sulfonylurea therapy, a reduction in the sulfonylurea dose should be considered to reduce the risk of hypoglycemia.

Rational Drug Selection

There is no significant difference among the drugs in terms of precautions or contraindications, or serious adverse effects. Albigutide has fewer drug interactions, but extended clinical use may change that profile. Nausea is more significant with exenatide that is given twice a day; it is a much less common complaint with the extended release forms (liraglutide, albigutide, and exenatide weekly). Number of injections per day and cost are compelling factors for drug choice. Timing of glucose control is a factor when comparing short- and long-acting formulations. Short-acting medications are best for making significant reductions in postprandial glucose levels; long-acting medications are better to control FPG levels. The initial selection of formula may be guided by which glucose peak is most critical to control for the individual patient. Reduction of A1C levels is larger with the extended-release drugs; daily dosing regimens result in 0.9% reductions but extended-release drugs typically have a 1.7% reduction. Onset of action is within a few days for the shorter-acting medications; it takes up to 2 weeks for actions to be evident for the long-acting formulas.

Monitoring

Glycemic control is monitored based on diabetic guideline protocols. If the patient must also take warfarin, INR is monitored closely, and if the patient is on digoxin, the levels of this drug and cardiac response to it are monitored closely if on exenatide. Renal function studies are monitored based on diabetic guideline protocols. Thyroid and abdominal assessments for pancreatitis are critical.

Patient Education

Administration

Each dose of these medications should be administered as a subcutaneous injection in the thigh, abdomen, or upper arm. Immediate-release exenatide is given about 60 minutes before morning and evening meals and doses should be at least 6 hours apart. Do not administer after a meal. If a dose is missed, the patient should resume the treatment regimen as prescribed with the next scheduled dose. Liraglutide is a daily medication given via prefilled pen without regard to meal times. The other medications are given weekly as doses without regard to meals.

Exenatide is dispensed for injection in prefilled pens. Pens should be primed before use and a new needle used for each injection. Extended-release exenatide comes in a

vial with a diluent that must be reconstituted and used immediately. The prefilled pens and vials come with a user manual that includes information on setup, storing, and disposing of the pen and needles, and cleaning the outside of the pen. Needles are not included and must be purchased separately. Albigutide comes in a single-dose pen that needs to be reconstituted by a twisting action. Waiting 15 to 30 minutes prior to injection is required to ensure full dissolving of the powder. Once reconstituted it must be given within 8 hours. Other pen formulations do not indicate a waiting period.

If using concurrently with insulin, do not mix drugs. Injections should be given separately. Sites should be rotated; the same body region may be used, but sites should not be adjacent to one another (Access Pharmacy, 2013). Dulaglutide has not be studied in combination with insulin.

Adverse Reactions

The most common adverse reactions are GI disturbances that tend to subside with time. Exenatide may reduce appetite, the amount of food eaten, and patient weight. No changes in dose are needed—the reactions are transient and actually have a positive effect on diabetes.

When taking exenatide, patient BG levels should be checked before and after every meal and at bedtime. Hypoglycemia should not occur unless the patient is also taking a sulfonylurea. Hypoglycemic reactions should be reported to the provider so that dosage may be adjusted if needed.

GLUCAGON

Glucagon is a hormone secreted by the pancreas. It has several actions, but its primary use clinically is in elevating BG levels during hypoglycemic episodes or for treating insulin overdose. It is also used to reverse the hypoglycemia induced by insulin shock therapy in psychiatric patients and to relax the GI musculature to facilitate radiographic examinations and scoping procedures. The increase in BG in patients who have been NPO for hours prior to a scheduled GI procedure can also be considered beneficial.

Pharmacodynamics

Glucagon is a polypeptide hormone produced by the alpha cells of the islets of Langerhans in the pancreas. It accelerates liver glucogenolysis by stimulating cAMP synthesis and increasing phosphorylase kinase activity. This results in increased breakdown of glycogen to glucose and inhibition of glycogen synthesis. The end result is an elevation in BG levels. Glucagon also stimulates hepatic gluconeogenesis by promoting the uptake of amino acids and converting them to glucose precursors. When administered parenterally, glucagon also produces relaxation of the smooth muscle of the GI tract, decreases gastric and pancreatic secretions, and increases myocardial contractility. These latter actions are not the primary reason for its clinical use.

Pharmacokinetics

Absorption and Distribution

Glucagon is well absorbed after parenteral administration. Its distribution is unknown.

Metabolism and Excretion

Glucagon is extensively metabolized by the liver and kidney and degraded in the plasma. Plasma half-life is about 8 to 18 minutes.

Pharmacotherapeutics

Precautions and Contraindications

The only contraindication to glucagon is hypersensitivity to it. It should be given with caution to patients with insulinoma or pheochromocytoma. It may produce an initial increase in BG in these patients, but because of its insulin-releasing effect, it may subsequently cause hypoglycemia. It also stimulates catecholamine release, causing a marked increase in blood pressure in patients with pheochromocytoma. It has positive inotropic and chronotropic effects in all patients.

Glucagon is Pregnancy Category B, but there are no adequate and well-controlled studies in pregnant women. It should be used in pregnancy only if clearly indicated. Because insulin is the drug of choice in managing gestational diabetes and other diabetic patients during their pregnancy, the potential for a hypoglycemic reaction exists. The rapid resolution of any moderate to severe hypoglycemia is clearly in the best interests of the fetus and would override any concerns about potential risk from exposure to glucagon. It is not known whether this drug is excreted in breast milk. Caution should be used in giving it to a nursing mother.

Adverse Drug Reactions

The most frequent adverse reactions to glucagon are nausea and vomiting. These may occur because of a possible reactive hypoglycemia after the initial BG rise. Rare allergic reactions resulting in urticaria, respiratory distress, and hypotension have been reported, possibly related to the phenol and glycerin in some products.

Drug Interactions

The anticoagulant effects of oral anticoagulants may be increased, with the possibility of bleeding. This interaction may occur after several days of therapy and appears to be dose-related. This interaction is not associated with single-dose therapy to resolve a hypoglycemic reaction. The hyperglycemic response is prolonged with epinephrine. The response is blunted with phenytoin.

Clinical Use and Dosing

Reversal of hypoglycemia is the main object for glucagon (Table 21-29). Because its actions depend on the presence of glycogen in the liver, glucagon is of little or no help in states of starvation, adrenal insufficiency, or chronic hypoglycemia.

Table 21–29 🔀 **Dosage Schedule: Glucagon**

Drug	Initial Dose	Dosage Form	Maximum Dose
Glucagon	*Children, weight <20 kg:* 0.5 mg SC, IM, or IV *Adult and children, weight >20 mg:* 1 mg SC, IM, or IV *Infants:* 0.3 mg/kg (may repeat Q4 h) *Insulin shock:* 0.5–1 mg SC, IM, or IV. If no response in 10–25 min, repeat dose.	1 mg powder with 1 mL diluent for reconstitution Emergency kit with 1 mg/1 mL prefilled syringe	If response not adequate in 5–15 min, administer 1–2 additional doses; accompany with IV glucose if patient fails to respond.

Supplemental glucose is typically used to help reverse severe hypoglycemia.

Monitoring

Monitoring of BG should be done immediately prior to and after the injection.

Patient Education

Patients with diabetes who are at high risk for hypoglycemia should have this drug on hand to be mixed and injected by a family member if oral glucose supplements are contraindicated with loss of consciousness or swallowing impairment. Education of the family member would include recognition of and testing for hypoglycemia and the procedure for mixing and administering glucagon parenterally.

THYROID AGENTS

Thyroid hormones include both natural and synthetic compounds. The natural hormones are derived from pork thyroid glands. Because their content and bioavailability are not consistent from dose to dose, they have largely been replaced with the synthetic compounds. This section discusses the synthetic thyroid hormones.

Pharmacodynamics

The hypothalamus-pituitary-thyroid hormone axis begins with the secretion of thyrotropin-releasing hormone (TRH) by the hypothalamus in response to cold, stress, and decreased levels of thyroxine (T4). TRH stimulates the synthesis and release of thyroid-stimulating hormone (TSH) by the anterior pituitary. TSH, in turn, stimulates an adenylyl cyclase mechanism in the thyroid cells to (1) immediately increase the release of stored thyroid hormones; (2) increase iodine uptake and utilization; (3) increase the synthesis of the two thyroid hormones, triiodothyronine (T3) and T4; and (4) increase the synthesis and secretion of prostaglandins by the thyroid gland. When thyroid hormones are secreted, they create a negative feedback loop, inhibit TRH and TSH secretion, and decrease further thyroid hormone synthesis and secretion. Figure 21-5 depicts the hypothalamus-pituitary-thyroid hormone axis.

As shown in Figure 21-5, thyroid hormones increase all the metabolic processes of the body and are central to the growth and differentiation of body tissues. The mechanism by which thyroid hormones exert their effect is not well understood, but it is believed that most of their effects are exerted through control of DNA transcription and protein synthesis. Administration of synthetic thyroid hormones—levothyroxine (T4), liothyronine (T3), and liotrix (a 4:1 mixture of T4 and T3)—produces the same effects on body tissues as the body's own thyroid hormones and produces the negative feedback loop to reduce further secretion of TSH and thyroid hormones.

Pharmacokinetics
Absorption and Distribution

Levothyroxine (T4) is variably absorbed, with 48% to 79% of the dose absorbed after oral administration (Table 21-30). Fasting increases its absorption, and malabsorption syndromes cause excessive fecal loss of this drug. Liothyronine (T3) is 95% absorbed within 4 hours after administration. More than 99% of both circulating hormones are bound to serum proteins, including thyroid-binding globulin (TBg), thyroid-binding prealbumin (TBPA), and albumin (TBa). The higher affinity of T4 for TBg and TBPA as compared with T3 partially explains the higher serum levels and longer half-life of T4. T4 and T3 exist in the body in equilibrium between bound and free drug, but only the free drug produces the hormone's effects.

Metabolism and Excretion

Thyroid hormones are distributed to most body tissues. They do not readily cross the placenta, and minimal amounts are excreted in breast milk. Under normal body functioning, the ratio of T4 to T3 released from the thyroid gland is 20:1. Approximately 35% of T4 is converted in peripheral tissues to T3 so that 80% of T3 comes from monodeiodination of T4. This process of deiodination of T4 occurs in the liver, kidney, and other body tissues, especially the skeletal muscles. The conjugated hormones then reenter the hepatic circulation, where they are excreted in the feces via bile.

Pharmacotherapeutics
Precautions and Contraindications

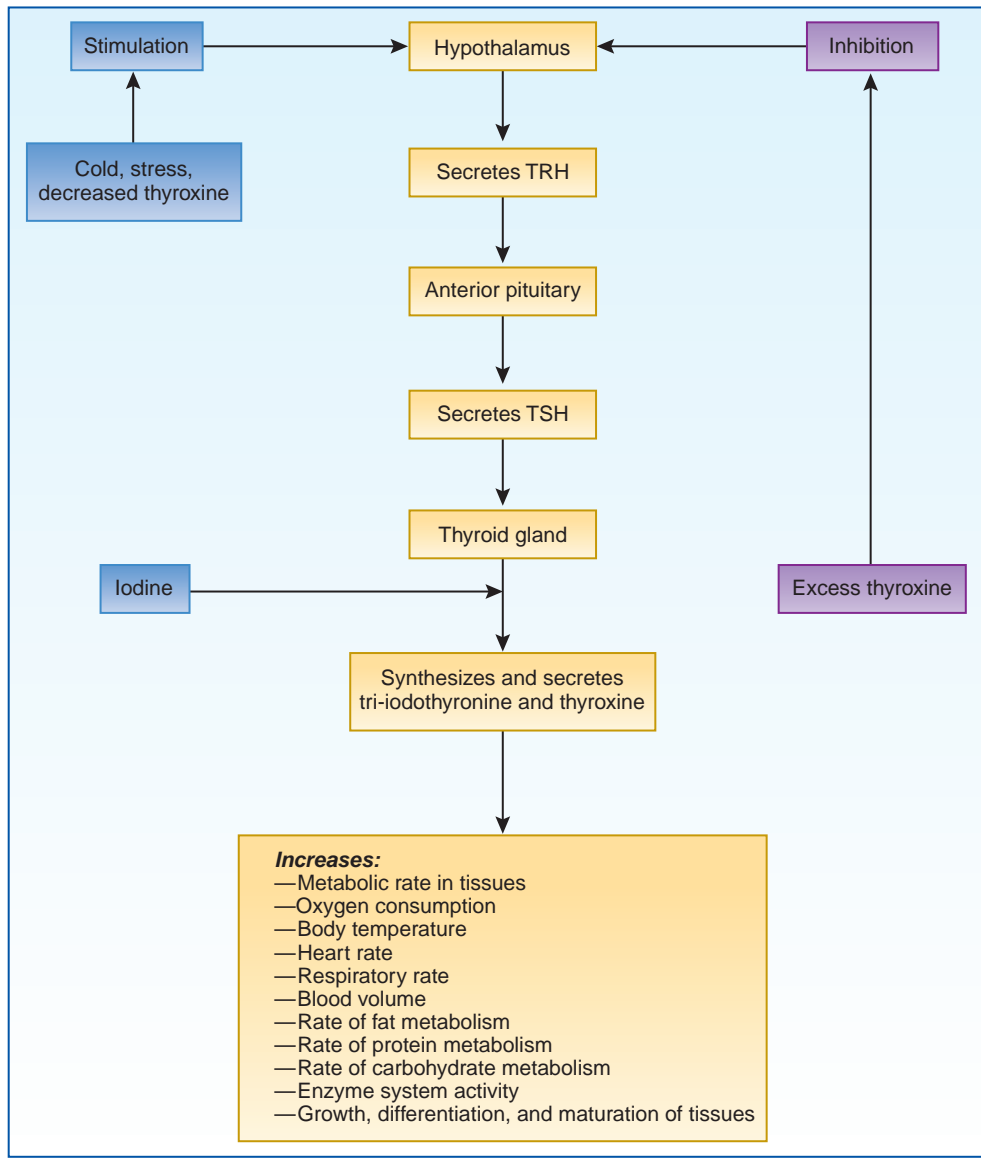
Cardiovascular disease, particularly coronary artery disease, may worsen when thyroid hormones are given; however, considering the increased risk of death from CHF in African Americans with even mild hypothyroid conditions, this should not dissuade cautious use (Rhee,


Figure 21–5. Hypothalamus-pituitary-thyroid hormone axis.

Table 21–30 ⊞ Pharmacokinetics: Oral Thyroid Hormones

Drug	Onset*	Peak*	Duration*	Biological Potency	Half-Life	Excretion
Levothyroxine (T4)	48 h	1–3 wk	1–3 wk	1	6–7 d**	In feces via bile
Liothyronine (T3)	48 h	24–72 h	72 h	4	<2.5 d	In feces via bile

*Effects on thyroid function tests.

  **3–4 d in hyperthyroidism; 9–10 d in myxedema.

Curhan, Alexander, Bhan, & Brunelli, 2013). Thyroid hormone replacement is contraindicated after recent MI. When hypothyroidism is a complicating or causative factor in MI or heart disease, judicious use of small doses may be indicated if coordinated with cardiology and endocrinology teams. The increased heart rate associated with thyroid hormone administration increases oxygen demand by the heart muscle and decreases oxygen supply by reducing diastolic filling time. A recent study has not found this CV risk as severe as traditionally considered (Hyland, Arnold, Lee, & Cappola, 2013).

Advance practice prescribers are cautioned not to change practice until major guidelines endorse this stance.

Long-term levothyroxine therapy has been associated with decreased bone density in the hip and spine in both pre- and postmenopausal women. A self-induced subclinical hyperthyroidism via insistence on unnecessary borderline-low TSH levels for "well-being" is linked to this bone loss. Use of only the lowest dose possible to achieve the desired effects, with strict periodic monitoring, is indicated for the osteoporosis patient.

Thyroid hormone therapy for patients with concomitant diabetes insipidus or adrenal insufficiency exacerbates the intensity of their symptoms. Dosage adjustments downward in thyroid hormone may be required. Severe or prolonged hypothyroidism can lead to decreased adrenocortical function. When thyroid replacement therapy is begun, the metabolism increases at a greater rate than adrenocortical activity and can precipitate adrenocortical insufficiency, requiring supplemental adrenocorticosteroids.

Adverse Drug Reactions

Adverse reactions other than those associated with hyperthyroidism due to overdose are rare. If the patient experiences indications of hyperthyroidism (increased heart rate, cardiac arrhythmias, chest pain, tremors, nervousness, insomnia, irritability, diarrhea, vomiting, weight loss, menstrual irregularities, or heat intolerance), the TSH level should be assessed and appropriate dosage adjustments made.

Drug Interactions

Bile-acid sequestrants, iron salts, and antacids decrease the absorption of orally administered thyroid preparations.

Estrogens increase TBg and may therefore decrease the response to thyroid hormone. The SSRI medications can sometimes alter thyroid dosing requirements. Thyroid hormones may decrease the effectiveness of warfarin, digoxin, and beta blockers. Table 21-31 mentions these and other drug interactions.

Many drugs affect thyroid function tests and may interfere with correct assessment of thyroid status. These drugs are discussed in Chapter 41. High-fat meals and those with high fiber may decrease absorption up to 40%. Calcium and iron supplements should be taken 2 to 4 hours apart from the hormone. Coffee and other caffeine-containing drinks are linked to less absorption, as is excess fluoride in drinking water. Some individuals are sensitive to excessive ingestion of goitrogenic foods, such as turnip greens, cabbage, soybeans, and rutabagas (Messina & Redmond, 2006).

Clinical Use and Dosing

Hypothyroidism

Treatment of hypothyroidism follows the "start low and go slow" principle to avoid excessive increase in metabolism

Table 21–31 ⦂⦂⦂ Drug Interactions With Thyroid Hormones

Interacting Drug	Possible Outcomes	Implications
Beta-adrenergic blockers	Actions of beta-adrenergic blocker may be impaired when patient is converted to euthyroid state	Monitor response to beta-adrenergic blockers; assess for continued need for drug or for dosage adjustment
Carbamazepine, hydantoins, phenobarbital, rifamycins	Increased hepatic degradation of T4 Increased levothyroxine requirements	Monitor thyroid function closely
Cholestyramine, colestipol	Interferes with thyroid hormone absorption with loss of efficacy	Administer at least 4 h apart
Digoxin	Serum levels of digoxin reduced when hypothyroid patient is converted to euthyroid state	Monitor response to digoxin and serum levels; assess for need for dosage adjustment
Estrogens	Increases TBg and may decrease response to thyroid hormone	Monitor therapeutic response
Glucocorticoids	Concurrent use may decrease peripheral conversion of T4 to T3	Monitor thyroid function and symptoms of hypothyroidism
Iodides (including amiodarone and iodine-based radiographic contrast agents, IV or oral)	Can trigger hypo- or hyperthyroid state that may persist for several months; IV agents have shorter impact	Monitor thyroid function and symptoms of hypo- or hyperthyroidism
Metformin, meglitinides, sulfonylureas, TZDs, and insulin	Initiating thyroid hormones may cause increases in insulin or oral hypoglycemic requirements	Monitor BG closely
Sertraline (an SSRI)	Increased levothyroxine requirements	Monitor thyroid function closely or select different SRI
Tricyclic and 3-times daily depressants	Concurrent use may increase toxic effects of both drugs. Toxic effects may include increased risk of dysrhythmias and CNS stimulation.	Avoid concurrent use
Warfarin	Increased anticoagulant action	May need to decrease dose of warfarin; monitor PT/INR carefully

INR = international normalized ratio; PT = prothrombin time.

before the body has a chance to adapt to the increase. For adults, levothyroxine is started at 50 mcg daily and is increased in increments of 25 mcg/d at 2- to 4-week intervals to 100 to 150 mcg/d. The target dose is based on TSH levels and is approximately 1.7 mcg/kg/d. Older adults may require less than 1 mcg/kg/d as their target. An initial dose for elders of 25 to 50 mcg/d is recommended, with gradual dosage increases of 12.5 to 25 mcg/d at 6- to 8-week intervals. Lower doses and longer intervals for changing doses are required for patients with cardiovascular impairment or long-standing hypothyroidism. In these cases or in severe hypothyroidism, the initial dose is 12.5 to 25 mcg/d, increased by 25 mcg/d at 4-week intervals. The target dose is also based on TSH levels. Most patients require less than than 200 mcg/d. Failure to respond adequately to doses of 300 mcg/d suggests lack of adherence or malabsorption; however, reduction in sensitivity to thyroid hormone is possible.

Liothyronine (T3) is started at 25 mcg/d. Dosage is increased by 12.5 to 25 mcg/d at 1- to 2-week intervals until a maintenance dose of 25 to 50 mcg is reached.

Liotrix is started with 50 mcg of levothyroxine/12.5 mcg of liothyronine per day. Doses are increased by 50/12.5 mcg at 4-week intervals until a maintenance dose of 50 to 100/12.5 to 25 is reached. For patients with myxedema or hypothyroidism with cardiovascular disease, the doses are reduced. This formulation is claimed to follow a more natural hormone secretion pattern; however, a meta-analysis demonstrated no benefits with combination medications, including improved mental health and quality-of-life measures (Grozinski-Glasberg, Fraser, Nashshoni, Weizman, & Leibovici, 2006). The subset of post–total thyroidectomy patients may be the exception (Garber et al, 2012).

For all of these drugs, dosages are different for infants, children, and geriatric patients. Table 21-32 presents the dosing schedules for all of these age groups.

Hashimoto's Thyroiditis

Approximately 70% or more of patients with Hashimoto's thyroiditis go on to develop permanent hypothyroidism. The treatment regimen is the same as for other causes of

Table 21–32 ✂ Dosage Schedule: Thyroid Hormones

Drug	Indication	Dose Form	Initial Dose	Maintenance Dose
Levothyroxine T4 (G) Synthroid levoxyl	Hypothyroidism and congenital hypothyroidism	Tablets: 25, 50, 75, 88, 100, 112, 125 mcg, 137 (B only), 150, 175 mcg, 200, 300 mcg	*Adults:* 50 mcg daily (0.05 mg)	Increase dose by 25 mcg at 4 to 6 wk intervals to maintenance dose of 100–150 mcg daily
			Older adults: 12.5–25 mcg daily	Increase dose by 25 mcg daily at 6 wk intervals to maintenance dose of 100–150 mcg daily
Triosint (levothyroxine)		Liquid-filled caps 13, 25, 50, 75, 88, 100, 112, 125, 137, 150 mcg	*Children >12 yr:* 2–3 mcg/kg daily	Increase in increments of 2 mcg/kg/d at 4 to 6 wk intervals to maintenance dose of 150–200 mcg daily
			Children 6–12 yr: 4–5 mcg/kg daily	Increase in increments of 4 mcg/kg/d at 4 to 6 wk intervals to maintenance dose of 100–150 mcg daily
			Children 1–5 yr: 5–6 mcg/kg daily	Increase in increments of 3 mcg/kg/d at 2 to 4 wk intervals to maintenance dose of 75–100 mcg daily
			Children 6–12 mo: 6–8 mcg/kg daily	Increase in increments of 5 mcg/kg/d at 2 to 4 wk intervals to maintenance dose of 50–75 mcg daily
			Infants 3–6 mo: 8–10 mcg/kg daily	Increase in increments of 5 mcg/kg/d at 4 to 6 wk intervals to maintenance dose of 25–50 mcg daily
			Infants 0–3 mo: 10–15 mcg/kg	Dosage may be increased after 4–6 wk to 50 mcg daily
			Infants less than 2,000 g or at risk for cardiac failure: 25 mcg daily	For infants with congenital hypothyroidism, initiate therapy with full dose as soon as diagnosis is made
Liothyronine Synthetic T3 (G) Cytomel	Mild hypothyroidism	Tablets: 5, 25, and 50 mcg	*Adults:* 25 mcg daily	Increase in increments of 12.5–25 mcg daily at 1 to 2 wk intervals to maintenance dose of 25–75 mcg daily

Table 21–32 ⨂ **Dosage Schedule: Thyroid Hormones—cont'd**

Drug	Indication	Dosage Form	Maintenance Dose	Initial Dose
			Older adults or patients with cardiovascular disease: 5 mcg daily	Increase in increments of no more than 5 mcg daily at 2 wk intervals
	Congenital hypothyroidism		5 mcg daily	Increase in increments of 5 mcg every 3–4 d until desired response. Maintenance dose for infants a few months old is 20 mcg daily; for children age 1 yr, dose is 50 mcg daily; above 3 yr, use adult dose
	Simple nontoxic goiter		5 mcg daily	Increase in increments of 5 mcg every 1–2 wk. When dose of 25 mcg daily is reached, increase by 12.5–25 mcg daily every 1–2 wk. Usual maintenance dose is 75 mcg daily
	Myxedema		5 mcg daily	Increase in increments of 5 mcg every 1–2 wk. When dose of 25 mcg daily is reached, increase by 12.5–25 mcg daily every 1–2 wk. Usual maintenance dose is 50–100 mcg daily
Liotrix Levothyroxine & Liothyronine (G) (Thyrolar)	Hypothyroidism	Tablets: 12.5 mcg/ 3.1 mcg; 25 mcg/ 6.25 mcg; 50 mcg/ 12.5 mcg; 100 mcg/ 25 mcg; 150 mcg/ 37.5 mcg. Or the grain formulation: ¼ grain ½ grain 1 grain 2 grain 3 grain	*Adults:* 30 mg equivalent daily	Increase in increments of 15 mg (1/4 grain) every 2–3 wk to maintenance dose of 60–120 mg daily
			Children and infants with congenital hypothyroidism	Follow dosage recommendations for levothyroxine (see available dosage forms table for T4 equivalents for liotrix)

hypothyroidism. Monitoring of thyroid antibodies assumes greater significance with these autoimmune patients.

TSH Suppression in Thyroid Cancer, Nodules, and Euthyroid Goiter

The required maintenance dosage for these indications is larger than that for primary hypothyroidism. The initial dose of levothyroxine is 50 to 100 mcg/d, and the dose is increased until the TSH level declines to 0.05 to 0.3 mU/L. This therapy is relatively contraindicated in older adults and in patients with cardiovascular disease.

Thyroid Suppression Therapy

The dose is 2.5 mcg/kg daily for 7 to 10 days for this indication. These doses usually yield normal serum T4 and T3 levels without a response to TSH.

CLINICAL PEARL

Thyroid Hormone Replacement During Pregnancy
Increasing the dose by 25% usually results in adequate coverage during pregnancy. Recheck TSH levels in 4 weeks to determine any dosage adjustment.

Pregnancy

Untreated hypothyroidism during pregnancy may increase the incidence of maternal complications, spontaneous abortion, fetal death or stillbirth, low birth weight, and abnormal fetal brain development (American Association of Clinical Endocrinologists [AACE], 2012; DeGroot et al, 2012). These outcomes can be avoided by thyroid hormone replacement.

Thyroid hormones are Pregnancy Category A, and replacement is advised for all symptomatic pregnant women. Therapy begun before pregnancy should not be stopped. The increased metabolic rate common to pregnancy often requires higher doses. Increasing a patient's maintenance dose by 25% usually provides adequate coverage but a 45% increase may be required. T4 requirements increase by the eighth week and typically plateau at 16 weeks. TSH levels should then be checked every trimester to determine the need for any further dosage adjustment. AACE, American College of Obstetricians and Gynecologists (ACOG), and The Endocrine Society recommend levothyroxine.

Hormones are excreted in breast milk but have not been associated with adverse effects in nursing infants. Infants must be monitored after birth for issues related to maternal levels. Preliminary data from studies measuring lowered thyroid levels in male infants taking formulas from BPA-containing bottles have not triggered special alerts. Concerned mothers should avoid bottles with a 7 in the recycle number, avoid placing bottles in the microwave, and use powder formula, not those shipped in plastic bottles (Chevier, 2013).

Postpartum thyroiditis (5% to 10% of deliveries and miscarriage, abortion, and ectopics) can result in either hypo- or hyperthyroid states. Current recommendations do not suggest screening before or after deliveries unless patients are symptomatic. Women with symptoms may or may not be treated within the first 8 to 12 weeks postpartum, as hormonal levels typically return to normal. Propanolol may be used for symptom control of tachycardiac symptoms. Elevated TSH is not strongly associated with postpartum depression. Those who have rebalanced levels within a few months are at risk for future thyroid imbalances within the next 5 to 10 years (DeGroot et al, 2012).

Congenital Hypothyroidism

Congenital hypothyroidism occurs in 1 in 3,000 to 4,000 newborns and requires referral to a pediatric endocrinologist. Of all the causes of mental retardation, it is the easiest to screen for and treat. Most impacted infants have no signs or symptoms. Levothyroxine is the drug of choice. Full weight-based doses are started immediately on diagnosis of the condition. Tablets may be crushed and added to infant formula. There is some evidence that soy may impair thyroxine absorption from the gut, so special attention is given to monitoring in infants requiring soy-based formula (National Institute of Environmental Health Sciences, 2010); this precaution does not pertain to adults.

Inappropriate Use of Thyroid Hormones

Obesity

In euthyroid patients, hormone replacement doses are ineffective for weight reduction. Larger doses may produce serious or even life-threatening toxicity, particularly when given with anorexiants. Use of thyroid hormones for this indication is not justified (Pierce, 2012).

Infertility

Thyroid hormone therapy is *not* justified for the treatment of infertility in male or female patients by primary care providers unless the condition is accompanied by hypothyroidism.

Depression

Undiagnosed hypothyroidism can present as a depressive state. These patients can benefit with hormone correction. However, use of thyroid supplementation for chronic depressive states without abnormal TSH is not supported by evidence. Quality of life, perceived energy levels, and complaints of hypothyroid symptoms are not altered with other than standard doses of thyroid medications; therefore, practitioners are cautioned not to up dosages "to feel better" due to the chronic bone and potential CV issues.

> ### 🔵 CLINICAL PEARL 🔵
>
> **Levothyroxine** tablets can be crushed and suspended in a small amount of formula or water for infants who cannot swallow whole tablets. For children who cannot swallow the intact tablet, it may be crushed and sprinkled over a small amount of food such as cooked cereal or applesauce. The suspension cannot be stored for any period of time. The tablet should be crushed, mixed to form a suspension, and given immediately.

Lithium preparations are antithyroid and can cause goiter. Patients can develop overt hypothyroidism. The goiter size will eventually return TSH levels toward normal. Treated patients should be monitored using T4 levels.

Rational Drug Selection

Pharmacokinetics

Levothyroxine (T4) is the drug of choice for thyroid replacement and suppression therapy because of its longer half-life. This means that it can safely be withheld for up to 2 weeks, if necessary, without altering the patient's thyroid status. Because T4 is converted to T3 in the body, use of this drug produces both hormones. Both levothyroxine and liothyronine (T3) have content stability. Liothyronine is 3 to 4 times more active than levothyroxine, and this greater potency increases the risk for cardiotoxicity. Levothyroxine should be used with patients who have cardiovascular disease. There are no randomized controlled studies comparing T4 with "natural" thyroid extracts (Cappola, 2012).

Cost

Generic forms of levothyroxine and the brands Levoxyl and Levothroid typically have similar low costs. Cost varies between Synthroid and the other brands and the generic form of levothyroxine and also between strengths of the same drug.

Ease of Monitoring

Levothyroxine is the easiest to monitor via TSH and free T4 laboratory measurements of thyroid function. The monitoring

of therapy with these laboratory tests is more difficult with liothyronine due to its rapid T3 release. It will suppress TSH, but monitoring the more expensive T3 test is also required. Liotrix offers no clear benefit on any of these parameters.

Monitoring

Thyroid function is monitored with TSH and free T4 levels. Because of the negative feedback loop between TSH and thyroid hormones, elevations in TSH indicate insufficient thyroid hormone, and TSH levels below desired levels indicate excessive thyroid hormone. TSH and free T4 levels are checked initially and at 6 weeks after the first adjustment. Recheck the levels 4 to 6 months after achieving the target dose. Remember that steady state must be present to reliable values; steady state takes 4 to 6 weeks to be achieved. Once the adult primary hypothyroid patient is stable on an appropriate dose, TSH can be checked only annually; serum T4 measurements are unreliable for monitoring levothyroxine dosing. The exception is for secondary hypothyroidism. In that case, TSH is typically suppressed and the T4 is used to regulate dosing. See Chapter 41 for additional thyroid disease care.

Infants must be checked every 1 to 2 months. Children should be monitored every 3 to 6 months, especially during growth spurts. Age-based normal values from a consistently used ordering laboratory should be used for dose adjustments.

Diagnostic TSH levels (0.5 to 5.0 mU/L) are not the same as therapeutic levels. Newest TSH levels for maintaining dosing have been revised to be 0.3 to 3.0 mU/L. Laboratory work-ups plus patient symptomology are used to find the right dosing, with most patients best maintained between 1.0 and 2.5 mU/L. Hormone overreplacement (low TSH with normal T4 and T3) results in a subclinical hyperthyroidism. Dangers include bone thinning and cardiac irregularities with a 24% increase risk of CV death and all-cause mortality (Selmer et al, 2013).

Patient Education

Administration

Thyroid hormones are taken as a single daily dose in the morning before breakfast to prevent insomnia. Taking levothyroxine on an empty stomach enhances absorption. Other types may be taken without regard to food. If a dose is missed, it may be taken that same day as soon as it is remembered. If more than three doses are missed, the health-care provider should be informed.

Caution patients not to change brands of thyroid preparation. If brands are switched to generics, titrating of doses over several months may be required. The additional costs of laboratory tests may offset any cost savings from selecting another manufacturer.

Although some health food stores may sell desiccated thyroid preparations OTC at a lower cost, these formulations do not have consistent amounts of thyroid hormone in them and should not be substituted for the FDA-approved prescribed

drug (Cappola, 2012). The serum fluctuations are more likely to cause cardiac symptoms than are the synthetic versions. Liquid formulations from compounding pharmacies are not FDA-supervised. They do not have the same shelf-life as tablets (Cappola, 2012).

Brand-name manufacturers have color-coded the tablets to assist in identification of nonstandard dosing divisions. These unusual dosing levels (i.e., 88 or 112 mcg) require careful attention. These shortened dosing intervals facilitate intermediate dosing levels that can eliminate the need for pill splitting. The potential confusion with unusual dosing formulations is compounded by most doses coming in micrograms, not milligrams. Care must be taken in writing prescriptions to avoid dosing errors, for example, 100 mcg = 0.1 mg and 75 mcg = 0.075 mg.

Adverse Drug Reactions

Teach the patient how to measure pulse rate. If the pulse rate is greater than 100 beats per minute at rest, the dose should be withheld and the health-care provider notified. This may indicate excessive amounts of hormone. Other signs or symptoms that require notification include nervousness, chest pain, hypertension and unexplained weight loss of more than 2 lb in 1 week. Extreme fatigue may indicate inadequate dosing.

Some children on thyroid hormone therapy may experience partial hair loss. This is usually temporary, but parents and children should be informed that it may happen. Elders are at higher risk of developing atrial fib; therefore, patients at higher risk for this issue might be more safely maintained at levels at the higher end of normal.

Lifestyle Management

Thyroid disorders are usually chronic illnesses managed with self-monitoring of symptoms as well as drug therapy. Emphasize the importance of keeping follow-up appointments for evaluation of thyroid function. For children, evaluation of physical and psychomotor growth and development is also central to their management. Explain to the patient that replacement therapy must be taken for life (except in transient cases). The drug will treat the disorder, but not cure it. Further patient teaching related to management of thyroid disorders is discussed in Chapter 41. Patients should be cautioned not to take "thyroid health" OTC supplements as they are potential sources of exogenous hormone, iodine, or kelp products that can counter the effectiveness of the prescription.

ANTITHYROID AGENTS

Antithyroid agents function by either inhibiting the synthesis of thyroid hormones or destroying thyroid gland tissue. They are used to treat hyperthyroidism. Hyperthyroidism, also known as *thyrotoxicosis,* occurs when there is a breakdown in the feedback loop and the body's tissues are exposed to excessive levels of thyroid hormone. The cause of this excessive secretion varies, with the most common cause an

autoimmune disorder called Graves' disease. The hyperfunction of the thyroid gland leads to suppression of TSH and TRH.

Hyperfunction of the thyroid gland results in a dramatic increase in iodine uptake and thyroid gland metabolism. A disproportionate increase in T3 production is combined with a decreased concentration of TBg so that increased circulating levels of thyroid hormone are seen. Severe levels may lead to thyroid storm, a life-threatening situation not covered in this chapter.

Regardless of the etiology of hyperthyroidism, the clinical features are attributable to metabolic effects of increased circulating levels of thyroid hormone. These effects include heat intolerance and increased sensitivity to stimulation of the sympathetic division of the autonomic nervous system. Table 41-3 (Chapter 41) shows the most common systemic effects of hyperthyroidism and outlines the management of hyperthyroidism.

The two drugs used in the outpatient setting to treat hyperthyroidism are propylthiouracil and methimazole, referenced in the literature as the thionamides or thioureas. Radioactive iodine 131 (I[131]) is prescribed and administered by specialists. Nonradioactive iodine solutions can also be used to suppress thyroid levels.

Pharmacodynamics

Propylthiouracil and methimazole inhibit the synthesis of thyroid hormones. They do not inactivate existing thyroxine and tri-iodothyronine that are stored in the thyroid gland or circulating in the blood, nor do they interfere with the effectiveness of exogenous thyroid hormones. Propylthiouracil partially inhibits the peripheral conversion of T4 to T3. Both drugs are concentrated in the thyroid gland; however, neither of these drugs treats the underlying pathology in hyperthyroidism.

Iodine tablets and solutions (SSKI or Lugol's) are no longer first-line medications; however, they have a role in pre-operative thyroid cancer care, in thyroid storm, and in individuals requiring persistent thyroid suppression if first-line care does not achieve desired outcomes. A bolus increase in iodine intake can have a suppressive effect on normal hormone synthesis for up to 10 days (longer in those previously receiving I[131]). This suppression is the basis for iodine use in cases of radiation bomb or reactor accidents, a topic beyond the scope of this text. The reader is referred to http://www.fda.gov for dosing recommendations at the time of such an incident.

I[131], like other iodine substances, is preferentially taken up by the thyroid gland via the sodium/iodine symporter. Agents that affect any iodine uptake include cigarette smoking and perchlorate, a possible water contaminant. I[131] in subtherapeutic doses can be used to help diagnose whether thyroid masses localize uptake of iodine before or after ablation therapy. Full doses are given to cancer patients post-thyroidectomy to continue eradication of abnormal tissue. Because thyroid cells preferentially take up iodine molecules, the impact is mostly limited to thyroid tissue. Controversy exists whether long-term outcomes of survival or recurrence are altered for patients with low-risk masses. The endocrine team makes the decision for use.

Pharmacokinetics

Absorption and Distribution

Propylthiouracil is rapidly absorbed after oral administration, reaching a peak serum level within 1 hour (Table 21-33). This drug is highly protein bound (75% to 80%) and concentrates in the thyroid gland. Concentrations in breast milk are low. It crosses the placenta in low concentrations. Currently it is used only in adults (FDA, 2009).

Methimazole is completely absorbed after oral administration but at variable rates. This drug is not protein bound and also concentrates in the thyroid gland. Concentrations in breast milk are high. It readily crosses the placenta in high concentrations and is associated with birth defects in early pregnancy (Bahn et al, 2011; FDA, 2010).

I[131] comes in capsules and solutions that must be prepared in special nuclear isotope pharmacies. It is rapidly absorbed by the thyroid, even faster under autoimmune conditions. I[131] uptake by thyroid tissues is facilitated by following a low-iodine diet for a week prior to scanning. Research has not established optimal doses, but higher levels have been associated with phenomena wherein thyroid tissues are "stunned" and do not absorb as much isotope. This is being investigated, as is a lesser "stun" factor with different iodine isotopes (McDougall & Iaguru, 2011; Norden, Larsson, & Tedelind, 2007). The higher doses, however, have better, longer-term results.

I[131] can be the initial therapy but frequently is administered after the thionamides have returned the patient to a

Table 21–33 ❖ Pharmacokinetics: Antithyroid Drugs

Drug	Onset*	Peak*	Duration*	Bioavailability	Protein Binding	Placental Transport and Breast Milk Levels	Half-Life	Excretion
Methimazole	1 wk	4–10 wk	Weeks	80%–95%	0%	High	6–13 h	Less than 10% in urine
Propylthiouracil	10–21 d	6–10 wk	Weeks	80%–95%	75%–80%	Low	1–2 h	35% in urine

*Effect on thyroid function.

near euthyroid state. Pretreatment with methimazole may increase the success of sustained good outcomes and decreases the possible transient spike in hyperthyroid symptoms at the onset of therapy. Propylthiouracil is associated with more cases of radiation therapy failures (Ross, 2012b). Elders and those with cardiovascular disease are more vulnerable to these spike effects. Pretreatment is stopped 6 days prior to the isotope dosing. Ablation of thyroid tissue is achieved with one dose 80% of the time.

Metabolism and Excretion

Propylthiouracil is completely metabolized by the liver with a significant first-pass effect. Methimazole is mostly metabolized by the liver, but some drug (10%) is excreted unchanged in the urine. Both drugs have a short half-life, but this has little influence on the duration of antithyroid action or the dosing intervals because they are concentrated in the thyroid gland.

Pharmacotherapeutics

Precautions and Contraindications

Pregnancy creates a serious cautionary condition for the use of antithyroid drugs. I^{131} is contraindicated (Category X) due to its impact on the infant when it crosses the placenta and into breast milk (Bahn et al, 2011). Methimazole is associated with birth defects, leaving propylthiouracil as the option for early pregnancy when it is clinically necessary to administer an antithyroid drug. Propylthiouracil and methimazole cross the placenta and can induce goiter and even cretinism in the fetus. Pregnancy typically reduces Graves' disease symptoms, so dosing is lower than normal and drops as the pregnancy advances (Bahn et al, 2011). The newborn should be tested at birth.

Adverse Drug Reactions

The most common serious adverse reaction to therapy with the thionamides is agranulocytosis and possible aplastic anemia. This risk is higher for patients who already have decreased bone marrow reserve, for those older than 40 years, and for those receiving more than 40 mg/day. These drugs

must be discontinued, should this adverse reaction occur. It is important to remember that about 10% of patients with untreated hyperthyroidism have leukopenia (WBC count less than 4,000/mm³), often with related granulocytopenia.

Drug-induced hepatitis and abnormal hair loss may occur with either drug. The FDA (2010b) issued a Black-Box Warning concerning propylthiouracil and liver failure, so it should be reserved for those patients where surgery or methimazole is not appropriate. Use in pediatric patients is restricted unless there is a methimazole allergy (FDA, 2009). Less serious and less frequent adverse reactions to both thioamides include drowsiness, headache, paresthesias, vertigo, diarrhea, nausea, arthralgia, and a pruritic skin rash. The nausea and skin rash are more common with propylthiouracil, but there is an element of cross-sensitivity with metimazole.

I^{131} is considered safe for outpatient therapy. There can be localized pain and edema for 2 to 3 weeks if thionamides were not used prior to treatment. Short-dose corticosteroids help alleviate it. Precautions about household contacts are covered in Chapter 41. Dosing for thyroid cancer is higher than it is for hyperthyroidism therapy. Controversies exist over long-term (40-year) minimal increases in post-therapy malignancies. Many patients complain of dry mouth. Use of lemon candies within the first 24 hours remains contentious but is considered appropriate thereafter. Iodine-free laxatives can be used to purge residual radioactive activity from the colon if normal bowel movements do not occur within the first day. Body or blood dosimetry is not done except for those with distant metastasis.

Drug Interactions

Any drugs that produce bone marrow depression have an additive effect with antithyroid drugs (Table 21-34). Additive antithyroid effects occur with lithium, potassium iodide, or sodium iodide given with propylthiouracil. Potassium iodide and amiodarone decrease antithyroid effects when given with methimazole. The risk of agranulocytosis is increased with concurrent administration of phenothiazines with both thioamines. The anticoagulant activity of warfarin may be potentiated by the anti–vitamin K activity attributed to propylthiouracil.

Table 21–34 ⚏ Drug Interactions With Antithyroid Drugs

Drug	Interacting Drug	Possible Effect	Implications
Methimazole, propylthiouracil	Any drug that produces bone marrow depression	Additive bone marrow depression	Monitor white blood cell counts with differential; dosage adjustments or discontinuance of one of the drugs may be needed.
Propylthiouracil	Lithium, potassium iodide, warfarin	Additive antithyroid effects Anticoagulant effects potentiated	Avoid concurrent administration. Monitor PT/INR closely.
Methimazole	Potassium iodide, amiodarone	Decreased antithyroid effects	Avoid concurrent administration.
Methimazole, propylthiouracil	Phenothiazines	Increased risk for agranulocytosis	Avoid concurrent administration.

INR = international normalized ratio; PT = prothrombin time.

Patients treated with I [131] and later treated with amiodarone may develop hypothyroidism, sometimes acutely. This is in contrast to the amiodarone-induced hyperthyroid effects found in most other circumstances (Ross, 2012a).

Clinical Use and Dosing

Hyperthyroidism/Graves' Disease

Any of the antithyroid drugs may be used in adults. Propylthiouracil is available in 50 mg tablets. Standard dosing varies from 150 to 300 mg daily. Because of its short half-life, the dose is divided and taken 3 times daily. Methimazole comes in 5, 10 and 20 mg tablets. Dosing is usually started at 10 to 15 mg daily. Methimazole works faster than propylthiouracil. Low doses are as efficacious as higher doses over time except when treating severe cases and enlarged goiters. For moderate disease the methimazole dose is 30 to 40 mg/d and for severe disease the dose is 60 mg/d. Patients with severe hyperthyroidism may have initial 300 to 900 mg/d doses of propothiuriacil depending on the severity of the disease. After lab values normalize, maintenance doses are 100 to 150 mg/d. Treatment is for 6 to 18 months, with most patients being treated for 1 year (Table 21-35).

Toxic Goiter

Patients with toxic goiter require higher doses of antithyroid drugs. Methimazole is initiated at a dose of 60 mg/d divided into three equal doses given 8 hours apart. Propylthiouracil is initiated with 600 to 900 mg/d in three equally divided doses given 8 hours apart. Maintenance doses are the same as for hyperthyroidism. Some treatment regimens give either medication for 1 month to "calm" the thyroid and then administer a dose of radioactive iodine.

Rational Drug Selection

Pregnancy and Lactation

Because the amount of drug that crosses the placenta is lower with propylthiouracil, the lowest effective dose of this drug is selected if one must be used. In many pregnant women, the thyroid dysfunction diminishes as the pregnancy continues, so the dose can be reduced. In some cases, the drug can be withdrawn 2 to 3 weeks prior to delivery. Postpartum patients receiving antithyroid drugs should not nurse their infants. If it is necessary, however, propylthiouracil is the preferred drug.

Cost

There is a significant difference in cost between methimazole and propylthiouracil. Unless the provider is willing to try once-daily dosing and sees this as an advantage, propylthiouracil is about 10% of the cost of methimazole. The cost of I[131] runs into thousands of dollars, with additional charges for hospital services, scanning requirements, and special handling. Costs for simple iodine (SKKI or Lugol's) are extremely low.

Monitoring

TSH and free T4 levels are evaluated prior to beginning therapy and whenever symptoms recur, whenever dosages are adjusted, and every 2 to 3 months throughout therapy. TSH levels may be misleading, especially early in therapy. T4 and T3 levels are monitored with the thionamides because the T3 may stay high even though the T4 returns to a normal baseline. Once TSH is back to normal, monitoring of T3 is no longer necessary. Overt symptoms typically resolve weeks before laboratory values stabilize. If the hyperthyroid state has been prolonged, the pituitary axis may not become rebalanced for months (Ross, 2012b). In addition to laboratory assessment, both the provider and the patient should regularly assess for signs and symptoms of hyperthyroidism (too low a dose) or hypothyroidism (too high a dose).

The majority of patients receiving antithyroid medication will develop hypothyroidism over time. Recurrent hyperthyroidism is more likely in smokers and those who do not remain euthyroid for more than 6 months. Therefore, monitoring TSH levels after therapy is completed becomes a long-term primary care responsibility (Bahn et al, 2011).

To monitor for the risk for agranulocytosis, a complete blood count, including white blood cell count and differential, is done prior to initiating therapy. This adverse reaction may develop rapidly, usually within the first 2 months of therapy. During that time, both the provider and the patient should be especially vigilant. It is more common in persons older than 40 years and those who are receiving more than 40 mg/d. Only if symptoms suggestive of this disorder occur should it be monitored after the initial period (Ross, 2012b).

Drug-induced hepatitis has become a concern. Liver function tests should be done prior to any thioamide therapy, especially if there are any indications of hepatic issues or a

Table 21–35 ⊗ Dosage Schedule of Antithyroid Drugs

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
Methimazole (G)(Tapazole)	TSH suppression	5 mg (scored) tablet 10 mg (scored) tablet 15 mg tablet 20 mg tablet	*Adults:* 10–15 mg/d *Pediatric:* per specialist	Moderate disease: 30–40 mg/d
	Severe disease			60 mg/daily
Propylthiouracil (G)	TSH suppression	50 mg tablet	*Adults:* 150 mg/d in three divided doses *Pediatric:* per specialist	150–300 mg daily in three divided doses Severe disease: 300–900 mg/d

history of liver impairment, with monitoring during and 6 months after treatment (FDA, 2009).

Administration

If the drug is to be taken every 8 hours, it is not necessary to awaken at night to take the drug at exactly 8-hour intervals because the drug is concentrated in thyroid tissue. If a dose is missed, the patient should take it as soon as remembered. If it is almost time for the next dose, the two doses may be taken together. The health-care provider should be notified if several doses are missed so that an assessment of thyroid function can be made.

Dietary sources of iodine should be discussed and reduced or eliminated because they interfere with the action of the antithyroid drugs. Many OTC drugs, especially those used to treat colds, have iodine in them. Teach the patient to read the labels.

Adverse Reactions

The most common potential adverse reaction related to the antithyroid medications is agranulocytosis. Patients are taught to report sore throat, fever, chills, rash, and unusual bleeding or bruising, as well as the reasons for them.

Another potential adverse reaction is drug-induced hepatitis. Patients are also taught to report headache, malaise, weakness, and yellowing of the eyes or skin and the reasons for them. The patient should be told that any abnormal hair loss is probably temporary.

I^{131} may have a slight overall mortality from cardiovascular deaths in patient cohorts followed for over 40 years. The increased risk of cerebrovascular accident is probably due to the effects of hyperthyroidism, not the radiation itself. Any suppressed testicular function returns to normal quickly. Any link to an increased risk of ophthalmopathy already associated with Graves' disease is controversial but probably unfounded.

Lifestyle Management

Hyperthyroidism and goiter are often chronic illnesses managed with self-monitoring of symptoms as well as drug therapy. Emphasize the importance of keeping follow-up appointments for evaluation of thyroid function. For children, evaluation of physical and psychomotor growth and development is also central to their management. Explain to the patient that antithyroid drug therapy will be required for 6 to 18 months and perhaps longer, because recurrence of hyperthyroidism happens when lower doses are used. Such is the case in children. Further patient teaching related to management of thyroid disorders is discussed in Chapter 41.

AROMATASE INHIBITORS

The aromatase inhibitors are typically thought of as part of the arsenal against breast cancer. Their actions within the hormone system places them within the category of endocrine medications. They can be used in both men and women.

Pharmacodynamics

Aromatase is a naturally occurring enzyme involved with estrogen synthesis; it is sometimes called estrogen synthetase or synthase in the classic literature. It is one enzyme in the complex P450 cytochrome system that plays a role in steroid hormone balance to include sexual maturity, and health of tissues of the genitals, brain, and fatty tissues; though it is found in many tissues, it has strong impact in the estrogen-sensitive tissues of the uterus, adrenal glands, placenta, gonads, and breast (McCance & Huether, 2014). Aromatase plays a critical role in estrogen generation from androgen building blocks. Testosterone is changed to estradiol and androstenedion becomes estrone through a complex series of steps. It has many other major functions to include a role in determination of gender expression in the the developing embryo and neuroprotection during brain injury.

Inhibition of the enzyme is the major role of the class of aromatase inhibitors. The drugs approved for use in post-breast cancer treatment in women are the primary focus of this section. Men can take the medications if they have estrogen sensitive breast cancer or to try to resolve gynecomastia or fertility issues associated with an imbalance of testosterone to estradiol ratio.

Pharmacokinetics

Anastrazole (Arimidex) and letrozole (Femara) are non-steroidal medications that create a reduction in circulating estrogens. Exemestane (Aromasin) is classified as a steroidal agent. All are oral medications. Anastrazole and letrozole are well absorbed with or without food; exemestane has increased circulating levels if taken after a fatty meal and shifts from a 2 hour time peak to 5 hours. Half-life of anastrazole is 24 hours, exemestane is 50 hours, and letrozole is 2 days. Fecal elimination accounts for 90% of anastrazole after metabolism. Exemestane has a 45% urine elimination with the rest in the feces. Ninety percent of letrozole is excreted in the urine.

Renal dosing is not required of any of three agents discussed. Liver impairment Child-Pugh class C requires reducing doses of letrozole; dosing may not have been tested for the other two medications in pre-release studies (Table 21-36).

Pharmacotherapeutics

Aromatase inhibitors are used as adjuvant therapy in estrogen receptor positive postmenopausal breast cancer patients. They are added to the plan after 3 to 5 years of tamoxifen therapy and continued for at least 5 years. They are also used as first-line treatment in cases of advanced or metastatic cancer. There are unlabeled uses for ovarian cancer and to stimulate ovulation in anovulatory women done within specialty care.

The aromatase inhibitors are oral agents taken once daily. Anastrazole is given as a 1 mg tablet, exemestane is a 25 mg tablet, and letrozole comes in a 2.5 mg dose. There is no increasing in dosage over time. All forms of these medications

Table 21–36 ⊞ Pharmacokinetics of Aromatase Inhibitors

Drug	Site of Metabolism	Peak	Protein Binding	Half-Life (in hours)	Elimination
Exemestane	Liver	1.2 h	90%	24	Urine 42%; feces 42%
Anastrozole	Liver	2 h without food; 5 h with food	40%	50	80% liver; 20% renal
Letrozole	Liver	2–6 wk for steady state	weak	48	90% renal

are considered hazardous agents that require special handling and disposal. All are contradindicated in pregnancy and breast feeding (Table 21-37).

Adverse Drug Reactions

Adverse effects for the drug class include various pain syndromes, vertigo, insomnia resulting in daytime sleepiness and confusion, increased risk of blood clots, and hair loss. A key concern is the loss of bone mass. Bone loss can be significant when considering the concurrent osteoporotic risks of postmenopause. Closer monitoring is required. All patients should be on calcium and vitamin D supplementation. A relative leukopenia can occur, but the incidence of viral and bacteria infections is not considered greater than matched groups (about 10%). Hypertension occurs in 10% of patients. A life-threatening increase in blood clotting can result in MI, stroke, or pulmonary embolus. Hot flashes can be intense.

Drug Interactions

Drug interactions vary by agent, but none should be taken with tamoxifen or an estrogen product. Anastrazole cannot be taken with pimozide. Both anastrazole and letrozole will decrease the effect of digoxin and vitamin K antagonists.

Exemestane should not be taken with axtinib or simeprevir. It will decrease the effect of aripiprazole and saxagliptin and increase the effect of methadone and vitamin K antagonists. Letrozole cannot be taken with tegafur (Table 21-38).

Education and Lifestyle Management

Patient education follows the standards for how to take the medication, when to report adverse effects, and the need for close monitoring of LFT labs. Frequent reports of weakness should be countered by encouragement for exercise and pacing of activities. Advice on how to recognize development of DVT, stroke, and MI is important. Patients should be encouraged to discuss issues of pain and fatigue with the provider prior to just stopping the medications. Switching from one drug in the class to another has sometimes proven to be an effective solution to lower the symptoms to a more tolerable level. Providers and patients need to evaluate whether the degree of fatigue and insomnia is being accelerated by the expected concurrent depressive syndrome experienced by all oncology patients or a possible alteration in thyroid function. Unlike Tamoxifen, the SSRI medications do not appear to decrease the effectiveness of the aromatase inhibitors.

Table 21–37 ⊗ Dosing and Indications Aromatase Inhibitors

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
Anastrazole (Armidex)	Postmenopausal breast cancer inhibition	1mg tablet	1mg ; no change for most renal patients or elders	Usually taken for 5 yr after tamoxifen, but can be first line medication as well and extend beyond 5 yr of use.
Letrozole (Femara)	Postmenopausal breast cancer inhibition	2.5 mg tablets	2.5 mg; no renal dosing or change for elders	As above
Exemestabe (Aromasin)	Postmenopausal breast cancer inhibition	25 mg tablets	25 mg	As above
Ospemifene (Osphena)	Vaginal atrophy, dyspareunia	60 mg tablets	60 mg for moderate or severe issues	
Bazedoxifene & conjugated estrogen (Duavee)	Hot flashes and osteoporosis	20 mg–0.45 mg tablets	One tablet daily for both indications	Use for shortest duration possible to minimize estrogen-related risks

Table 21–38 ▦ **Drug interactions of Aromatase Inhibitors**

Drug	Interacting Drug	Possible Effect	Implications
Anastrozole (Arimidex); Exemestane (Aromasin); Letrozole (Femara)	Estrogen products	Defeats purpose of both	Avoid coadminstration
Exemestane (Aromasin)	Rifampin	Decreases levels and effectiveness	May need to increase dose; consult oncology
	Phenytoin	Decreases levels and effectiveness	May need to increase dose; consult neurology
Letrozole (Femara)	Tamoxifen	Reduces plasma levels of letrozole	Not a combination medication
Conjugated estrogens + bazedoxifene (Duavee)	No studies conducted—see estrogen. For bazedoxifene: Rifampin, phenobarb, carbamazepine, phenytoin	No known CYP interactions with bazedoxifene UGT interactions increase metabolism of bazadoxifene	May need additional uterine protection/monitoring.

UGT = uridine diphosphate glucuronosyltransferase in the gut.

DRUGS AFFECTING THE REPRODUCTIVE SYSTEM

Diana L Dewel

There are many medications that are prescribed for reproductive problems in both men and women. This chapter discusses androgens and antiandrogens, commonly prescribed for men, as well as appropriate prescribing of these medications for women. Prescribing of estrogens and progesterone, as well as their antagonists, is reviewed, as well as drugs for lactation and erectile dysfunction. Medications discussed in this chapter are limited to medications prescribed in primary care and gynecology and do not include medications prescribed in specialty endocrine or reproductive health care.

ANDROGENS AND ANTIANDROGENS

Testosterone is the primary male androgen. In many tissues, its activity depends on reduction to dihydrotesterone, which binds to cytosol-receptor proteins. The androgen-receptor complex is then transported to the nucleus of the cell, where it initiates transcription events and cellular changes. Endogenous androgens are responsible for the following:

- Normal growth, maturation, and maintenance of the male sex organs and secondary sexual characteristics
- The skeletal growth spurt in adolescence and for the termination of linear growth by fusion of the epiphyseal growth plate
- Activation of sebaceous glands, accounting for some cases of acne during puberty
- Enhancing production of erythropoietic stimulating factor, resulting in increased red blood cell production
- Playing a role in libido

A more detailed discussion of the roles and therapeutic uses of androgens is given in the Pharmacodynamics section.

The androgens—testosterone propionate (in oil, Depo-Testerone), testosterone enanthate (in oil, Delatestryl), testosterone cypionate (in oil, Depo-Testosterone), methyltestosterone (Android, Methitest, Testred, Virilon), testosterone

gel (AndroGel 1%, AndroGel 1.62%, Axiron, Testim), fluoxymesterone, transdermal testosterone (Testoderm, Androderm), and buccal testosterone (Striant)—have been used to treat disorders in both the male and female reproductive systems. Androgens are indicated for the symptomatic treatment of (1) deficiency states in males associated with hypogonadism and (2) in both sexes for disorders such as cancer and HIV. Androgen therapy has also been used to treat libido, endometriosis, and postmenopausal symptoms in women. However, there is limited evidence supporting the correlation of testosterone levels and symptom reduction in women. Androgens have also been used illicitly to enhance athletic performance and increase muscle mass.

Antiandrogens fall into several different categories. Androgen hormone inhibitors in this section are also known as 5-alpha-reductase inhibitors. These enzyme inhibitors block the conversion of testosterone to dihydrotesterone. Key agents in this class include finasteride (Propecia, Proscar) and dutasteride (Avodart). This class of drugs is used to treat benign prostatic hyperplasia, and finasteride (Propecia) has been approved to treat male-pattern baldness. Leuprolide acetate (Lupron) is a gonadotropin-releasing hormone analogue, also known as a luteinizing hormone–releasing hormone antagonist.

These agents create a reversible chemical orchiectomy state in males and an oophorectomy state in females. Through this mechanism of action, these agents are effective in the treatment of advanced prostatic cancer and for the management of endometriosis and uterine leiomyomata (fibroids).

Flutamide (Eulexin), bicalutamide (Casodex), and nilutamide (Nilandron) are direct antiandrogens; these agents inhibit androgen uptake or nuclear binding of androgen at target tissues. These agents are used as part of a combination therapy treatment of prostatic carcinoma. Spironolactone (Aldactone) is an aldosterone antagonist and inhibitor of 5-alpha-reductase that is indicated for use as a potassium-sparing diuretic (see Chaps. 16, 36, and 40 for further discussion regarding cardiovascular use). Additionally, it has an off-labeled use in the treatment of female hirsutism and acne due to its antiandrogenic properties. Symptoms of premenstrual syndrome/premenstrual dysphoric disorder (PMS/PMDD) have also been relieved by spironolactone doses of 25 mg 4 times a day beginning on day 14 of the menstrual cycle.

Box 22-1 provides information on antiandrogens. Note that the discussion in this chapter focuses on utilization and monitoring of androgen therapy in the primary care setting rather than in specialized practice.

BOX 22–1   COMPOUNDS WITH ANTIANDROGENIC PROPERTIES

The problems of reduced potency in the oral form and the virilizing side effects of androgens led investigators to develop drugs that inhibit synthesis and block sex hormone production receptors. This approach of countering the effects of undesirable androgen excess has enabled therapy at higher dosages. Dihydrotestosterone is the essential androgen in the prostate. The effect of androgens can be reduced by inhibiting 5-alpha-reductase in its target tissues. PSA levels and digital prostate examination are required monitoring for men on these agents. Users of alpha$_1$-adrenergic antagonists may experience hypotension, syncopy, impotence, and decreased libido. Caution is advised with concurrent use of agents that potentiate the alpha$_1$-adrenergic blocking and agents that increase the risk of hypotension.

Finasteride (Propecia, Proscar)

Finasteride, a steroid-like drug, inhibits 5-alpha-reductase, an intracellular enzyme that converts testosterone to 5-alpha-dihydrotestosterone (DHT). It has a 100-fold selectivity for 5-alpha-reductase type 2, the isoenzyme found primarily in the prostate, seminal vesicles, epididymides, and hair follicles. It is well absorbed orally, and the reduction in DHT begins within 8 hours of administration and lasts for about 24 hours. Finasteride undergoes extensive hepatic metabolism, with 39% being excreted in the urine and 57% in feces.

Approximately 90% is bound to plasma proteins. The FDA approved doses of 5 mg per day to treat benign prostatic hyperplasia (BPH). Although early improvement may be seen, 6 to 12 months of therapy may be needed to determine if a beneficial response has been achieved. Most patients experience a rapid regression in prostate gland size, and about 50% experience an increase in urinary flow and improvement in BPH symptoms (*Drug Facts and Comparisons,* 2005). In 1998, the FDA approved a 1 mg dose for treating male pattern baldness. Three months of therapy are usually required to demonstrate benefits. Stopping the drugs reverses the effect within 12 months. The main undesirable adverse effects are decreased libido and impotence, which occur with both doses.

Dutasteride (Avodart)

Like finasteride, **dutasteride** inhibits 5-alpha-reductase, an intracellular enzyme that converts testosterone to 5-alpha-dihydrotestosterone (DHT). It inhibits both type 1 and type 2 forms of the isoenzyme. It does not bind to the human androgen receptor. It is absorbed well after oral administration and reaches peak serum concentration within 2 to 3 hours. However, peak clinical effect does not occur until 6 to 12 months of therapy have been completed. Heavily bound to plasma protein (99%), it is extensively metabolized by the liver, utilizing the CYP450 3A4/5 substrate. The drug and its metabolites are excreted mainly in feces (45%). Only trace amounts are found in the urine. This drug is approved for the treatment of BPH. BPH patients treated with this drug had a decrease of 94% of DHT after 1 year. Because of its long half-life, serum concentrations remain detectable for up to 6 months after discontinuance of treatment. Dutasteride is absorbed through the skin, so women who are pregnant or may become pregnant should not handle dutasteride capsules due to the potential risk of fetal anomaly to a male fetus. The main undesirable adverse effects are decreased libido and impotence.

BOX 22–1   COMPOUNDS WITH ANTIANDROGENIC PROPERTIES—cont'd

Leuprolide Acetate (Lupron)

Leuprolide is a luteinizing hormone–releasing agonist. This drug produces gonadal suppression when blood levels are continuous in the treatment of prostate cancer. It may be given in a dose of 1 mg SC daily or IM every 3 months in the depot formulation. Mean plasma levels are achieved in 4 hours and are maintained after an initial drop in concentration. It has even greater suppression when used with flutamide. In pediatric patients, its use is to treat central precocious puberty. In gynecology, its use is in reducing uterine fibroids, endometriosis, and polycystic ovary syndrome. Approximately 90% of women with unstaged endometriosis have relief of pain, and 50% regain fertility with leuprolide.

Flutamide (Eulexin, Euflex)

Flutamide behaves like a competitive antagonist at the androgen receptor site, although it is truly a nonsteroidal agent. It has been used with leuprolide for the treatment of advanced prostate cancer and with female androgen excess syndrome. The adverse effects in men are gynecomastia and reversible liver toxicity. Flutamide is rapidly absorbed orally. It is metabolized into six compounds and bound 97% to plasma proteins, reaching a steady state by the fourth dose. Flutamide is excreted in the urine but has not required changes in dose unless renal function is less than 29 mL/min. There is a Black-Box Warning regarding hepatic failure, hepatic encephalopathy, and death with this agent. Most of these events have occurred within the first 3 months of therapy. Baseline and monthly liver function testing is necessary for the first 4 months of therapy and then periodically. Medication should be discontinued if any symptoms of hepatic injury or jaundice develop.

Spironolactone (Aldactone)

Spironolactone is another competitive inhibitor of the dihydrotestosterone, aldosterone, and interferes with the androgen receptors in the prostate. It also reduces 17-alpha-hydroxylase activity, lowering plasma levels of testosterone and androstenedione. Refer to Chapter 16 for its uses as a diuretic. Spironolactone is absorbed orally, reaches peak levels in 2 hours, and is metabolized by the liver and excreted through the portal system. Spironolactone has short-term use for primary hyperaldosteronism in patients preoperatively. It is used long-term for those patients who are not good candidates for surgery or those with idiopathic hyperaldosteronism. There are also edematous conditions that require potassium conservation, such as congestive heart failure and cirrhosis of the liver associated with ascites. An off-labeled use is in females with androgen excess for the treatment of hirsutism and acne in dosages of 50 to 200 mg/day. Adverse reactions are usually dose-related and reversible when the drug is discontinued. The most common adverse reactions are GI upset, drowsiness, gynecomastia, impotence, cutaneous eruptions, and urticaria. Early animal chronic toxicity studies demonstrated tumorigenicity. Therefore, use should be balanced against risk (there is a Black-Box Warning regarding this concern). This drug is contraindicated in pregnancy, yet the American Academy of Physicians has stated that it is compatible with breastfeeding. Although this drug is classified as a diuretic, its use in premenstrual syndrome is probably effective because of its antiandrogen effect, even at low doses (25 to 50 mg daily).

Pharmacodynamics

Testosterone is the most important androgen in humans. It is highly protein bound, and only a small portion (2%) is found free in plasma and converted to dihydrotestosterone in the skin, prostate, seminal vesicles, and epididymis. In men, testosterone is produced primarily within the testes in interstitial or Leydig cells, located in the spaces between the seminiferous tubules. The testis, like the ovary, has both reproductive and endocrine functions. Women produce small amounts of testosterone in the menstruating ovary and the adrenals, and both sexes produce testosterone peripherally from androstenedione, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEAS).

At puberty, the normal male produces testosterone that stimulates maturation of the male reproductive tract and causes penile and scrotal growth. Secondary sexual characteristics associated with androgens also become noticeable. Skin changes occur, resulting in pubic, axillary, and facial hair growth, along with stimulation of sebaceous glands, making the skin thicker and oilier. Even the vocal cords become thicker, resulting in a lower-pitched voice. Lean body mass increases and more growth occurs in all bones, with epiphyseal closure occurring at around 21 years of age.

Androgens continue to play a crucial role in the maintenance of sexual function across the male life span. Androgen levels remain stable until age 55 years, when a gradual decline begins. At 70 years, a more rapid decline in hormone levels occurs, and men experience decreased muscle mass, strength, and libido. Androgens have metabolic effects in protein metabolism, liver synthesis of clotting factors, and renal production of erythropoietin. Androgens affect lipoprotein metabolism, resulting in lower high-density lipoprotein (HDL). For example, men have HDLs of 20 to 40 mg/dL, and women have HDLs in the range of 40 to 60 mg/dL.

The use of synthetic androgens is intended to supplement or replace endogenous hormones. The mechanism of action and effects of synthetic androgens are similar to those described above. When men attempt to improve athletic prowess by taking large doses of exogenous testosterone, the normal feedback mechanisms in the male reproductive process are altered and spermatogenesis is reduced through suppression of follicle-stimulating hormone (FSH).

Pharmacokinetics

Absorption and Distribution

Several delivery modes for testosterone replacement are available. Oral testosterone is rapidly metabolized by the gut as methyltestosterone and fluoxymesterone and is converted in its target tissues by the enzyme 5-alpha-reductase. The further conversion of testosterone to estradiol by cytochrome P450 (CYP450) aromatase occurs in adipose tissue, the liver, and the hypothalamus. Buccal administration lengthens the half-life. IM administration (esters) in depot preparations can last 2 to 4 weeks. Depo-Testosterone is slowly absorbed into the bloodstream between dosing intervals. Varying rates of absorption from IM administration are associated with this method, and significant fluctuation in serum testosterone levels and effects are reported. For this reason, the selection of transdermal or implanted testosterone therapy may be preferred.

Transdermal application is available in either a topically applied gel or through patch delivery systems. Both gel and patch delivery methods require once-daily application to intact, nonscrotal skin. These agents (Androderm, AndroGel, Axiron, and Testim) are well absorbed through the skin and result in rises in serum testosterone levels within 2 to 4 hours of application. Testoderm is associated with a rapid return to baseline within 2 hours after removal. Other transdermal formulations have continuous absorption during a 24-hour dosing period. Specific precautions for the use of transdermal applications will be discussed later in this section. Testopel is a subcutaneous pellet that produces sustained testosterone effects for 3 to 6 months. The use of this subcutaneous version requires specific provider training in appropriate technique for in-office administration.

Testosterone in plasma is 98% bound to a specific testosterone-estradiol-binding globulin known as sex hormone–binding globulin (SHBG). SHBG is increased in plasma by estrogen, thyroid hormone, and cirrhosis of the liver. It is decreased by androgens, growth hormone, and obesity. The final 2% remains free to enter the cell (*Drug Facts and Comparisons* [*DF & C*]*,* 2010).

Metabolism and Excretion

Testosterone uses the CYP450 3A4 substrate for metabolism. Forty-four percent of testosterone degradation occurs in the liver, where it is inactivated to androsterone and etiocholanolone and then conjugated and excreted in the urine. The majority (90%) is excreted in the urine and 6% is excreted in the feces. There is considerable variation in the reported half-life of testosterone: from 10 to 100 minutes. The amount of bound testosterone will determine the percentage of free drug and the free drug concentration determines half-life.

Onset, Peak, and Duration

Oral administration of testosterone reaches peak levels in 2 hours, buccal in 1 hour, and IM in 8 days to 2 weeks. Onset, peak, and duration of action of transdermal forms vary. Table 22-1 depicts the pharmacokinetics of the various

Table 22–1 **Pharmacokinetics: Androgens and Anti-Androgens**

Drug	Onset	Peak	Duration	Protein Binding (in %)	Half-Life	Elimination
Androgens						
Testosterone cypionate (in oil) (Depo-Testerone)	UK	UK	2–4 wk	98%	8 d	90% in urine as conjugates and metabolites; 6% in feces
Testosterone enanthate (in oil) (Delatestryl)	UK	UK	2–4 wk	98%	8 d	90% in urine as conjugates and metabolites; 6% in feces
Testosterone, buccal (Striant)	UK	10–12 h	12 h	UK	10–100 min	90% in urine. Avoids first-pass effects of liver. Metabolized in liver and reproductive tissue.
Methyltestosterone (Android, Methitest, Testred)	UK	UK	1–3 d	98%	10–100 min	90% in urine as conjugates and metabolites; 6% in feces
Fluoxymesterone (Androxy)	UK	UK	UK	98%	9.2 h	90% in urine as conjugates and metabolites; 6% in feces
Testosterone (Testoderm). Must apply to scrotal skin	UK	2–4 h	*		*	90% in urine as conjugates and metabolites; 6% in feces
Testosterone (Testoderm TTS). Apply to nonscrotal skin	UK	2–4 h	*		*	90% in urine as conjugates and metabolites; 6% in feces
Testosterone (Androderm). Apply to nonscrotal skin	UK	4–6 h	24 h	24 h		90% in urine as conjugates and metabolites; 6% in feces
Testosterone gel (AndroGel 1%, Androgel 1.62%, Testim)	30 min	4 h	48 h		5 d	90% in urine as conjugates and metabolites; 6% in feces

Table 22–1 ⬛ **Pharmacokinetics: Androgens and Anti-Androgens—cont'd**

Drug	Onset	Peak	Duration	Protein Binding (in %)	Half-Life	Elimination
Anti-Androgens						
Finasteride (Propecia)	NA	1–2 h	24 h	None	Normal renal function: 4.8–6 h Men > 70 yr: 7 h	39% urine, 57% feces
Leuprolide (Eligard, Lupron, Lupron Depot)	NA	Depot: 4 h	4 wk	45%–49%	NA	NA
Spironolactone (off-labeled use) (Aldactone)	24–28 h	48–72 h	48–72 h	90%	1.3–2 h	Total: renal Unchanged: NA

NA = not available; UK = unknown.

　*Serum levels return to normal within 2 h of removal. Serum levels plateau after 3–4 wk of use.

formulations of androgens and antiandrogens, including the variable half-lives of transdermal formulations.

Pharmacotherapeutics

Precautions and Contraindications

Contraindications for the use of testosterone include male breast cancer, prostate cancer, pregnancy (Category X due to fetal harm/virilization of the female fetus), and lactation.

Transdermal systems and testosterone gel are not indicated for women and must not be used by them. Safety and efficacy of Testoderm and AndroGel products in pediatric patients have not been established. Men who use topical gels must not have skin contact with pregnant women or with children, because skin-to-skin transfer of testosterone may occur. Men should wash their hands after application and allow skin to dry before it touches clothing to decrease the risk of inadvertent transfer of medication.

Edema, with or without congestive heart failure, may be a serious complication. These drugs should be used cautiously in patients with preexisting cardiac, renal, or hepatic disease, and frequent monitoring is required (see the Monitoring section). In addition to discontinuing the drug, diuretic therapy may be needed.

Men, especially elderly men, treated with androgens are at increased risk for developing prostatic hypertrophy, prostatic hyperplasia, and prostatic carcinoma. The treatment of hypogonadal men with testosterone may potentiate sleep apnea. This risk increases in men with obesity or chronic lung disease.

The areas of clinical usage of androgens that are more controversial include stimulating growth in boys with delayed puberty and in aging men to increase strength and muscle mass. It is advisable for primary care providers to refer these populations of patients for consultation with endocrine specialists regarding initiating therapies.

Athletes try to use these drugs to illegally improve competitive performance. In this regard, there has been abuse by coaches and athletes alike. The adverse effects far outweigh the potential benefits. Because of the abuse potential of anabolic steroids, providers must supply their federal Drug Enforcement Administration [DEA] number on all prescriptions written for hormone combinations with androgens. Patients receiving steroid therapy require periodic laboratory and clinical evaluation. Prescribers may wish to limit prescription quantities and refills to match monitoring time frames to aid in adherence to follow-up evaluations and to reduce the potential for misuse.

Adverse Drug Reactions

The androgens as a class are potent agents and can have serious or even fatal reactions if used improperly. When properly used, androgens mimic the body's endogenous processes. However, prolonged use of high doses of androgens has been associated with the development of potentially life-threatening hepatitis, hepatic neoplasms, cholestatic hepatitis, jaundice, and hepatocellular carcinoma. Cholestatic hepatitis and jaundice occur at relatively low doses of fluoxymesterone and methyltestosterone. These conditions are reversible with drug discontinuance.

Gender-specific side effects have been reported with the use of androgen therapy. Men may develop gynecomastia and reduced sperm levels that threaten fertility. Acne and baldness may occur, even with short-term therapy. Men can paradoxically have decreased libido, depression, and headache with exogenous administration of androgens. Scrotal pain, groin pain, or changes in urination may be associated with stimulation and changes of the prostate gland and need further evaluation. Men may develop priapism (a sustained erection) and will require education to seek emergent evaluation if this occurs. In women, menstrual irregularities may occur with these drugs through suppression of gonadotropin secretion. Hypercalcemia and virilization are reported.

All patients on androgen therapy may experience gastrointestinal (GI) symptoms, including nausea, vomiting, change in liver function, edema, and cholestatic jaundice. Suppression of clotting factors, as well as increased red blood cell production, can contribute to hemorrhage and thrombus formation simultaneously.

Both testosterone and anabolic steroids have the potential for abuse. The anabolic steroids have a high anabolic–low androgenic ratio of activity. The U.S. Food and Drug Administration (FDA) warns that androgens may cause peliosis hepatis. Peliosis is the replacement of normal liver tissue with bloody cysts. This vascularity may cause a silent, fatal abdominal hemorrhage. Liver tumors that are benign or malignant may develop. The lipoprotein changes with these steroids may hasten coronary artery disease. Drugs classified as anabolic steroids include oxymetholone, stanozolol, oxandrolone, nandrolone phenylpropionate, and nandrolone decanoate.

Drug Interactions

Various drug interactions have been reported with androgens. The main classes of associated drug interactions with androgens include anticoagulants, diabetic agents, and corticosteroids. The interaction of anticoagulants such as warfarin (Coumadin) with the 17-alkyl testosterone derivatives poses the most significant potential problem. The 17-alkyl testosterone drugs are the methyl- and fluoxy- forms used for hypogonadism and male climacteric.

Although testosterone has been used for breast tenderness in the past, its use is discouraged because of lack of proven efficacy and the masculinizing effect that it has on women. Laboratory values of decreasing protein-bound T_4 and increased T_3 uptake need to be mentioned. But, because the free T_4 levels are not affected, no deficiency state occurs. Table 22-2 presents drug interactions.

Clinical Use and Dosing

The primary clinical use of these agents is for the replacement or augmentation of endogenous androgen for primary hypogonadal males or hypogonadotropic hypogonadism and for male climacteric. After 30 years of clinical use, the World Health Organization (WHO) selected testosterone enanthate as the prototype hormone in its contraceptive efficacy studies.

In rare situations, androgens are used in endometriosis, in refractory anemia, and with estrogen for osteoporosis and loss of libido. Androgens have anabolic effects with food and exercise for post-operative trauma patients and with some types of metastatic breast cancer. The masculinizing effect on women detracts from wider usage.

Testosterone is controversial in pediatrics as a height stimulator and in sports as a performance enhancer. Primary care providers prescribe androgens largely for replacement

Table 22–2 ▦ Common Drug Interactions: Androgens and Anti-Androgens

Drug	Interacting Drug	Possible Effect	Implications
Androgens			
Testosterone	Anticoagulants	Increased anticoagulant effect	More frequent monitoring of prothrombin time
	Imipramine	Paranoid response	Consider switching to another class of antidepressants
	Diabetic agents	Decrease blood sugar	Frequent blood sugar monitoring. Dose adjustment of diabetic agents.
	Cyclosporine	Impaired hepatic metabolism	Consider switching to another agent
Anti-Androgens			
Finasteride	Nevirapine	Combination induces hepatic metabolism of finasteride	Monitor for effectiveness of finasteride
Leuprolide	Pituitary, gonadotropic, and gonadal function Lab tests	Misleading results	Consider if lab test reports show unexpected values
Flutamide	Warfarin	Increased INR and risk of bleeding	Monitor INR closely. As lutamide is indicated for advanced prostate cancer, the option to select an alternative treatment may be limited.
Spironolactone	Renal impairment and agents that affect renal function	Alteration in renal function and electrolytes	Monitor potassium levels in young patients with reduced renal function and in patients >65 yr
	Digitalis	May increase or decrease digitalis half-life	Monitor closely for signs of digitalis toxicity and electrolyte and digitalis levels. Consider alternative treatments.
	Potassium	Additive effect—increases risk of hyperkalemia	Recommend alternative
	Eplerenone (aldosterone receptor antagonist used for CHF)	Severe hyperkalemia	Combination is contraindicated. Do NOT use together; select an alternative agent.

therapy, and for that reason this discussion is limited. Table 22-3 presents the dosage schedule for androgens and antiandrogens.

Rational Drug Selection

Slow-Acting Versus Long-Acting Form

As discussed previously, there are various formulations of androgen supplementation from which a provider may select. There are various advantages and concerns for each formulation that should be considered. Providers should include patient preference, adherence concerns, and lifestyle as factors in agent selection.

IM forms have longer half-lives than do oral and transdermal agents but less uniform absorption and steady serum drug levels. IM aqueous preparations need to be administered 2 to 3 times per week. The patient or a family member can be taught to administer these long-term medications to simplify daily routines. Preparations in oil can be administered at 2- to 4-week intervals. Oral preparations cause less discomfort to administer but may cause gastric irritation and require twice-daily administration. Transdermal agents have demonstrated improved steady-state hormone levels; however, transfer to partners and children is a concern. Subcutaneous pellets offer a long-acting option with infrequent administration

Table 22–3 ⚗ Dosage Schedule: Androgens and Anti-Androgens

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
Androgens Testosterone	Replacement therapy for primary or hypogonadotropic hypogonadism			Dose adjustment based on testosterone levels
Androderm		Patch: 2 mg Patch: 4 mg	4 mg daily	Level >930 ng/dL: decrease dose to 2 mg daily Level 400–930 ng/dL: continue 4 mg daily Level <400 ng/dL: increase dose to 6 mg daily
AndroGel 1%		Gel pump: 25 mg/2.5 g 1.25 g/actuation	50 mg applied once daily to the shoulder and upper arms or abdomen	Less than normal range: increase dose 25 mg (max 100 mg) Greater than normal range: decrease dose by 25 mg. Discontinue if consistently above normal at 50 mg daily.
AndroGel 1.62%		Gel pump: 40.5 mg/2.5g 20.25 mg/actuation	40.5 mg applied once daily in the morning to the shoulder and upper arms	Level >750 ng/dL: decrease dose by 20.25 mg daily Level ≥350 ng/dL to ≤750 ng/dL: maintain current dose Level <350 ng/dL: increase dose by 20.25 mg daily to max dose 81 mg daily
Axiron		Solution pump: 30 mg/actuation	60 mg once daily applied to the axilla	Dose range 30–120 mg daily Level <300 ng/dL: increase by 30 mg daily. Level 105 ng/dL: decrease by 30 mg increments. If persistent elevation, discontinue therapy.
Fortesta		Pump 10 mg/actuation	40 mg once daily applied to the thighs	Dosing range: 10–70 mg daily Level <550 ng/dL: increase dose by 10 mg daily Level ≥500 to ≤1,250 ng/dL: maintain current dose Level ≥1250 to ≤2,500 ng/dL: decrease dose by 10 mg daily Level ≥2,500 ng/dL: decrease dose by 20 mg daily
Testim		50 mg/g	5 g applied once daily to the shoulder and upper arms	Less than normal range: increase dose from 5 g to 10 g (maximum) Greater than normal range: decrease dose. Discontinue if consistently above normal at 5 g daily.

Continued

Table 22–3 ⚘ **Dosage Schedule: Androgens and Anti-Androgens—cont'd**

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
Testosterone cypionate (Depo-Testosterone) Testosterone enanthate (Delatestryl) Generic		Oil, generic 200 mg/mL Oil, cypionate 100 mg/mL; 200 mg/mL Generic: 100 mg/mL; 200 mg/mL Oil, enenthate 200 mg/mL Generic: 200 mg/mL	50–400 mg IM every 2–4 wk	50–400 mg IM every 2–4 wk
Anti-Androgens				
Finasteride (Proscar)	Benign prostatic hyperplasia	5 mg tablet, oral	5 mg daily, with or without meals	5 mg daily
(Propecia)	Androgenic alopecia	1 mg tablet, oral Generic: 1 mg, 5 mg tablet, oral	1 mg daily, with or without meals	1 mg daily
Flutamide	Prostatic carcinoma	Capsule, oral Generic: 125 mg	250 mg 3 times/d, alternatively, once-daily doses of 0.5–1.5 g have been used (unlabeled dosing)	250 mg 3 times/d
Leuprolide (Eligard)	Prostatic carcinoma	Kit, subcutaneous, as acetate 7.5 mg, 22.5 mg, 30 mg, 45 mg	7.5 mg monthly or 22.5 mg every 3 mo or 30 mg every 4 mo or 45 mg every 6 mo	7.5 mg monthly or 22.5 mg every 3 mo or 30 mg every 4 mo or 45 mg every 6 mo
(Lupron Depot)	Endometriosis	Kit, intramuscular, as acetate 3.75 mg, 11.25 mg, 22.5 mg, 30 mg, 45 mg Generic: 1 mg/0.2 mL	3.75 mg every mo for up to 6 mo	3.75 mg every mo for up to 6 mo
(Lupron Depot)	Uterine leiomyomata (fibroids)	Kit, intramuscular, as acetate 3.75 mg, 11.25 mg, 22.5 mg, 30 mg, 45 mg Generic: 1 mg/0.2 mL	11.25 mg every 3 months for up to 2 doses	11.25 mg every 3 months for up to 2 doses
Spironolactone (off-labeled use) (Aldactone)	Acne Hirsutism	Tablet, oral: 25 mg, 50 mg, 100 mg (scored) Generic: 25 mg, 50 mg, 100 mg	To reduce delay in onset of effect, a loading dose of 2–3 times the daily dose may be administered on the first day of therapy	25–200 mg once daily 50–200 mg daily in 1–2 divided doses

(every 3 to 6 months). However, this formulation does not afford for easy dose titration and requires specialty skill in administration.

Cost

Oral testosterone products are less expensive than those administered via other routes, in part because equipment and technical skills are not required for administration. Buccal preparations avoid the 44% metabolism in the liver, but the tablets are more costly. Transdermal patches are the most recent addition to hormone replacement therapy for men and women, and the convenience is associated with increased cost. Transdermal is the preferred route of administration for children because there are no taste issues or painful injections, and older adults with poor eyesight or swallowing problems have less difficulty with patch application.

In addition to the health-care needs and delivery preference, agent selection may also be influenced by a third-party payer source. Frequently, the patient's third-party payer (insurance) limits available formulations. Table 22-3 presents the available dosage forms.

Monitoring

Clients using supplemental and replacement androgen therapy will require monitoring for serum testosterone levels as well as therapeutic effect. In general, all patients on androgen therapy will require serum testosterone level monitoring, lipid tracking, liver function tests, and complete blood count evaluation. The goal of therapy is to maintain a normal range of serum testosterone levels. These laboratory evaluations should be performed at baseline, 3 to 6 months after initiating treatment, then annually while on therapy. Closer monitoring of serum testosterone

is needed at initiation and during dose titration. Male patients will additionally require prostate-specific antigen (PSA) and digital prostate evaluation prior to initiation of therapy and throughout the duration of treatment due to the increased risk of prostate hypertrophy and cancer associated with androgens. Abnormalities of liver function and elevation of lipids can be seen with these agents, as well as polycythemia. There appears to be a trend that men with low levels of testosterone have higher death rates than those with normal levels; however, the FDA is concerned about potential CV risks for the population as a whole. This may be linked to the finding that many men on supplements actually do not have low lab values. See Chapter 49 for more information about men's health.

Calcium levels in serum and urine may become abnormal in patients with breast cancer. Methyltestosterone and fluoxymesterone are apt to cause hepatic toxicity, and liver function tests should be drawn every 6 months. Individuals with renal or cardiovascular comorbidities will also require monitoring of electrolytes and for symptoms of edema and congestive heart failure (CHF). Blood glucose levels and antidiabetic medication may be affected by androgen therapy, and closer monitoring will be required. When using testosterone in prepubertal males, perform an x-ray every 6 months for bone maturation to avoid early closure of epiphyseal centers.

PATIENT EDUCATION

Administration

Avoid coadministering with other medications that cause gastric irritation. With buccal forms, food or liquids reduce absorption. Do not swallow buccal tablets; instead, park the tablet between gums and teeth. If the skin is sensitive to the patch adhesive, a small application of aerosolized cortisone (e.g., Asthmacort or Nasacort) to the skin will reduce irritation without loss of efficacy. A specific description of how to apply transdermal systems is given in Table 22-3.

Adverse Reactions

Common adverse drug reactions and site effects of androgens have been discussed previously in this section. Some adverse effects are reversible if the drug is reduced or temporarily stopped. Significant adverse events with the use of androgens include hepatic injury, worsening of cardiovascular comorbidities, prostatic hypertrophy, and female virilization.

Hepatic injury has been associated with the use of orally administered synthetic androgen agents. Additional use of agents that are associated with risk of hepatic injury should be avoided to prevent additive hepatic risk. Patient education should include a discussion regarding the need to report abdominal pain, jaundice, anorexia, muscle pain, and weakness because these may be symptoms of hepatic injury. Patients with underlying dyslipidemia or angina may experience a worsening of symptoms and should be further evaluated. Caution women to report signs of virilization, such as hoarseness, hair thinning, and menstrual disruption. Older

men should be routinely screened with questions regarding changes in urine stream and nighttime voiding patterns; prostatic hypertrophy with secondary urinary retention may develop while they are on androgen therapy.

Lifestyle Management

Children and young adults with hypogonadism need to treat their chronic problem cautiously because long-term use of androgens can precipitate adverse reactions. If managed early and carefully, males with hypogonadism may be able to conceive a child. Adolescents requiring therapy need to know that testosterone replacement is a far different matter from anabolic steroid use by athletes looking for a competitive edge in their sport. Older patients need to reduce sodium in their diet to avoid CHF while on androgen therapy.

ESTROGENS AND ANTIESTROGENS

Estrogen, like testosterone, is an endogenous hormone with multiple actions. The primary role of estrogen is the maturation and function of the female reproductive system. However, because there are estrogen receptor sites in the bone, cardiovascular system, central nervous system, and gastrointestinal tract, estrogen exerts significant nonreproductive health effects.

The first supplemental estrogens were prescribed for replacement therapy more than 50 years ago. The first marketed estrogens were conjugated equine estrogens (Premarin). Later, estrogens were esterified (80% estrone sulfate; 15% sodium equilin sulfate), and other synthetic and bioidentical formulations have been introduced to the market. Estradiol was synthesized into oral and IM preparations, vaginal creams, transdermal patches, and vaginal rings. Ethinyl forms of estradiol became the primary forms of estrogen used in combination oral contraception (preparations containing both estrogen and progesterone). Ethinyl estradiol has approximately 10 times the potency of estradiol.

Phytoestrogens and estrogen-like herbal preparations have shown some symptomatic improvement for perimenopausal symptoms. Studies have yet to demonstrate that phytoestrogens convey the same osteoporosis prevention benefits of traditional estrogen therapy. Extensive discussion of the use of estrogens, phytoestrogens, and related herbal therapies both for hormonal replacement and for prevention of osteoporosis is found in Chapter 38.

The following section focuses the discussion on estrogen and its related pharmacodynamic/pharmacokinetic principles for prescribing. It should be noted that the use of estrogen-only products is contraindicated in women with an intact uterus. For these women, combination estrogen and progesterone products should be used. An extended discussion regarding the use of estrogen in the treatment of menopause and contraception is presented in Chapters 31 and 38. Information about a few antiestrogens is presented in Box 22-2. The aromastase inhibitors are covered in Chapter 21.

BOX 22–2 ANTIESTROGENS

Although naturally occurring hormones such as progesterone and testosterone may modify the action of **estrogen**, the following discussion focuses on the synthetic estrogen antagonists. Drugs in this class may have limited use by most practitioners in primary care. Clomiphene is used for ovulation stimulation by infertility clinics. **Danazol** is primarily used for endometriosis by gynecologists, and tamoxifen is used for female cancers by oncologists. Monitoring by primary care providers is essential.

Clomiphene (Clomid)

Clomiphene was the first chemical used to initiate ovulation in normogonadotropic, normoprolactinemic, and anovulatory patients. It has also been used as a component in the management of luteal-phase dysfunction, oligo-ovulation, artificial insemination, unexplained infertility, and in vitro fertilization. Although clomiphene has been used for 30 years, it is still a drug that remains in a specialized practice setting. The list of adverse side effects are hot flashes, multiple gestation, visual symptoms, cervical mucus abnormalities, luteal-phase defect, luteinized unruptured follicle syndrome, ovarian cancer, teratogenicity, enlargement of ovarian cysts, and liver disease.

The agonist–antagonist characteristics of clomiphene depend on the hormone climate. Clomiphene initiates ovulation in the presence of high estrogen levels in anovulatory females. It does this as long as other endogenous mechanisms trigger an LH surge and follicle rupture. Clomiphene blocks endogenous estrogen-negative feedback at the level of the hypothalamus. It also elevates estrogen and progesterone levels higher than normal. Its function may even affect the ovary and pituitary glands. Clomiphene also decreases serum insulin-like growth factors and increases SHBG, which assists those infertile women with polycystic ovary (PCO) disease. It has direct antiestrogenic effects on the endometrium and cervical mucus-producing glands. Elevated estrogen levels of women in the reproductive years can override the direct antiestrogen effects on the endometrium and cervical mucus.

This compound is active when taken orally, but little is known about its metabolism. Half of the compound is excreted in the feces within 5 days of administration. The hypothesis is that it is excreted through a slow enterohepatic pathway.

Danazol (Danocrine)

Although the major use of danazol has been to treat endometriosis, it has been employed in severe fibrocystic breast changes, hematological disorders, and idiopathic thrombocytopenic purpura. Danazol must be used with great caution in hepatic dysfunction and carries a Black-Box Warning for this and for the risk of thromboembolism. The list of adverse effects is long, which is, in part, why this drug is not indicated for most primary care settings.

Danazol suppresses the pituitary-ovarian axis, inhibiting the midcycle surge of LH and FSH to suppress ovarian function. It has weak progestational and androgenic properties, as does its major metabolite, ethisterone. Danazol binds to androgen, progesterone, and glucocorticoid receptors and alters androgen metabolism. It does not inhibit aromatase, the enzyme required for estrogen synthesis. It also increases the clearance rate of progesterone by competing with the hormone for binding proteins. Danazol is taken orally and is slowly metabolized by the liver (CYP450 3A4 inhibitor), being excreted primarily in the urine after a 24 hour half-life.

Tamoxifen (Nolvadex)

Tamoxifen is the first agent in the selective estrogen receptor modulator (SERM) class of medications used to treat conditions that respond to adding or withdrawing estrogens. As the class name implies, these agents target selective estrogen receptors, while not stimulating others. It is used primarily as part of adjuvant therapy for breast cancer in patients with estrogen receptor (ER)–positive tumors. Recent studies have demonstrated a reduction in breast cancer in those individuals at high risk for developing the disease within 5 years. In the Gail model, age, family history, medical history of premalignant biopsies, and age at first live birth calculate the patient's absolute risk.

An antiestrogen in mammary tissue, tamoxifen blunts the effect of estrogen and has direct antigrowth activity of its own in the absence of estrogen. The mechanism may be that it blocks estradiol-induced cancer cell growth by altering the local production of growth factors and/or inhibiting the development of the tumor's blood supply. Tamoxifen continues to stimulate estrogen receptors in the endometrial tissue and causes hyperplasia in the postmenopausal woman's endometrium and vagina. Several large-scale, longitudinal trials are under way to evaluate its effectiveness in preventing disease in high-risk women. The results will try to address its potential benefits on bone and lipids while reducing the risk on breast tissue.

This is a nonsteroidal agent that is given orally. Peak plasma levels are reached in a few hours with an initial half-life of 7 to 14 hours. The liver extensively metabolizes tamoxifen, and 65% of the drug is excreted through the gut within 2 weeks.

Raloxifene (Evista)

Raloxifene is also a SERM. Indications initially were for osteoporosis prevention in women who cannot or will not take hormone replacement therapy. Post-marketing studies have shown a positive lipid effect, which may improve cardiovascular disease risk. Results from the recent MORE randomized trial demonstrated a 76% reduced risk of invasive breast cancer

> ## BOX 22–2   ANTIESTROGENS—cont'd
>
> among the women taking raloxifene for osteoporosis. This was attributed to the effect of the drug on ER-positive tumors. This drug can be used only in women past menopause who have never had thromboembolic problems.
>
> Raloxifene is a selective estrogen receptor modulator similar to tamoxifen with different degrees of estrogen agonist or antagonist activity in different tissues. It is an estrogen agonist on bone and an antagonist on breast and uterus. Unlike tamoxifen, it appears to be neutral on the vaginal tissues. A comparison of the beneficial effect on bone mineral density is slightly less than that of estrogen. Whether this bone effect will decrease the incidence of fractures has yet to be proved.
>
> Raloxifene is taken orally without regard to meals, with a 60% absorption rate, but is extensively glucuronidated, and only 2% is bioavailable. It is excreted though the GI tract with a half-life of 32.5 hours.
>
> Raloxifene is not indicated for pediatric patients or for premenopausal women. Concomitant hormone replacement therapy is not recommended.
>
> The primary reasons sited by patients for discontinuing therapy were hot flashes and leg cramps. One reported that these symptoms may have lasted up to 6 months.
>
> Raloxifene is highly bound (95%) to plasma proteins. Close monitoring or alternative treatments should be considered for patients using bile acid sequestrants, thyroid hormones, and warfarin.
>
> One short-term trial indicated that it might be effective for prevention of postmenopausal bone loss without the risk for breast or uterine cancer. It may also have a beneficial effect on lipid metabolism. More studies are needed to validate that the effect on lipids actually confers a cardio-protective effect. This drug may be useful for advance practice nurses in primary care practices, but at this time, the long-term safety effects are not known. Like estrogens, there is some increase in thromboembolic disease, and it is teratogenic.
>
> Patients on concurrent anticoagulant therapy will require frequent INR levels initially during therapy, and dose adjustments of anticoagulants may be needed. Women should also be advised to continue with supplemental calcium and vitamin D for bone health.
>
> Raloxifene can be administered orally without regard to food. Patients need to know that hot flashes can sometimes occur at the beginning of therapy, even in postmenopausal women.
>
> The risk of thromboembolic disease (1%) is the same as it is for estrogen users. Individuals on raloxifene should discontinue use 72 hours prior to surgery to decrease risk of thrombosis and embolism. When traveling, patients should get up and move around every hour to avoid long periods of inactivity.

Pharmacodynamics

Estrogens occur naturally in several forms. The primary sources of estrogen in the normally cycling adult woman is the ovarian follicle, which secretes 70 to 500 mcg of estradiol daily, depending on the phase of the menstrual cycle (*DF & C*, 2010). This estradiol is converted to estrone, which circulates in about equal amounts to the estradiol and to small amounts of estriol. After menopause, most endogenous estrogen is generated from conversion by peripheral tissues of androstenedione, secreted by the adrenal cortex, to estrone.

Effects of estrogen on the reproductive system include:

- Maturation of reproductive organs
- Development of secondary sexual characteristics
- Regulation of the menstrual cycle
- Endometrial regeneration postmenstruation.

Other physical effects of estrogen include:

- Closure of long bones after the pubertal growth spurt
- Maintenance of bone density by decreasing the rate of bone resorption through antagonizing the effects of parathyroid hormone (PTH)
- Maintenance of the normal structure of skin and blood vessels through its actions on the endothelial cells in the arterial walls, including the induction of nitric oxide to facilitate vasodilation and oxygen uptake by cells
- Reduction of the motility of the bowel through its modulation of sympathetic nervous system control over smooth muscle
- Altering of the production and activity of selected proteins, resulting in higher levels of thyroxine-binding globulin, sex-hormone binding globulin, transferrin, and renin substrate
- Enhancing the coagulability of blood by increasing the production of fibrinogen
- Facilitating the loss of intravascular fluid into extracellular space by its action on the renin-angiotensin-aldosterone cycle (retention of sodium and water by the kidney), resulting in edema and decreased extracellular fluid (ECF) volume
- Maintaining the stability of the thermoregulatory center in the brain

Control of estrogen secretion is by the hypothalamus through the pituitary gland. Gonadotropin-releasing hormone (GnRH) from the hypothalamus controls FSH and luteinizing hormone (LH) from the anterior pituitary. FSH and LH stimulate follicular development in the ovary. In the presence of adequate estrogen, LH surge is responsible for ovulation. Primary hormone pathways in the reproductive system are modulated by both negative and positive feedback loops.

Pharmacokinetics

Absorption and Distribution

Estrogens used as therapy are well absorbed in oral, transdermal, and parenteral administration routes. Orally administered estrogen, whether tablet or the newer chewable form, is well absorbed given its lipophilic nature. However, oral estrogens are subject to extensive hepatic first-pass metabolism and require larger doses in order to achieve significant bioavailability. Substitution of an ethinyl group along with the estrogen or estrogen stabilized with piperazine has inhibited the first-pass effect and allows for lower dosing amounts. The current dosing scheme has accounted for bioavailability, and prescribing clinicians are not required to make dosing adjustments. Conjugated estrogens are well absorbed from the GI tract. The tablet releases the drug slowly over several hours.

Compared to oral estradiol, transdermal formulations are metabolized in the skin to a small extent and are not subject to hepatic first pass. This results in a therapeutic serum level of estradiol with lower circulating levels of estrone and its metabolites so that smaller total doses are required. An additional benefit of transdermal patches is that they release a constant stream of hormone, providing a steady serum hormone level. Topical applications given vaginally for local impact can still be sufficient to cause systemic effects. Topical delivery formulations include creams, hormone-impregnated rings, and tablets. Vaginal absorption varies among women and treatment will require titration to achieve symptom control and limit unnecessary estrogen exposure. More of the hormone is absorbed if the degree of atrophy is great in the surrounding tissues.

Parenteral formulations that have an oil-based preparation have slow absorption with a prolonged duration of action. A single dose of IM estradiol valerate or estradiol cypionate is absorbed over several weeks.

The majority of estradiol estrogen (69% to 80%) binds strongly to the SHBG, and another 18% to 30% binds to albumin with less affinity. The remaining 1% to 2% of the free and unbound fraction is physiologically active and is responsible for the observed effects of estrogen. The distribution of exogenous forms of estrogen is similar to that of endogenous forms.

Metabolism and Excretion

The liver converts estradiol into less potent metabolites, estrone and estriol, which are excreted in the bile. A significant portion undergoes enterohepatic recirculation in the liver, resulting in undesirable side effects such as increased clotting factors and plasma renin substrate. The water-soluble forms that result from this recirculation are acidic, favoring renal excretion. Estrogen formulations that are administered by non-oral routes are not subject to first-pass metabolism, but they still undergo significant hepatic uptake, metabolism, and enterohepatic recycling.

Onset, Peak, and Duration

Naturally occurring estradiol levels vary during the menstrual cycle. Supplemental estrogen has a rapid onset of action ranging from less than an hour to 3 hours, depending on the route of administration. Peak concentrations occur within the first days of use, and patients generally report symptom improvement within the first few days of therapy. The duration of action depends on the route of delivery and can range from several hours to a few days. The majority of patients report symptoms of estrogen deficiency after missing several days of therapy. Table 22-4 presents the pharmacokinetics of estrogens.

Pharmacotherapeutics

Estrogens have been synthesized for several decades and are used in the primary care setting for replacement after oophorectomy and in natural menopause for treatment of hot flashes, vaginal atrophy, and irregular menstrual bleeding. The first oral contraceptive pills contained only progesterone. However, these early progesterone-only pills were associated with significant breakthrough bleeding. To combat that problem, estrogen was added to contraceptive pills in the 1960s. These early combined progesterone/estrogen pills used a much higher dose of estrogen than is currently used in combined contraceptive pills. The dose of estrogen needed for contraception is higher than the dosage needed for replacement therapy. The potency ratio of replacement estrogens to contraception estrogens is approximately 1:10.

Chapter 38 goes into greater detail about replacement estrogens, and Chapter 31 deals with estrogen use as a contraceptive. Many advance practice nurses commonly prescribe oral contraceptives for a noncontraceptive use in the treatment of dysmenorrhea, cycle control, and acne management and for other secondary benefits. Oral contraceptives may be also prescribed to treat amenorrhea and hirsutism associated with polycystic ovary disease.

Precautions and Contraindications

There are absolute and relative contraindications that clinicians must consider when initiating estrogen therapy. Absolute contraindications include current or prior history of an estrogen-dependent cancer, current pregnancy, undiagnosed dysfunctional uterine bleeding, deep vein thromboembolism, arterial thromboemboli within the prior year, clotting disorders, and severe hepatic disease. Relative contraindications require added discussion with patients regarding the risk of estrogen therapy and its perceived benefits. Relative contraindications include cardiovascular disease, uncontrolled hypertension, diabetes mellitus, gallbladder disease, obesity, endometriosis, seizure disorder, and migraine. Women who experience migraine with aura are at increased risk for stroke and should not be prescribed estrogen. Women with an intact uterus should not be prescribed unopposed estrogen because of the risk of endometrial hyperplasia and endometrial cancer.

There is not a significant risk of non-estrogen–dependent breast cancer in the short-term use of oral contraceptives.

Table 22–4 Pharmacokinetics: Estrogens and Antiestrogens

Drug	Site of Metabolism	Active Metabolism	Half-Life (in hours by formulation and metabolites in individuals with normal renal function)	Elimination
Estrogens				
Ethinyl estradiol	Liver	Estradiol Estrone	1–2 4–18	Urine Feces
Conjugated estrogens	Liver	Estradiol Estrone	1–2 4–18	Urine
Estradiol transdermal system	Skin/liver	Estrone	1–4 4–18 estrone	Urine
Estradiol vaginal ring	Vagina/liver	Estrone	1–2	Unchanged: NA
Antiestrogens				
Clomiphene	NA	NA	5–7 d	42.4% feces; 7.8% in urine
Danazol	Liver	NA	24	NA
Tamoxifen	Liver	N-desmethyl-tamoxifen	5–7 d 14 d (metabolite)	Primarily in feces
Raloxifene	Liver		32.5	Primarily in feces
Ospemifene (Osphena B)	Liver	4-hydroxyospemifene	26	Feces 75% and urine 7%

NA = not available.

But, with every 10-year increment of use, there is a 14% rise in breast cancer risk (Zhu, Lei, Feng, & Wang, 2012).

Estrogens have been implicated in the risk of endometrial cancer. The rates have increased dramatically since 1969 even though the dose of estrogen for both contraception and replacement has significantly decreased. At the same time, the survival rate of woman with endometrial cancers has been higher in estrogen users than in those who do not use estrogen—perhaps in part due to early detection, as women on estrogen are required to have routine follow-up care.

"Natural" and synthetic estrogens have the same risks for users. The absolute and relative contraindications for estrogen use are looked at in more detail in Chapters 31 and 38, with special emphasis on clinical trials such as the Women's Health Initiative (WHI). The WHI findings have had a considerable impact on the prescribing patterns of clinicians and the perception of hormone therapy by the public. It is critical that prescribers understand the current literature and can adequately evaluate the risks versus the benefits of estrogen-containing therapies and partner with patients to determine the best course of treatment.

Although it was thought that estrogen replacement therapy (ERT) and estrogen plus progestin therapy (HRT) would provide some protection against coronary heart disease (CHD), the results of several trials from the PEPI trials (Writing Group of the PEPI Trial, 1996) to the WHI (Writing Group for the Women's Health Initiative Investigators, 2002) have shown that not only does HRT not provide protection, it actually causes some increase in morbidity and mortality

related to CHD. The WHI study revealed a higher incidence of CHD, stroke, and thromboemboli both in women taking estrogen only or HRT therapy.

Increased risk for thromboembolic events has been a long-standing concern related to hormone replacement, whether estrogen alone or in combination with progestins. The WHI found significantly increased risk for stroke in postmenopausal women on both ERT and HRT. For HRT, the risk was apparent in each decade of age, but for ERT the risk appeared to emerge after age 60 years (Langer, 2005). The risk for venous thromboembolic disease, including pulmonary embolism, was doubled in women in the HRT arm of the study, with no difference based on age. There was a nonsignificant increase by about one-third with ERT alone (Anderson et al, 2004). There is some evidence to suggest that the timing of initiation of ERT and HRT may play a role in the CHD and atherosclerosis. The highest risk for cardiovascular events occurs within the first year of therapy until later ages.

Several design limitations have been identified in the WHI trial that deserve consideration when prescribing ERT and HRT. The majority of women in the WHI study were older (mean age of 63 years), had been menopausal for almost a decade, and were not experiencing menopausal symptoms, and many of the participants had comorbidities of obesity and cardiovascular disease. Findings from the Women's HOPE (Health, Osteoporosis, Progestin, Estrogen) study, along with age-adjusted meta-analysis, suggest that lower doses of estrogen and progesterone may not raise the risk of CVD and that women who initiate treatment at the time of

menopause may not be at as great a risk for heart disease–related complications as women who started HRT at an older age (greater than age 65 years) and more distant from menopause (greater than 10 years) (Warren, 2010).

Estrogens are Pregnancy Category X. Use of estrogens during pregnancy is contraindicated because of the high rate of teratogenicity in male and female offspring. In the past, strong estrogens (DES) were used empirically to treat women who habitually spontaneously aborted in an effort to help them retain a subsequent pregnancy. Time, teratogenic outcomes, and research have shown there is no benefit in using estrogens for preventing miscarriages. The risks to the developing fetus have become understood to be mutagenic in terms of transfer of genetic abnormal tendencies toward uterine abnormalities and vaginal cancer in subsequent generations.

These precautions for any therapy that contains estrogen are the same regardless of the indication. The exception is that ethinyl estradiol is contraindicated in patients who smoke and are older than 35 years. Smoking patients may use postmenopausal hormone replacement therapy (ERT/HRT) due to the lower dosages of hormone; however, the risk of clotting and cardiovascular events remains higher than for nonsmokers. The interaction of estrogens and smoking showing dose-related morbidity and mortality has been well documented.

Adverse Drug Reactions

Most of the adverse reactions to estrogens are dose-related. As a result, the majority of adverse effects are seen in patients using oral contraceptives. Some of the most concerning adverse reactions with estrogen are cardiovascular and hematological—myocardial infarction, hypertension, alteration in clotting factors, and thromboembolism. Unopposed estrogen use in women with an intact uterus increases the risk of abnormal uterine bleeding, endometrial hyperplasia, and gynecological cancers and should not be prescribed. Women using estrogen therapy need adequate screening for risks that may predispose them to greater risk of adverse events, and should receive education on the risks and possible warning symptoms associated with these events.

Additional adverse reactions are discussed in further detail in subsequent chapters for managing migraine headaches, mood changes, eye discomfort, skin pigmentation, breast changes, weight gain, change in vaginal secretion, and leg discomforts. The adverse reactions more common with menopausal estrogens are elevation of systemic blood pressure, gallbladder disease, and irregular bleeding. Women who have estrogen-dependent tumors may have worsening of their cancer while on any form of estrogen therapy; therefore, it is not advised for women with a current cancer or a history of estrogen-dependent cancer to use estrogen therapies.

Drug Interactions

Estrogens can interfere with laboratory measurements of endocrine and liver function tests and thyroid-binding globulin; however, in most cases it does not. In addition, the prothrombin time and factors VII, VIII, IX, and X show increased levels in patients taking estrogens at the time of testing. Women may experience impaired glucose tolerance and increased triglycerides when oral estrogens are administered. The most common drug interactions are with anticoagulants, tricyclic antidepressants, barbiturates, antituberculosis drugs, corticosteroids, seizure control medication, and drugs for spasticity. Table 22-5 presents drug interactions.

Table 22–5 ⚏ **Common Drug Interactions: Estrogens and Antiestrogens**

Drug	Interacting Drug	Possible Effect	Implications
Estrogens	Oral anticoagulants	Estrogens increase the risk of thromboembolitic events	The use of estrogen-containing products is contraindicated in individuals at high risk for coagulopathy
	Fosamprenavir	Alter efficacy of both agents; alter hepatic metabolism	Combination is contraindicated. Use nonhormonal contraception.
	Benzodiazepines, rifampin	Barbiturates, rifampin, and other agents that induce hepatic microsomal enzymes with concomitant estrogens may produce lower estrogen levels than expected	Use a backup birth control method
	Corticosteroids	Estrogen coadministration may reduce the clearance and increase the elimination half-life of corticosteroids	It may be necessary to lower steroid dosage if there is an increase in adverse effects
	Dantrolene	Hepatotoxicity occurred more often in women >35 yr receiving dantrolene and estrogen	Check liver function tests after first 4 wk of therapy in women >35 yr
	Anticonvulsants	Breakthrough bleeding, spotting, and pregnancy have resulted when these medications were used concurrently. A loss of seizure control has also been suggested and may be due to fluid retention	Check blood levels of seizure medications after first 2 wk of therapy. Using a backup birth control method or switching to an IUD is preferred.

Table 22–5 Common Drug Interactions: Estrogens and Antiestrogens—cont'd

Drug	Interacting Drug	Possible Effect	Implications
Antiestrogens			
Clomiphene	Bromsulphalein (BSP) lab studies	BSP retention of >5% reported in 10%–20% of patients; retention is usually minimal but elevated during prolonged clomiphene administration or with apparently unrelated liver disease. In some, preexisting BSP, retention decreased even though clomiphene was continued. Other liver function tests usually normal.	Use other liver function tests when patient is taking clomiphene
Danazol	Insulin and diabetic agents	Insulin requirements may increase in patients with diabetes; abnormal glucose tolerance tests may be seen	More frequent glucose monitoring; possible decreased dosing of antidiabetic agents
	Warfarin	Prolongation of PT reported with concomitant use	Measure PT more frequently
	Amiodarone, clarithromycins, erythromycins	QT prolongation, cardiac arrhythmias	Avoid combination/select alternative agents
	Statin agents	Inhibits metabolism of statin agent, increases risk of rhabdomyolysis	Avoid combination/select alternative agents
Tamoxifen	Anticoagulants	Hypoprothrombinemic effect may be increased by concurrent tamoxifen administration	Monitor PT more frequently. Consider a nonhormonal, non-SERM alternative
	Medications that utilize the CYPP450 3A4, 2C9, 2D6 pathways	Altered metabolism	Evaluate each agent individually
	Lab studies	T_4 elevations occurred in a few postmenopausal patients but not accompanied by clinical hyperthyroidism	Measure TSH instead of T_4
Raloxifene	Bile-acid sequestrants (Cholestyramine)	Raloxifene absorption and enterohepatic cycling reduced 60%	Avoid combination. Consider statins to decrease cholesterol
	Warfarin	In single-dose studies, 10% decreases in PT have been observed	Monitor PT closely, or consider alternative agent to raloxifene
	Thyroid agents	Combination may cause hypothyroidism	Separate dosing by at least 12 hours; closely monitor TSH at initiation of therapy—may require increased dose of thyroid hormones while using raloxifene
Conjugated estrogens + bazedoxifene (Duavee)	No studies conducted—see estrogen. For bazedoxifene: Rifampin, phenobarb, carbamazepine, phenytoin	No known CYP interactions with bazedoxifene. UGT interactions increase metabolism of bazadoxifene	May need additional uterine protection/monitoring
Osepemifene (Osphena)	Estrogen, fluconazole, ketoconazole	May increase SE	
	Rifampin	May decrease osepemifene effect	

UGT = uridine diphosphate glucuronosyltransferase in the gut.

Clinical Use and Dosing

Relief of Perimenopausal and Postmenopausal Symptoms

Relief of menopausal vasomotor symptoms can be dramatic after the initiation of hormonal therapy. The lowest effective dose of estrogen should be used for the shortest duration possible. Estrogen is available in various formulations, including estrogens derived from animal, plant, and synthetic sources. For women who have no objections to estrogens from animal sources, conjugated equine estrogen (Premarin) is available in doses from 0.3 mg to 2.5 mg. Suppression of

hot flashes has been shown to be best at 0.625 mg, followed by 0.45 mg and 0.3 mg/d (Liu, 2004). Studies reported by Liu indicate that vasomotor symptoms begin to decrease by the second week of therapy and reach maximal effect by the eighth week of therapy. Dosage increases should not occur, however, until at least a 6 to 8 week interval to give the drug time to reach maximal effect at that dose.

Micronized estradiol (Estrace, Gynodiol) is the only bioidentical estrogen-alone product that is available in pill form. It is available in 0.5 mg to 2 mg doses. Vasomotor suppression is found at 1 mg and 2 mg doses. The typical regimen is 1 mg taken daily. The lower dose (0.5 mg) has been used for osteoporosis prevention but is less useful for vasomotor symptom relief. The bisphosphonates should be considered if treatment of osteoporosis is the primary goal of therapy. They are only used together in extreme cases where both are required for full bone effect.

For women who prefer estrogens derived from plant sources, estrone-based drugs are available. In a randomized, blinded, four-arm trial conducted by Sood and associates, compounded hormones were associated with lower and inconsistent levels of serum estrogen in subjects compared to a standard estradiol patch or oral doses. They also determined that further studies were needed to find comparable doses (Sood et al, 2013). Synthetic conjugated estrogen-A (Cenestin) is available in doses from 0.3 mg to 1.25 mg. Liu (2004) found that the majority (77%) of women randomized to Cenestin required a total daily dose of 1.25 mg to relieve vasomotor symptoms, whereas the remaining 23% required 0.625 mg or less. By week 8, the vasomotor symptoms were significantly decreased. Synthetic conjugated estrogen-B (Enjuvia) is available in doses of 0.3 mg to 1.25 mg, with the lower dose producing relief in many women. Estropipate (Ogen, Ortho-EST) is also derived from plant sources and is available in 0.75 to 6 mg tablets. Following the rule to use the lowest dose to control symptoms, the dosing regimen should start at 0.75 mg.

Findings from the WHI, Women's HOPE study, and multiple meta-analyses suggest that therapy to treat the vasomotor and urogenital symptoms associated with menopause should be started early in menopause in an effort to reduce adverse cardiovascular events (Warren, 2010). When initiating therapy, begin with lowest starting dose of the selected estrogen product. Clinicians may wish to initiate an even slower taper or defer to a specialist for those women who have relative contraindications or precautions to estrogen therapy and who still elect to proceed with estrogen therapy. One proposed example is to use small doses (0.3 mg) of conjugated estrogens every other day for 2 months. Then, gradually increase the estrogens to daily use for another 2 months. If symptoms such as bleeding or breast pain do not occur, increase the estrogen up to 0.625 mg daily. Some women may need only the lower estrogen dosages to adequately control their symptoms as long as they have an adequate diet. Remember, estrogen must be partnered with progesterone to prevent endometrial hyperplasia and cancer in women with an intact uterus. ERT and HRT should be reevaluated on an annual basis, with the goal of utilizing therapy for 5 or fewer years.

Complementary and alternative therapies include phytoestrogens, botanicals, and herbs. These alternatives have varying degrees of effectiveness and research support.

Prevention and Management of Vulvovaginal Atrophy and Dryness

A decline in estrogen causes the vaginal mucosa and vulvar skin to become thin and atrophic. The result is discomfort, itching, dyspareunia, and increased cases of vaginitis. Low-dose oral ERT with estrogen from plant or animal sources has been shown to decrease vaginal pH, thus reducing vaginal infections. It also thickens and revascularizes the vaginal epithelium, increases the number of superficial cells, and reverses vaginal atrophy (Tan, Bradshaw, & Carr, 2012). Vaginal estrogen also produces these positive effects, and the changes begin in as short a time frame as 2 weeks. Topical creams and intravaginal delivery of estrogen are equally as efficacious as oral agents in the management of vulvovaginal symptoms.

An option for dryness and dyspareunia is an estrogen agonist-antagonist ospemifene (Osphena). It is technically a SERM medication, but does not have the bone health indication. The agonist action of this molecule is akin to estrogen, but at tissue level, so it increases the thickness moisture of the vaginal canal. The package insert has many similar adverse effects to estrogen such as increasing the risk of blood clots, hot flashes, and uterine cancer (though no cases have been reported). It has only weak effect on the uterus and breast, but the FDA requires listing of all the major estrogen risks without strong data to prove otherwise. Its impact on breast cancer risk is unknown, but considered weak. Therefore, this is used for the shortest possible time to overcome issues of moderate to severe painful intercourse. Because it is a newly released medication, the post-marketing data is not available to provide any reliable information on which to base a rationale drug selection. The known pharmacokinetic and drug interactions are included in the chapter tables for reference upon which to build future understanding of this medication. The starting dose is 60 mg daily. No dosage adjustments are needed in renal patients. Contraindications include prior blood clots, active thromboembolic disease or a family history of such, known estrogen-dependent hyperplasia or neoplasia, and abnormal genital bleeding.

Reduced Risk for Colon Cancer

Colorectal cancer is the third most common cancer in women in the United States and the third most common cause of cancer death in women (Thorneycroft, 2004). Because this cancer is also associated with aging, it clearly is a cancer to be considered concurrently with menopause. ERT and HRT have been shown to reduce the risk of colon cancer; however, the use of estrogen-containing products for colon cancer risk reduction alone is not approved.

Prevention and Treatment of Osteoporosis

Estrogen is associated with bone formation and has osteoprotective benefits. Until the WHI report, estrogen had been used solely for both prevention and treatment of osteoporosis. Estrogens prevent osteoporosis by reducing the bone-resorbing

action of PTH. Estrogen receptors have been found in bone, which validates the hypothesis that estrogen may have direct effects on bone remodeling. Studies have shown that there is a direct correlation between the rate of bone loss in menopausal women and estradiol levels (Youngkin, Davis, Schaldewald, & Juve, 2013). Bone resorption has also been shown to be highest in the first postmenopausal year. Bone density declines between 1% and 4% in the first several years after menopause and then stabilizes to about 1% per year. Women in the immediate postmenopausal years are the ones who are most in need of protection from osteoporosis.

Chapter 38 looks at the use of estrogen alone and in combination with other drugs in the treatment of osteoporosis. ERT and HRT use can significantly slow the natural progression of bone loss in postmenopausal women. Numerous studies have shown significant improvement in bone mineral density (BMD) and the reduction of hip and vertebral fractures in women using ERT and HRT; however, current practice cautions against selecting ERT and HRT exclusively for the prevention of osteoporosis. The WHI findings that ERT and HRT raised the risk for coronary events, stroke, pulmonary emboli, and breast cancer in women who took a combination of estrogen and progesterone have led leading national women's health organizations, the FDA, and U.S. Preventative Services Task Force to encourage clinicians to consider alternative options for osteoporosis prevention and treatment when women are not experiencing moderate to severe menopausal symptoms. Balancing the risks and benefits of estrogen therapy and the availability of other drugs to prevent and treat osteoporosis should be discussed with women, who can then make an intelligent decision about whether to use estrogen. Dosing for osteoporosis may not work for menopausal symptoms. The long-term efficacy of taking estrogen in lower doses for prevention of osteoporosis remains unknown at this time. The use of SERM medications for this indication is covered in Chapter 38.

Contraception

There are currently two formulations of estrogen available in combination contraceptive preparations, ethinyl estradiol (EE) and mestranol. Mestranol is the weaker of the two preparations and must be metabolized into EE before it is able to bind with estrogen receptors. Fifty mcg of mestranol is equivalent to 35 mcg of EE. EE is the estrogen used in the vast majority of hormonal contraceptive formulations in wide use today with most preparations containing between 20 and 35 mcg of EE. The estrogen component of hormonal contraception improves efficacy by suppressing FSH release and therefore development of a dominant follicle. Estrogen also adds to cycle control, decreasing the irregular bleeding patterns commonly found with progestin-only methods.

Combined oral contraceptives come in three main formulations. The most common formulation is a monophasic combined oral contraceptive (COC) that contains the same dose of hormone in each active pill. Biphasic pills alter the hormone dose in the middle of the cycle, and triphasic pills alter the estrogen dose, the progesterone dose, or both each week during a 28 day-dose pack. Additionally, there are progesterone-only contraceptives available; these are discussed later in this chapter. Chapter 31 summarizes the brand-name and synthetic hormone formulas commonly available.

The theoretical effectiveness of prevention of pregnancy with COCs is 99% or greater. Patients who receive education on the proper use of COCs have lower discontinuation rates and therefore fewer unwanted pregnancies. Additionally, clinicians should provide patients with information on emergency hormonal contraception and the use of a backup method such as spermicide and condoms.

Because the different COCs have similar effectiveness and are well tolerated, choosing among them may seem difficult. Although there are some advantages to selecting one type of progesterone option over another, for the majority of patients it is generally best to use a drug that has the lowest estrogen dose while still offering cycle control. Thin teens can frequently use the low-estrogen pills; women typically need a higher dose. Issues of acne breakout are dealt with by reducing the amount of androgen in the formulation selected.

Off-Label Uses

COCs have been used to treat conditions for which a formal FDA approval has not been awarded. Many of these off-label uses have considerable literature and research to support clinical use. Some pharmaceutical companies have sought FDA approval for specific indications for marketing purposes (such as acne management). Prescribers must disclose to patients when agents are being used for off-label purposes, thoroughly review the risks and benefits, and obtain informed consent. Table 22-6 presents the dosage schedule of estrogens other than those used for contraception.

Rational Drug Selection

Short-Acting Versus Long-Acting

A consistent and expected level of estrogen is maintained with same-time daily dosing. Some women may have problems remembering or difficulty in swallowing the oral form, so intravaginal, transdermal, or parenteral administration is preferable. Giving injections every 3 to 4 weeks is uncomfortable. The daily levels may vary, depending on the circulation in the muscle into which the dose is injected.

Formulation

Oral formulations of estrogen are the most commonly selected formulation by patients and prescribers, but there may be reasons for selecting another formulation. Most estrogens are available in transdermal formulation. The major advantage of transdermal formulations is their once- or twice-weekly application. A disadvantage is the incidence of skin irritation that occurs in 20% to 40% of users (Wysocki & Alexander, 2005). Vaginal instillation is possible for patients unable to tolerate oral formulations or for severe urethral and urogenital atrophy, as in vulvar dystrophies and dyspareunia. Low-dose vaginal estrogens (with the ring or cream) are not associated with as much risk of endometrial hyperplasia as are the oral forms. The estradiol-releasing

Table 22–6 ⚕ Dosage Schedule: Estrogens and Antiestrogens

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
Estrogens				
	Moderate to severe vasomotor symptoms associated with menopause			Attempts to discontinue should be made at 3–6 mo intervals
Estrogen (Conjugated A/Synthetic) (Cenestin)		Tablet, oral: 0.3 mg, 0.45 mg, 0.625 mg, 0.9 mg, 1.25 mg	0.45 mg/d	May be titrated up to 1.25 mg/d
Esterified estrogen/ methyltestosterone (Covaryx, Covaryx HS, EEMT, EEMT HS)		Tablet, oral: Covaryx 1.25/2.5 mg Covaryx HS 0.625/1.25 mg EEMT 1.25/2.5 mg EEMT HS 0.625/1.25 mg	0.625 mg/d 3 wk on and 1 wk off	0.625–1.25 mg/d 3 wk on and 1 wk off
Estrogen (Conjugated B/Synthetic) (Enjuvia)		Tablet, oral: 0.3 mg, 0.45 mg, 0.625 mg, 0.9 mg, 1.25 mg	0.3 mg/d	May titrate up to 1.25 mg/d
Estrogen (Esterfied) (Menest)		Tablet, oral: 0.3 mg, 0.625 mg, 1.25 mg, 2.5 mg	1.25 mg/d 3 wk on and 1 wk off	1.25 mg/d 3 wk on and 1 wk off
Estrogen (Conjugated/ Equine) (Premarin)		Tablet, oral: 0.3 mg, 0.45 mg, Tablet, oral: 0.625 mg, 0.9 mg, 1.25 mg	0.3 mg/d Cyclically or daily	0.3–1.25 mg Adjust based on patient response, lowest dose to control symptoms
Estrogen (Conjugated/ Equine) and Medroxyprogesterone (Premphase, Prempro)		Premphase (pak) Conjugated estrogens 0.625 mg (14/tab) and conjugated estrogen 0.625 mg/medroxyprogesterone 5 mg (14/tab) Prempro (conjugated estrogens/medroxyprogesterone) 0.3/1.5 mg (28 tab), 0.45/1.5 mg (28 tab), 0.625/2.5 mg (28 tab), 0.625/5 mg (28 tab)	Start estrogen at 0.625 mg daily	Adjust per symptoms
	Female hypogonadism			
(Menest)		Tablet, oral: 0.3 mg, 0.625 mg, 1.25 mg, 2.5 mg	2.5 mg/d 3 wk on and 1 wk off	2.5–7.5 mg/d 3 wk on and 1 wk off
(Premarin)		Tablet, oral: 0.625 mg, 0.9 mg, 1.25 mg	0.3 mg/d cyclically	0.3–0.625mg/d
	Breast cancer Palliation therapy			
(Menest)		Tablet, oral: 0.3 mg, 0.625 mg, 1.25 mg, 2.5 mg	Males and postmenopausal females 10 mg 3 times/d for at least 3 mo	10 mg 3 times/d for at least 3 mo
(Premarin)		Tablet, oral: 0.625 mg, 0.9 mg, 1.25 mg	10 mg 3 times/d for at least 3 mo	10 mg 3 times/d for at least 3 mo
	Prostate cancer Palliation therapy			

Table 22–6 ⊗ Dosage Schedule: Estrogens and Antiestrogens—cont'd

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
(Menest)		Tablet, oral: 0.3 mg, 0.625 mg, 1.25 mg, 2.5 mg	Advanced cancer 1.25 mg 3 times/d	1.25–2.5 mg 3 times/d
(Premarin)		Tablet, oral: 0.625 mg, 0.9 mg, 1.25 mg	1.25 mg 3 times/d	1.25–2.5 mg 3 times/d
	Vaginal dryness/ vulvar and vaginal atrophy associated with menopause			
(Enjuvia)		Tablet, oral: 0.3 mg, 0.45 mg, 0.625 mg, 0.9 mg, 1.25 mg	0.3 mg/d	0.3 mg/d
(Estrace)		Vaginal cream: 0.1 mg/g (42.5 g)	2–4 g/d for 1–2 wk; gradually reduce to ½ the initial dose for 1–2 wk	1 g 1–3 times/wk
(Estring)		Vaginal ring: 2 mg/ring	2 mg	Ring in place for 90 days
(Premarin)		Tablet, oral: 0.625 mg, 0.9 mg, 1.25 mg	0.625 mg daily	Adjust based on patient's response
(Vagifem)		Vaginal tablet: 10 mcg/tablet	1 tablet once daily for 2 weeks	1 tablet twice weekly
	Female castration; primary ovarian failure			
(Menest)		Tablet, oral: 0.3 mg, 0.625 mg, 1.25 mg, 2.5 mg	1.25 mg/d 3 weeks on and 1 week off	Adjust dosage upward or downward according to symptoms; maintenance is lowest level that will provide effective control
(Premarin)		Tablet, oral: 0.625 mg, 0.9 mg, 1.25 mg	1.25 mg/d cyclically	Adjust dosage upward or downward according to symptoms; maintenance is lowest level that will provide effective control
(Premarin)	Osteoporosis	0.625 mg, 0.9 mg, 1.25 mg	0.3 mg/d cyclically or daily	Adjust based on bone mineral density
Antiestrogens				
Clomiphene (Clomid, Serophene)	Treatment of ovulary failure in patients desiring pregnancy whose partners are potent and fertile	Clomid: 50 mg Serophen: 50 mg Generic: 50 mg	50 mg/day for 5 days Begin 5th day of cycle	Adjust as needed; max dose 100 mg. Lower dose of 12.5–25 mg for women sensitive to med or who consistently develop large ovarian cysts
Danazol (Danazol)	Endometriosis	Tablet, oral: 50 mg, 100 mg, 200 mg Generic available	Mild disease: 200–400 mg/d in 2 divided doses Moderate to severe disease: 800 mg/d in 2 divided doses	Dosage should be individualized. Continue therapy for 3–6 mo (up to 9 mo)

Continued

Table 22–6 ⊗ **Dosage Schedule: Estrogens and Antiestrogens—cont'd**

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
	Fibrotic breast disease		100–400 mg/d in 2 divided doses	Therapy based on symptoms: Pain and tenderness to 2–3 mo Nodularity 4–6 mo
	Hereditary angioedema (males/females)		200 mg 2–3 times/d	After favorable response, decrease by 50% or less for 1–3 mo For acute attack, increase dose to 200 mg/d
Tamoxifen (Soltamox)	Breast cancer (females) Metastatic (males and females) Ductal carcinoma in situ (DCIS) (females) Breast cancer risk reduction Endometrial carcinoma, recurrent, metastatic, or high-risk (unlabeled use) Induction of ovulation (unlabeled use) Ovarian cancer, advanced or recurrent (unlabeled use) Paget's disease of the breast (risk reduction; with DCIS or without associated cancer)	Solution, oral: 10 mg/5 mL (150 mL) Generic Tablet, oral: 10 mg, 20 mg	Adjuvant therapy 20 mg/d for 5 yr ER-positive up to 10 yr 20–40 mg/d in divided dose if >20 mg 20 mg/day for 5 yr 20 mg/d for 5 yr Monotherapy: 20 mg twice daily until disease progression Combination therapy: 20 mg twice daily for 3 wk 20 mg/d for 5 days 20 mg twice daily 20 mg/d for 5 yr	20 mg/d No clinical benefit demonstrated with doses above 20 mg daily 20 mg/d 20 mg/d 20 mg/twice daily 20-80 mg/d 20 mg twice daily 20 mg/day
Raloxifene (Evista)	Prevention of osteoporosis in postmenopausal women Invasive breast cancer risk reduction (females)	Tablet, oral: 60 mg	60 mg/d 60 mg/d for 5 yr	60 mg/d 60 mg/d
Anastrazole (Armidex)	Postmenopausal breast cancer inhibition	1 mg tablet	1 mg ; no change for most renal patients or elders	Usually taken for 5 yr after tamoxifen, but can be first line medication as well and extend beyond 5 yr of use.
Letrozole (Femara	Postmenopausal breast cancer inhibition	2.5 mg tablets	2.5 mg; no renal dosing or change for elders	As above
Exemestabe (Aromasin)	Postmenopausal breast cancer inhibition	25 mg tablets	25 mg	As above
Ospemifene (Osphena)	Vaginal atrophy, dyspareunia	60 mg tablets	60 mg for moderate or severe issues	
Bazedoxifene & conjugated estrogen (Duavee)	Hot flashes and osteoporosis	20 mg–0.45 mg tablets	One tablet daily for both indications	Use for shortest duration possible to minimize estrogen related risks

vaginal ring/string also has a positive effect on urethral and vaginal atrophy symptoms. Estrace is a bioidentical vaginal cream approved for the treatment of vaginal and urinary symptoms.

The usual doses for all the creams include nightly application. Topical application with vaginal rings and vaginal tablets may be preferred by patients because they may be perceived as easier to administer and less "messy" than the creams. The differences between the oral versus topical formulations are 2-fold: (1) the oral formulations retain the positive effects of ERT that accrue because of liver metabolism and the topical formulations lose this benefit; and (2) the total amount of estrogen to which the body is exposed is less with the topical formulations, which may be a consideration for women who have risk factor concerns with ERT. A dose of 25 mcg per day of estradiol administered vaginally does not significantly raise blood levels of estrogen, especially if vaginal cornification has already taken place. Studies reported by Thorneycroft (2004) found no evidence of increased risk of CHD, breast cancer, or endometrial cancer with the use of vaginal ERT. Low-dose vaginal estrogens have not been shown to be associated with endometrial hyperplasia; however, decades of application have not been studied (Tan et al, 2012).

Cost

The pricing of oral estrogen and estrogen-combination products can vary significantly. Because oral preparations have been around the longest, several generic versions are available and are the least expensive. Several vaginal creams are also available in generic versions. The latest products and brand-name products tend to be the most expensive. Transdermal preparations, the vaginal ring, and prepackaged punch-out cards or dial packs for convenience are generally priced higher. Cost may be a determining factor in product selection for women on Medicare, those who have fixed incomes, or those who have multiple medications to purchase.

Route of Administration

As previously discussed, the route of administration affects hepatic metabolism of estrogen and can impact potential side effects and risks. Beyond these considerations, patient preference and affordability determine route selection. Oral formulations are typically preferred by patients and are easy for most patients to administer at mealtime or bedtime. A small percentage of women experience elevated triglycerides with oral estrogens; these patients can avoid liver metabolism of the medication through transdermal absorption. Transdermal patches allow patients the freedom of less frequent dosing and may be preferred by caregivers who assist patients with limited dexterity and an inability to swallow. Vaginal application reduces liver metabolism. It is systemically absorbed less after the initial vaginal atrophy is treated. Estrogen levels are not as high after the first 6 months of therapy. As some older women and the disabled lack the finger dexterity to fill an applicator and instill the cream, clinicians should assess the ability of patients to use this route of administration. Table 22-6 presents the available dosage forms of estrogen.

Monitoring

Oral contraception, ERT, and HRT are chronic medications that are taken for months or years. All patients should have their blood pressure monitored. If the patient has a coexisting medical condition, monitoring of adverse effects is necessary (see Chaps. 31 and 38). Schedule 1-month, 3-month, 6-month, or annual evaluation appointments, depending on the degree of illness or the severity of symptoms. Patient education regarding the symptoms and reporting of potentially worrisome adverse effects are necessary at the institution of therapy. Drawing baseline blood tests, including a lipid panel, and ordering mammograms prior to prescribing ERT or HRT are recommended. Additionally, women should have annual mammograms, pelvic evaluations, and cardiovascular assessments while on ERT or HRT. Patients with diabetes need to perform daily blood glucose measurements until stable on ERT or HRT because adjustment to diabetes agents may be needed. Patients with hypertension need monthly blood pressure readings. Patients with seizure disorders will need initial increased frequency of laboratory monitoring of seizure medications and then every 6 months because estrogen therapy may alter drug metabolism, affecting therapeutic levels of antiepileptic medications.

PATIENT EDUCATION

Administration

Patients taking oral hormonal contraceptives and HRT need to take the drug daily at about the same time to avoid breakthrough bleeding. Specific patient education regarding anticipated transient and nuisance side effects at the time of initiating therapy will improve adherence to therapy. Women may experience transient adverse effects such as mild nausea and breast tenderness or midcycle spotting during the first 2 months of therapy. Sometimes taking the medication at bedtime solves the nausea problem. Advise the patient to seek follow-up to discuss alternatives to oral therapy if nausea or vomiting or other issues make oral therapy unsuccessful. Advise the patient to rotate the application sites for transdermal patches and to avoid applying patches to breast tissue.

Devices to improve adherence to a daily regimen include pill organizer boxes and ways of making the drug part of the daily routine. For example, some women find it easier to put the birth control packet by their toothbrush or alarm clock or set an alarm on their phone to avoid forgetting the medication.

Adverse Reactions

The breasts, uterus, and vagina are the more obvious organs dependent on estrogen. Although adverse drug reactions were discussed earlier in this section, clinicians need to communicate the following information to patients who are initiating or renewing estrogen-containing prescriptions. Leg

pain, visual disturbances, and severe headache could herald thromboembolic phenomena that could be life-threatening. Patients who smoke and those who are diabetic are at increased risk for this type of complication. Abnormal bleeding patterns or genital pain needs to be reported in all age groups. In younger women who experience irregular bleeding, infection or pregnancy is suspected. But bleeding in a postmenopausal woman may be the first symptom of uterine or ovarian cancer. Dysfunctional uterine bleeding in any perimenopausal or postmenopausal woman should be considered to be cancer until proved otherwise, and the appropriate steps should be taken to determine the presence or absence of cancer.

Lifestyle Management

Smoking increases the risk of thrombolytic events in patients taking estrogen. The use of estrogen-containing contraception in women who smoke and are over the age of 35 is contraindicated. All patients who smoke should be counseled on the added risks associated with concurrent tobacco use and estrogen products. Patients who quit smoking for at least 1 year are considered nonsmokers.

Routine exercise and dietary changes have been associated with a reduction in vasomotor symptoms of menopause and reduced symptoms of dysmenorrhea.

The use of condoms and barrier devices to reduce the risk of sexually transmitted infections is also an important component of contraceptive management and should be assessed and encouraged at prescription initiation and refill.

PROGESTERONES AND PROGESTERONE ANTAGONISTS

The progesterones include progesterone (Prometrium, Progesterone in Oil, Crinone, Prochieve), medroxyprogesterone acetate (Provera), norethindrone (Aygestin), and megestrol acetate (Megace). Most are used in oral contraceptives and for HRT. Many formulations (sometimes referred to as "generations") of progesterone have been developed to address issues of mood change, breakthrough bleeding, and sensitivity to progesterone agents.

Currently there are several different androgen-derived progestins available in oral contraceptive preparations: norethindrone, norethindrone acetate, ethynodiol diacetate, norgestrel, desogestrel, levonorgestrel, and norgestimate. Norethindrone acetate and ethynodiol diacetate are converted to norethindrone in the body. Levonorgestrel is the levorotatory form of norgestrel and its active metabolite.

Desogestrel and norgestimate offer a decrease in androgenicity when compared to other progesterones. Desogestrel undergoes conversion to its active metabolite etonogestrel, which is the progestin used in the vaginal ring. Norelgestromin is the primary metabolite of norgestimate and is available as a contraceptive patch. Decreased androgenicity theoretically reduces adverse effects on carbohydrate and lipid metabolism found in previous formulations, as well as improves acne and hirsutism. Medroxyprogesterone acetate is available for injectable contraception.

Drospirenone is a progestin developed as a derivative of spironolactone. As a derivative of spironolactone, it has a mild diuretic effect as well as antimineralocorticoid effects. The drug has been granted FDA approval for the treatment of premenstrual syndrome and contraception when it is a component of a COC pill. Drospirenone may cause hyperkalemia and should be used cautiously with women who are using drugs that cause a potassium-sparing effect, such as ACE inhibitors, or have underlying renal disease. Box 22-3 presents information on progesterone antagonists. Drospirenone is associated with a higher risk of venous thromboembolism (VTE) than COCs containing the progestin levonorgestrel or some other progestins.

Pharmacodynamics

Effects of progestin on the reproductive organs include thickening of the endometrium and increasing its complexity in preparation for pregnancy; thickening of cervical

---

BOX 22–3 **PROGESTERONE ANTAGONISTS**

Mifepristone (Mifeprex)

Mifepristone was approved by the FDA on September 28, 2000, for termination of intrauterine pregnancy. It has a long half-life (18 h) and may prolong the follicular phase of the subsequent cycle. It is strongly bound to plasma proteins (98%). This binding is saturable and the drug has nonlinear pharmacokinetics with relation to plasma concentration and clearance. The antiprogestational activity results from competitive interaction with progesterone at progesterone receptor sites. The drug inhibits the activity of both endogenous and exogenous progesterone. When there is no progesterone to maintain a pregnancy, termination results. In 85% of women, mifepristone will act as an abortifacient when used in conjunction with misoprostol during the first 7 weeks of pregnancy. Women should expect to experience bleeding or spotting for an average of 9 to 16 days. Persistent heavy or moderate bleeding for more than 30 days could indicate an incomplete abortion. There are very specific requirements associated with administration of this drug, and it is best done in clinics that can meet these requirements. The drug is available only from the manufacturer and not through licensed pharmacies.

Mifepristone also exhibits antiglucocorticoid and weak antiandrogenic activity. Off-labeled uses in the treatment of endometriosis, Cushing's syndrome, and uterine leiomyomata are under study.

mucus; thinning of the vaginal mucosa; and relaxation of smooth muscles of the uterus and fallopian tube. During pregnancy, progestin maintains the thickened endometrium, relaxes myometrial muscles, thickens the myometrium for labor, is responsible for placental development, and prevents lactation until the fetus is born. In the absence of pregnancy, the reduced production of estrogen and progestin by the corpus luteum results in the shedding of endometrium to produce menstruation. Progestin is also responsible for alveolobular development of the secretory apparatus of the breast. Progestin also has actions outside the reproductive system. It stimulates lipoprotein activity and seems to favor fat deposition; increases basal insulin levels and insulin response to glucose; promotes glycogen storage in the liver; promotes ketogenesis; competes with aldosterone in the renal tubule to decrease Na^+ resorption; increases body temperature; and increases ventilatory response to CO_2, resulting in a measurable decrease in $PaCO_2$. The latter occurs only during pregnancy.

No significant differences in endometrial lining were noted with vaginal estrogen therapy alone. The North American Menopause Society states that progesterones are not indicated in low-risk, asymptomatic women on lower-dose vaginal estrogen forumlations. Endometrial monitoring is not indicated except for postmenopausal bleeding (Tan et al, 2012).

Pharmacokinetics

Absorption and Distribution

Progesterone is rapidly absorbed following any route of administration. Oral progestins are rapidly absorbed from the GI tract and quickly undergo hepatic degradation. Following IM administration, progesterone in oil is rapidly absorbed and undergoes hepatic metabolism. Long-acting forms can be maintained for 3 to 6 months. The gel formulation has sustained-release properties, so absorption can be lengthened to 50 hours. Subdermal implants of progesterone are also available. In the United States, Implanon/Nexplanon is available to providers who have completed specific training on insertion. Nexplanon is the newest subdermal implant. The difference between the two is that Nexplanon is radiopaque and the earlier Implanon is not. Subdermal implant progesterone is well absorbed through the dermis at a continuous rate and is effective for 3 years. Progesterone formulation in the form of an IUD is also available. The Mirena IUD is effective for 5 years. Progesterone binds to plasma albumin and corticosteroid-binding globulin.

Metabolism and Excretion

Oral progesterone is rapidly metabolized in the first pass through the liver. In the liver, progesterone is metabolized to pregnanediol and with the glucuronide metabolites conjugated with glucuronic acid. It is excreted in the urine. IM and implantable progesterone is extensively bound to serum proteins. Its metabolites are excreted 60% by the kidney and 10% through the bile and feces. The gel formulation is also eliminated through the renal route.

Onset, Peak, and Duration

Onset, peak, and duration vary based on the form of progesterone. After oral administration, the peak concentrations for oral progesterone occur after 1 to 2 hours. Half-life also varies by the form of progesterone and can be from 4 to 40 hours. IM preparations reach peak levels by 24 hours and have a half-life of approximately 10 weeks. The liver quickly metabolizes the gel formulation, but the long absorption half-life provides the steady serum concentrations. The absorption half-life of the vaginal gel can be from 25 to 50 hours. With the subdermal implant, maximum serum etonogestrel concentrations were reached within the first 2 weeks after insertion. Levonorgestrel in the Mirena IUD peaks at 20 mcg/d approximately 2 weeks after insertion. Table 22-7 presents the pharmacokinetics of progestins.

Table 22–7 Pharmacokinetics: Progesterones and Progesterone Antagonists

Drug	Peak	Active Metabolite	Half-Life	Elimination
Progesterones				
Progesterone	1–2 h	5β-pregnan-3A, 20A-diol glucuronide	8–9 h	50%–60% in urine, 10% in bile and feces; small amount unchanged in bile
Progesterone gel	3.5 h (on daily dosing), 5.4 h (for bid dosing)	5β-pregnan-3A, 20A-diol glucuronide	45 h (for daily dosing), 25.9 h (for bid dosing)	50%–60% in urine, 10% in bile and feces; small amount unchanged in bile
Medroxyprogesterone acetate		5β-pregnan-3A, 20A-diol glucuronide	IM: 10 wk	15%–22% in feces; small amount unchanged in bile
Megestrol acetate	2.2 h	5β-pregnan-3A, 20A-diol glucuronide	34.2 h (mean)	50%–60% in urine, 10% in bile and feces; small amount unchanged in bile
Progesterone Antagonists				
Mifepristone (Mifeprex)	1–3 h	3 active metabolites	20–54 h	NA

NA = not available.

Pharmacotherapeutics

Precautions and Contraindications

Patients with thromboembolic disease or a history of it should not use progestins. Breast cancer may become worse under hormone influence. Patients with impaired liver function would have trouble metabolizing exogenous hormones.

Mental depression has been associated with both short-acting and long-acting progestins. The drug may need to be discontinued if depression recurs or occurs to a serious degree.

Fluid retention may occur. Patients with disorders that may be affected negatively by excess fluid (e.g., epilepsy, migraine, asthma, congestive heart failure, or renal dysfunction) require careful observation.

A decrease in glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combination drugs. Diabetic patients should increase their glucose monitoring when receiving progestin therapy.

Progesterone is Pregnancy Category D and norethindrone acetate is Pregnancy Category X. Progesterone gel is used to support embryo implantation and maintain pregnancies as part of assisted reproductive technology (ART) treatments. Lactation may be enhanced by medroxyprogesterone, although the effects on the infant have not been determined.

Adverse Drug Reactions

The most common adverse reaction associated with progestins is irregular, breakthrough vaginal bleeding. Some patients may experience amenorrhea. Acne and chloasma have occurred with several of the more androgenic progestin products. Patients report increased breast tenderness and galactorrhea. Nausea, depression, and weight gain have also been reported.

Injectable and implanted progesterone for contraception use is associated with an increased incidence of weight change and irregular menstrual bleeding. Because of low estrogen levels associated with IM progestin (Depo-Provera), patients on this therapy are at increased risk for osteoporosis. In 2004,

the FDA issued a Black-Box Warning for Depo-Provera. In the warning, the FDA cautioned about using this form of contraception for longer than 2 years unless other forms of contraception are not viable options. The bone density loss may extend beyond the duration of treatment. Clinicians need to perform a risk assessment and have a thorough discussion of this information with patients prior to the initiation of therapy. Delays to return to fertility may also occur with IM progestin use.

Drug Interactions

The two drugs known to have specific interactions with progestins are aminoglutethimide and rifampin. The primary result is to decrease effectiveness of progestin therapy, which can result in unplanned pregnancy. In addition to drug–drug interactions, progesterone can cause erroneous laboratory results in testing hepatic function, coagulation, thyroid, metyrapone, and other endocrine functions. Table 22-8 presents drug interactions.

Clinical Use and Dosing

Progestins are used for their effect on endometrial tissue. The major uses of progestational hormones are for perimenopausal and postmenopausal hormonal therapy and as a contraceptive alone and in combination with estrogen.

Perimenopausal and Postmenopausal Hormone Replacement

Combinations of estrogen and progestin are used when the uterus is intact. The risk for endometrial cancer secondary to endometrial hyperplasia has been consistently demonstrated in research studies of ERT and exists for all dose levels of ERT. To prevent this increased incidence, progestins, which reduce the buildup of endometrial tissue, are added to the treatment regimen. There are several combination therapies for use in menopause. These are discussed in more detail in the Rational Drug Selection section.

Table 22–8 ⊞ **Common Drug Interactions: Progesterones and Progesterone Antagonists**

Drug	Interacting Drug	Possible Effect	Implications
Progesterones			
Progesterone	Lab studies	Results of hepatic function, coagulation tests (increase in prothrombin; factors VII, VIII, IX, and X); thyroid, metyrapone test, and endocrine functions may be affected by progestins	Anticipate that laboratory levels of liver function and hormonal assays may not be accurate while the patient is taking these drugs
Medroxyprogesterone acetate (DMPA)	Aminoglutethimide	Aminoglutethimide may increase the hepatic metabolism of DMPA	Chemotherapy drug used for metastatic cancer. If spotting occurs, give DMPA earlier than 12 wk
Progesterone Antagonists			
Mifepristone (Mifeprex)	Agents that utilize the CYP450 3A4 pathway	Multiple interactions regarding changes in agent metabolism	Seek alternative options or close monitoring based on agents

Progestin-Only Contraception

Progestins exhibit a negative effect in the hypothalamic-pituitary-ovarian axis, essentially suppressing the LH surge necessary for ovulation. They also cause thickening of cervical mucus, making penetration by sperm difficult. Tubal motility is slowed, delaying transport of the ovum and sperm. In addition, progestins cause atrophy of the endometrium, preventing implantation.

There are several brand-name progestin-only pills available that each contain 0.35 mg of norethindrone. These pills contain no estrogen and are primarily used with special populations in which estrogen is contraindicated because of medical conditions or breastfeeding. Because progestin-only pills contain very low levels of hormone, users need to be particularly diligent to take their medications correctly.

The FDA approved the use of medroxyprogesterone acetate (Depo-Provera) for contraception in 1993. When administered IM at the recommended 150 mg dose every 3 months (12 weeks), it inhibits secretion of gonadotropins, which prevents follicular maturation and results in endometrial thinning. Most women using Depo-Provera experience disruption in menstrual bleeding patterns. These disruptions include irregular or unpredictable bleeding, spotting, or, rarely, heavy or continuous bleeding. Over half of all women on IM therapy will experience amenorrhea or some form of irregular menstrual bleeding. If abnormal bleeding persists or is severe, it should be investigated to rule out an underlying pathology. Depo-Provera has been associated with reduced bone density after chronic administration. Women using this form of contraception need to be made aware of the potential for osteoporosis, and this risk should be considered in choosing this form of contraception. Adolescents and young adults are of special concern, because growth in bone mineral density is largest during this age period and loss at this time reduces the total bone mass available later in life. As with all progestin products, there is a risk for thromboembolic events.

Off-Label Use of Progestins

Other off-label uses for progestins in the treatment of dysmenorrhea, endometriosis, hirsutism, and menstrual bleeding disorders are implemented when estrogen is contraindicated. The gel form of progesterone is used to assist in fertility programs for women with progesterone deficits. Refer to Chapter 31 for a more detailed discussion of progesterone as contraception and to Chapter 38 for its use in conjunction with estrogen for postmenopausal hormone therapy. Table 22-9 presents the dosage schedule of progestins and progesterone antagonists.

Table 22–9 ⊗ Dosage Schedule: Progesterones and Progesterone Antagonists

Drug	Indication	Dosage form	Initial Dose	Maintenance Dose
Progesterones				
Progesterone	Amenorrhea	Capsule, oral: Prometrium: 100 mg, 200 mg (contains peanut oil) (B) Generic: 100 mg, 200 mg (G)	IM: 5–10 mg/d for 6–8 consecutive days	IM: 5–10 mg/d for 6–8 consecutive days
	Amenorrhea, secondary		Intravaginal gel: 45 mg (4% gel) every other day for 6 doses	If response is inadequate, may increase to 90 mg (8% gel)
	ART in patients who require progesterone supplementation	Gel, Vaginal Crinone 4% (1.45 g); 8% (1.45 g) (B) Insert, Vaginal: Endometrin: 100 mg (21 each) (B) Oil, Intramuscular: Generic: 50 mg/mL (10 mL) (G)	Intravaginal gel: 90 mg (8% gel) once daily Intravaginal tablet: 100 mg 2–3 times daily starting at oocyte retrieval and continuing for up to 10 wk	Intravaginal gel: 90 mg (8%) gel) once daily. If pregnancy occurs, may continue for 10–12 wk. 100 mg 2–3 times daily
	ART in patients with partial or complete ovarian failure	Suppository, Vaginal: First-Progesterone VGS 25: 25 mg (30 each) (B) First-Progesterone VGS 50: 50 mg (30 each) First-Progesterone VGS 100: 100 mg (30 each) (B) First-Progesterone VGS 200: 200 mg (30 each) (B) First-Progesterone VGS 400: 400 mg (30 each) (B)	Intravaginal gel: 90 mg (8%) gel twice daily	Intravaginal gel: 90 mg (8%) gel twice daily. If pregnancy occurs, continue treatment for 10–12 wk
	Endometrial hyperplasia prevention		In postmenopausal women with a uterus in conjunction with daily conjugated estrogen tablet. Oral: 200 mg every evening for 12 consecutive days in a 28-day cycle	200 mg every evening for 12 consecutive days in a 28-day cycle
	Functional uterine bleeding		IM: 5–10 mg/d for 6 doses	5–10 mg/d for 6 doses

Table 22–9 ⊗ **Dosage Schedule: Progesterones and Progesterone Antagonists—cont'd**

Drug	Indication	Dosage form	Initial Dose	Maintenance Dose
Medroxyprogesterone acetate	Amenorrhea	Suspension, IM: Depo-Provera 150 mg/mL (1 mL) (B)	Oral: 5–10 mg/d for 5–10 days	5–10 mg/d for 5–10 days
	Abnormal uterine bleeding	Depo-Provera 400 mg mL (400 mg/mL (2.5 mL) (B)	Oral: 5–10 mg for 5–10 days starting on day 16 or 21 of cycle	5–10 mg for 5–10 days starting on day 16 or 21 of cycle
	Contraception	Generic: 150 mg/mL (1 mL) (G)	IM: 150 mg every 3 mo	IM: 150 mg every 3 mo
		Suspension, Subcutaneous Depo-SubQ Provera 104: 104 mg/0.65 mL (0.65 mL) (B)	SubQ: 104 mg every 3 mo (12–14 wk)	SubQ: 104 mg every 3 mo (12–14 wk)
	Endometriosis		SubQ: 104 mg every 3 mo (12–14 wk)	SubQ: 104 mg every 3 mo (12–14 wk)
	Endometrial carcinoma, recurrent or metastatic (adjunctive/palliative treatment)	Tablet, oral Provera 2.5 mg, 5 mg, 10 mg (B) Generic: 2.5 mg, 5 mg, 10 mg (G)	IM: 400–1,000 mg/wk	400–1,000 mg/wk
	Postmenopausal therapy with accompanying estrogen		Oral: 5–10 mg for 12–14 consecutive days starting on day 1 or day 16 of 28-day cycle	5–10 mg for 12–14 consecutive days starting on day 1 or day 16 of 28-day cycle
	Paraphilia/hypersexuality in males (unlabeled use)		IM: 100–600 mg weekly	100–600 mg weekly
Megestrol acetate	Breast carcinoma (females)	Suspension, oral: Megace ES: 625 mg/5 mL (150 mL) (B)	Oral, tablet: 40 mg 4 times/d	40 mg 4 times/d
	Endometrial carcinoma	Megace Oral: 40 mg/mL (240 mL) (B) Generic: 40 mg/mL (10 mL, 240 mL, 480 mL); 400 mg/10 mL (10 mL) (G)	Oral, tablet: 40–320 mg/d in divided doses	40–320 mg/d in divided doses. Maximum doses have been up to 800 mg/day
	HIV-related cachexia (males/females)	Tablet, oral: Generic: 20 mg, 40 mg (G)	Oral, suspension: 800 mg/d ES: 625 mg/d	400–800 mg found to be clinically effective
Norethindrone acetate	Contraception (females)	Tablet, oral: Camila: 0.35 mg (B) Errin: 0.35 mg (B) Heather: 0.35 mg (B) Jencycla: 0.35 mg (B) Jolivette 0.35 mg (B) Nor-QD 0. (B) Nora-BE 0.35 mg (B) Ortho Micronor 0.35 mg (B) Generic: 0.35 mg (G) Tablet, oral, as acetate Aygestin 5 mg (B) Generic: 5 mg (G)	Oral, tablet: 0.35 mg daily Start on first day of menstrual period or the day after a miscarriage or abortion	0.35 mg daily
	Amenorrhea and abnormal uterine bleeding		Oral, tablet: Two 5–10 mg/d for 5–10 days during the second half of the menstrual cycle	Two 5–10 mg/d for 5–10 days during the second half of the menstrual cycle
	Endometriosis		Oral, tablet: 5 mg/d for 14 days	Increase in increments of 2.5 mg/d every 2 weeks to reach 15 mg/d. Continue for 6–9 mo.
Progesterone Antagonists				
Mifepristone	Hyperglycemia in patients with Cushing's syndrome	Tablet, oral: Korlym 300 mg (B) Mifeprex 200 mg (B)	Oral, tablet: 300 mg/d	Increase in 300 mg increments every 2–4 wk. Maximum dose: 1,200 mg/d or 20/mg/dg/d

Table 22–9 ⊗ **Dosage Schedule: Progesterones and Progesterone Antagonists—cont'd**

Drug	Indication	Dosage form	Initial Dose	Maintenance Dose
	Termination of pregnancy (restricted use in U.S.)		Oral, tablet: Day 1: (mifepristone): 600 mg (three 200 mg tabs) Day 3: (misoprostol) 400 mcg (two 200 mcg tabs) Day 14: confirmation of complete termination by US (unlabeled use) Day 1: misepristone 200 mg Day 3: misepristone 800 mcg vaginally 24–48 h later	No maintenance dosing
	Meningioma, unresectable (unlabeled use)		Oral, tablet: mifepristone 200 mg/d	Mifepristone 200 mg/day

Rational Drug Selection

Short-Acting Versus Long-Acting

Oral contraceptive products are dosed in a convenient dial pack. These products are short-acting, and the patient chooses when to stop and become fertile again. Progesterone is available for contraception in two parenteral forms, which are long-acting, and both have greater than 99% theoretical efficacy. Patient preference is a primary concern when selecting the route for contraceptive delivery with progesterone agents. For patients who have difficulty remembering to take the medication daily, the use of a long-acting method may be preferred. Table 22-9 presents available dosage forms.

Prevention of Endometrial Cancer

Endometrial cancer is a risk associated with estrogen therapy. In an attempt to decrease this risk, combinations of estrogen and a progestin have been prescribed to perimenopausal and postmenopausal women who have an intact uterus. There are several dosing regimens and related concerns in their use. Estrogen (0.625 mg) plus medroxyprogesterone acetate (MPA) 2.5 mg daily (Prempro) is the medication combination used in the WHI study in which concern was raised about increased CHD risk. Estrogen (0.625 mg) days 1 to 25 plus MPA days 16 to 25 is an alternative regimen. It has the disadvantage of increasing hot flashes. Estrogen (0.625 mg) plus progestin Monday through Friday is less commonly used and has more vasomotor flashing reports than the continuous-use form.

When initiating therapy in older women, begin with low doses (0.3 mg) of conjugated estrogens every other day for 2 months. Next, increase the estrogens to daily doses and use for another 2 months. Add a progestin from the treatment regimens above if the patient has a uterus. If symptoms such as bleeding or breast pain do not occur, increase the estrogen to up to 0.625 mg daily. Some women may need only the lower estrogen dosages as long as they have an adequate diet. Use of formulations other than oral may reduce the need for the addition of progestin because of reduced cancer risk. This reduced risk for different estrogen formulations is discussed in the estrogen therapy Rational Drug Selection section.

A newer alternative to using progestins for uterine protection, as well as vasomotor symptoms, is the combination of conjugated estrogen with bazedoxifene (Duavee). Because it contains conjugated estrogens, all the warnings associated with estrogen apply. The bazedoxifene, an estrogen agonist/antagonist, component is also associated with increased risk of blood clots; its impact on breast cancer is unknown. The reason for its use is that it reduces endometrial hyperplasia induced by the estrogen. Alone bazedoxifine is a SERM medication approved for osteoporosis treatment and prevention. Data comparing the impact on bone health when used together does not appear to be much greater than each medication alone. Bazedoxifine is not metabolized by the CYP450 system, but this does not mean no drug interactions. A lessor known uridine diphosphate glucuronosyltransferase (UGT) enzyme system in the gut is the site of metabolism. Therefore medications that induce UGTs like rifampin, carbazapeine, phenobarbital, and phenytoin can reduce its effectiveness in preventing vaginal lining growth.

Vaginal Bleeding

The most common reason women give for discontinuing HRT is unacceptable vaginal bleeding. Continuous regimens eliminate monthly withdrawal bleeding but are associated with a higher rate of breakthrough bleeding, especially in the first 6 months. This is most likely in women who are early into postmenopause because endogenous production of estrogen is more labile from cycle to cycle in these women. The most positive risk/benefit profiles for all indications for HRT may accrue when the therapy is started near the time of menopause onset. The use of cyclical or sequential therapy reduces the risk for breakthrough bleeding

and is preferred until endogenous hormone production stabilizes, typically 2 to 3 years after menopause. Differences in potency of various progestins may result in differences in rates of bleeding. The PEPI study found micronized progestin was associated with less bleeding during the first 6 months than either continuous or cyclical MPA (Lindenfeld & Langer, 2002).

Effects on Lipids

Different types of progestin not only have differing effects on the endometrium, they also have differing effects on estrogen-associated benefits to lipids. Norethindrone acetate has been shown to reverse any estrogen impact on HDL cholesterol while still offering effective endometrial protection. MPA and micronized progestin do not attenuate the effects of estrogen on lipid levels. Norgestimate improves HDL to a level intermediate between MPA and micronized progestin, also while providing good endometrial protection (Langer, 2005). The overall impact is not favorable toward long-term CV health; hence, the caution to keep HRT therapy to a maximum of 5 years and only in younger women. Reevaluation of the WHI data implies that the worst CV outcomes occurred in women who were started on HRT years after menopause onset.

Monitoring

Pretreatment physical examination to assess health and possible contraindications to progestins is mandatory. The examination should be age specific. Patients with seizure disorders need monitoring of their symptoms because increased fluid retention may lower the seizure threshold. Women with migraines are vulnerable to any changes in physiological states, and fluid retention may give them cyclic migraines. Depression should be assessed early in therapy for those women with a history of previous affective disorders. Patients with diabetes may see changes in blood glucose levels, triggering the need for more frequent measurement. Patients with a history of or risk for thromboembolic events or who use tobacco products should not use these products. Additionally, women on injectable progesterone will require education and possible screening for osteoporosis based on age and risk factors. Women on HRT require careful monitoring for cardiovascular, thromboembolic, and cancer risks.

Patient Education

Administration

Most hormone regimens require daily dosing for efficacy, especially for the progestin-only oral contraceptive. The most common adverse effect is breakthrough bleeding, especially if doses are missed. The injectable form requires administration every 12 weeks, so a follow-up appointment should be scheduled for the time the injection is due to avoid loss of pregnancy protection. If a woman is outside the 2 week window to receive a shot, she should use alternate protection such as condoms or abstain from intercourse. She will need a repeat pregnancy test prior to restarting injections. The use of injectable progesterone for contraception requires added screening at initial administration. Patients must present for initial administration of an injectable progesterone therapy while they are actively menstruating and have a negative pregnancy test. The use of injectable progesterone is associated with significant teratogenic effects. Patient-specific education regarding the need to maintain the specific redosing schedule should also be provided.

Estrogen/progestin combinations used for HRT require daily dosing. No specific instructions are required beyond those already discussed.

Adverse Reactions

Progestins should not be used in the first 12 weeks of gestation because of masculinization of the female fetus. Depression and mood swings are common and represent a significant factor in postmenopausal HRT cessation. Irregular menstrual patterns and unpredictable spotting contribute to the proportion of women stopping progestin-only oral contraceptives. Breast tenderness and galactorrhea are the third most common reason women switch from a progesterone contraceptive and another reason that postmenopausal women stop HRT altogether.

Lifestyle Management

Progesterone therapy may be associated with hyperpigmentation and weight gain. To help reduce these complications, clinicians should encourage patients to use sunscreen to prevent skin changes, such as blotchy pigmentation. Promotion of routine physical exercise is used to combat the increase in body weight sometimes seen with Depo-Provera.

Smoking cessation is encouraged in all patients, but especially in young women using hormonal contraception. The association of both estrogen and progesterone with morbidity and mortality in patients older than 35 years who smoke may be a powerful motivator to quit smoking.

OTHER DRUGS AFFECTING THE REPRODUCTIVE SYSTEM

Other drugs affecting the reproductive system include those that are commonly used to treat infertility (GnRH, FSH, LH, and human chorionic gonadotropin [hCG]), those used as lactation inhibitors (bromocriptine), and those used in erectile dysfunction. Though the primary care advanced practice nurse may not prescribe these medications, it is important to understand all the medications that the patient is using within the role of coordination of care.

Drugs Commonly Used in Fertility Clinics

Gonadotropin-Releasing Hormone

GnRH is produced in the arcuate nucleus of the hypothalamus and controls the release of FSH and LH for both males and females. GnRH is used as a stimulant in pulsatile doses

if the patient has a functional pituitary gland and an ovary to produce the LH surge initiating ovulation. GnRH agents may be used in pulsate form to stimulate ovulation and treat endometriosis and uterine fibroids and as continuous therapy to suppress prostate cancer. Leuprolide acetate (Lupron, Lupron Depot) may be administered subcutaneously (SC) or IM. Goserelin (Zoladex) is an SC implant that is used to treat prostate cancer, breast cancer, and severe endometriosis. It is administered every 28 days.

The use of GnRH is contraindicated in conjunction with medications that stimulate ovarian function. The use of GnRH for infertility treatments may result in multiple gestations. Long-term use of GnRH agents may result in bone demineralization, and DEXA (Dual Energy X-ray Absorptiometry) scans should be considered for patients who require ongoing treatment. Patients may report hot flashes, headache, and menstrual irregularities during treatment.

Follicle-Stimulating Hormone/Gonadotropins

FSH has an analogue, human menopausal gonadotropin (hMG) (follitropin [Fertinex], menotropins [Pergonal, Humegon]). The drug is used in fertility treatments for both men and women. In men, the use of gonadotropins stimulates spermatogenesis and in women stimulates the maturation of follicles and ovulation. Used in specialty practices, these agents are administered IM. Onset, peak, and duration are not established for all of them. As these agents are used to stimulate ovarian function, there is a risk of hyperstimulation syndrome that can cause ovarian enlargement, ascites, hydrothorax, hypovolemia, hemoperitoneum, fever, or arterial thromboembolism.

Luteinizing Hormone and Human Chorionic Gonadotropin

Luteinizing hormone (LH) like FSH is produced in the anterior pituitary and used in conjunction with FSH to stimulate ovulation. It also stimulates the corpus luteum to produce progesterone and androgens. No LH preparation is available for use clinically. Instead, a similar preparation, hCG, is substituted successfully (analogue hCG:A.P.L., Chorex-5, Profasi).

Lactation Inhibitors

Bromocriptine

Although not a true hormone, bromocriptine (Parlodel) has an inhibitory effect on the pituitary gland. It is widely used for shrinking pituitary prolactin-secreting tumors, reducing the prolactin levels of idiopathic prolactinemia, galactorrhea, and infertility. Bromocriptine is similar to dopamine in structure and binds to dopamine receptors within the pituitary gland to inhibit prolactin secretion. It is well absorbed from the GI tract and can begin to exert an effect within 2 hours of administration. Bromocriptine is metabolized through the CYP450 3A4 substrate and excreted primarily in bile. When used for hyperprolactinemic indications, the initial dosage is 0.5 to 2.5 mg daily with meals; 2.5 mg may be added as tolerated every 3 to 7 days or until optimal therapeutic response

is achieved. Therapeutic dosage is usually 5 to 7.5 mg, with a range of 2.5 to 15 mg/d.

For acromegaly, the initial dose is 1.25 to 2.5 mg for 3 days at time of sleep. An additional 1.25 to 2.5 mg is added as tolerated every 3 to 7 days. Therapeutic dosage is usually 5 to 7.5 mg, with a range of 20 to 30 mg/d.

Multiple drugs interact with bromocriptine. Some of the most notable interactions include acetaminophen, erythromycin, phenothiazines, sympathomimetics, isometheptene, and phenylpropanolamine.

Drugs Used for Erectile Dysfunction

Phosphodiesterase Type 5 Inhibitors

Erectile dysfunction (ED) is a common health condition that is associated with increased age and various comorbidities, such as diabetes and hypertension. The causes of erectile dysfunction are beyond the scope of this chapter. However, clinicians should complete a full history and physical to confirm proper diagnosis prior to initiating medication therapy. This section focuses on ED treatment with the use of phosphodiesterase type 5 inhibitors (PDE5 inhibitors). Additional information is found in Chapter 49.

Sildenafil citrate (Viagra), the first PDE5 inhibitor indicated for the treatment of impotence in men with ED, was originally studied as a selective vasodilator for use in angina. Although not effective in the coronary arteries, it was effective as a selective inhibitor of cyclic guanosine monophosphate (cGMP), specifically PDE5. It has found an effective role in pulmonary hypertension as well. The dosing and discussion of this indication is not included in this chapter.

The PDE5 class has a 10-fold selectivity for the enzyme that produces smooth muscle relaxation in the corpus cavernosum of the penis. As smooth muscles in the corpus cavernosum relax, blood flow into the penis is increased, resulting in an erection. There is no drug effect without sexual stimulation. They have no effect if the cause of ED is not biological in nature. The drug class also relaxes bladder smooth muscle giving a second indication of benign prostatic enlargement if used daily. They are rapidly absorbed after oral administration and eliminated by hepatic metabolism (mainly CYP450 3A4). Ingestion of food reduces its rate of absorption, especially high-fat, high-protein meals. The peak onset for sildenafil occurs 60 minutes after dosing, with a duration up to 4 hours; tadalafil is the fastest acting and lasts the longest in circulation at 17 hours with reports of up to 36 hours.

For erectile dysfunction, the dosage of sildenafil is 50 mg (25 to 100 mg, based on effectiveness) taken as needed approximately 1 hour before sexual activity for sildenafil and vardenafil, and 15 minutes for tadalafil. The intended frequency is about every 3 days. Studies in healthy elderly volunteers (over 65 years) showed a reduced clearance with free plasma concentrations 40% higher than in younger volunteers (18 to 45 years). An initial starting dose of 25 mg is recommended for men over age 65 years. Tadalafil and vardenafil starting doses are 10 mg with a maximum of 20 mg for the initial occasional use formula. The daily use dose for Tadalafil is 2.5 mg.

There is an absolute contraindication for concomitant use with any form of nitrates because of the risk of severe hypotension, cardiovascular collapse, and death. Other potential drug interactions are many, including antifungals, macrolide antibiotics (such as erythromycin), cimetidine, rifampin, alpha blockers, nonspecific beta blockers, and diuretics. These drugs should not be used concomitantly or doses of the phosphodiesterase inhibitor should be adjusted downward. Common adverse effects include headaches, flushing, dyspepsia, and blue-hue vision change (most common with sildenafil).

All PDE5 inhibitors have been shown to have equal efficacy in treating ED. The main difference between the agents is longer duration of action. Vardenafil (Levitra) shares a pharmacokinetic profile similar to that of sildenafil but is purported to have a shorter time to onset of action and lasts for up to 6 hours. Maximum plasma concentrations are reached between 30 minutes to 2 hours. Tadalafil (Cialis) has a different chemical structure than the other two PDE5 inhibitors. This allows for greater binding affinity in skeletal smooth muscle, the testes, and prostate and less affinity in the retina. This may account for the low back pain and decreased incidence of visual disturbances with tadalafil that some users report. As with sildenafil, there is reduced clearance in both of these medications in elderly patients, with plasma concentrations up to 52% higher. A lower starting dose of 5 mg is recommended with this population. No adjustments are required for renal impairment, but the same recommendations are made as related above to drug interactions.

Once-daily use of tadalfil is now approved for erectile dysfunction and benign prostatic hyperplasia at a dose lower than the initial version. Daily dosing is 2.5 to 5 mg based on efficacy and tolerability. Steady-state plasma concentration is reached after 96 hours of continuous daily use. Using the higher dose tablets in a daily pattern is not recommended due to the eventual toxicity from the prolonged duration of effects and associated acute hypotension.

All PDE5 inhibitors share the same contraindication in patients who are using nitrates because of a risk of severe hypotension. Concurrent use with alpha blockers is also not recommended because of additive hypotensive effects; they are considered contraindicated for vardenafil and tadalafil. Patients with underlying cardiovascular disease require additional pretreatment evaluation. The American College of Cardiology and the American Heart Association have suggested that patients with unstable coronary artery disease, active ischemia, heart failure, and low blood pressure, and patients on multiple antihypertensive agents or medications that inhibit the CYP 450 3A4 pathway should not take PDE5 inhibitors. They are not given after stroke, MI, or recent life-threatening dysrhythmias due to heightened sensitivity to blood pressure changes for up to 6 months. Vardenafil can cause QT prolongation and should not be used in patients with underlying arrhythmias, on dysrhythmic medications, or with hepatic insufficiency. Tadalafil is not indicated for persons with retinal pigmentosa.

Patient education regarding the anticipated effectiveness of therapy and potential side effects should be given at the initiation of therapy and at each refill. Patients who experience chest pain or dizziness with sexual activity should refrain from additional use of these agents and sexual activity until they have been reevaluated.

Priapism is a rare but emergent adverse event that can occur with PDE5 inhibitors. Patients who experience an erection that lasts for longer than 4 hours need to be evaluated in the emergency department. There have been several reports of nonarterial anterior ischemic optic neuropathy (NAION) and cyanopsia (blue vision) within hours of taking PDE5 inhibitors (Thurtell & Tomsak, 2008). NAION is a permanent loss of vision resulting from ischemia of the optic nerve head. The U.S. Federal Aviation Administration recommends that pilots do not use sildenafil or vardenafil for 6 hours prior to flying. The half-life for both is below 6 hours. Tadalafil is not approved for pilots (or workers requiring color recognition) due to its half-life of 17.5 hours. Sudden hearing loss has also been reported. While patients are on this therapy, periodic medication and health evaluation are encouraged to identify any new potential cardiovascular or health risks that may alter the ability to continue ED therapy.

The effects of PDE5 inhibitors for treating women with sexual dysfunction have been evaluated in small clinical trials. The results are mixed, with many studies unable to demonstrate efficacy. PDE5 inhibitors have been used to treat children with persistent pulmonary hypertension, although the FDA has issued a statement reiterating that sildenafil is not labeled for use in children. The FDA notes that while sildenafil is approved for use in adults with pulmonary arterial hypertension, it is not approved for this use in children, since the studies in children indicate increased mortality with long term use (FDA, 2014). The FDA notes that providers need to weigh the risk benefit when treating children with PAH. (Baquero, Soliz, Neira, Venegas, & Sola, 2006). Adults with pulmonary arterial hypertension and those with high-altitude pulmonary edema are also treated with this drug class. The identical drugs are marketed under different brand names to prevent any hesitancy to take "ED" meds for a pulmonary vascular problem (i.e., Revato, Staxyn, and Adcirca). These forms are not interchangeable for the ones marketed for ED primarily due to significant differences in dosing.

DRUGS AFFECTING THE INTEGUMENTARY SYSTEM

Cally Bartley

This chapter discusses a wide variety of medications used to treat disorders of the skin or integumentary system, including topical anti-infective medications used to treat bacterial, fungal, and viral infections of the skin; topical corticosteroids and immunomodulators used for a variety of inflammatory diseases; and topical antipsoriasis and acne medications. Systemic medications used for skin disorders are discussed here only if not covered in another chapter. Systemic antibiotics and antifungal medications used to treat more serious skin infections, with the exception of griseofulvin and terbinafine, are discussed in Chapter 24. Systemic medications used for acne are discussed in this chapter, with the exception of systemic antibiotics, which are also covered in Chapter 24.

ANTI-INFECTIVES

TOPICAL ANTIBACTERIALS

Bacterial infections of the skin are common in patients of all ages. Antibacterial medications commonly used in primary care include topical agents and oral antibiotics. The most common pathogens seen in bacterial skin infections are *Staphylococcus aureus* and *Streptococcus pyogenes.* Skin infections with gram-negative bacilli are rare, but they may occur in patients who are immunocompromised or patients with diabetes. These patients usually require IV antibiotic therapy for their infections.

Impetigo is usually treated topically unless it is a moderate to severe case. First-line therapy for impetigo is mupirocin (Bactroban, Centany). A newer medication, retapamulin (Altabax), is also effective in treating impetigo. Over-the-counter (OTC) products like triple antibiotic ointment (neomycin, bacitracin, and polymyxin B) and double antibiotic ointment (polysporin and bacitracin) are less effective than prescribed topical agents and do not treat MRSA (*S. aureus*) (Bangert, Levy, & Herbert, 2012). Moderate to severe impetigo, a boil or abscess, perianal streptococcal infections, and cellulitis all require prompt treatment with appropriate systemic antibiotics. Methicillin-resistant *S. aureus* (MRSA) is increasing in prevalence and providers need to have a suspicion for MRSA in the differential of any skin infection. If MRSA is suspected, appropriate systemic antibiotics should be used (TMP/SMZ, doxycycline, minocycline, or vancomycin). See Table 23-1 for dosing schedules for topical antibacterials.

Table 23–1 ⊗ **Dosage Schedule: Selected Anti-Infectives Used to Treat Skin Disorders**

Drug	Indication	Available Dosage Forms	Dosage
Antibacterial			
Bacitracin (Baciguent)	Superficial wound infections	500 U/g ointment	Apply a small amount to the affected area 1–2×/d; do not use >1 wk
Mupirocin (Bactroban)	Impetigo	2% ointment 2% cream	Apply a small amount to the lesions 3×/d for 10 days. Reevaluate after 3–5 days if no response
	Nasal colonization with MRSA	2% nasal ointment	1/2 the ointment from a single-use tube of nasal ointment into one nostril, and the other 1/2 into the other nostril 2×/d for 5 days
Retapamulin (Altabax)	Impetigo	1% ointment	Apply thin layer 2×/d for 5 days. Reevaluate if no improvement in 3–4 days
Double antibiotic (polymyxin B, bacitracin)	Superficial wound infections	Polysporin 10,000 U/g, bacitracin 500 U/g ointment	Apply small amount to affected area 1–3×/d
Triple-antibiotic ointment (polymyxin B, neomycin, bacitracin)	Superficial wound infections	Polysporin 10,000 U/g, neomycin 3.5 mg/g, bacitracin 400 U/g	Apply a small amount to affected area 1–3×/d
Antifungals			
Butenafine (Lotrimin Ultra, Mentax)	Fungal skin infections	1% cream	Apply to affected and immediately surrounding area 1×/d for 2 wk. Pedis: 2×/d × 1 wk and then 1×/d × 2 wk
Ciclopirox olamine (Loprox) (Penlac)	Fungal skin infections and candidiasis	0.77% cream 0.77% gel 1% shampoo 8% solution 0.77% suspension 8% solution (nail lacquer)	Massage into affected skin 2×/d Nail lacquer solution: apply evenly over nail plate 1×/d to affected nails, remove with alcohol every 7 days
Clotrimazole (Mycelex Troche)	Oral candidiasis	10 mg troche	Adults and children >3 yr: 1 troche 5×/d for 2 wk; dissolve slowly in mouth

Table 23–1 🔗 **Dosage Schedule: Selected Anti-Infectives Used to Treat Skin Disorders–cont'd**

Drug	Indication	Available Dosage Forms	Dosage
(Lotrimin, Lotrimin AF)	Fungal skin infections	1% cream 1% solution	Apply to affected area 2×/d for 4 wk
Econazole (Spectazole)	Fungal skin infections	1% cream	Apply to affected area 1×/d for 2 wk Pedis: 4 wk
Ketoconazole (Nizoral, Nizoral A-D, Xolegel)	Fungal skin infections and candidiasis	2% cream 2% foam 2% shampoo 2% gel	Candidiasis, cruris, corporis: Apply 2×/d for 2 wk Pedis: 6 wk
	Pityriasis veriscolor		Apply shampoo, leave on 5 min, rinse or apply cream 1×/d for 2 wks
Miconazole (Micatin)	Fungal skin infections	2% cream 2% powder 2% spray	Cruris: Apply to affected area 2×/d for 2 wk Corporis, pedis: 4 wk
Naftifine	Fungal skin infections	1% and 2% cream 1% gel	Apply 1% cream 1×/d for 2 wk; 2% cream for up to 4 wk; gel 2×/d for up to 4 wk
Nystatin oral suspension	Oral candidiasis	100,000 U/ML oral suspension	Adults and children: 2–3 mL in each inner cheek (total dose 4–6 mL) 4×/d; have patient hold medication in mouth as long as possible before swallowing; treat for 48 h after clinical cure to prevent relapse Infants: 1 mL each cheek 4×/d (2 mL/dose total), until 48 h after clinical cure; may apply medication to inner cheeks and tongue with cotton swab prior to administering the 1 mL dose via dropper
Nystatin	Candidiasis	100,000 U/GM cream 100,000 U/GM ointment 100,000 U/GM powder	Apply to affected areas 2–3×/d until clear
Oxiconazole (Oxistat)	Fungal skin infections	1% cream 1% lotion	Pityriasis veriscolor, corporis, cruris: Apply to affected area 1–2×/d for 2 wk Pedis: 4 wk
Sertaconazole (Ertaczo)	Tinea pedis	2% cream	Dry area Apply to affected and adjacent areas 2×/d for 4 wk
Sulconazole (Exelderm)	Fungal skin infections	1% cream 1% solution	Cruris, corporis, versicolor: Massage medication into affected area 1–2×/d for 3 wk Pedis: 4 weeks
Terbinafine (Lamisil)	Fungal skin infections	1% cream 1% spray	Pedis, cruris, corporis, versicolor: Apply to affected area 1×/d for 1–4 wk
Tolnaftate (Tinactin)	Fungal skin infections	1% cream 1% powder 1% spray	Pedis, cruris, corporis: Apply to affected area 2×/day for 2–4 wk
Antivirals Acyclovir (Zovirax)	Initial herpes genitalis and labialis Mucocutaneous herpes simplex virus (HSV) infections in immunocompromised patients	5% ointment 5% cream	Apply ointment to affected area every 3 h (6×/d) for 7 days Labialis: 5×/d for 4 days
Docosanol (Abreva)	Recurrent oral-facial herpes simplex episodes	10% cream	Gently rub into affected area 5×/d until healed. Begin treatment at earliest sign or symptom.
Penciclovir (Denavir)	Recurrent herpes labialis	1% cream	Apply every 2 h while awake for 4 days. Begin treatment at earliest sign or symptom.

MRSA = methicillin-resistant *staphylococcus aureus*.

Pharmacodynamics

Topical or systemic antibacterial agents may be either bacteriostatic or bactericidal. Mupirocin has a wide range of coverage against gram-positive bacteria, including MRSA, and does have limited coverage against some gram-negative organisms. Mupirocin is bactericidal at concentrations achieved by topical administration of the 2% ointment. Mupirocin acts by binding to bacterial isoleucyl-tRNA synthetase. Retapamulin is bacteriostatic against *S. aureus* and *S. pyogenes* by inhibiting bacterial protein synthesis.

Bacitracin is bacteriostatic but may also be bactericidal, depending on the antibiotic concentration and the susceptibility of the organism. Bacitracin is primarily active against gram-positive organisms; it inhibits bacterial cell wall synthesis by preventing transfer of mucopeptides into the growing cell wall. Neomycin is an aminoglycoside; it is bactericidal by binding the 30s subunit of the bacterial ribosome to inhibit protein synthesis. Polymyxin acts as a surfactant that disrupts bacterial membranes. Polymyxin has bactericidal activity against some gram-negative organisms including *P. aeruginosa*, *E. coli*, *Enterobacter* sp. and *Klebsiella* sp.

Pharmacokinetics

Absorption and Distribution

The topical agents commonly used to treat bacterial skin infections are minimally absorbed through normal skin. Mupirocin does not appear to be appreciably absorbed systemically following topical application to intact skin. If it is applied to large areas of abraded skin, it may allow for deeper penetration into the epidermal layers. Limited data is available on the absorption of mupirocin following intranasal application in adults. Distribution of mupirocin is by serum protein binding

Retapamulin ointment is minimally absorbed via intact skin; however, absorption is increased when applied to abraded skin. The distribution of retapamulin is unknown.

Bacitracin, when used topically, is minimally absorbed. However, bacitracin is readily absorbed through large areas of denuded or burned skin. Topical preparations of bacitracin that include neomycin and polymyxin B are minimally absorbed through normal skin. Distribution of bacitracin, neomycin, and polymyxin B is unknown.

Metabolism and Excretion

Metabolism and excretion of the topical antibacterial agents mupirocin, bacitracin, neomycin, and polymyxin B are unknown. Retapamulin is metabolized by liver enzymes in vitro; excretion is not known because of the low systemic absorption with topical administration.

Pharmacotherapeutics

Clinical Use and Dosing

Impetigo

Impetigo is a contagious superficial skin infection caused by *S. aureus, S. pyogenes,* or both organisms. Using an antibiotic that is effective against both organisms, either topical or oral, ensures successful treatment. Bullous impetigo is usually pure *S. aureus* and should be treated with an oral antibiotic.

The decision of how to treat impetigo depends on the number of lesions, their location (face, eyelid, or mouth), and the need to limit spread of infection to others. The first-line topical agent is mupirocin; other agents, such as bacitracin and neomycin, are considerably less effective. If the patient has up to five singular lesions, topical mupirocin ointment may be applied 2 times a day until the lesions are healed (5 days). Topical retapamulin is applied twice a day for 5 days. Mupirocin and retapamulin are available only by prescription. There are no reported drug interactions with either mupirocin or retapamulin.

Patients who have numerous lesions or who are not responding to topical agents should receive oral antimicrobials effective against both *S. aureus* and *S. pyogenes.* Antibiotics that are effective against *S. aureus* or *S. pyogenes* include cephalexin (Keflex) or dicloxacillin (Stevens et al, 2014). If MRSA is suspected, clindamycin, TMP/SMZ, or doxycycline should be prescribed depending on local resistance patterns (Stevens et al). A macrolide antibiotic such as erythromycin or azithromycin (Zithromax) or clindamycin can be used if the patient is penicillin allergic and MRSA is not suspected (Stevens et al). There is resistance of *S. aureus* to the macrolides, so the patient needs to be monitored closely. The patient treated with systemic antibiotics should be treated for 7 days (5 days with azithromycin).

Furuncle

Furuncles, commonly known as boils, are infections of the hair follicle and are usually caused by *S. aureus.* The first-line treatment for a small furuncle is use of a warm, moist compress. Larger furuncles are treated by incision and drainage. Incision and drainage alone without use of adjunctive antibiotic therapy are usually sufficient to treat a single abscess smaller than 5 cm.

Systemic antibiotics should be reserved for abscesses larger than 5 cm or if cellulitis and/or symptoms of infection are present such as temperature >38°C or 24 breaths per minute, tachycardia >90 beats per minute, or white blood cell count >12 000 /µL (Stevens et al, 2014). Other situations that warrant the use of antibiotics are occurrence on the central facial area, in pediatric or elderly patients, and in the presence of comorbidities such as immunosupression (Stevens et al). Gram's stain and culture of the drainage from the abscess can determine if the organism will be sensitive to the antibiotic of choice. Prior to Gram's stain results, an appropriate first-line antibiotic would be doxycycline or TMP-SMX (Stevens et al). Length of treatment should be 5 to 10 days.

Recurrent Skin Abcesses

Some patients may experience recurrent skin abcesses. Initial therapy is early incision and drainage, with drainage sent for culture. When culture and sensitivity results are available an antibiotic active against the identified pathogen is started (Stevens et al, 2014). Antibiotics are continued for 5 to

10 days. A 5 day decolonization regimen of twice daily nasal mupirocin, daily chlorohexadine washes, and daily washing of personal towels, sheets, and clothing may be considered (Stevens et al).

Cellulitis

Cellulitis is a skin infection involving the deep layers of the dermis and subcutaneous tissue. The patient may become septic if left untreated. Use of topical antibacterial agents is not appropriate. Patients with cellulitis need to be managed with oral or parenteral antibiotics. Use of oral antibiotics is discussed in Chapter 24.

Nasal MRSA Carrier

Eradication of nasal MRSA colonization in adult patients and health-care workers may be achieved with intranasal mupirocin. However, increased use of topical mupirocin is correlated to the development of resistance. Therefore, routine eradication therapy is not necessary unless MRSA colonization is confirmed in the nares or another site (McConeghy, Mikolich, & LaPlante, 2009). Intranasal mupirocin is supplied in 1 g, single-use tubes twice a day. The patient applies approximately half the ointment from a single-use tube of nasal ointment into one nostril and the other half into the other nostril in the morning and evening for 5 days. Children may require smaller amounts of ointment.

Rational Drug Selection

Antibacterial Activity

The choice of a topical antibiotic is based on susceptibility. Mupirocin and retapamulin are considered broad-spectrum topical antibiotics. Bacitracin and the combination of bacitracin, neomycin, and polymyxin B are OTC products that combine different antimicrobial spectrums to provide a single broad-spectrum product. Mupirocin is considered a broader-spectrum antibiotic than the double- or triple-antibiotic formula. If resistance to the topical product is suspected or if the infection is not responding to topical antibiotics, then systemic antibiotics are warranted.

Cost

The OTC topical antibiotic products are relatively inexpensive. Bacitracin is usually sold as a generic product and is quite inexpensive. The combination product of neomycin, polymyxin B, and bacitracin is available in brand names (Neosporin), which are slightly more expensive than the generic product (triple-antibiotic ointment). Likewise the double-antibiotic brand-name products (Polysporin) are more expensive than generic double-antibiotic ointment.

Combination Products

Due to the possibility of developing neomycin sensitivity, most providers are recommending that patients use double-antibiotic (Polysporin) rather than triple-antibiotic (Neomycin) products.

Monitoring

No specific monitoring is required beyond that related to the disease process for which the patient is being treated.

Patient Education

Administration

Patients should be taught how to appropriately apply the topical antibiotic ointment. They should be instructed to wash their hands before applying the ointment or to use a gloved hand or a clean cotton swab. The antibiotic ointment should be applied sparingly only to the affected infection area. Overapplication of the antibiotic ointment can increase adverse effects. Patients should not use the antibiotic ointment for longer than 1 week unless instructed to do so by their provider. To avoid contamination of the antibiotic ointment, care must be taken not to touch the tip of the antibiotic ointment container to the infected area or to any other surface.

Adverse Reactions

The patient should be instructed that adverse reactions to topical antibiotics are rare but that skin irritation is possible with any topical ointment. Any adverse reactions should be reported to the provider as soon as possible, and the antibiotic ointment should be discontinued until examined. The patient should not use the antibiotic ointment over large surface areas (more than 20% of body surface) without prior instruction from the provider.

Lifestyle Management

Patients need to be instructed on general infection control measures, especially if the patient has impetigo or if MRSA is suspected; both are highly contagious diseases. Patients should wash their hands after any contact with the infected area. Within the family, the infected patient should use care not to share towels or other utensils with other family members to prevent the spread of infection. In addition to topical or oral antibiotic therapy for impetigo, crusts should be removed by soaking with wet compresses and washing the involved areas with antibacterial soap twice a day.

ANTIFUNGALS

Fungal infections of the skin are common in all age groups. These infections, which occur in both healthy and immunocompromised persons, are caused by dermatophytes and yeasts. Dermatophyte infections are classified according to the anatomic location. Infants and immunocompromised patients may have thrush and *Candida* infections in the diaper area. Tinea corporis, also known as ringworm, can be found in patients of all ages. Tinea capitis is most common in children. Tinea pedis, also known as athlete's foot, can be found at any age but generally in postpubertal patients. Fungal overgrowth occurs in immunocompromised patients or patients on antibiotics. Antifungal medications are used to treat superficial fungal infections caused by dermatophytic fungi and yeast. Oral agents must be used in the treatment of disease that is extensive, that affects hair and nails, or does not respond to topical agents.

The topical antifungal medications can be roughly divided into four major categories: allylamine/benzylamine, imidazole, polyene, and other.

Terbinafine (Lamisil) is a topical allylamine antifungal indicated for the treatment of tinea capitis, tinea pedis, and tinea corporis. Another topical allylamine antifungal, naftifine (Naftin, Naftine-MP), is indicated in the treatment of tinea cruris, tinea corporis, and tinea pedis. Butenafine (Mentax) is a benzylamine antifungal indicated for the topical treatment of interdigital tinea pedis, tinea corporis, and tinea cruris due to *Epidermophyton floccosum, Trichophyton mentagrophytes, Trichophyton rubrum,* and *Trichophyton tonsurans.*

The category of imidazole, which includes clotrimazole (Lotrimin), ketoconazole (Nizoral, Extina), miconazole (Monistat), econazole (Spectazole), sertaconazole (Ertaczo), oxiconazole (Oxistat), and sulconazole (Exelderm), are active against common dermatophytes and yeasts. Econazole also has some antibacterial activity.

Nystatin is a polyene antifungal antibiotic that is not effective against the dermatophytes.

Ciclopirox olamine (Loprox) is a broad-spectrum *N*-hydroxypyridinone antifungal used in the treatment of tinea corporis, tinea cruris, or tinea pedis. Tolnaftate (Tinactin) is an OTC product used to treat superficial fungal infections. Systemic antifungals are used to treat tinea capitis and onychomycosis. Griseofulvin is the first-line drug choice in the treatment of tinea capitis (Goldstein & Goldstein, 2011). Onychomycosis may be treated with topical ciclopirox (Penlac) or systemic griseofulvin, itraconazole, or terbinafine.

Pharmacodynamics

Topical Antifungals

Nystatin is a topical polyene antifungal antibiotic. It is effective against most oral, mucosal, and cutaneous infections caused by *Candida* species. Nystatin binds to sterols in the cell membranes of both fungal and human cells. When the nystatin binds to the sterols in the cell membrane of the fungus, it causes a change in membrane permeability that allows leakage of intracellular components.

The topical azole antifungals all act in a similar fashion. They appear to alter the fungal cell membrane by inhibiting ergosterol synthesis through interacting with 14-alpha-demethylase, an essential component of the membrane. This causes leakage of cellular contents, such as potassium- and phosphorus-containing compounds. Clotrimazole is active against a wide variety of fungi, yeasts, and dermatophytes. Organisms that are susceptible to clotrimazole include *Aspergillus fumigatus, Candida albicans, Cephalosporium, Malassezia furfur, T. rubrum,* and some strains of *S. aureus* and *S. pyogenes.* Miconazole inhibits the growth of common dermatophytes *T. rubrum, T. mentagrophytes, C. albicans,* and the active organisms in tinea versicolor, *Pityrosporum orbiculare* and *Pityrosporum ovale.* Ketoconazole is a broad-spectrum antifungal agent that is active against the dermatophytes *T. rubrum, T. mentagrophytes, T. tonsurans, Microsporum canis, E. floccosum,* and the yeast organisms *C. albicans, C. tropicalis, P. ovale,* and *P. orbiculare.* Econazole and oxiconazole have activity

similar to that of ketoconazole. Sertaconazole is only indicated for use in the treatment of interdigit tinea pedis and is active against *T. rubrum, T. mentagrophytes,* and *E. floccosum.*

Terbinafine and naftifine are allylamine antifungals that probably exert their antifungal effectiveness by inhibiting squalene epoxidase, a key enzyme in sterol biosynthesis in fungi. This results in the accumulation of squalene within the fungal cell and causes fungal cell death. Terbinafine has fungicidal activity against dermatophytes. It is less active, however, against *Candida.*

Tolnaftate distorts hyphae and stunts mycelial growth in susceptible fungi.

Butenafine is the first of a newer class of topical antifungal agents, the benzylamines. Butenafine is effective against a wide variety of pathogenic fungi including *E. floccosum, T. mentagrophytes, T. rubrum,* and *T. tonsurans.* The inhibition of squalene monooxygenase creates a deficiency in a component of fungal membranes necessary for normal cell growth; it is less active against *Candida* species. It acts to inhibit fungal ergosterol biosynthesis by interfering with the conversion of squalene into 2,3-oxidosqualene.

Ciclopirox olamine is a broad-spectrum antifungal agent. It acts on the cell membrane to block transmembrane transport of amino acids into the fungal cell, causing intracellular depletion of essential substrates and/or ions. Ciclopirox is used to treat tinea corporis, tinea cruris, or tinea pedis. It has fungicidal activity against in vitro isolates of *T. rubrum, T. mentagrophytes, E. floccosum, M. canis, and C. albicans.* Ciclopirox also inhibits the growth of pathogenic dermatophytes, yeasts, and *M. furfur.* Ciclopirox nail lacquer penetrates the nail to achieve minimum inhibitory concentration (MIC) levels high enough to be fungicidal to most organisms responsible for onychomycosis.

Systemic Antifungals

The systemic antifungal agents used in the treatment of fungal infections of the skin include griseofulvin; the azoles ketoconazole, itraconazole, and fluconazole; and the oral allylamine terbinafine.

Griseofulvin is an antifungal antibiotic produced by certain species of *Penicillium.* Griseofulvin exerts its fungistatic activity by disrupting the mitotic spindle structure of the fungal cell. This arrests metaphase cell division. Griseofulvin may also produce defective DNA. Griseofulvin, which has a greater affinity for diseased tissue than for healthy tissue, has an affinity for keratin precursor cells. These are gradually exfoliated and replaced by uninfected tissue. It is tightly bound to the new keratin, which becomes highly resistant to fungal infections.

Fluconazole is a synthetic, broad-spectrum triazole antifungal agent of the imidazole class. Fluconazole has a broader spectrum than the other imidazole antifungals. It exerts its effect by altering the fungal cell membrane and is a highly selective inhibitor of fungal CYP450 and sterol 14-alpha-demethylase. This inhibition results in increased cellular permeability, causing leakage of cellular contents.

Ketoconazole alters the permeability of the cell membrane and inhibits fungal synthesis of phospholipids. Itraconazole is

a synthetic triazole antifungal medication that is closely related to ketoconazole. Similar to ketoconazole, it exerts its effect by altering the fungal cell membrane. Itraconazole inhibits the CYP450-dependent synthesis of ergosterol, which increases cellular permeability and causes leakage of cellular contents.

Terbinafine is an allylamine antifungal that exerts its antifungal effect through interfering with fungal sterol biosynthesis by inhibiting the enzyme squalene monooxygenase. This causes accumulation of squalene, which weakens the cell membrane in sensitive fungi. The accumulation of squalene within the fungal cell causes fungal cell death. Terbinafine has fungicidal activity against dermatophytes; it is less active against *Candida.* Naftifine's mechanism of action is not known, but it is thought to work similarly to terbinafine.

Pharmacokinetics
Absorption and Distribution
Topical Antifungals

Topical antifungals are poorly absorbed from intact skin. Nystatin is not absorbed from intact skin or mucous membranes. The topical azoles have little or no systemic absorption following topical application. When applied topically, ciclopirox olamine is minimally absorbed (average of 1.3%). Butenafine, when applied topically, is absorbed through the skin into the systemic circulation in amounts that have not been quantified. Absorption and distribution of tolnaftate have not been described. Systemic absorption of topically administered terbinafine is significantly lower than that of orally administered terbinafine. Naftifine is minimally absorbed when applied topically, with 4.2% of the dose absorbed.

Systemic Antifungals

Griseofulvin and terbinafine are the two systemic antifungals discussed in this chapter, as they are primarily used in dermatological diseases. See Chapter 33 for further information on systemic antifungal medications.

Griseofulvin is poorly absorbed, and therefore oral formulations have been developed in an attempt to increase bioavailability. Microsize griseofulvin has a variable and unpredictable oral absorption. Ultramicrosize griseofulvin has almost complete absorption. Oral griseofulvin is absorbed mainly from the duodenum. Its absorption may be increased by the intake of high-fat food. Griseofulvin is widely distributed and concentrates in the skin, hair, nails, fat, and skeletal muscles. It does cross the placenta, and distribution in breast milk is unknown but should be assumed because of griseofulvin's affinity for fat.

Terbinafine, when administered orally, is well absorbed from the gut. Bioavailability is approximately 40%. Administration with food increases the serum area under the curve (AUC) of terbinafine by 20%. It is widely distributed, including the central nervous system (CNS), hair, and nailbeds. Following 2 weeks of therapy at recommended doses, terbinafine remains in the skin for up to 3 months. The drug may be detected in the nails for up to 90 days following treatment. It is unknown whether terbinafine crosses the placenta, but it is excreted in the breast milk of nursing mothers with a milk/plasma ratio of 7:1.

Metabolism and Excretion
Topical Antifungals

Topical antifungals are either not absorbed or absorbed minimally. Therefore, metabolism information regarding nystatin, tolnaftate, oxiconazole, sulconazole, butenafine, sertaconazole, ciclopirox olamine, and topical ketoconazole is not available. Topically administered miconazole is minimally absorbed following application to intact skin, with 1% of a dose applied 6 times daily for 14 days recovered in urine and feces. Metabolism of oral miconazole occurs mainly in the liver, and the small amount of topical medication that is absorbed is assumed to be also metabolized in this manner. Topical application of econazole results in lower systemic absorption. Less than 1% of an applied dose is recovered in urine and feces. Metabolism of econazole is unknown. There is little systemic absorption of clotrimazole following topical application. The small amounts absorbed are metabolized in the liver and excreted in the bile.

Systemic Antifungals

Griseofulvin is metabolized in the liver, mainly through oxidative demethylation and conjugation with glucuronic acid. The major metabolite is inactive. Griseofulvin is excreted through the urine, feces, and perspiration.

Terbinafine is metabolized in the liver through oxidation and hydrolysis to five inactive metabolites. Seventy percent of the oral terbinafine dose is excreted in the urine as conjugated and unconjugated metabolites. Clearance of terbinafine is decreased by approximately 50% in patients with renal impairment or hepatic cirrhosis.

Pharmacotherapeutics
Precautions and Contraindications
Topical Antifungals

There are few contraindications to the topical antifungal medications. Hypersensitivity to the antifungal agent or any of the components of the formulation is a contraindication. Patients with azole hypersensitivity are often sensitive to all azole derivatives. The antifungal agent should be discontinued if sensitization occurs. The use of antifungals around the eyes should be avoided. Ketoconazole cream contains sulfites that may cause allergic types of reactions, including anaphylactic symptoms and life-threatening or less severe asthmatic episodes in susceptible persons. Ciclopirox topical nail lacquer (Penlac) should not be used in immunocompromised or diabetic patients with onychomycosis.

The topical antifungals that are classified Pregnancy Category B are clotrimazole, oxiconazole, ciclopirox olamine, naftifine, and butenafine. The topical antifungals classified as Pregnancy Category C are nystatin, ketoconazole, sulconazole, tolnaftate, miconazole, sertaconazole, and econazole. Of these, only ketoconazole and econazole have demonstrated teratogenic effects in animal tests with doses 10 times the maximum

recommended human dose. Therefore, ketoconazole and econazole should be used in pregnant women only when potential benefits to the mother outweigh the potential risk to the fetus. Although systemic absorption following topical application is extremely low, caution is advised in prescribing econazole or ketoconazole to breastfeeding women. The use of topical antifungals on the breast during lactation is not advised. If antifungal medication is needed to treat such a topical infection in a lactating woman, application of oral nystatin suspension to the affected area on the breast is suggested for safety.

The safety of topical antifungals for infants and children varies from product to product. Nystatin, oxiconazole, econazole and miconazole are all safe for use in infants and children. Tolnaftate, topical ketoconazole, and topical clotrimazole are contraindicated in children younger than 2 years. The safety of ciclopirox olamine for use in children younger than 12 years is product specific. Butenafine, sertaconazole, terbinafine, and naftifine have not had safety and effectiveness established for children younger than 12 years.

Systemic Antifungals

Griseofulvin should be used cautiously in patients with hepatic disease. It may be hepatotoxic on rare occasions. Patients with systemic lupus erythematosus (SLE) or lupus-like syndromes should use griseofulvin with caution because it has been known to exacerbate lupus. Griseofulvin is contraindicated in patients with porphyria or hypersensitivity to griseofulvin. There is a possibility of cross-sensitivity to griseofulvin in patients with penicillin hypersensitivity because griseofulvin is produced by a species of *Penicillium*. This cross-sensitivity is theoretical, and patients have been treated with griseofulvin without adverse effects.

Griseofulvin use during pregnancy is contraindicated. Men should wait at least 6 months after completion of griseofulvin therapy before fathering a child. Its use should be avoided in pregnant women because some women who received the drug during pregnancy reportedly have had spontaneous abortions or delivered infants with congenital abnormalities. Griseofulvin may be used safely in children as young as 2 years.

Terbinafine is contraindicated in patients who have known hypersensitivity to terbinafine or any of its components. Terbinafine should be used with caution in patients with hepatic disease. Terbinafine is rated Pregnancy Category B. It should be used in pregnancy only if the potential benefit to the mother outweighs the potential risk to the fetus; treatment of onychomycosis can be postponed until after pregnancy is completed. Oral terbinafine treatment is not recommended during lactation. Terbinafine may be prescribed for children 4 years of age or older to treat tinea capitis.

Adverse Drug Reactions

Topical Antifungals

Adverse reactions are minimal with topical antifungal medications. Nystatin may cause mild skin irritation when applied topically to some patients, usually related to the preservative (parabens) in the formulation. The topical azoles may all cause itching, stinging, burning, or general skin irritation. Note that cross-sensitization among the topical azoles has been reported. Adverse reactions to topical azoles occur in approximately 1% to 3% of patients treated. The only adverse reaction reported with tolnaftate is mild skin irritation. The allylamine antifungals butenafine and naftifine may cause burning, stinging, dryness, erythema, pruritus, local irritation, and rash. Ciclopirox olamine may cause skin irritation, pruritus at the application site, redness, pain, burning, and worsening of clinical symptoms. Ciclopirox nail lacquer may cause a change in shape or discoloration of the nail.

Systemic Antifungals

The most common adverse reaction with griseofulvin is hypersensitivity, such as skin rashes, urticaria, and, rarely, angioedema. Less commonly reported adverse reactions are oral thrush, nausea, vomiting, epigastric distress, and diarrhea. Several CNS effects have been reported. Headache occurs frequently in the beginning of therapy but often disappears with continued therapy. Other CNS adverse effects include fatigue, dizziness, insomnia, confusion, and impaired performance of routine activities. Hepatitis and elevated hepatic enzymes have been reported in a few patients after prolonged use or high doses of griseofulvin. A rare adverse effect of granulocytopenia or of leukopenia has been reported from prolonged use of high doses of griseofulvin. It should be discontinued if the patient exhibits these conditions. When rare serious reactions occur with griseofulvin, they are usually associated with high doses or long periods of therapy.

The most common adverse reactions with oral terbinafine are gastrointestinal (GI) symptoms such as diarrhea, dyspepsia, abdominal pain, nausea, headache, fever, rash, elevated liver enzymes, and taste disturbance. Rare but serious adverse reactions observed with oral terbinafine include serious skin reactions (Stevens–Johnson syndrome and toxic epidermal neurolysis). Rare cases of blood dyscrasia have been reported with terbinafine use. Severe neutropenia, lymphopenia, thrombocytopenia, and agranulocytosis have all been reported. In clinical trials (Novartis Pharmaceuticals, 2001) 1% to 2% of patients treated with oral terbinafine developed decreased absolute lymphocyte cells (less than 1,000/mm^3). These hematological adverse reactions are reversible with discontinuation of oral terbinafine.

Drug Interactions

Topical Antifungals

There are few drug interactions found with topical antifungal medications. The only significant interactions noted are with clotrimazole and econazole. Clotrimazole and theoretically the other azole antifungals inhibit the synthesis of the fungal sterol ergosterol; the polyene antifungals, such as amphotericin B and nystatin, act by binding to ergosterol. Therefore, the azole antifungals could interfere with the action of either amphotericin B or nystatin by depleting polyene-binding sites. This appears to be the most significant when the azole antifungal is given prior to amphotericin B. Clotrimazole intravaginal preparations should not be

administered concurrently with nonoxynol-9 and octoxynol. Clotrimazole may inactivate the spermicides, leading to contraceptive failure. Corticosteroids may inhibit the antifungal activity of econazole against *C. albicans* in a concentration-dependent manner. When the concentration of cortico-steroid is equal to the concentration of econazole, the antifungal activity of econazole is inhibited. When the corticosteroid concentration is 10% of that of econazole, there is no inhibition of antifungal activity.

Systemic Antifungals

Systemic antifungal medications have a number of drug interactions. Griseofulvin can increase some of the effects of ethanol, causing the patient to experience tachycardia, diaphoresis, and flushing. Griseofulvin can accelerate the hepatic metabolism of some medications. Griseofulvin may also decrease the hypoprothrombinemic activity of warfarin, which decreases its anticoagulant effect. Prothrombin time should be monitored closely if griseofulvin is either added or discontinued from warfarin therapy. Estrogens or estrogen-containing oral contraceptives can be affected by coadministration of griseofulvin. Patients may experience breakthrough bleeding, amenorrhea, or unintended pregnancy. They should use an alternative or second form of contraception while they are taking griseofulvin and for 1 month after griseofulvin is discontinued. Griseofulvin may reduce cyclosporine levels, resulting in decreased pharmacological effects. An increase in the cyclosporine dose may be necessary if griseofulvin is added. A second dosage adjustment may be necessary if griseofulvin is discontinued. Serum salicylate concentrations may be decreased with griseofulvin use. Certain medications, including barbiturates and primidone, may impair the absorption of griseofulvin, resulting in decreased serum concentrations. Food can also affect the absorption of griseofulvin. Eating a high-fat meal at the time of dosing may increase microsize griseofulvin absorption.

Terbinafine clearance is affected by a number of medications. It is decreased by cimetidine and terfenadine and increased by rifampin. Caffeine clearance is decreased by terbinafine. Cyclosporine clearance is increased by terbinafine. Theophylline clearance is decreased by terbinafine. Patients taking theophylline, aminophylline, or cyclosporine concurrently with terbinafine should be monitored closely for increased or decreased effects of these medications with a narrow therapeutic window. Terbinafine may affect the metabolism of warfarin, leading to bleeding and coagulopathy.

Clinical Use and Dosing

Candidiasis

Of the more than 150 recognized species of *Candida*, only a few cause disease in humans. The most common sites for mucocutaneous candidiasis are the mouth, where it causes stomatitis or thrush; the esophagus, where it causes esophagitis; and the vagina, where it causes yeast vaginitis. *Candida* can also be invasive or systemic, aspects that are not discussed in this chapter. In most patients, candidiasis is an opportunistic disease. *C. albicans* is the most common pathogen in humans; other

common pathogens in humans are *C. glabrata, C. parapsilosis,* and *C. tropicalis. Candida* species are normal human flora of the mucosal membranes of the gastrointestinal, genitourinary, and respiratory tracts. It normally lives in balance with other microorganisms within the body. When drugs or conditions, such as broad-spectrum antibiotics, corticosteroids, diabetes mellitus, or HIV infection, offset this balance, *Candida* may become a pathogen and cause mucocutaneous disease. *Candida* species may be transmitted from person to person, by direct contact either by hands or sexual contact, or during birth from a colonized vagina to the neonatal oropharynx. Candidiasis has emerged as the most common opportunistic fungal disease.

The first-line treatment for cutaneous *Candida* infections are the OTC azoles, miconazole and clotrimazole, which are applied twice daily to the affected skin area until clear. For thrush in patients older than 3 years, a 10 mg clotrimazole troche is slowly and completely dissolved in the mouth 5 times a day for 14 days. Longer therapy may be needed in immunosuppressed patients.

For the patient who does not tolerate the azole antifungals, nystatin can be prescribed. Nystatin in cream, ointment, or powder formulation can be applied to the affected area 2 to 3 times per day until clear (see Table 23-1). Cream is preferred to ointment in intertriginous areas. Treatment should continue for at least 2 weeks. For thrush, the dose in adults and children is 4 to 6 mL of nystatin suspension, which is swished around the mouth and swallowed 4 times per day. The dose in infants is 2 mL, with 1 mL applied on each side of the mouth 4 times per day. The dose of nystatin for neonates is 0.5 mL applied to each side of the mouth 4 times per day. Adults and older children can use nystatin troches, which are slowly dissolved in the mouth. Treatment should continue until symptoms have been resolved for 48 hours.

Second-line treatment for cutaneous *Candida* infections includes other prescription azole antifungal medications. Econazole is applied to the affected area twice daily for at least 2 weeks. Ketoconazole is applied once daily for at least 2 weeks. Oxiconazole is applied to the affected and immediately surrounding areas once or twice daily until clear. Sulconazole may be gently massaged into the affected areas and surrounding skin once daily until clear.

Other antifungals effective against *Candida* species include ciclopirox olamine, naftifine, and butenafine. Ciclopirox olamine is gently massaged into the affected skin and surrounding area twice daily until clinical improvement occurs. Naftifine is gently massaged into the affected area once a day for the cream formulation and twice a day for the gel formulation until clinical clearing is observed. Topical butenafine is used in adults and children older than 12 years, and it is applied to the affected areas once daily until clear. Safety in children younger than 12 years has not been established.

An optional second-line treatment for oropharyngeal candidiasis (thrush) is systemic fluconazole. The dosage in adults is 200 mg orally for 7 days. Dosing in children, infants, and neonates older than 14 days is 6 mg/kg PO on the first day, followed by 3 mg/kg PO once daily for 14 days. Neonates

younger than 14 days have the same dose as infants, except it should be given every 72 hours instead of once daily until age 2 weeks. Clinical improvement is rapid with fluconazole, with lesions on the inner cheeks often clearing within the first 1 or 2 days of treatment, but treatment should continue for the full 14 days. This point should be stressed to patients.

Tinea Capitis

Tinea capitis is commonly called ringworm of the scalp. The causative organism is *Trichophyston tonsurans*; exposure to affected pets is associated with *M. canis*. Tinea capitis occurs mainly in children, although it may be seen at all ages. *Trichophyston* causes "black dot" tinea, which presents with tiny black dots that are the remains of broken hair shafts, flush with the scalp. Definitive diagnosis is obtained by fungal culture. As fungal cultures may take 2 to 4 weeks for results, treatment is begun while awaiting results. Microscopy by performing KOH examination of spores on the hair shaft provides the most rapid means of diagnosis.

Treatment of tinea capitis consists of oral antifungal therapy with griseofulvin and biweekly shampooing with sporicidal shampoo. Tinea capitis should always be treated with a systemic antifungal. The treatment of choice is griseofulvin, with treatment to continue for 2 to 4 months, or for at least 2 weeks after negative laboratory examinations are obtained. Griseofulvin is absorbed more easily with a high-fat meal (whole milk, cheese, or ice cream), and the patient should be instructed about this point when beginning treatment.

The patient should also be treated with a sporicidal shampoo such as selenium sulfide or ketoconazole. The patient should shampoo with either the selenium sulfide 2.5% shampoo or ketoconazole 2% shampoo twice weekly until clear. Close contacts should be empirically treated with sporicidal shampoo twice per week.

If the patient is not responding to therapy, a culture should be obtained. Cases resistant to griseofulvin may be treated with systemic terbinafine, fluconazole, or itraconazole, based on the sensitivity of the organism as determined by culture. Resistance to griseofulvin is not common. By obtaining a fungal culture from the patient at the beginning of therapy, the provider will have sensitivity studies on which to base the treatment decision if there is no response after 4 weeks of treatment. Dosing information regarding systemic terbinafine, fluconazole, and itraconazole can be found in Chapter 24.

Tinea Corporis

Tinea corporis is a superficial fungal infection of the skin, also known as ringworm. The causative organism is *T. rubrum, M. canis, T. verrucosum,* or *M. gypseum.* Tinea corporis presents as an annular lesion with raised borders and center clearing. There may be scaling and some erythema. It is spread by direct contact with an infected person or animal. Diagnosis is made by KOH scrapings, Wood's lamp, or fungal culture. Treatment is topical antifungal cream, with miconazole, tolnaftate, or clotrimazole the most common medications used. Other topical antifungals may be used, including terbinafine, butenafine, sulconazole, naftifine, ciclopirox olamine, ketoconazole, and econazole.

Tinea Cruris

Tinea cruris is also known as jock itch. It is a superficial fungal infection of the groin, upper thighs, and intertriginous folds. It is more common in males and rarely occurs before adolescence. The causative fungal organisms are *E. floccosum, T. rubrum,* and *T. mentagrophytes. C. albicans* may also be a causative organism. The lesions are pruritic, erythematous, scaly, well-demarcated patches with central clearing. The treatment for tinea cruris is the same topical antifungal medications that are used for tinea corporis, with the same dosing schedule.

Tinea Pedis

Tinea pedis is a superficial fungal infection of the skin of the feet, commonly called athlete's foot. It is caused by the dermatophytes *E. floccosum, T. rubrum,* and *T. mentagrophytes. C. albicans* may also be a causative organism. Tinea pedis is more common in males and rarely occurs before puberty. Diagnosis is made by the classic clinical presentation of scaling, maceration, fissuring, and inflammation on the feet, especially in the inner digital areas. Treatment for tinea pedis is the same topical agents used for tinea corporis. Length of treatment is extended with tinea pedis, often with 4 weeks of treatment needed.

Tinea Versicolor

Tinea versicolor is a superficial fungal infection of the skin caused by yeasts in the genus *Malassezia.* Clinically, tinea versicolor appears as hyper- or hypopigmented coalescing scaly macules on the trunk and upper arms. The treatment for tinea versicolor consists of topical application of selenium sulfide shampoo or a topical antifungal. Selenium sulfide shampoo is applied to the tinea versicolor patch and left on for 10 to 15 minutes every day for 1 week. Selenium sulfide can be used prophylactically once a month. The topical azoles miconazole, clotrimazole, and econazole may be used twice a day for 2 to 4 weeks in the treatment of tinea versicolor.

Onychomycosis

Onychomycosis, also known as tinea unguium, is a fungal infection of the nail, either fingernail or toenail. Treatment of onychomycosis usually involves months of treatment with a systemic antifungal medication. Topical treatment is usually not effective, with the exception of ciclopirox nail lacquer (Penlac). When treating onychomycosis, medications such as terbinafine and itraconazole appear to have higher rates of cure than griseofulvin. Clearing of onychomycosis takes months of treatment regardless of treatment modality.

Itraconazole may be used for first-line therapy in adult patients with onychomycosis. It may be dosed in one of two methods, either daily dosing or pulse dosing. The daily dosing regimen for adults with toenail onychomycosis is 200 mg daily for 12 weeks. The pulse regimen for adults with toenail involvement is 400 mg/d for 1 week per month for 3 to 4 consecutive months. If only the fingernail area is involved, the adult dose is 200 mg bid for 7 days, then 3 weeks without treatment, and then 200 mg bid for for 2 months. Safety in children has not been established. For onychomycosis, the pediatric pulse dose is 5 mg/kg/d for 1 week per month for

3 to 4 consecutive months. For any patient who takes itraconazole for more than 8 consecutive weeks, liver enzymes and electrolytes should be drawn prior to and every 8 weeks during treatment. Itraconazole should not be administered to pregnant women or women considering pregnancy.

Systemic terbinafine is also used as first-line treatment for onychomycosis in adults (Lipner & Scher, 2014). The dose for treating onychomycosis of the fingernail is 250 mg daily for 6 weeks. To treat an infected toenail, the dose is 250 mg daily for 12 weeks. Liver enzymes and complete blood count (CBC) should be monitored every 6 weeks if treatment lasts longer than 6 weeks.

Griseofulvin has been used extensively in the treatment of onychomycosis as second-line therapy and has a proven safety profile in adults and children. The medication should be administered for at least 4 months for onychomycosis of the fingernail. Treatment of the toenail should last at least 6 months. Renal, liver, and hematopoietic functions should be measured at least every 8 weeks during therapy. The adult dose of griseofulvin microsize for onychomycosis is 600 mg to 1 g/d; the dose for ultramicrosize is 375 mg to 750 mg/d. The dose for children is 10 to 15 mg/kg/d of microsize griseofulvin and 5 to 10 mg/kg/d of ultramicrosize griseofulvin. The medication should be taken with a high-fat meal.

Topical monotherapy with ciclopirox (Penlac) is indicated in superficial white onychomycosis, when there is distal subungual onychomycosis that affects less than 50% of the nail surface, when four or fewer nails are infected and for children with thin, fast growing nails (Gupta, Paquet, & Simpson, 2013). Topical ciclopirox nail lacquer (Penlac) is applied once daily to the infected nail, preferably at bedtime. The solution is applied to the entire nailbed and surrounding 5 mm of skin. The solution must remain on the nail 8 hours before bathing. Once a week (every 7 days) previous coats of lacquer are removed with alcohol and excess nail is trimmed and filed. This routine is repeated for 24 to 48 weeks. The patient should not use nail polish during treatment.

Combining an oral antifungal with topical ciclopirox has been found in multiple studies to be more effective than either treatment alone. The combination of terbinafine and ciclopirox has the most published studies (Avner, Nir, & Henri, 2005; Baran & Kaoukhov, 2005; Gupta, Onychomycosis Combination Therapy Study Group, 2005). Dosing ciclopirox daily for 48 weeks combined with terbinafine 250 mg/d for 12 weeks or terbinafine 250 mg/d for 4 weeks, then 4 weeks of rest and an additional 4 weeks of terbinafine produced similar cure rates (70.4% versus 66.7%) (Gupta et al, 2005). A slightly higher cure rate (88.2%) is achieved when terbinafine 250 mg/d for 16 weeks is combined with 9 months of topical ciclopirox (Avner et al, 2005). Although further studies are needed, it is reasonable to consider combining therapies in patients with onychomycosis.

Rational Drug Selection

Indication

For treating topical dermatophyte infections, generally the OTC azoles are the first-line therapy because they are easily available without prescription and are low cost. If OTC products are not effective, then a broader-spectrum antifungal can be prescribed, with little difference found in efficacy in treating common organisms that cause tinea infections.

Cost

The cost of medication varies greatly among the antifungals. Generally, OTC products are less expensive than prescriptions. In the treatment of thrush, nystatin is a low-cost, effective therapy for topical fungal infections and is usually covered by insurance plans. When treating cutaneous fungal infections, the OTC products clotrimazole and miconazole should be the first medications used because of their low cost and their safety profile. If they are ineffective, then a prescription product with a broader spectrum may be used, but it is generally more expensive. In the treatment of tinea pedis, tolnaftate is available OTC in a variety of formulations; the generic products are generally the least expensive.

> Metholated ointment (Vicks VapoRub) is a common lay treatment for onychomycosis. A small study (*n* = 18) of the use of daily topical mentholated ointment showed a positive treatment effect (83%), with mycological cure in 27.8% of study subjects and partial cure in 55.6% (Derby, Rohal, Jackson, Beutler, & Olsen, 2011).

Patient Variables

Many patients cannot tolerate systemic antifungals due to liver toxicity. Topical ciclopirox nail lacquer provides an alternative treatment for patients with onychomycosis who cannot tolerate systemic antifungals.

Monitoring

The patient being treated for oral candidiasis should be monitored for efficacy of treatment, with no laboratory monitoring necessary. The patient being treated for tinea capitis will need monitoring for adverse effects from the systemic antifungals. All of the systemic antifungal agents can possibly cause some alteration in hepatic function. If the patient is to be on continuous therapy, then baseline and ongoing monitoring of liver function is necessary. If liver enzymes become elevated, the medication should be discontinued. The patient being prescribed griseofulvin will require renal, liver, and hematopoietic function measurements every 8 weeks during therapy. Patients receiving ketoconazole require liver function tests prior to beginning therapy and monthly for the whole course of their treatment. Patients on itraconazole need liver enzyme and renal studies if the medication is prescribed for longer than 8 consecutive weeks. In that case, liver function and electrolytes should be monitored prior to beginning therapy and every 8 weeks during treatment. Liver enzymes and CBC should be monitored every 6 weeks in the patient receiving terbinafine who is treated for longer than 6 weeks.

Patient Education

Administration

Instruct patients to take the drug as prescribed for the full course of their treatment, even if they note clinical improvement. In the treatment of oral candidiasis, the patient should be instructed to continue therapy until 2 days after symptoms have disappeared. When treating infants with thrush, all pacifiers and bottle nipples should be washed in warm, soapy water and soaked in hot or boiling water for 20 minutes between each use. This step is important to prevent reinfection of the infant with candidiasis. If oral candidiasis is treated with clotrimazole troche, patients should be instructed to slowly dissolve the troche in their mouth, not chew.

Patients using topical antifungals for dermatophyte infections of the skin should be instructed to apply the medication to the infected area and the immediate surrounding area for the full length of treatment. Treatment is often continued beyond the point of clinical clearing to prevent recurrence of the infection. Generally, avoid occlusive dressings, which provide favorable conditions for yeast growth.

The treatment of tinea capitis or onychomycosis involves long-term therapy with oral antifungal medications. The patient should be encouraged to continue the medication for the full length of treatment and take the medication as prescribed. Griseofulvin must be taken with a high-fat meal to ensure adequate absorption of the medication. Itraconazole should be taken with food. Ketoconazole and terbinafine may both be taken without regard to meals.

In treating topical dermatophyte infections such as tinea corporis or ringworm, family members and pets should be checked for signs of infection and be treated also.

Adverse Reactions

The patient should be given written and oral instructions regarding the adverse drug reactions that may be expected with the medication that is being prescribed. If the patient is prescribed systemic antifungal medication, then an explanation of the possible adverse effects and the necessity for laboratory monitoring should be discussed. Patients should be instructed to immediately report to their provider any flu-like symptoms, which may be a sign of hepatic toxicity.

TOPICAL ANTIVIRALS

Topical antivirals are used to treat herpes simplex virus (HSV) and herpes zoster. The oral antiviral medications used to treat these conditions and varicella are discussed in Chapter 24. The two herpes simplex virus infections that are treated with topical medications are HSV-1 and HSV-2, with HSV-1 generally associated with nongenital infection and HSV-2 with genital infection. There are three topical antiviral medications: acyclovir (Zovirax), penciclovir (Denavir), and the OTC product docosanol (Abreva).

Pharmacodynamics

Both acyclovir and penciclovir must be phosphorylated to be active against herpes simplex virus. Intracellularly, both medications are converted to monophosphate forms by viral thymidine kinases, then further converted to diphosphate and finally to triphosphate by various cellular enzymes. Acyclovir triphosphate competes with deoxyguanosine triphosphate for a position in the DNA chain of the herpes virus. Once incorporated in the DNA chain, it terminates DNA synthesis. Penciclovir triphosphate selectively inhibits viral DNA polymerase by competing with deoxyguanosine triphosphate. This inhibits viral replication. In vitro, penciclovir triphosphate is retained inside the HSV-infected cells for 10 to 20 hours, compared with 0.7 to 1 hour for acyclovir.

Pharmacokinetics

Absorption and Distribution

After topical application of acyclovir, penciclovir, or docosanol there is minimal absorption, and no drug is detected in the blood or urine after application.

Pharmacotherapeutics

Precautions and Contraindications

The only true contraindication to acyclovir, penciclovir, or docosanol is hypersensitivity to the product or any of its components. Acyclovir should be used with caution in patients with ganciclovir hypersensitivity in that these two drugs have similar chemical structures and there may be cross-sensitivity.

Acyclovir and penciclovir are classified as Pregnancy Category B, although no complete or well-controlled pregnancy studies have been performed in humans. No adverse effects on pregnancy outcomes or fetal development are found in animal studies. However, there have been no adequate or well-controlled studies in pregnant women.

Orally administered acyclovir is excreted in breast milk. It is unknown whether topical acyclovir is excreted in breast milk. Because topical acyclovir cannot be measured in the serum, it is assumed that it is not excreted in breast milk. It is not known if penciclovir is excreted in human milk after topical administration. Both medications should be used with caution in a nursing mother until further studies clarify their safety.

Acyclovir, penciclovir, and docosanol have all been approved in the use of children older than 12 years of age.

Adverse Drug Reactions

Although systemic acyclovir has extensive adverse reactions, topical acyclovir has only transient local adverse reactions. The most common reaction to topical acyclovir use is mild pain with transient burning or stinging in 28.3% of patients. Pruritus is reported by 4.1% of patients, with rash and local edema found in less than 1%.

The only adverse reactions reported for docosanol is irritation at the site of application.

Drug Interactions

There are no known drug interactions identified with topical acyclovir, penciclovir, or docosanol.

Clinical Use and Dosing

Herpes Simplex

Acyclovir is indicated for the treatment of recurrent herpes labialis (cold sores); herpes genitalis; and in limited, non–life-threatening, mucocutaneous HSV infections in immunocompromised patients. Topical acyclovir is applied to cover all lesions every 3 hours, 6 times a day for 7 days. The dose size per application should be approximately a 0.5- to 1-inch ribbon of ointment per 4 square inches of surface area. A glove or finger cot should be used to apply the medication to prevent autoinoculation of other body sites and transmission of infection to other people.

Penciclovir is indicated in the treatment of recurrent herpes labialis (cold sores) on the lips and face. Application to mucous membrane is not recommended. In adults, penciclovir 1% cream is applied every 2 hours while awake, with treatment started as early as possible (during the prodrome or when lesions appear).

Docosanol (Abreva) is the only OTC product available for the treatment of herpes labialis. It is applied to the cold sore 5 times a day until healed. Treatment should begin at the first sign of outbreak.

Herpes Zoster

Neither topical acyclovir nor topical penciclovir is indicated in the treatment of herpes zoster.

Varicella

Although oral acyclovir is used in the treatment of varicella, topical acyclovir does not have this indication. Penciclovir is not used in the treatment of varicella.

Rational Drug Selection

Efficacy

Penciclovir is the first topical antiviral medication that has been clinically proved to be effective in the treatment of herpes labialis (cold sores). Docosanol is effective in decreasing the duration of a cold sore outbreak but must be started early in the course of the outbreak to be effective, whereas penciclovir may be started any time in the disease course. Although acyclovir may be used for herpes labialis, it has not been clinically proved to be effective in the treatment of HSV infections in immunocompetent patients. In genital herpes, acyclovir is the drug of choice for primary lesions in immunocompromised patients.

Cost

Topical acyclovir and penciclovir are both unique antiviral agents and their cost is not generally used as part of the decision of whether to prescribe the drug in treatment.

Monitoring

There is no laboratory monitoring necessary for patients treated with topical acyclovir or penciclovir. Monitoring for the adverse reactions noted previously is the only monitoring needed.

Patient Education

Administration

Patients should be instructed to start therapy with acyclovir as early as possible after the onset of the signs and symptoms of HSV infection. When applying acyclovir, patients should first wash their hands thoroughly and use a finger cot or rubber glove to apply the ointment to prevent the spread of infection. They should apply enough ointment to thoroughly cover all lesions. Patients should be instructed that acyclovir might cause transient burning, stinging, itching, and rash. They should notify their primary care provider if these symptoms become pronounced or persist.

Patients should be instructed to begin therapy with penciclovir as soon as symptoms begin, during the prodrome or when lesions appear. They should wash their hands thoroughly after applying penciclovir to prevent the spread of infection. Patients should avoid application on or near the eyes or mucous membranes. Although adverse reactions are rare, patients should be instructed to report any skin irritation to their provider.

Treatment with docosanol should begin at the earliest sign or symptom. Patients should wash hands before and after application. The medication should be rubbed in completely. Patients are to use the medication 5 times a day until cold sores are healed.

AGENTS USED TO TREAT ACNE

Acne is the most common skin condition in the United States, affecting approximately 40 to 50 million Americans (American Academy of Dermatology [AAD], 2011). Acne can occur at any age, with up to 25% of adults having some degree of acne. Acne is classified as mild, moderate, or severe, and pharmacological intervention is based on the severity of acne. The bacterium commonly found in acne is *Propionibacterium acnes (P. acnes);* thus, treatment often includes antibiotics active against *P. acnes* (Strauss, et al, 2007).

The medications used in the treatment of acne may be either topical agents or systemic. The topical agents used for acne can be divided into two categories: retinoids and antibiotics. Oral medications for systemic use are divided into three categories: oral antibiotics (discussed in Chap. 24), hormonal therapy (discussed in Chap. 31), and isotretinoin, an oral retinoid. Oral antibiotics are prescribed for moderate to severe acne, and isotretinoin is prescribed for severe nodulocystic acne.

Pharmacodynamics

Topical Retinoids

Tretinoin is a naturally occurring derivative of vitamin A that is structurally related to isotretinoin. After topical administration, tretinoin appears to reduce the cohesion between keratinized cells. They act specifically on microcomedones,

causing fragmentation and expulsion of the microplug, expulsion of comedones, and conversion of closed comedones to open comedones. New comedone formation is prevented by continued use. Tretinoin thins the cell layers of the stratum corneum. Tretinoin does not affect the bacteria found in *P. acnes.* Topical tretinoin is also used in the treatment of fine wrinkling, mottled hyperpigmentation, and roughness of the skin associated with sun damage. Retinoids enhance the penetration of other topical agents such as topical antibiotics and benzoyl peroxide.

Adapalene is a topical retinoid-like drug used for the treatment of mild to moderate acne vulgaris. Adapalene binds to specific retinoic acid nuclear receptors but does not bind to the cytosolic receptor protein. Although the exact mode of action of adapalene is not known, it is suggested that topical adapalene may normalize the differentiation of follicular epithelial cells, resulting in decreased microcomedone formation. It is also a modulator of cellular differentiation, keratinization, and inflammatory processes, all of which represent important features in the pathology of acne vulgaris.

Tazarotene is a retinoid. The exact mechanism of action of tazarotene in the treatment of acne is not well defined, but it is believed that the drug works by normalizing epidermal differentiation and by reducing the influx of inflammatory cells into the skin.

Topical Antibiotics

Benzoyl peroxide has antibacterial activity against *P. acnes,* the predominant organism in sebaceous follicles and comedones of acne vulgaris. This antibacterial activity is presumably due to the release of active or free-radical oxygen capable of oxidizing bacterial proteins. Benzoyl peroxide also has a drying effect, removes excess sebum, causes mild desquamation, and has a sebostatic effect.

Erythromycin is a bacteriostatic macrolide antibiotic, which binds to the P site of the 50S ribosomal subunit, interfering with protein synthesis.

Topical clindamycin has activity against *P. acnes* in vitro. Clindamycin reversibly binds to 50S ribosomal subunits, preventing peptide bond formation and thus inhibiting bacterial protein synthesis. It can be bacteriostatic or bactericidal.

Metronidazole is classified as an antiprotozoal and antibacterial agent. The mechanism by which topical metronidazole acts in reducing the inflammatory lesions is thought to disrupt bacterial and protozoal DNA, inhibiting nucleic acid synthesis.

The mechanism of action for azelaic acid in acne vulgaris is its antimicrobial effect against *P. acnes* and *S. epidermidis.* The mechanism of action may be due to inhibition of microbial cellular protein synthesis. Azelaic acid decreases the inflammation associated with acne lesions by reducing the concentration of bacteria present in the skin. Azelaic acid may also cause normalization of keratinization, leading to an anticomedonal effect. It may also decrease microcomedone formation by reducing the number and size by of keratohyalin granules and the amount and distribution of filaggrin in epidermal layers. Azelaic acid does not effect sebum excretion.

The mechanism of action of topical dapsone in the treatment of acne is unknown.

Systemic Retinoids

Isotretinoin is an isomer of *all-trans* retinoic acid, a metabolite of retinol (vitamin A). It reduces sebum production by reducing sebaceous gland size, normalizing follicular keratinization, and indirectly reducing *P. acne* and its inflammatory sequale.

Pharmacokinetics

Absorption and Distribution

Topical Retinoids

Tretinoin and adapalene administered topically are minimally absorbed systemically. However, there are published case reports of birth defects in the literature associated with topical tretinoin use, which are consistent with retinoid embryopathy (Bozzo, Chua-Gocheco, & Einarson, 2011). Women should be encouraged to not use topical retinoids during pregnancy. Tazarotene, when administered topically to the skin, has minimal systemic absorption However, this medication is categorized as a Category X drug and women of childbearing age should be alerted and avoid usage.

Topical Antibiotic

Only about 5% of benzoyl peroxide is absorbed by the skin and then it is completely metabolized to benzoic acid within the skin and excreted unchanged in the urine. Absorption of topical erythromycin is unknown. Clindamycin, when applied topically, does exhibit some systemic absorption, depending on the surface area covered. Following multiple topical applications at a concentration equivalent to 10 mg, very low levels of clindamycin are present in the serum. Metronidazole is absorbed when applied topically but in very small amounts. Approximately 4% of topically applied azelaic acid is absorbed systemically.

Systemic Retinoids

Due to its high lipophilicity, oral absorption of isotretinoin is enhanced when given with a high-fat meal. Isotretinoin is more than 99.9% bound to plasma proteins, primarily albumin, and is not stored in adipose tissue. Although severe fetal abnormalities have been noted, it is not known whether isotretinoin crosses the placenta, due to ethical restrictions imposed on such studies.

Metabolism and Excretion

Topical Retinoids

A minimal amount of tretinoin is absorbed systemically. This trace amount is metabolized by the CYP450 hepatic enzyme system. Approximately 1% to 5% of a topically applied dose is excreted in the urine. The metabolism of topically applied adapalene is low and it is eliminated by biliary excretion. Tazarotene is rapidly metabolized in the skin to the active metabolite tazarotenic acid, which is systemically absorbed and further metabolized by the liver to sulfoxides, sulfones,

and other metabolites. Elimination of the metabolites is via fecal and renal pathways.

Topical Antibiotics

Benzoyl peroxide is absorbed by the skin, where it is metabolized to benzoic acid and excreted as benzoate in the urine. Topical erythromycin absorption is minimal. Excretion of erythromycin is mainly unknown. Topical clindamycin is systemically absorbed, depending on the surface area covered. Topically applied azelaic acid is minimally absorbed and is mainly excreted unchanged in the urine.

Systemic Retinoids

Isotretinoin is metabolized in the liver primarily via oxidation. It is unknown whether its metabolite is pharmacologically active. The metabolites are eliminated renally, and unchanged drug and metabolites are excreted in the feces.

Pharmacotherapeutics

Precautions and Contraindications

Topical Retinoids and Topical Antibiotics

Topical retinoids should be avoided in patients with eczema, sunburn, or skin abrasions at the site of application. Topical retinoids are contraindicated in lactating women. Safety and efficacy in children younger than 12 years have not been established. Tretinoin and adapalene are classified as Pregnancy Category C. Tazarotene is Pregnancy Category X.

Topical antibiotics used in acne treatment have few true contraindications. Benzoyl peroxide may exhibit cross-sensitivity with benzoic acid derivatives. Erythromycin, when applied topically, is contraindicated only when the patient is hypersensitive to erythromycin or to any component of the preparation. Topical clindamycin is contraindicated in any patient who is hypersensitive to clindamycin or lincomycin. It is also contraindicated in patients with a history of regional enteritis, ulcerative colitis, or antibiotic-associated colitis. Azelaic acid products are contraindicated for use in patients with a history of hypersensitivity to any components of the preparation, and caution should be exercised in patients with dark complexion to avoid hypopigmentation. Azelaic acid is classified as Pregnancy Category B. Because small amounts of azelaic acid are absorbed systemically and may be excreted in breast milk, caution should be exercised in administering it to lactating women. Safety and efficacy of azelaic acid in children younger than 12 years have not been established. Hypersensitivity to metronidazole, nitroimidazole derivatives, or any component of the formulation is a contraindication to its use. Meteronidazole is Pregnancy Category B and use is not recommended in lactating women.

Systemic Retinoids

Isotretinoin should be avoided in patients with retinoid hypersensitivity, including vitamin A, tretinoin, and etretinate. Patients with parabens hypersensitivity should avoid isotretinoin because the drug is prepared with parabens, a preservative. Patients with a risk for osteoporosis (osteomalacia and anorexia nervosa) should avoid taking isotretinoin due to decreased bone mineral density seen during treatment. Adolescents who participate in impact sports while taking isotretinoin are at risk for bone injuries. The safety and effectiveness in children younger than 12 years have not been established for isotretinoin. Care should be exercised in administering isotretinoin to patients with hyperlipidemia, as they may have increased lipids during therapy. Isotretinoin should be prescribed cautiously to patients with psychotic disorders; it may cause major depression, psychosis, and, rarely, suicidal ideation.

Isotretinoin is classified Pregnancy Category X and is absolutely contraindicated in pregnancy. It may cause severe malformations of the craniofacial, cardiac, thymic, and CNS structures. Spontaneous abortions and premature births have been reported. The drug should not be administered to any woman of childbearing age until after pregnancy has been excluded and appropriate birth control measures are used for at least 1 month. Patients should also avoid pregnancy for at least 1 month after discontinuation of isotretinoin. Breastfeeding is not recommended during isotretinoin treatment because of the potential adverse affects to the nursing infant.

Only dermatologists prescribe isotretinoin due to its adverse effect profile. It must be stressed that, because of the safety issues, primary care providers usually do not prescribe this medication. As a requirement of the Risk Evaluation and Mitigation Strategy (REMS) program, access to this medication is restricted. All patients (male and female), prescribers, wholesalers, and dispensing pharmacists must register and be active in the iPLEDGE risk management program, designed to eliminate fetal exposures to isotretinoin (www.ipledgeprogram.com).

Adverse Drug Reactions

Topical Retinoids

Topical retinoids all cause some degree of skin irritation. Burning or pruritus immediately after applying a topical retinoid is common. All three retinoid products cause erythema, scaling, xerosis, and peeling. These symptoms occur frequently and appear to be necessary for the therapeutic effect. Because photosensitivity may occur with topical retinoid use, patients should use sunscreen to prevent severe sunburn. Both tretinoin and tazarotene may cause hyperpigmentation, or hypopigmentation, which will resolve after discontinuation of the medication.

Topical Antibiotics

Topical antibiotics used in the treatment of acne all cause some dryness, erythema, burning, peeling, and itching. Benzoyl peroxide may also cause marked peeling and desquamation, which appears to be a necessary component of the therapeutic effect. Benzoyl peroxide may also cause photosensitivity. Allergic contact sensitization may occur with any of the topical antibiotics used in the treatment of acne vulgaris. In patients with dark complexions, skin hypopigmentation may occur with the use of topical azelaic acid.

Systemic Retinoids

Isotretinoin has multiple reported significant adverse reactions. The most commonly reported adverse reactions involve mucocutaneous effects. Cheilitis (inflammation of the lips) occurs in more than 90% of patients, and dry skin, pruritus, and skin fragility occur in approximately 80% of patients. Conjunctivitis is reported by 40% of patients, with facial skin desquamation and drying of mucous membranes reported by approximately 30% of those treated with isotretinoin. Patients also report xerosis, xerostomia, and epistaxis. These mucocutaneous drying effects of isotretinoin are dose-related and are usually reversible after discontinuation of therapy.

Hypertriglyceridemia occurs in up to 45% of patients on isotretinoin therapy and elevations of total cholesterol and low-density lipoprotein are seen in approximately 30% (Zane, Leyden, Marqueling, & Manos, 2006). These elevations are transient in about 80% of subjects and are rarely severe enough to require termination of therapy. Alcohol consumption may potentiate serum triglyceride elevations. Lipid alterations occur most frequently at dosages greater than 1 mg/kg/d and are reversible upon discontinuation of isotretinoin.

Elevation of serum glucose and fasting serum blood glucose has been reported. Exacerbation of diabetes mellitus can occur. Decreases in hemoglobin and hematocrit concentrations and increased sedimentation rates have been reported. Patients may also experience anemia and thrombocytopenia.

CNS effects include headache, lethargy, and fatigue. Isotretinoin has also been associated with pseudotumor cerebri (benign increased intracranial pressure). Symptoms include headache, visual disturbances, and papilledema. In the post-marketing period, depression has been reported, as have psychosis and, rarely, suicidal ideation. If patients report depression, immediate discontinuation of therapy is indicated. Depression appears to subside with discontinuation of therapy and to recur upon reinstitution of therapy.

Adverse GI reactions include anorexia, nausea and vomiting, increased appetite, and thirst. Eighty percent of patients report dry mouth when taking isotretinoin. Inflammatory bowel disease, including regional enteritis, may occur.

Musculoskeletal adverse effects such as arthralgia and myalgia are reported in approximately 16% of patients taking isotretinoin. Skeletal abnormalities have been reported in adults and children receiving excessive doses (more than 2 mg/kg/d for prolonged periods, 6 months to 2 years). Bone mineral density (BMD) decreases have been seen in pediatric patients when administered a single course of isotretinoin at normal dosages. Adolescent or adult athletes who participate in sports with a repetitive impact may be at increased risk for bone-related injuries due to the decreased BMD seen with isotretinoin use (Bradford, 2008).

Isotretinoin has been associated with rare cases of hepatitis. Normalization of liver enzyme levels does not readily occur with dose reduction or continuation of the drug. If hepatitis is suspected during isotretinoin treatment, the drug should be discontinued.

Ophthalmic adverse effects including corneal opacification have been reported in patients receiving isotretinoin for acne. This ocular effect is reversible with complete resolution or continuing resolution at 6 to 7 weeks following discontinuation of therapy. Of patients taking isotretinoin, 25% report visual disturbances, including blurred vision, decreased visual acuity, tunnel vision, photophobia, diplopia, decreased night vision, and intolerability to contact lenses.

Drug Interactions

Topical Retinoids and Topical Antibiotics

Topical retinoids should not be used concomitantly with other topical medications that have strong drying effects, such as benzoyl peroxide, salicylic acid, or lactic acid (Table 23-2). Medicated or abrasive soaps or cleaners should also be

Table 23–2 ⬛ **Drug Interactions: Selected Acne Medications**

Drug	Interacting Drug	Possible Effect	Implications
Topical Acne Medications			
Retinoids • Adapalene • Tazarotene • Tretinoin	Skin irritants, like benzoyl peroxide, salicylic acid, lactic acid, medicated or abrasive cleansers Products that contain alcohol, lime, menthol, spices, or perfumes	Increased skin irritation	Avoid concurrent use of topical medications that have strong drying effects Before beginning therapy, the effects of strong topical drying agents need to subside to prevent significant skin irritation
Topical Antibiotics			
• Azelaic acid • Benzoyl peroxide • Clindamycin • Erythromycin	No known interactions Topical retinoids PABA-containing sunscreens Erythromycin Clindamycin	May transiently discolor skin Antagonize each other Antagonize each other	Avoid concurrent use Avoid concurrent use Avoid concurrent use
Metronidazole	No known interactions		

Table 23–2 ▦ **Drug Interactions: Selected Acne Medications—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
Dapsone	TMP/SMX	Levels of dapsone and its metabolites increased in the presence of TMP/SMX	Exposure from the proposed topical dose is about 1% of that from the 100 mg oral dose, even when coadministered with TMP/SMX
	Benzoyl peroxide	Localized discoloration of skin	Avoid concurrent use
	Antimalarial agents	May enhance the adverse effect of dapsone	Avoid concurrent use
Systemic Acne Medication			
Isotretinoin	Vitamin A	Potentiate the toxic effects of isotretinoin	Do not take concurrently
	Alcohol		Avoid concurrent use
	Tetracycline	Potentiate the toxic effects of isotretinoin	Avoid concurrent use
	Skin irritants, like benzoyl peroxide, salicylic acid, lactic acid, medicated or abrasive cleansers	May increase incidents of pseudotumor cerebri	Observe for skin irritation if using concurrently
	Products that contain alcohol, lime, menthol, spices, or perfumes	Can potentiate the drying effects of isotretinoin	Postpone lipid determinations for at least 36 h following ethanol consumption, if patients are taking isotretinoin
	Ethanol	Can increase the hypertriglyceridemic effects of isotretinoin	Monitor closely if using concurrently
	Carbamazepine	Reduced carbamazepine levels with concurrent use	

PABA = para-aminobenzoic acid.
TMP/SMX = trimethoprim/sulfamethoxazole.

avoided because they can potentiate the skin irritation caused by topical retinoids. Products that contain alcohol, lime, menthol, spices, or perfumes can further dry and irritate the skin and should not be used with topical retinoids. Before topical retinoids are begun, the effects of strong topical drying agents need to subside to prevent significant skin irritation. Topical retinoids should not be used in the same areas of skin at the same time as benzoyl peroxide or topical antibiotics. A physical incompatibility between the medications or a change in pH may reduce the efficacy of topical retinoids if used simultaneously. When used together for clinical effect, these medications should be used at different times of the day, such as morning and night, to minimize possible skin irritation.

Topical antibiotics have fewer significant drug interactions than systemic antibiotics. Benzoyl peroxide can interact with topical retinoids, as noted previously. PABA sunscreens may transiently discolor the skin if used concurrently with benzoyl peroxide. All of the topical antibiotics may have possible additive irritation when used with other topical acne agents (especially abrasives or keratolytics). Azelaic acid has no known drug interactions.

Systemic Retinoids

Concomitant use of isotretinoin and other sources of vitamin A can potentiate the toxic effects of isotretinoin. Alcohol may also potentiate the toxic effects of isotretinoin. Tetracycline may increase the incidence of pseudotumor cerebri. Simultaneous use of isotretinoin and other drying agents, such as benzoyl peroxide or other medicated or abrasive soaps or alcohol-containing products, can potentiate the drying effects of isotretinoin. Ethanol can increase the hypertriglyceridemic effects of isotretinoin. Lipid determinations should be postponed for at least 36 hours after ethanol consumption.

Clinical Use and Dosing

Acne Vulgaris

Topical retinoids are applied to the skin once daily as tolerated (Table 23-3). If bothersome or excessive dryness or peeling occurs, patients should reduce the number of applications per day or week. In the evening before retiring, the patient applies a thin film of medication after washing with a gentle cleanser. Care should be taken to avoid the eyes, lips, and mucous membranes. It is recommended that the patient wait 20 to 30 minutes after cleaning before applying tretinoin. Patients should wash their hands immediately after applying topical retinoids.

Topical antibiotics are applied to affected acne areas twice daily as tolerated, in a thin film. Patients should wash their skin with a gentle cleanser and pat dry before applying. Benzoyl peroxide cream or gel is applied once or twice a day to acne-affected areas. Benzoyl peroxide cleanser may be used for cleaning once or twice daily. Patients should wet the skin areas to be treated prior to administration, rinse thoroughly after cleaning, and pat dry. If bothersome or excessive dryness or peeling occurs, patients should reduce the number of applications per day. Clindamycin should be applied to all of the affected areas twice daily. If using the pledget formulation, more than one pledget may be used. Patients should remove the pledget from the foil just before use and discard after a single use. Patients should be instructed to wash their hands thoroughly after the use of any topical antibiotic.

There are combination products available that combine a topical antibiotic with benzoyl peroxide (Benzamycin, Benzaclin, Duac). Benzamycin, a product that combines benzoyl peroxide and erythromycin gel, is unique in that

Table 23–3 ⚕ Dosage Schedule: Selected Acne Medications

Drug	Available Dosage Forms	Dosage	Notes
Retinoids			
Adapalene (Differin)	0.1% cream 0.1%, 0.3% gel 0.1% lotion	Apply to affected areas 1×/d at bedtime, as tolerated	Allow 20–30 min for skin to dry after cleansing, before applying medication
Tazarotene 0.1% (Tazorac)	0.05%, 0.1% cream 0.05%, 0.1% gel		Avoid use near eyes, lips, and mucous membranes
Tretinoin (Atralin, Retin-A)	0.025%. 0.05%, 0.1% cream 0.01%, 0.025% gel		Wash hands after application
(Retin-A micro)	0.04%, 0.1% gel		
Topical Antibiotics			
Azelaic acid (Azelex)	20% cream	Apply a thin film on affected areas 2×/d	May decrease to once a day if irritating/drying
Benzoyl peroxide (OXY Maximum Face Wash, Clean & Clear, Neutrogena On The Spot)	10% cream 2.5%, 5%, 10% gel 5%, 10% liquid 5%, 10% liquid 9% pad 4%, 5%, 6%, 8%, 10% soap 8.5% solution	Cleansers: wash affected areas 1–2×/d Other forms: apply to affected areas 1–3×/d	May decrease to once a day if irritating/drying Wash hands after application Medication can bleach fabrics
Benzoyl peroxide and erythromycin gel (Benzamycin)	Erythromycin 3% and benzoyl peroxide 5% gel	Apply to affected acne areas 2×/d	Wash hands after application Medication can bleach fabrics
Benzoyl peroxide and clindamycin gel (Benzaclin, Duac, Acanya)	Benzoyl Peroxide 5% and clindamycin phosphate 1% gel; benzoyl peroxide 2.5% and clindamycin phosphate 1.2% gel	Apply to affected areas 2×/d (Benzaclin) Apply 1×/d (Acanya, Duac)	Wash hands after application Medication can bleach fabrics
Adapalene and benzoyl peroxide (Epiduo)	Adapalene 0.1% and benzoyl peroxide 2.5% gel	Apply once a day after washing	Apply pea-sized amount for each area of the face
Clindamycin (Cleocin T, Clindagel, ClindaMax)	1% foam 1% gel 1% lotion 1% pad 1% solution	Apply to affected areas 2×/d	Wash hands after application More than 1 pledget may be used; remove from foil just before use and discard after, single-use only
Clindamycin and tretinoin (Veltin, Ziana)	Clindamycin phosphate 1.2% and tretinoin 0.025%	Apply to affected area once daily at night	Apply a pea-sized amount. Avoid the eyes, lips, and mucous membranes.
Erythromycin (Akne-Mycin, Ery, Erycette)	2% solution 2% gel 2% pad 2% solution	Apply to affected acne areas 1–2×/d	Wash hands after application
Metronidazole (Metrogel, Metrocream, Metrolotion, Noritate)	0.75%, 0.1% gel 0.75% cream 0.75% lotion 1% lotion	0.75%: Apply to affected areas 2×/d 1%: Apply to affected areas 1×/d	Wash hands after application
Dapsone (Aczone)	5% gel	Apply to affected areas 2×/d	Wash hands after application. Reevaluate if no improvement in 12 wk.
Acne Medication			
Isotretinoin (Absorica, Amnesteem, Claravis, Myorisan, Sotret)	10, 20, 30, 40 mg capsule	Initially: 0.5–1 mg/kg/d in 2 divided doses; severe acne may require 2 mg/kg/d; treatment continues for 15–20 wk	Provider registered with iPledge must prescribe medication

the medication is supplied in a package in which the two medications are separate and are then mixed immediately prior to dispensing. This combination product forms a gel and should be stirred prior to application. Benzamycin should be stored in the refrigerator and expires 3 months after reconstitution. The product should not be allowed to freeze. Benzamycin Pak is also a combination of benzoyl peroxide and erythromycin packaged in single-use foil pouch that the patient opens and then mixes the two ingredients in the palm before applying to acne-affected areas. Benzamycin Pak does not require refrigeration. Products that combine benzoyl peroxide with clindamycin (Benzaclin, Duac) are also effective in acne treatment. Patients should apply these products to clean, dry skin twice daily for Benzamycin or Benzaclin and once daily before bed for Duac. If irritation occurs, patients may decrease application to once daily. It must be pointed out that all benzoyl peroxide–containing products bleach fabrics and hair, and care should be taken when handling such products.

Dapsone gel should be applied twice a day to skin that has been washed and patted dry. A pea-size amount of dapsone gel is spread into a thin layer over all acne-affected areas. Patients should wash their hands after application.

Acne Rosacea

The topical treatment of rosacea is based on the severity of clinical presentation. The most commonly used initial therapy for the treatment of mild forms of rosacea is topical metronidazole. Metronidazole 0.75% cream or gel (Metro-Gel and MetroCream) or 1% emollient cream (Noritate) is applied in a thin film twice a day after washing with a gentle cleanser. There may be some mild skin irritation associated with topical metronidazole use. Significant therapeutic results should be noticed within 3 weeks. Patients may use cosmetics after application of topical metronidazole. If irritation occurs, patients should reduce frequency, interrupt therapy, or discontinue use. They should avoid getting metronidazole in the eyes.

Rosacea may also be treated with combination products that combine an antibacterial with a keratolytic. Formulas that combine sulfacetamide 10% and sulfur 5% (Clenia, Rosula, Sulfacet-R) are applied 1 to 3 times a day to clean skin. Sulfacetamide and sulfur washes (Clenia, Rosula Cleanser) are used once or twice a day. Another product available is azelaic acid 15% gel (Finacea), which is an antibacterial/antikeratinizing agent. It is applied to clean, dry skin twice a day. Patients should avoid getting any of these products in their eyes and wash their hands after applying.

Rational Drug Selection

Severity

The choice of acne medications is generally dependent on several factors: clinical type of acne (e.g., comedonal, inflammatory, nodular), severity of acne, skin type (dry, oily), presence of acne scarring or post-inflammatory hyperpigmentation, menstrual history, signs of hyperandrogenism in women,

history of prior successful and failed treatments, history of acne-promoting medications, and psychological impact of acne on the patient.

Noninflammatory comedonal acne is treated with topical retinoids and/or benzoyl peroxide products. Antibiotics are not considered necessary for this type of acne. Azelaic acid is also effective for noninflammatory acne.

Antibiotics (oral or topical) may be used in the treatment of inflammatory papulopustular acne. Benzoyl peroxide is an effective antimicrobial and comedolytic agent for treating inflammatory and noninflammatory acne. Resistance to topical antibiotics easily develops when used as monotherapy. Addition of a topical retinoid or benzoyl peroxide will improve outcomes. Topical dapsone and topical metronidazole may be useful for mild inflammatory acne. Adding a topical retinoid or azelaic acid to improve follicular keratinization can also be helpful.

Papulopustular or nodulocystic acne with severe inflammation is treated with a combination of a topical antibiotic, benzoyl peroxide, and an oral antibiotic. Combining antibiotic therapy with the use of benzoyl peroxide decreases the development of antibiotic resistance and improves treatment efficacy.

When acne has not responded to the above treatments, therapy with oral isotretinoin should be considered. Therapy with isotretinoin is indicated for severe nodulocystic acne or moderate noncystic inflammatory acne with the potential for scarring.

Hormonal therapy is indicated in mild to moderate acne in women (Ortho-Tri-Cyclen, Estrostep Fe, Yaz or Yasmin).

Monitoring

There is no special laboratory monitoring required with the use of topical antibiotics or topical retinoids. Monitoring of the patient who is started on isotretinoin includes baseline CBC, both baseline and monthly liver function tests throughout treatment, baseline and monthly pregnancy testing for female patients throughout treatment, and serum lipid profile. If visual difficulties occur, an ophthalmological examination is recommended, with a second examination 6 to 7 weeks after discontinuation of the medication.

Patient Education

Administration

When retinoids are applied topically, it should be explained that the increased turnover of follicular epithelial cells causes extrusion of comedones, even comedones that may not be seen on the skin surface. Clinically, this causes an initial worsening of acne, as comedones that were previously under the skin are extruded. This "worsening" of acne is not a reason for discontinuation of treatment, and the patient should be reassured that the face will likely improve after approximately 4 to 16 weeks of treatment. The patient should also be instructed to use the medication as prescribed; there is no improved response to topical retinoids if they are used more often than recommended.

Adverse Reactions

It is important to instruct patients that all topical antibiotics used in the treatment of acne may cause skin irritation to some degree. Benzoyl peroxide may cause excessive drying, photosensitivity, and allergic contact sensitization. Azelaic acid may cause skin hypopigmentation in patients with dark complexions. Patients should be instructed to notify their provider if this problem develops.

Isotretinoin has many significant adverse reactions, as previously described. Patients should be fully informed about these adverse reactions prior to beginning therapy and should have written information to refer to at home if any adverse effects occur.

Lifestyle Management

The nonpharmacological management of acne includes gentle facial cleansers such as mild soaps or facial washes. Scrubbing, picking, and squeezing of comedones should be avoided. Patients should be advised to use skin products that will not aggravate their acne. That includes avoidance of oil-based cosmetics, hair spray, mousse, and facial creams and moisturizers. Oil-free sunscreen should be used at all times because of the increased photosensitivity due to acne preparations.

TOPICAL CORTICOSTEROIDS

Topical corticosteroids are adrenocorticosteroid derivatives incorporated into a vehicle suitable for application to the skin. Topical corticosteroids are utilized for their anti-inflammatory, antimitotic, immunosuppressive, and vaso-constrictive properties. They differ widely in potency and formulation; potency ranges from super potent (group 1) to least potent (group 7). Table 23-4 contains selected forms of corticosteroids.

Pharmacodynamics

The therapeutic effects of topical corticosteroids are due to their nonspecific anti-inflammatory effects. They act against most causes of inflammation, including mechanical, chemical, microbiological, and immunological. At the cellular level, they appear to inhibit the formation, release, and activity of endogenous mediators of inflammation, such as prostaglandins, kinins, histamines, liposomal enzymes, and the complement system. When applied to inflamed skin, steroids inhibit the migration of macrophages and leukocytes into the area by reversing vascular dilatation and permeability. This results in decreasing edema, erythema, and

Table 23–4 ❀ **Available Dosage Forms: Topical Corticosteroids**

Drug	Potency	Dosage Form	Rx Required

pruritus by suppressing DNA synthesis. Corticosteroids applied topically have an antimitotic effect on epidermal cells. This is their primary action in proliferative disorders such as psoriasis.

At the molecular level, unbound corticosteroids readily cross the cell membrane and bind with high affinity to specific cytoplasmic receptors. Inflammation is reduced by diminishing the release of leukocytic acid hydrolyses. Corticosteroids also prevent macrophage accumulation at inflamed sites. Interference with leukocyte adhesion to the capillary wall and reduction of capillary membrane permeability and subsequent edema also reduce inflammation.

Pharmacokinetics

Absorption and Distribution

Absorption of topical corticosteroids varies, depending on the drug used, the vehicle used, the amount of skin surface area the medication is applied to, and the condition of the skin. Absorption is enhanced by increased skin temperature, hydration, and application to denuded areas, intertriginous areas, or skin surfaces with a thin stratum corneum layer (face or scrotum). Occlusive dressings enhance skin penetration and therefore increase drug absorption. Infants and children have more body surface area compared to body weight, and

therefore proportionally more medication is absorbed into their system.

The penetration of topical steroid through the skin varies with the vehicle the medication is in. Ointments are more occlusive and therefore more potent. Creams are less occlusive and usually less potent. Lotions are usually the least potent. Gels, aerosols, lotions, and solutions are useful in hair-bearing areas. Occlusive dressings such as plastic wrap increase skin penetration approximately 10- to 100-fold by increasing the moisture content of the stratum corneum. This may be beneficial in resistant cases but may also lead to increased adverse effects because increased absorption of the corticosteroid may produce systemic side effects.

The relative potency of a product depends on several factors, including the characteristics and concentration of the drug, the vehicle used, and the vasoconstrictor assay. The vasoconstrictor assay is developed by applying an agent to the skin under occlusion and assessing the area of skin blanching.

Metabolism and Excretion

Following topical administration, corticosteroids enter the bloodstream and are metabolized and excreted via the same pathways as systemic steroids. Corticosteroids are metabolized in the liver, although some topical preparations are partially metabolized in the skin. Inactive metabolites, as well as a small portion of unchanged drug, are excreted in the urine.

Pharmacotherapeutics

Precautions and Contraindications

Corticosteroids are contraindicated in any patient with a history of hypersensitivity to other corticosteroids or any ingredient in the preparation.

Corticosteroids are contraindicated as monotherapy in primary bacterial infections, treatment of rosacea, or acne vulgaris. Use of high-potency or very-high-potency agents on the face, groin, or axilla is contraindicated. Ophthalmic use should be reserved for specialty practice only, because prolonged ocular exposure may cause steroid-induced glaucoma and cataracts. When applied to the eyelids or the skin near the eyes, the drug may enter the eyes.

Corticosteroids are Pregnancy Category C. They are teratogenic in animals when administered systemically at relatively low dosages. There are no adequate and well-controlled studies of topical steroid use in pregnant women. Therefore, use during pregnancy is advised only if the potential benefits outweigh the potential hazards to the fetus. In pregnant patients, they should not be used extensively.

Systemic corticosteroids are excreted into breast milk in quantities not likely to have an adverse effect on the infant. Nevertheless, exercise caution when administering topical steroids to a nursing mother.

Children may be more susceptible to the effects of topical corticosteroids because of their larger body surface area compared to weight. Therefore, in infants and young children, the lowest effective strength of topical steroid should be used to prevent systemic corticosteroid effects. Use of high-potency or very-high-potency agents should be avoided. Hypothalamic-pituitary-adrenal (HPA) axis suppression, Cushing's syndrome, and intracranial hypertension have been reported in children receiving topical corticosteroids. Many of the topical corticosteroids have been relabeled recently and are not to be used in children due to HPA suppression. Chronic high-dose corticosteroid therapy in children may interfere with growth and development.

Adverse Drug Reactions

Topical corticosteroid preparations may all cause localized skin irritation (pruritus, dryness, burning, and dermatitis). Use of topical corticosteroids also increases the risk for secondary infection due to immunosuppression. Topical corticosteroids can also worsen and alter the appearance of tinea skin infections. Other localized effects include acneiform rash, allergic contact dermatitis, folliculitis, hypertrichosis, miliaria, and maceration of the skin. Skin atrophy, hypopigmentation, striae, and xerosis may occur. Tolerance may occur with prolonged use of topical corticosteroids; it is reversible and may be prevented by interrupted or cyclic schedules of application for chronic dermatological conditions.

Systemic absorption may produce reversible HPA axis suppression, Cushing's syndrome, hyperglycemia, and glycosuria. They are more likely to occur with occlusive dressings and with more potent steroid preparations. Patients with liver failure or children may be at higher risk for systemic steroid effects.

Following prolonged application of topical corticosteroid around the eyes, cataracts and glaucoma may develop.

Changing to a less potent topical corticosteroid preparation may minimize the risk of adverse reactions.

Drug Interactions

There are no significant drug interactions noted with topical corticosteroid use.

Clinical Use and Dosing

Inflammatory Skin Diseases

Topical corticosteroids are used for numerous inflammatory or pruritic dermatoses. Some of the conditions for which topical corticosteroids have been proved effective are contact dermatitis, atopic dermatitis, nummular eczema, psoriasis, lichen planus, lichen simplex chronicus, insect bite reactions, discoid lupus erythematosus, and seborrheic dermatitis. Topical corticosteroids have a repository effect; with continuous use, one or two applications per day may be as effective as three or more (Table 23-5). One dosing schedule that may

Table 23–5 � **Dosage Schedule: Selected Topical Corticosteroids**

Drug	Dosage	Comments
Least Potent (group 7)		
• Hydrocortisone 1% or 2.5%	Apply a thin layer 2–4×/d	May be used in children
Mild Potency (group 6)		
• Fluocinolone acetonide 0.01% cream	Apply a thin layer 2–4×/d	May be used in children
• Triamcinolone acetonide cream, lotion 0.025%	Apply a thin layer 2–4×/d	May be used in children
• Desonide lotion, foam, cream 0.025%	Apply a thin layer 2–3×/d	May be used in children
Lower Mid-Strength Potency (group 5)		
• Fluocinolone acetonide cream 0.025%	Apply a thin layer 3–4×/d	May be used in children
• Desonide gel, ointment 0.5%	Apply a thin layer 2–3×/d	May be used in children >3 months of age
Mid-Strength Potency (group 4)		
• Desoximetasone 0.05% cream	Apply a thin layer 2×/d	If no improvement after 4 wk, reassess diagnosis
• Fluocinolone acetonide 0.025% ointment	Apply a thin layer 2–4×/d	May be used in children >3 months of age
• Triamcinolone acetonide 0.1% cream, ointment	Apply a thin layer 2–3×/d	May be used in children
Upper Mid-Strength Potency (group 3)		
• Mometasone furoate 0.1% ointment	Apply a thin layer 1×/d	Do not use longer than 3 wk in pediatrics
• Triamcinolone acetonide 0.5% cream, ointment	Apply a thin layer 2–4×/d	May be used in children
High Potency (group 2)		
• Desoximetasone 0.05%, 0.25% cream, ointment, and gel	Apply a thin layer 2×/d	If no improvement after 4 wk, reassess diagnosis
• Fluocinonide acetonide 0.05% cream, gel, ointment, solution	Apply a thin layer 2–4×/d	May be used in children
• Halcinonide 0.1% cream, ointment	Apply a thin layer 1–3×/d	If no improvement, reassess diagnosis
Super High Potency (group 1)		
• Halobetasol propionate 0.05% cream, ointment	Apply a thin layer 1–2×/d	Treatment should not exceed 2 consecutive wk and total dosage should not exceed 50 g/wk. Do not apply on face, groin, or axillae.
• Flurandrenolide tape	Apply tape to clean, dry, affected skin; replace tape every 12 to 24 h.	Use should not exceed 2 wk
• Clobetasol 0.05% cream, foam, gel, lotion, ointment, shampoo, solution	Apply a thin layer 2×/d	Treatment should not exceed 2 consecutive wk and total dosage should not exceed 50 g/wk. Do not apply on face, groin, or axillae.

be used is to apply the medication twice daily until clinical response is achieved and then only as frequently as needed to control symptoms.

Another dosing schedule that may be used to achieve therapeutic response with fewer adverse effects is short-term or intermittent therapy with high-potency agents for a short period (3 or 4 consecutive days per week or once per week). This may be more effective and cause fewer adverse effects than continuous use of lower-potency products.

It must be stressed that topical corticosteroids should not be abruptly discontinued. After long-term use or after using a high-potency agent, a rebound effect may occur. Switching to a less potent agent, alternating topical corticosteroids and emollient products, or gradually reducing the frequency of application (similar to tapering oral corticosteroids) can prevent a rebound effect.

In children, low- to mid-potency agents should be used. Low-potency topical corticosteroids should also be used on body sites with a thinner stratum corneum layer (face, scrotum, axilla, and skinfolds). If treating large surface areas, a lower-potency agent should be used. Higher-potency agents should be used for areas such as the palms and soles, which are more resistant to treatment. Higher-potency agents are also used for crusting and thickened conditions, which are also more resistant to treatment.

Treatment with very-high-potency topical corticosteroids should not exceed 2 consecutive weeks. The total dosage should not exceed 50 g/wk because of potential HPA axis suppression.

To increase absorption of corticosteroids, occlusive dressings may be used. The technique for properly using occlusive dressings is as follows: First, the area must be soaked in water and gently washed. While the skin is still moist, the medication is gently rubbed into the affected area. The area is then covered with plastic wrap. For hands, a plastic glove may be used; for feet, a plastic bag may be used; and a shower cap may be used for the scalp. After the plastic is applied, the edges should be sealed with tape to ensure that the wrap adheres closely to the skin. Do not use for more than 12 hours in a 24-hour period.

Psoriasis

Topical corticosteroids are used to treat psoriasis because of their anti-inflammatory effects on the plaques. Moderate- to high-potency steroids are used because the psoriasis lesions are generally steroid-resistant. Occlusion with plastic may be necessary for best results. The steroid cream or ointment is applied 2 to 3 times per day. Intermittent or "pulse" therapy minimizes some of the adverse effects and has the best long-term outcome. If using topical corticosteroids in the intertriginous areas or on the face, a low-potency medication should be chosen. Longer courses of therapy may be necessary for patients with chronic diseases, and these individuals should be closely monitored for the development of adverse effects.

Rational Drug Selection

Potency

The choice of steroid based on potency is determined by the area of skin to be treated, the condition of the area, and the patient's condition (see Table 23-5). In general, low- to mid-potency topical corticosteroids are used on children. On the face or other areas with thin skin, low-potency agents should be used. High-potency agents may be used for brief periods, up to 3 weeks, in areas that are resistant to lower-potency treatment. There are many available topical steroid preparations, and it is impossible for any practitioner to be familiar with all of them. It is reasonable for the practitioner to be familiar with one or two agents in each potency category. Each provider needs to be familiar with what medications are allowed from each category in the formulary he or she is using.

Vehicle

The vehicle used may increase or decrease the potency of the corticosteroid. As previously mentioned, ointments are more occlusive and are effective for dry or scaly lesions. Creams may be used more frequently on oozing lesions on intertriginous areas, where the occlusive effects of ointments may cause increased adverse effects. Gels, aerosols, lotions, and solutions are used on hair-bearing areas. The urea that is added to some products may enhance the penetration of hydrocortisone and other steroids by hydrating the skin. Steroid-impregnated tape (Cordran) is useful for occlusive therapy in small areas.

Cost

In general, lower-potency and generic products are less expensive than higher-potency and brand-name products, although this difference may be offset by increased efficacy in short-term burst therapy with some dermatoses. Therefore, cost must be evaluated, and the practitioner must determine whether it will be a part of the drug-selection process. Cost must also come into effect when prescribing off-formulary. If possible, prescribe medications that will be covered by the patient's insurance.

Monitoring

Adrenal function should be monitored in children if a high-potency steroid or occlusion is used. Adrenal function should also be assessed in adults who are applying more than 50 g weekly of a high-potency steroid preparation. Growth should be monitored in children who are using mid- or high-potency topical corticosteroids. The patient should also be monitored for adverse effects, as noted previously.

Patient Education

Administration

The patient should be instructed to use the topical corticosteroid exactly as prescribed. Demonstration of the amount of medication that should be applied will be helpful for most patients. The provider can use a sample-size dose in the area to be treated to show the amount of medication to use. The fingertip unit (FTU) provides the means to assess how much cream to dispense and apply. A fingertip unit is the amount of ointment expressed from a tube with a 5-mm-diameter nozzle, applied from the distal skin crease to the tip of the index finger. One FTU weighs approximately 0.5 g. An estimate of the number of FTUs required to cover various areas of the body is as follows: head and neck = 4.5, trunk (front or back) = 7, one arm = 3, one hand = 1, one leg = 6, and one foot = 2 (Goldstein & Goldstein, 2012). The patient should also understand the serious adverse effects that may occur with overuse of topical corticosteroids. If mid- or high-potency topical steroids are prescribed, the patient must understand that these medications are much stronger than, for example, hydrocortisone 1% cream and that these medications therefore have more significant adverse effects associated with them if they are not used appropriately. If occlusion is to be used, clear directions regarding it need to be provided to the patient, preferably in writing.

Adverse Reactions

The patient should have written information regarding the adverse effects that may occur with overuse of corticosteroids. Patients should report any adverse effects, including worsening of their condition. When prescribing topical corticosteroids to children, the provider must clearly outline the course of treatment for the parent. If

mid-potency steroids are used, the parent should understand the concern about growth in children. Patients should also be instructed not to abruptly discontinue their topical steroid medications, which also may cause adverse effects.

Lifestyle Management

Patients who are using topical corticosteroids often can benefit from nonpharmacological management. Many conditions require the use of moisturizers or emollients to provide optimal outcome in the disease process. Patients should be encouraged to use these nonpharmacological measures, in addition to the prescribed topical cortico - steroid, to have the most optimal management of their skin condition. Bathing may improve the outcome with some skin conditions, but this must be individualized based on the patient and the condition.

TOPICAL IMMUNOMODULATORS

The immunomodulators are a class of topical medications used in the short-term or intermittent long-term treatment of atopic dermatitis. Pimecrolimus (Elidel) and tacrolimus (Protopic) are additional nonsteroidal options for treatment of atopic dermatitis when it's not responsive to conventional therapy or when conventional therapy is not appropriate.

Pharmacodynamics

The therapeutic effects of the topical immunomodulators are related to their ability to inhibit calcineurin. The topical immunomodulators work through inhibition of phosphorylase activity of the calcium-dependent serine/threonine phosphatase calcineurin and the dephosphorylase activity of the nuclear factor of activated T-cell protein (NF-ATp). NF-ATp is a factor necessary for the cytokines IL-2, IL-4, and IL-5. They might also inhibit the transcription and release of other T-cell proteins, which can contribute to allergic inflammation. Tacrolimus has been found to inhibit T cells, Langerhans cells, mast cells, and keratinocytes, with skin biopsy after topical tacrolimus treatment finding markedly diminished T-cell and eosinophilic activity in the epidermal cells. Pimecrolimus was specifically developed to treat inflammatory skin conditions and is active by binding to FKBP/macrophilin 12 and interfering with calcineurin action. It inhibits the release of inflammatory cytokines and mediators from mast cells.

Pharmacokinetics

Absorption and Distribution

Topical tacrolimus and pimecrolimus are minimally absorbed. It is unknown if these medications cross the placenta or are excreted into breast milk.

Metabolism and Excretion

Both tacrolimus and pimecrolimus are metabolized in the liver via the CYP3A4 system and excreted in the feces.

Pharmacotherapeutics

Precautions and Contraindications

The only contraindication to either tacrolimus or pimecrolimus is hypersensitivity to the product or any component of the cream. The products should not be applied to a site with active cutaneous viral infection. Both products have received a U.S. Food and Drug Administration (FDA, 2006) Black-Box Warning regarding the long-term safety of topical immunosuppressant calcineurin inhibitors because of rare cases of malignancy (skin and lymphoma) that have been reported in patients using the topical forms of these medications. The FDA advisory stated, "Animal studies have shown that three different species of animals developed cancer following exposure to these drugs applied topically or given by mouth, including mice, rats and a recent study of monkeys" (FDA, 2006). Both tacrolimus and pimecrolimus should be avoided in children younger than 2 years and in immunosuppressed patients. Consider discontinuing the medication if lymphadenopathy of unknown etiology or infectious mononucleosis occurs. Use of these products should be avoided in malignant or premalignant skin conditions. Any bacterial or viral skin infections should be cleared before starting either product.

Both tacrolimus and pimecrolimus are Pregnancy Category C; neither product is recommended in the breastfeeding mother, as breast milk excretion is unknown. Both products are not to be used in children younger than 2 years. If prescribing tacrolimus to children 2 to 15 years, the 0.03% ointment is recommended.

Adverse Drug Reactions

Tacrolimus and pimecrolimus both may have a local reaction at the site of application, consisting of burning, pruritus, and tingling. Other side effects include headache, fever, flu-like symptoms, acne, and folliculitis.

Drug Interactions

There are no drug interactions reported with topical application of tacrolimus or pimecrolimus. There is a theoretical interaction between CYP3A4 inhibitors (such as erythromycin, irtraconazole, ketoconazole, fluconazole, calcium channel blockers, and cidemtidine) in widespread erythrodermic diseases due to increased absorption, and patients should be observed for toxicity.

Clinical Use and Dosing

Pimecrolimus is to be used as a second-line drug in the short-term or intermittent long-term treatment of mild to moderate atopic dermatitis in immunocompetent patients older than 2 years. Pimecrolimus (Elidel) is applied to

affected areas twice daily. The area where the medication is applied should not be occluded. Tacrolimus (Protopic) is used for short-term or intermittent long-term treatment of moderate to severe atopic dermatitis in children older than 2 years and in adults. Children aged 2 to 15 years should use the 0.03% strength, and patients 16 years or older can use either the 0.03% or 0.1% strength. The tacrolimus ointment is applied twice a day and should not be occluded or applied to wet skin. The patient should be reevaluated 6 weeks after therapy is started.

Rational Drug Selection

Drug selection is based on the severity of atopic dermatitis, as tacrolimus is approved for moderate to severe disease and pimecrolimus is approved for mild to moderate disease.

Monitoring

Monitor patients' skin for worsening conditions, such as pruritus, erythema, excoriation, infection, and lichenification.

Patient Education

Administration

Patients should use the medication exactly as prescribed. When applying the medication, the patient should be instructed to avoid contact with eyes, nose, mouth, and cut or scraped skin. The patient should be instructed not to occlude the area that the medication is applied to. Hands should be washed with soap and water before and after application of the medication. It may take 2 to 3 weeks for improvement and patients need to be advised of this.

Adverse Reactions

Patients should contact their provider if any signs of infection occur. Patients should also report lymphadenopathy or other adverse effects they experience.

Lifestyle Management

Patients using either tacrolimus or pimecrolimus should avoid exposure to sunlight and artificial light sources such as tanning beds. Patients should use sunscreen and lip sunscreen (SPF [sun protection factor] 30 or higher) and wear protective clothing such as wide-brimmed hats. Patients can continue to use emollients for their atopic dermatitis.

TOPICAL ANTIPSORIASIS AGENTS

The management of psoriasis consists of topical medication and phototherapy for mild to moderate psoriasis (less than 20% of the body involved), and for severe psoriasis (more than 20% of the body involved) the addition of systemic medications. Patients with severe disease are usually referred to a dermatologist, and therefore systemic treatments with immunosuppressants (Amevive, methotrexate), retinoids (Soriatane), tumor necrosis factor blocker (Enbrel), and Adalimumab (Humira) are not covered in this chapter. Providers need to be mindful of the negative emotional impact of psoriasis and refer patients for more intensive therapy and/or mental health therapy if needed (Skevington, Bradshaw, Hepplewhite, Dawkes, & Lovell, 2006.)

Topical therapy recommended by the American Academy of Dermatology evidence-based guidelines (Menter et al, 2009) for psoriasis consists of nonmedicated topical moisturizers, coal tar, topical corticosteroids, vitamin D analogues, calcineurin inhibitors, and tazarotene. Management of psoriasis is discussed in Chapter 33.

Pharmacodynamics

Calcipotriene, a vitamin D_3 derivative, regulates cell differentiation and proliferation and suppresses lymphocyte activity. In humans, the natural supply of vitamin D depends mainly on exposure to the ultraviolet rays of the sun for conversion of 7-dehydrocholesterol to vitamin D_3 in the skin. After entering the bloodstream, it is metabolized in the liver and kidneys to its active vitamin D form. Vitamin D_3 receptors occur in many parts of the body, including the skin cells known as keratinocytes. Calcipotriene has a similar affinity for the vitamin D receptor in the keratinocyte.

Coal tar affects psoriasis by enzyme inhibition and antimitotic action. It is manufactured as a by-product of the processing of coke and gas from bituminous coal and is extremely complex, rich in polycyclic hydrocarbons, and variable in composition. Little is known about its mechanism of action.

Tazarotene is a topical retinoid prodrug that is used in the treatment of psoriasis. The exact mechanism of action is unclear at this time. Following topical application, tazarotene undergoes esterase hydrolysis in skin to form its active metabolite, tazarotenic acid. Tazarotenic acid is further metabolized in skin. It is believed that the drug works by normalizing epidermal differentiation, reducing hyperproliferation, and reducing the influx of inflammatory cells into the skin.

Pharmacokinetics

Absorption and Distribution

Approximately 6% of calcipotriene is absorbed systemically when it is applied topically to psoriasis plaques. Distribution of calcipotriene is unknown. There is evidence that calcipotriene does cross the placenta. It is not known whether calcipotriene is excreted in breast milk. Absorption and distribution of anthralin are unknown, as is the absorption of coal tar.

When administered topically to the skin, tazarotene has minimal systemic absorption because of its rapid metabolism in the skin to the active metabolite, tazarotenic acid, which is systemically absorbed and further metabolized. There is no apparent accumulation of tazarotene within body tissues. Retinoids may cross the placenta, and therefore it is assumed that tazarotene is also harmful to the fetus.

It is not known if tazarotene is distributed into human breast milk; however, animal studies show detection of tazarotene in maternal milk.

Metabolism and Excretion

Calcipotriene is rapidly and extensively metabolized in the liver into inactive metabolites and excreted in the bile.

Tazarotene is rapidly metabolized in the skin to the active metabolite tazarotenic acid, which is absorbed and further metabolized. Tazarotenic acid is hydrophilic and quickly metabolized systemically. It is more than 99% plasma protein bound. Metabolism of tazarotene to tazarotenic acid occurs via esterase hydrolysis in the skin. After systemic absorption, it is hepatically metabolized to sulfoxides, sulfones, and other metabolites. Elimination is via the fecal and renal routes.

The metabolism and excretion are unknown for coal tar.

Pharmacotherapeutics

Precautions and Contraindications

Calcipotriene should not be prescribed to any patients with preexisting hypercalcemia or evidence of vitamin D toxicity. It should also not be used in any patient with hypercalciuria, as this may increase renal calculi formation. Calcipotriene should not be applied to the face, as there have been several reports of facial dermatitis following application of this drug to the face. Calcipotriene is contraindicated in any patient with known hypersensitivity to any components of the preparation.

The safety and efficacy of calcipotriene in children have not been established. Children are at a greater risk of developing systemic adverse effects. Calcipotriene should be used cautiously in the elderly because patients older than 65 years have significantly more severe skin-related reactions than do younger patients treated with topical medication.

Calcipotriene is classified as Pregnancy Category C. It should be avoided during breastfeeding because adverse effects on the nursing infant may occur.

Coal tar preparations should not be applied to abraded skin. They should also be avoided on skin that is inflamed, broken, or infected because exacerbation of the condition can occur and systemic absorption of the drug can be increased. Sunlight (UV) exposure should be avoided for at least 24 hours after application of coal tar products unless patients are otherwise directed by their health-care provider. Exposure to sunlight causes a photosensitivity reaction. Coal tar does not have an FDA pregnancy classification. It is not known what effects coal tar may have on the fetus. Whether coal tar is distributed into breast milk is unknown, although it is advised that coal tar should be used by lactating women only when clearly needed.

Tazarotene should not be used on eczematous skin because it may cause severe irritation and worsen eczema. Tazarotene should be used cautiously in patients with known retinoid hypersensitivity reactions. Exposure to sunlight should be avoided, as well as UV exposure (including sun lamps). Patients must be warned of their increased photosensitivity and their increased potential for sunburn while using tazarotene. Tazarotene is classified as Pregnancy Category X and is contraindicated in women who are pregnant or may be considering pregnancy. Adequate pregnancy prevention is essential when childbearing-age women are prescribed tazarotene. It is not known if tazarotene is distributed into human breast milk; however, it should be used cautiously for breastfeeding women. The safety and efficacy of tazarotene in children younger than 12 years have not been established.

Adverse Drug Reactions

The most common reactions reported by patients using topical calcipotriene are application site pain, dermatitis, dry skin, erythema, peeling, pruritus, and worsening of psoriasis. Rare reports of allergic contact dermatitis have also occurred. Hypercalcemia and hypercalciuria occur almost exclusively when the recommended dosage of 100 g/wk is exceeded. A significant increase in urine calcium has been seen when calcipotriene is administered at the maximum weekly dose (100 g/wk) for 4 weeks.

Coal tar may stain hair or fabrics. Excessive or long-term use may cause folliculitis, sensitization, and photosensitivity.

The most commonly reported adverse reactions from tazarotene topical use are burning, stinging, xerosis, and erythema. Worsening of psoriasis may occur. Skin irritation and skin pain may also develop. Reactions reported in less than 10% of patients include rash, desquamation, irritant contact dermatitis, and skin inflammation. Photosensitivity may occur with tazarotene.

Drug Interactions

No drug interactions with calcipotriene have been reported (Table 23-6). However, concurrent administration of high-dose calcipotriene with other agents may produce hypercalcemia. Those agents include vitamin D or vitamin D analogues or calcium supplements. Avoid prescribing large doses of calcipotriene to patients taking vitamin D analogues or calcium supplements.

No drug interactions are known for coal tar.

Concomitant use of tazarotene and other topical medications that have strong drying effects, such as benzoyl peroxide, salicylic acid, or sulfur preparations, should be avoided. The manufacturer suggests that a patient's skin "rest" until the effects of such preparations subside before using tazarotene.

Clinical Use and Dosing

Psoriasis

Calcipotriene is applied in a thin film to the affected psoriasis plaques and rubbed into the skin gently and completely (Table 23-7). In adults, the ointment is applied twice daily in the morning and evening. The patient does not exceed 100 g/wk of calcipotriene applied to the skin because of increased adverse drug reactions (ADRs) of hypercalcemia or parathyroid hormone suppression (Menter et al, 2009).

Table 23–6 ⬛ **Drug Interactions: Selected Psoriasis Medications**

Drug	Interacting Drug	Possible Effect	Implications
Calcipotriene	Agent that may cause hypercalcemia: vitamin D, vitamin D analogues, calcium supplements	Concurrent administration of *high-dose* calcipotriene may produce hypercalcemia	Avoid using large doses of calcipotriene in patients taking vitamin D analogues or calcium supplements
Coal tar products	Psoralens	Increased photosensitivity	Avoid concurrent use
Tazarotene	Topical retinoids Skin irritants, like: benzoyl peroxide, salicylic acid, lactic acid, medicated or abrasive cleansers Products that contain alcohol, lime, menthol, spices, or perfumes	Increased skin irritation	Avoid concurrent use of topical medications that have strong drying effects Before beginning therapy, the effects of strong topical drying agents need to subside to prevent significant skin irritation

Table 23–7 ✂ **Dosage Schedule: Topical Psoriasis Medications**

Drug	Available Dosage Forms	Dosage	Notes
Calcipotriene (Calcitrene, Dovonex, Sorilux)	0.005% ointment, cream, solution	Apply to affected area 2×/d	Improvement is usually noted after 1–2 wk
Coal tar products (DHS Tar Gel) (MG217) (Balnetar) (Neutrogena T/Gel)	2.9% shampoo 10% coal tar ointment 5% coal tar lotion 2.5% oil for use in bath 2%, 4% shampoo	Cream or ointment preparations: Apply enough to cover the affected area and rub in gently, 1–2×/d Shampoo: Apply to wet hair, massage in, and rinse; repeat application and leave on for 5 min. Rinse thoroughly after application. Cleansing bar or gel formulas: Apply to the affected area, rub in gently, leave on for 5 min, and then remove excess Coal tar solution: May be used full strength or diluted in 3 parts water and applied to a cotton or gauze pad, then massaged gently into the affected area Baths: The solution may also be used as a bath by adding 4 to 6 tbsp coal tar solution to a tub of lukewarm water. The patient should be immersed into the bath to soak for 10–20 min. Bathing should be performed once daily to once every 3 d; the usual duration of therapy is 30–45 d. The patient must rinse skin thoroughly after a coal tar bath if exposure to UV or sunlight is to follow.	All products are staining
Tazarotene (Tazorac)	0.05%, 0.1% gel	The 0.05% or 0.1% gel is applied in a thin film once daily, in the evening, to psoriatic lesions	Apply to clean, dry skin. No more than 20% of body surface area should be covered

Calcipotriene is inactivated by UVA; it is important to apply calcipotriene before or after UVA exposure. Safety and efficacy in children have not been established. For the treatment of mild to moderate scalp psoriasis, the patient applies the topical solution twice daily. Improvement will be noted as soon as 1 to 2 weeks after treatment has begun. The patient should be reevaluated after 6 to 8 weeks. Calcipotriene may be used in combination with topical steroids. A combination of calcipotriene and betamethasone propionate (Taclonex) ointment is available for use.

Coal tar has been used in the treatment of psoriasis for more than 100 years. However, it is generally not used in the United States because of poor efficacy, odor, and messiness. Coal tar is still commonly used outside the United States. With newer psoriasis products available, the AAD ranks coal tar as having Level II evidence for efficacy; more effective products such as topical corticosteroids or vitamin D derivatives are available (Menter et al, 2009). Regardless, a variety of tar preparations, including creams, shampoos, ointments, lotions, gels, and oils, are available. The tar preparation is

Drugs Affecting the Integumentary System • 675

applied to the affected psoriatic lesions once or twice daily. For cream or ointment preparations, the patient should apply enough to cover the affected area and rub in gently. Shampoo should be applied to wet hair, massaged in, and then rinsed. The application is then repeated and left on for 5 minutes. The shampoo should be rinsed out thoroughly after application. The cleansing bar or gel formulas should be applied to the affected area, rubbed in gently, and left on for 5 minutes; then the excess is removed. Coal tar solution may be used full strength or diluted in 3 parts water, applied to a cotton or gauze pad, and then massaged gently into the affected area. The solution may also be used as a bath by adding 4 to 6 tablespoons of coal tar solution to a tub of lukewarm water. The patient should soak immersed in the bath for 10 to 20 minutes. Bathing should be performed once daily to once every 3 days; the usual duration of therapy is 30 to 45 days. Patients must rinse their skin thoroughly after a coal tar bath if exposure to UV or sunlight is to follow.

The AAD ranks tazarotene as having Level I evidence for efficacy in treating psoriasis, with 50% or more improvement seen in the majority of patients (Menter et al, 2009). Tazarotene should be applied to clean, dry skin. The 0.05% or 0.1% gel is applied once daily in the evening to psoriatic lesions for 12 weeks. The patient should use enough to cover only the lesions with a thin film. No more than 20% of the body surface area should be covered. Because unaffected skin may be more susceptible to irritation, avoid application of tazarotene to these areas. The AAD notes tazarotene is best used in combination with topical corticosteroids (Menter et al).

Rational Drug Selection

Potency

With multiple medications available for treatment of psoriasis, the provider must decide which medication provides the most improvement to psoriatic lesions without severe adverse effects. Response to antipsoriasis medications is highly individualized; therefore, different medications may be needed for similar presentations of psoriasis.

Vehicle

The patient's clinical presentation often determines which antipsoriasis medication should be used first. The optimal topical formulation is the oiliest one that the patient will use. Large surface areas may respond to bath emulsions of coal tar solutions, where large surface areas can be treated. For scalp psoriasis, coal tar shampoo may be used.

Monitoring

The patient who is being treated for psoriasis should be monitored for the effectiveness of therapy and for adverse effects of the medication. There is no laboratory monitoring required unless treatment levels of calcipotriene approach 100 g/wk. At that point, serum and urine calcium should be measured to determine the patient's risk for hypercalcemia or hypercalciuria.

Patient Education

Administration

Patients should be instructed to use their psoriasis medications exactly as prescribed. Vitamin D derivatives need to be applied as directed, because more than 100 g/wk may cause hypercalcemia. Coal tar may cause staining or discoloration of the skin, especially if not used correctly. Use of tazarotene on healthy skin increases adverse reaction. The patient should be advised not to increase the number of doses per day; doing so increases adverse effects.

Adverse Reactions

Proper application of topical medications will not only optimize treatment but also decrease the adverse effects of the medication. The provider should review the use of medication prior to any change in therapy. Some psoriasis medications cause photosensitivity; therefore, the patient should be instructed to apply sunscreen or avoid sun exposure during therapy.

TOPICAL ANTISEBORRHEIC MEDICATIONS

Topical antifungals are the treatment mainstay for seborrheic dermatitis (Naldi & Rebora, 2009). In addition, antiseborrheic shampoos and topical steroid preparations may be used. Selenium sulfide, pyrithione zinc, coal tar, and salicylic acid are commonly used seborrhea shampoos (Table 23-8). Sulfacetamide sodium is another option available in many formulations.

Pharmacodynamics

Seborrhea is an inflammatory dermatitis that produces greasy-looking, yellowish scales distributed on areas rich in sebaceous glands such as the scalp, the external ear, the center of the face, the upper part of the trunk, and the intertriginous areas. The mildest and most common form of scalp seborrheic dermatitis is dandruff, which occurs as fine, white scaliness on the scalp without erythema. Selenium sulfide (Selsun) appears to have a cytostatic effect on the cells of the epidermis and follicular epithelium, leading to reduced corneocyte production. Pyrithione zinc (Head & Shoulders) is a cytostatic agent that reduces the cell turnover rate; it also exhibits antifungal and antibacterial properties. The mechanism of action of pyrithione zinc is thought to be a nonspecific toxic effect on the epidermal cells. Tar derivatives treat seborrhea by correcting abnormal keratinization and by decreasing epidermal proliferation and dermal infiltration. Tar derivatives also have antiseptic, astringent, antifungal, vasoconstrictive, and photosensitizing properties. The antifungals ketoconazole (Nizoral) and ciclopirox work against dandruff and seborrheic dermatitis by altering the fungal cell membrane, particularly of *P. ovale*, a pathogen implicated in seborrhea. Sulfacetamide sodium (Sebizon) is an antibacterial

Table 23–8 ✂ **Dosage Schedule: Topical Antiseborrheic Medications**

Drug	Indication	Available Dosage Forms	Dosage	Notes
Ketoconazole shampoo (Nizoral, Nizoral AD)	Dandruff, seborrheic dermatitis	1%, 2% shampoo	Apply to wet hair, massage in, leaving on scalp for 5 min, then rinse. Use 2×/wk for up to 8 wk, with at least 3 d between use	May remove curl from permanently wavy hair; can cause discoloration and changes in hair texture
Pyrithione zinc (Head & Shoulders, DermaZinc, DHS Zinc, Selsun Blue)	Dandruff, seborrheic dermatitis	1%, 2% shampoo	Shampoo is applied to wet hair, lathered, rinsed. Repeat once or twice weekly to maintain control.	
Selenium sulfide (Selsun Blue, Head & Shoulders Clinical Strength)	Dandruff, seborrheic dermatitis	1%, 2.5% shampoo	Shampoo is massaged into wet hair, left on for 2–3 min, and rinsed well. Apply 2×/wk, then 1–4×/mo, to maintain control	
Sulfacetamide sodium (Ovace Plus)	Seborrheic dermatitis	10% shampoo	Wash affected areas with 10% wash 2×/d for 8–10 d, and then decrease usage to maintain control	
Tar-derivative shampoos (Neutrogena T/Gel) (MG217 Medicated Tar Extra Strength)	Dandruff, seborrheic dermatitis	2%, 4% shampoo 15% shampoo	Apply to wet hair, lather, leave on for 5 min, then rinse. Use 2×/wk, then decrease to 1×/wk to maintain control.	

agent that exerts a bacteriostatic effect against gram-positive and gram-negative microorganisms, the common organisms isolated from secondary cutaneous infections.

Pharmacokinetics

Absorption and Distribution

Absorption and distribution of topical pyrithione zinc and sulfacetamide sodium are unknown. Topical ketoconazole does not have significant systemic absorption. Repeated topical application of ketoconazole 2% shampoo, however, will lead to absorption of the drug into hair keratin. Systemic absorption of selenium sulfide may occur if applied to open skin areas.

Metabolism and Excretion

Metabolism and excretion of topical selenium sulfide, pyrithione zinc, ketoconazole, and sulfacetamide sodium are unknown.

Pharmacotherapeutics

Precautions and Contraindications

Selenium sulfide is contraindicated in patients with acute inflammation and exudate, as absorption can be increased. It is also contraindicated in patients who are sensitive to any ingredients. There are no contraindications to the use of pyrithione zinc. Tar preparations should not be used on open or infected lesions or on areas of acute inflammation. Ketoconazole, selenium sulfide, and pyrithione zinc are contraindicated in patients who are sensitive to any ingredients.

Ketoconazole also contains sulfites, and patients who are sensitive to sulfites should be advised not to use ketoconazole shampoo. Sulfacetamide sodium should not be prescribed if sensitivity to sulfonamides is present because cross-reactions to topical sulfa preparations may occur.

Selenium sulfide and sulfacetamide sodium are Pregnancy Category C. Tar preparation (Zetar) has no FDA pregnancy classification listed. Tar preparations should not be used in children younger than 2 years. Ketoconazole shampoo is Pregnancy Category C.

Adverse Drug Reactions

Skin irritation can occur with any of the topical antiseborrheic products. They may also cause greater-than-normal hair loss, hair discoloration, and scalp and hair oiliness or dryness.

Drug Interactions

There are no identified drug interactions with any of the topical antiseborrheic products.

Clinical Use and Dosing

Seborrhea and Dandruff

Selenium sulfide shampoo is available as an OTC product, which is 1% selenium sulfide (Selsun Blue, Head & Shoulders), or by prescription, which contains 2.5% selenium sulfide (Excel, Selsun). Selenium sulfide shampoo is massaged into wet hair and left on for 3 to 5 minutes before rinsing thoroughly. It should be applied twice a week until the dandruff is under control, usually within 2 weeks, and then weekly to maintain control.

Ketoconazole shampoo is applied to wet hair, left in place for 3 to 5 minutes, lathered and rinsed. It should be used every 3 to 4 days for up to 8 weeks.

Ciclopirox shampoo (Loprox) is applied to wet hair, lathered, left in place for about 3 to 5 minutes and then rinsed, and repeated twice weekly for 4 weeks, allowing a minimum of 3 days between use.

Pyrithione zinc is the active ingredient in OTC dandruff shampoos such as Head & Shoulders. Pyrithione zinc is applied to wet skin or hair, left in place for about 3 to 5 minutes and then rinsed. The treatment is used once or twice a week to maintain control of dandruff and/or seborrheic dermatitis.

Tar shampoos are available OTC and range in strength from 0.5% (DHS Tar) to 12.5% (Extra Strength Denorex) coal tar. The different products vary in their application instructions from daily to weekly, and the patient should be advised to follow the label instructions. The variety of antiseborrheic medications and their dosage forms are found in Table 23-8.

Cradle Cap

For cradle cap in infants that is resistant to nonpharmacological treatment, selenium sulfide and zinc pyrithione have been used; however, clinical trials have not established the efficacy and safety in infants.

Rational Drug Selection

There are few clinical data to suggest that one antiseborrheic product is better than another. Selenium sulfide 2.5% shampoo is commonly prescribed or 1% shampoo purchased OTC. Ketoconazole shampoo is available OTC (Nizoral A-D) and has comparable results to selenium sulfide 2.5% in the treatment of dandruff.

Monitoring

There is no laboratory monitoring necessary for any of the topical antiseborrheic agents.

Patient Education

Administration

The patient should be instructed to use the medication exactly as directed. Overuse increases adverse effects without clinical improvement in seborrhea. Seborrheic dermatitis cannot be cured, only controlled; therefore, continued use of the medication will be necessary to maintain control. All of the medications should be rinsed well with plain water after use.

Adverse Reactions

Patients should be advised to notify their provider if they have an adverse reaction to the medication prescribed.

TOPICAL ANTIHISTAMINES AND ANTIPRURITICS

The topical antihistamine commonly used is diphenhydramine (Benadryl) to relieve itching. Doxepin (Zonalon) cream can be used for moderate to severe pruritus associated with atopic dermatitis.

Pharmacodynamics

Topical diphenhydramine provides local relief from pruritus and edema because its local effect on the H_1-receptors suppresses the formation of edema, flare, and pruritus. It may also provide local anesthetic activity by decreasing the permeability of the nerve cell membrane to sodium ions, thus blocking the transmission of nerve impulses.

Doxepin's topical mechanism of action is unclear but probably related to its H_1- and H_2-receptor blocking action. Histamine-blocking drugs appear to compete at histamine receptor sites and inhibit the activation of histamine receptors.

Pharmacokinetics

Absorption and Distribution

Diphenhydramine can be measurable in the serum following topical administration to large areas of the body or on chicken pox or measles, in young children and infants, or when applied to large surface areas or a denuded area.

Significant amounts of doxepin for topical use can be absorbed systemically if it is used over 10% of the body surface area or for long periods. Absorption is increased by occlusion. Serum levels may be similar to those achieved with oral administration. It is unknown whether doxepin crosses the placenta.

Metabolism and Excretion

Metabolism and excretion of topical diphenhydramine are unknown.

Absorbed doxepin is metabolized in the liver into an active metabolite, *N*-desmethyldoxepin. Parent drug and metabolite are excreted in gastric juice. *N*-desmethyldoxepin is reabsorbed and further metabolized. Primary excretion is renal. Doxepin and its metabolites are known to be excreted in breast milk.

Pharmacotherapeutics

Precautions and Contraindications

Topical diphenhydramine is contraindicated if the patient is sensitive to the medication in any form. It is for external use only, and contact with the eyes should be avoided. Prolonged use of topical diphenhydramine (more than 7 days) should be avoided. Topical diphenhydramine should not be used to treat chicken pox, measles, poison ivy, or sunburn, or used on blistered or oozing skin. Applying diphenhydramine to denuded skin or to large surface areas increases the potential for toxic psychosis, especially in children. It is recommended that topical diphenhydramine be used in children 2 years and older. Diphenhydramine is Pregnancy Category B.

Drowsiness occurs in more than 20% of patients using doxepin cream, especially on more than 10% of body surface

area. Patients with untreated narrow-angle glaucoma and urinary retention should not use doxepin orally or in topical form because of its anticholinergic effect, even in the topical form. Doxepin cream is contraindicated for use in children and is classified as Pregnancy Category B. Doxepin use during lactation may result in neonatal sedation; use during breastfeeding is not recommended.

Adverse Drug Reactions

Topical diphenhydramine may cause skin irritation if used for prolonged periods.

Patients have reported burning and stinging upon application of topical doxepin; 25% of those patients classify the burning as "severe." Pruritus, dry skin, and eczema exacerbation are reported in fewer than 10% of patients.

Drug Interactions

There are no known drug interactions with topical diphenhydramine (Table 23-9). Topical diphenhydramine should not be used concurrently with oral or systemic diphenhydramine; doing so increases the likelihood of toxicity.

Doxepin cream interacts adversely with alcohol, cimetidine, and monoamine oxidase inhibitors (MAOIs), and these drugs should be avoided during therapy. Doxepin may also interact with any drug that is metabolized by the CYP450 2D6 enzymes.

Clinical Use and Dosing

Local Reactions to Insect Bites, Stings, and Minor Skin Disorders (Poison Ivy, Sumac, and Oak)

Topical diphenhydramine is applied to the affected area 3 to 4 times a day for up to 7 days (Table 23-10).

Severe Pruritus

Doxepin cream (Prudoxin) is applied in a thin layer 4 times a day in 3- to 4-hour intervals for up to 8 days of treatment. Treatment for longer than 8 days may result in higher systemic levels of doxepin. Other available topical antipruritics that are safer to use than doxepin are the emollients Aveeno cream (colloidal oatmeal-based) and Sarna anti-itch lotion.

Rational Drug Selection

Selection of a topical antihistamine is based on the severity of the pruritus, with doxepin reserved for severe cases.

Table 23–9 ▦ Drug Interactions: Topical Antihistamine and Antipruritic Medications

Drug	Interacting Drug	Possible Effect	Implications
Diphenhydramine	No known drug interactions		
Doxepin	Alcohol	Increased sedative effects of doxepin	Use together with caution. Advise patients to limit alcohol use when using topical doxepin.
	Cimetidine	May affect serum doxepin levels	Avoid concurrent use
	MAOIs	Serious side effects and death reported with the use of MAOIs and drugs related to doxepin	Separate use of two medications by at least 2 wk
	Medications metabolized by CP450 2D6 enzymes	Decreased metabolism of doxepin, leading to increased plasma levels	Monitor closely. May need to adjust dosage of doxepin or other drug. Use together with caution.

MAOIs = monoamine oxidase inhibitors.

Table 23–10 � Dosage Schedule: Topical Antihistamine and Antipruritic Medications

Drug	Indication	Available Dosage Form	Dosage	Comments
Diphenhydramine (Benadryl)	Local reactions to insect bites, stings, minor skin cuts, and burns and rashes (poison ivy, oak, sumac)	2% cream, spray	Apply to affected area 3–4×/d	Avoid use >7 d
Doxepin (Zonalon, Prudoxin)	Short-term (<8 d) management of moderate to severe pruritus	5% cream	Apply a thin film 4×/d with at least 3–4 h intervals between applications	Do not occlude. If excessive drowsiness occurs, do one of the following: 1. Decrease body surface area treated 2. Reduce the number of applications/d.

Monitoring

There is no laboratory monitoring necessary with the use of topical diphenhydramine or short-term use of topical doxepin.

Patient Education

Administration

The patient should be instructed to use the medication exactly as prescribed (see Table 23-10). Overuse or incorrect use may increase the adverse effects of these topical medications.

Adverse Reactions

Parents should be cautioned against extensive use of topical diphenhydramine in infants and young children, as well as avoiding concurrent use of topical and oral products. Patients who are prescribed doxepin should be told about the potential for drowsiness and be warned against driving or operating hazardous machinery until they are reasonably certain that doxepin does not affect their ability to operate safely.

Lifestyle Management

Patients should be encouraged to use nonpharmacological measures to control their pruritus, including avoidance of sensitizing agents. OTC emollient products may be used to treat their pruritus.

MOISTURIZERS, EMOLLIENTS, AND LUBRICANTS

Moisturizers, lubricants, and emollients help to retain water in the skin. They are composed of petrolatum, lanolin, or other agents such as colloidal oatmeal in an emulsion.

Pharmacodynamics

Emollients, moisturizers, and lubricants are applied after the patient bathes. This procedure acts to trap the moisture in the skin. Ointments provide the most occlusive barrier; creams are the next best. Lotions offer the convenience of easy application over large areas of skin but are not as occlusive as ointments and creams.

Pharmacokinetics

Topical emollients interact only with the outermost layers of the skin and are not absorbed systemically.

Pharmacotherapeutics

Precautions and Contraindications

There are no true contraindications to emollients, other than to avoid getting them in the eyes. Patients who are allergic to wool should avoid lanolin-containing products.

Adverse Drug Reactions

There are minimal to no adverse drug reactions reported with the use of emollients.

Drug Interactions

There are no known drug interactions with emollients.

Clinical Use and Dosing

Dry Skin

To treat dry skin, the emollient is applied 1 to 4 times per day and after the patient bathes. Patients pat their skin dry and then liberally apply lotion, cream, or ointment to all affected areas. This procedure acts to trap the moisture in the skin. Ointments provide the most occlusive barrier; creams are the next best. Lotions offer the convenience of easy application over large areas of skin but are not as occlusive as ointments and creams. Before using a lotion, make sure it does not contain alcohol, which is drying and irritating.

There are many emollient products available, but many are eliminated from patient use by their additives of perfumes or other chemicals, to which many eczema patients are sensitive. Commonly used emollients are Aveeno cream or lotion, Eucerin cream or lotion, Aquaphor ointment, Cetaphil cream or lotion, CeraVe cream or lotion, and Vanicream cream or lotion. White petrolatum (Vaseline) or vegetable shortening (Crisco) can be used in severe cases.

Rational Drug Selection

Cost

Expense can play a role in choosing an emollient because large amounts, over a long period, are needed to be effective. White petrolatum is inexpensive and a treatment option for eczema patients who have limited resources. Discussing the cost of emollients prior to recommending them to the patient will determine if the provider needs to assist the patient in finding resources to pay for emollients, which are usually not covered by health insurance plans. The use of generic equivalents will decrease the cost of emollients.

Monitoring

No laboratory monitoring is necessary with the use of emollients. Ongoing monitoring of clinical status is necessary to determine if the emollient is effective.

Patient Education

Administration

The patient should be instructed to apply liberal amounts of the emollient to the areas of dry skin. The emollient is most effective if applied just after bathing. Daily use offers the best results.

Lifestyle Management

Nonpharmacological measures used to treat dry skin include hydrating baths and avoidance of offending agents that cause exacerbations. Patients should be told to use gloves when their hands may be exposed to harsh chemicals or detergents, which may increase dryness. They should avoid wearing irritating fabrics such as wool. Soft cotton clothing allows the skin to breathe.

Baths hydrate the skin. The patient should take a warm—not hot—brief bath. The skin is patted dry, and emollients are applied immediately (within 3 minutes) to maintain the skin's hydration. The patient should use mild soap to cleanse the groin and axillae and avoid harsh deodorant soaps. After the bath is also a good time to apply corticosteroid creams or ointments, if needed.

AGENTS USED IN THE TREATMENT OF BURNS

In primary care, the most commonly prescribed preparation for a partial-thickness burn is silver sulfadiazine (Silvadene). Alternative treatment for a partial-thickness burn includes the topical antibiotic bacitracin. Although generally not used in primary care practice, biological and synthetic dressings can also be used to treat partial-thickness burns.

Pharmacodynamics

Silver sulfadiazine is a topical anti-infective active against both bacteria and yeast. It is bactericidal; it acts on the cell membrane and cell wall to produce a toxic effect on bacteria. It is active against both gram-positive and gram-negative organisms. The organisms that are generally susceptible to silver sulfadiazine include *S. aureus, S. epidermidis,* b-hemolytic streptococci, *C. albicans, Klebsiella* sp., *Escherichia coli, Enterobacter* sp., *Proteus, Pseudomonas, Clostridium perfringens, Morganella morganii, Serratia* sp., and *Providencia* sp. Reduction of bacterial growth after a partial-thickness burn promotes spontaneous healing by preventing conversion of partial-thickness burns to full thickness by sepsis.

Pharmacokinetics

Absorption and Distribution

Silver sulfadiazine is absorbed through intact skin. On burns, up to 10% of the sulfadiazine may be absorbed from silver sulfadiazine, with only 1% of the silver absorbed. Serum concentrations of 10 to 20 mcg/mL of sulfadiazine have been reported when large surface areas have been treated. Once absorbed, sulfadiazine is distributed into most body tissues. It is not known whether it crosses the placenta or is excreted in breast milk.

Metabolism and Excretion

The portion of sulfadiazine that is absorbed is metabolized in the liver and excreted renally.

Pharmacotherapeutics

Precautions and Contraindications

Silver sulfadiazine is contraindicated in patients sensitive to any of the contents of the preparation, including sulfa-sensitive patients.

Silver sulfadiazine is Pregnancy Category B but is considered Pregnancy Category D in the near-term pregnancy. Pregnant women at or near term should not use silver sulfadiazine. It is also contraindicated in premature infants and infants 2 months or younger because the sulfonamide displaces bilirubin and causes kernicterus. Use with caution in breastfeeding women.

Silver sulfadiazine should be used cautiously in patients with G6PD deficiency because sulfonamides may cause hemolytic anemia in these patients. Silver sulfadiazine should be used with caution in patients with hepatic or renal disease, as well as patients with thrombocytopenia, leukopenia, or other hematological disorders, as they may worsen these disorders. Sulfonamides should be used with caution in patients with porphyria, as they may precipitate porphyria.

Adverse Drug Reactions

Leukopenia (white blood cell [WBC] count less than 5,000) can occur in patients who use silver sulfadiazine, especially if large surface areas are treated. This occurs within 2 to 4 days of beginning therapy and resolves spontaneously upon discontinuation of the medication. Patients may also experience discoloration of skin, pruritus, erythema multiforme, photosensitivity, or rash at the site of application. Systemic sulfonamide reactions have also been reported.

Clinical Use and Dosing

Silver sulfadiazine is applied to burns once or twice daily, in a sterile fashion. It is applied to a thickness of 1/16 inch. Silver sulfadiazine should cover the burn at all times; reapply if the medication is removed. Dressings are not necessary but are helpful to prevent the medication from getting on the patient's clothing. Silver sulfadiazine should be stopped when there is evidence of reepithelialization.

Monitoring

If the area that the silver sulfadiazine is applied to is large or if treatment is prolonged, the patient's CBC, platelet count, liver function, and renal function need to be monitored. The burn should also be monitored for signs of superinfection or delayed separation.

Patient Education

Administration

Patients can treat small partial-thickness burns themselves and apply the silver sulfadiazine at home, although the first one or two applications are best done by a trained health-care provider to teach the patient the proper technique for applying the medication in a sterile fashion.

Adverse Reactions

Patients should be informed of the possible adverse drug reactions that may occur with the use of silver sulfadiazine and report any adverse symptoms to their provider.

SCABICIDES AND PEDICULICIDES

Skin and hair infestation is a frequently seen problem in primary care, with arthropods, scabies, and lice the most common. The pharmacological management of scabies and lice consists of ectoparasiticides (Table 23-11). The specific medication used varies according to the type of infestation and the age of the patient. There is a choice of OTC products (Nix and RID) for the treatment of head lice. Prescription-strength permethrin (Elimite) and lindane are the commonly prescribed ectoparasiticides. Benzoyl alcohol (Ulesfia) was approved for use in 2009 and was the first FDA-approved non-neurotoxin for head lice. Topical ivermectin (Sklice) was approved in 2012 to treat head lice. Malathion (Ovide) is a pediculicide that is available OTC in the United Kingdom and has been reapproved as a treatment for infestations in the United States. Oral use of ivermectin will not be discussed in this chapter.

Nonpharmacological, environmental measures are a key part of the treatment of any infestation because patients can reinfect themselves or other family members and restart the infestation cycle.

Pharmacodynamics

Pyrethrins are derived from chrysanthemums and are found in combination with piperonyl butoxide in OTC pediculicide products (RID, Pronto, A-200). Pyrethrins are absorbed through the chitinous exoskeleton of arthropods. Once absorbed, pyrethrins block sodium channel repolarization of

Table 23–11 ✕ **Dosage Schedule: Ectoparasiticides**

Drug	Indication	Available Dosage Forms	Dosage	Comments
Permethrin (Nix)	Head lice	1% cream rinse	Apply permethrin 1% cream rinse after shampooing. Leave in hair for 10 min, then rinse off. Remove nits with comb. Repeat treatment in 1 wk.	Treatment should be repeated in 1 wk, regardless of whether signs of infestation are present
(Elimite)	Scabies	5% cream	Apply 5% cream to entire body and leave on for 8–14 h, then shower off. Repeat application in 2 wk if living mites are present.	All family members must be treated. Dispense 30 g per adult. Usually only requires 1 treatment.
Pyrethrins (RID, Pronto, A-200)	Head, body, and pubic lice	0.33% shampoo	Pyrethrin shampoo is applied to dry hair/skin and left on for 10–20 min. Repeat in 1 wk.	It is important for the product to be applied to dry hair to enable the pediculicide to better enter the insect's body. Do not use spray on humans or animals.
Lindane	Head, body, and pubic lice	1% shampoo	Lindane is applied to dry hair, working small quantities of water in to create a good lather. Leave shampoo in hair for 4 min, then rinse with water. Remove nits with comb.	The amount of shampoo prescribed for short hair is 30 mL; for long hair, prescribe 60 mL. Sexual partners should be treated concurrently. Bedding and clothing should be washed.
	Scabies	1% lotion	Apply cream or lotion from the neck to toes, and leave on for 8 h. Then shower off.	All family members should be treated. Dispense 2 oz per adult.
Malathion (Ovide)	Head lice	0.5% lotion	Apply to dry hair, then wet hair and scalp. Let dry naturally. Shampoo after 8–12 h. Repeat second application in 7–9 d, if needed.	Flammable; do not use hair dryer
Benzyl alcohol (Ulesfia)	Head lice	5% lotion	Apply lotion to dry hair, saturating scalp; leave on 10 min, rinse with water, and then repeat in 7 d.	Hair length 0–2 in.: 4–6 oz 2–4 in.: 6–8 oz 4–8 in.: 8–12 oz 8–16 in.: 12–24 oz 16–22 in.: 24–32 oz >22 in.: 32–48 oz
Ivermectin (Sklice)	Head lice	0.5% lotion	Apply to dry scalp, working from the scalp outward, leave on 10 min, rinse well, and use a nit comb.	Single use only Children >6 months

the arthropod neuron, leading to paralysis and death. Pyrethrins are pediculicidal, not ovicidal, and have no residual activity after rinsing. Application should be repeated 7 days later to ensure resolution.

Permethrin is a synthetic compound that is related to pyrethrins. It acts on the nerve cell membrane to disrupt the sodium channel current. This disrupts the sodium channel polarization, leading to paralysis. Permethrin cream rinse has residual activity against lice for up to 10 days.

Lindane is absorbed through the exoskeleton of parasites, causing CNS excitation, which leads to convulsions and death. It has low ovicidal activity (30% to 50% of the eggs are not killed) and resistance has been documented worldwide.

Malathion is an organophosphate agent that acts as a pediculicide by inhibiting cholinesterase activity in vivo. It is very effective against head lice and is both ovicidal and pediculicidal, with 96% mortality in 30 minutes (Downs, Narayan, Stafford, & Coles, 2005). Some residual activity remains and can kill newly hatched lice for up to 7 days.

The active ingredient in benzoyl alcohol appears to stun the breathing spiracles of the lice open, enabling the vehicle to penetrate the respiratory mechanism (spiracles), leading to asphyxiation. Benzoyl alcohol does not elicit ovicidal activity.

Ivermectin interferes with the function of invertebrate nerve and muscle cells by binding to glutamate-gated chloride channels located in invertebrate nerve and muscle cells; this results in parasite paralysis and death.

Pharmacokinetics

The pharmacokinetics of pyrethrins is unknown.

Permethrin is absorbed in unknown amounts, although it is thought to be less than 2% of the dose. It is then rapidly metabolized by ester hydrolysis into inactive metabolites, which are excreted in the urine. It is unknown whether permethrin crosses the placenta or is excreted in breast milk.

Lindane is slowly and incompletely absorbed through intact skin. Absorption is increased though damaged or occluded skin. Measurable amounts of lindane are absorbed. It is stored in the body fat, metabolized by the liver, and excreted in the urine and feces. It is unknown whether lindane crosses the placenta. Lindane is excreted in breast milk.

Malathion is rapidly and effectively absorbed by practically all routes, including the gastrointestinal tract, skin, mucous membranes, and lungs. It is excreted in the urine and does not accumulate in organs or tissues. Malathion (Ovide) is Pregnancy Category B and it is unknown whether it is excreted in breast milk. The safety and effectiveness of malathion lotion have not been assessed by the FDA in children younger than 6 years of age.

Benzoyl alcohol is minimally absorbed. The metabolism and excretion of locally applied benzoyl alcohol is unknown.

The pharmacokinetics of topical ivermectin is unknown.

Pharmacotherapeutics

Precautions and Contraindications

Hypersensitivity to any component of the products is a contraindication to their use. Pyrethrins are contraindicated in people who are allergic to chrysanthemums or ragweed.

Although all of the head lice and scabies treatments are relatively safe, they are classified as neurotoxic agents and they should be used exactly as directed. To limit exposure, the medication should be washed off at a sink, rather than in a shower. Cool or lukewarm water should be used to minimize absorption caused by vasodilatation (Centers for Disease Control and Prevention [CDC], 2010c, 2011).

Permethrin should not be used near the eyes. If it gets in the eyes, they should be flushed with water immediately. Permethrin should not be used on infants younger than 2 months.

The American Academy of Pediatrics (AAP, 2012) no longer recommends the use of lindane. Lindane is a neurotoxin and has been banned in some countries and also in the state of California. It should not be used to treat premature infants, persons with HIV or a seizure disorder, women who are pregnant or breastfeeding, infants, children, the elderly, or persons who weigh less than 110 pounds. Lindane should not be used on abraded or inflamed skin, which increases the absorption of the medication. The FDA (2009) has labeled lindane with a Black-Box Warning due to association with severe neurologic toxicities.

Malathion (Ovide) is contraindicated in neonates and infants due to their scalp being more permeable and therefore leading to possibly increased absorption of the lotion. Safety has not been established in children younger than 6 years. Ovide is flammable due to its high alcohol content and care should be taken not to expose the lotion or wet hair to open flames (including cigarettes) or electric heat sources such as hair dryers or curling irons.

The safety and efficacy of benzoyl alcohol (Ulesfia Lotion) in pediatric patients below the age of 6 months has not been established. Ulesfia Lotion is Pregnancy Category B.

There are no contraindications listed in the manufacturer's labeling for topical ivermectin. It has been approved for use in children older than 6 months; it is Pregnancy Category C and has been found to be excreted in breast milk.

Adverse Drug Reactions

All of the topical ectoparasiticides can cause skin irritation, some burning, or pruritus. Contact dermatitis can occur, usually as the result of incorrect use.

CNS toxicity can occur with lindane, but this is most commonly associated with ingestion or misuse of the product.

Organophosphate poisoning and severe respiratory distress may occur with ingestion of malathion. The product should be used by adults only and care taken to avoid prolonged exposure or over large surface areas.

The common adverse effects of benzoyl alcohol (Ulesfia) during clinical trials were pruritus, erythema, and pyoderma.

The most common adverse effects of topical ivermectin (Sklice) during clinical trials were eye irritation, dandruff, dry skin, and a burning sensation of the skin.

Clinical Use and Dosing

Head Lice

Treat only those family members who are actively infested (lice or nits seen on the head). Do not treat head lice prophylactically. The CDC, Division of Parasitic Diseases, recommends that a cream rinse, combination shampoo/conditioner, or conditioner should not be used before using lice medicine. Hair should not be washed for 1 to 2 days after lice treatment (CDC, 2011). The dosing for ectoparasiticides is found in Table 23-11.

Pyrethrin shampoo is applied to dry hair and left on for 10 to 20 minutes, with the time varying by brand. It is important for the product to be applied to dry hair to enable the pediculicide to enter the insect's body more efficiently. The patient should be re-treated in 1 week, regardless of whether there is evidence of infestation.

Permethrin is a cream rinse that is applied after shampooing. It is important that the shampoo not have any conditioners in its formula, which makes the permethrin less effective. The cream rinse is left in the hair for 10 minutes and then rinsed out. Treatment should be repeated in 1 week, regardless of whether signs of infestation are present. Permethrin is not approved by the FDA for use on children younger than 2 years of age (CDC, 2011).

Lindane is applied to dry hair and left on for 4 minutes. At the end of 4 minutes, a small amount of warm water is used to lather the shampoo, then the hair is rinsed well with water. The amount of shampoo prescribed for short hair is 1 oz; for long hair, 2 oz.

Malathion (Ovide) is applied to dry hair in an amount sufficient to wet the hair and scalp. Hair should be allowed to dry naturally. Malathion lotion is flammable. The lotion and wet hair should not be exposed to open flames or electric heat sources, including hair dryers or curlers. Do not smoke while applying lotion or while hair is wet. Hands should be washed with soap after applying Ovide. Ovide is left on for 8 to 12 hours and then shampooed out. If lice are present in 7 days, Ovide may be repeated.

Benzoyl alcohol (Ulesfia Lotion) is applied to dry hair, completely saturating the hair and scalp, and left on for 10 minutes. The lotion is then rinsed off well with water. Treatment with another application of Ulesfia should be repeated in 7 days if live lice are seen.

Topical ivermectin lotion (Sklice) is applied to dry hair to coat the hair and scalp, and left on for 10 minutes. The lotion is rinsed off with water. Topical ivermectin does not have to be reapplied; one treatment is usually effective.

After use of any head lice product, a nit or fine-tooth comb should be used to remove any dead lice or eggs.

Nonpharmacological treatments for head lice are popular. With the growing problem of resistance and concern over exposing children to repeated doses of pediculicides, parents are looking for various nonmedicated therapies. Popular and safe remedies are mayonnaise (full-fat variety), olive oil, and petroleum jelly. These remedies likely asphyxiate the lice by blocking their breathing apparatus or immobilize them and affect their ability to feed. A small study of six home remedies found petroleum jelly had the highest egg mortality; only 6% of the eggs hatched (Takano-Lee, Edman, Mullens, & Clark, 2004). The authors suggested that none of the remedies they studied were as effective as pediculicides, which are insecticidal and ovicidal. If a family would like to try these treatments, they should apply a thick layer of the product and cover with a shower cap. The product is left on from 1 hour to overnight and then shampooed out. Removal of nits and lice is critical to the success of treatment.

Body Lice

Because body lice live on clothing and underwear and come to the skin only to feed, instruct patients to wash all clothing and bedding in hot water to kill lice and nits that are on it, as well as treat their bodies with a pediculicide (CDC, 2010a). A low-potency corticosteroid can be prescribed for the pruritus associated with body lice.

Permethrin 5% (Elimite) is massaged into skin from the head to the soles of the feet, left on for 8 hours (overnight), and then showered off. Dispense 30 grams for an average adult.

Lindane has more ADRs than permethrin, so it is second-line therapy. It is applied to the total body as a cream or lotion and left on 8 to 12 hours (overnight). The amount needed for an adult is 2 oz.

Pubic Lice

Pubic lice are treated with the same medications used to treat pediculosis capitis (head lice), which are permethrin 1% or pyrethrin. Thoroughly saturate hair with lice medication and leave medication on for 10 minutes. Lindane is a second-line treatment that is not recommended for first-line therapy because of neurotoxicity (CDC, 2010b). If using lindane, leave on for only 4 minutes and then thoroughly rinse off the medication with water. Dry off with a clean towel. Reapply in 7 days if there is evidence of live lice. Sexual partners should be treated concurrently, and bedding and clothing should also be washed. Infestation of eyelashes by pubic lice is treated with petrolatum (Vaseline) ointment applied 3 to 4 times daily for 8 to 10 days. Nits should be removed by hand from the pubic area, axilla, and eyelashes.

Scabies

All family members should receive treatment for scabies, even those who are asymptomatic, because they may be in the incubation period and so need treatment to prevent recurrence. The CDC recommends that sexual and any close personal contacts that have had direct, prolonged, skin-to-skin contact with an infested person also be examined and treated (CDC, 2010c).

Permethrin 5% cream (Elimite, Acticin) is the drug of choice for the treatment of scabies in young children and pregnant women. The cream is massaged into the skin from the neck to the soles of the feet. It should be left on for 8 to 14 hours and then washed off in the shower. One ounce or a 30-gram tube of permethrin per family member is prescribed.

Lindane 1% lotion or cream is used for scabies in children older than 6 months and in nonpregnant adult patients. It is applied in a thin layer from the neck down to the soles of the feet, left on for 8 to 12 hours (overnight), and then washed off thoroughly. If there are crusted lesions present, a tepid bath should be taken prior to application to soften the lesions. Patients should dry the skin thoroughly before applying lindane. One ounce or a 30-gram tube of lindane per family member is recommended.

Topical corticosteroids are used after scabies treatment to treat the pruritus and inflammation associated with the scabies mite. Hydrocortisone 1% or 2.5% or a stronger corticosteroid, if indicated, is applied to affected areas twice a day until the lesions are healed.

Rational Drug Selection

Cost

The relative costs of the different OTC ectoparasiticides for head lice are similar, so cost is not usually a consideration in the treatment.

Adverse Effects

The provider may choose the drug based on the patient's age and the toxicity of the agent. Lindane and malathion should be avoided in pregnant patients. Lindane is contraindicated in children younger than 2 years, and malathion in children younger than 6 years.

Monitoring

No specific laboratory monitoring is necessary with the use of ectoparasiticides.

Patient Education

Administration

Patients should be instructed to use the prescribed medication exactly as directed. Treatment failure due to incorrect use of the medication is common. Give written instructions about how to apply the medication and the length of time that the medication should be left on the skin or hair.

Careful instruction should be given regarding the flammability of malathion (Ovide). Lotion and wet hair should not be exposed to open flames or electric heat sources, including hair dryers and electric curlers. Do not smoke while applying lotion or while hair is wet. Allow hair to dry naturally and to remain uncovered after application of Ovide Lotion.

Adverse Reactions

When used as directed, there are minimal adverse effects from the use of ectoparasiticides. Skin irritation or toxicity may occur, but the incidence increases if patients use the medication incorrectly.

Lifestyle Management

Environmental measures should be discussed and written instructions given to patients or family members to take home to refer to as they delouse the home.

CAUTERIZING AND DESTRUCTIVE AGENTS

The cauterizing agent used in primary care is silver nitrate. Podophyllum resin (Podophyllin) and podofilox (Condylox) are used for genital warts.

Pharmacodynamics

Silver nitrate is a strong caustic agent and escharotic. The silver acts as antiseptic, astringent, and germicide. The silver attaches to the protein ion and decreases the protein's solubility. The local effects of silver are self-limiting, and the spread of damage occurs only when the dose of silver overwhelms the capacity of the tissues to fix the ion at the site of application.

Podophyllum resin contains podophyllotoxin, which binds to the microtubules in the cell, causing mitotic arrest in metaphase. Podophyllum is considered cytotoxic to the wart cells.

Pharmacotherapeutics

Precautions and Contraindications

Cauterizing agents should be used with great care because they damage any skin they touch; inappropriate use may cause chemical burns

Silver nitrate used for prolonged periods discolors the skin. It also stains any clothing or linens it contacts. Only a health-care provider should apply podophyllum resin, a powerful caustic and severe irritant that must be handled carefully. Podophyllum resin should not be used in pregnancy because it has led to birth defects, fetal death, and stillbirth. It is also contraindicated in breastfeeding women. Podophyllum resin is contraindicated in diabetic patients and other patients with poor circulation. It is also contraindicated in the treatment of malignant or premalignant lesions, bleeding warts, and warts with hair growing from them. The use of podophyllum should be avoided if the wart or surrounding tissue is inflamed or irritated.

Adverse Drug Reactions

Cauterizing agents are powerful keratolytics and cauterants. Use with caution to avoid contact with healthy skin.

Irritation and ulcerative local reactions are the major side effects of podophyllum. It may also cause paresthesias. Serious neuropathy and death have occurred from the use of podophyllum in large amounts on multiple lesions.

Use and Dosing

Umbilical Granuloma

Use a silver nitrate stick and touch to the granulomatous area. One treatment is usually curative.

Aphthous Ulcer, Vesicular, or Bullous Lesion

Touch the lesion with a silver nitrate stick. One treatment is usually all that is necessary to provide styptic action.

Poorly Healing Wounds or Ulcers

Apply a cotton pad dipped in silver nitrate solution to the affected area. A silver nitrate stick may also be used.

Verruca (Warts)

Podophyllum resin is only applied by a health-care provider to genital warts; it is not to be dispensed to the patient. After the area is cleansed, podophyllum resin is applied sparingly to the lesion. Avoid contact with healthy skin. The first treatment should be left in place for 30 to 40 minutes and then washed off thoroughly with soap and water. Later treatments may require 1 to 4 hours of contact to produce the desired result. Do not treat numerous lesions or large areas in one treatment, which increases the incidence of neuropathy occurring from podophyllum use. Multiple treatments may be necessary.

Podofilox (Condylox) is used for the treatment of genital warts. The patient applies the medication twice daily to the wart for 3 days and then discontinues treatment for 4 days. Treatment may be repeated up to 4 times. It should not be used for warts on the mucous membranes.

KERATOLYTICS

Keratolytic agents are used to treat a variety of hyperkeratotic and scaling cutaneous lesions, such as corns, calluses, and warts. Salicylic acid is the only OTC product considered safe and effective by the FDA. Lactic acid is used to treat xerosis and ichthyosis vulgaris.

Pharmacodynamics

Salicylic acid produces desquamation of the horny layer of the skin without affecting the viable epidermis. It acts by dissolving the intercellular cement substance in the stratum corneum.

Lactic acid, alpha-hydroxy acid, which may act as a humectant when applied to the skin, is thought to diminish corneocyte cohesion by interfering with the formation of ionic bonds.

Pharmacotherapeutics

Precautions and Contraindications

Salicylic acid products are contraindicated if the patient is sensitive to salicylic acid. Prolonged use in infants and patients with decreased renal or hepatic function is contraindicated, because it may lead to salicylism. Topical salicylic acid use is contraindicated in patients with diabetes or impaired circulation.

Lactic acid should be used carefully on the face or in patients with fair skin because it may cause irritation. Minimize the exposure to UV light or sun when using lactic acid topically. Lac-Hydrin (12% lactic acid) lotion is Pregnancy Category C. It is not known how this medication affects normal levels of lactic acid in human milk.

Adverse Drug Reactions

Local irritation can occur from salicylic acid contact with normal skin surrounding the wart or callus.

Transient stinging or burning has been reported with the use of topical Lac-Hydrin (12% lactic acid). Erythema, peeling, dryness, hyperpigmentation, or eczema flare may also occur.

Clinical Use and Dosing

Warts, Corns, and Calluses

There are many salicylic acid products available. Products that are 5% to 17% in collodion are used for safe, effective removal of common and plantar warts. Transdermal patches are available in 40% and 15% strengths for use on warts, corns, and calluses. Patients should refer to the individual product's label for instructions for use. To ensure successful treatment, patients should soak the affected area in warm water for at least 5 minutes before applying salicylic acid. Loose tissue or dried wart tissue is removed with a washcloth or emery board.

Xerosis, Dry Skin, and Ichthyosis

Lac-Hydrin (12% lactic acid) is applied to the affected area twice a day. The lotion or cream should be rubbed in when applied. Lac-Hydrin cream is not recommended in children younger than 2 years.

Patient Education

Administration

When instructing patients to use OTC salicylic acid, the provider should tell them to soak the affected area in warm water for at least 5 minutes or to bathe just before applying the medication. This will soften the area and allow better penetration of the medication. Patients should be advised that total healing might take several weeks to months.

TOPICAL ANESTHETICS

This section discusses the use of EMLA (lidocaine-prilocaine), Synera (lidocaine-tetracaine), and LMX-4 (4% lidocaine cream) for local anesthesia. These products are unique in that they bridge the gap between topical and infiltration anesthesia. It is useful in preparing for painful procedures such as bone marrow biopsies, IV starts, and blood draws. A lidocaine 5% patch (Lidoderm) is available for the treatment of postherpetic neuralgia.

Pharmacodynamics

EMLA is a unique mixture of lidocaine 2.5% and prilocaine 2.5%. The combination has a lower melting point than does either agent alone. EMLA cream produces anesthesia to a depth of 5 mm. Local anesthetics inhibit conduction of nerve impulses from sensory nerves because of an alteration in the cell membrane permeability to ions. The onset, depth, and duration of analgesia on intact skin depend

primarily on the duration of application and to the area to which it is applied. Absorption from the mucosa is more rapid and onset time is shorter. When applied to intact skin and covered with an occlusive dressing, local anesthesia is achieved in 1 hour.

Synera is a transdermal patch containing lidocaine 70 mg and tetracaine 70 mg used for local dermal analgesia for superficial venous access or superficial dermatological procedures. The patch is applied to skin 30 minutes before the procedure.

LMX-4 (previously ELA-Max) is a 4% lidocaine cream in a liposomal delivery system and is available OTC. Little information is available regarding this product although it is marketed for the treatment of minor cuts, abrasions, sunburns, and insect bites. It has been used for cosmetic procedures such as chemical peels, IV catheter placement, venipuncture, circumcision, and lumbar puncture.

Lidocaine patch 5% (Lidoderm) is composed of an adhesive material containing 5% lidocaine, which is applied to a nonwoven polyester felt backing and covered with a polyethylene terephthalate (PET) film release liner. Each adhesive patch contains 700 mg of lidocaine (50 mg per g adhesive) in an aqueous base. The penetration of lidocaine into intact skin after application of Lidoderm is sufficient to produce an analgesic effect but less than the amount necessary to produce a complete sensory block (Endo Pharmaceuticals, 2010). It is approved for pain associated with postherpetic neuralgia.

Pharmacokinetics

Absorption and Distribution

Lidocaine is absorbed systemically, with greater amounts absorbed based on the amount of medication used and where it is applied on the skin. Absorption is increased across abraded skin or mucous membranes. Once absorbed, lidocaine and prilocaine are widely distributed.

Metabolism and Excretion

It is not known if lidocaine or prilocaine are metabolized in the skin. Lidocaine is metabolized rapidly by the liver. Prilocaine is metabolized in both the liver and kidneys. Lidocaine is excreted in the urine.

Pharmacotherapeutics

Precautions and Contraindications

EMLA is contraindicated in the patient with methemoglobinemia. EMLA increases the risk of methemoglobinemia if used in patients with G6PD deficiency or in young infants. It is contraindicated in patients with known hypersensitivity to lidocaine or other local anesthetics.

If instilled into the middle ear, EMLA can be ototoxic. Therefore, use in the ear near the tympanic membrane is contraindicated.

In patients with severe hepatic disease, older adults, or debilitated and acutely ill patients, topical lidocaine should be used with caution. The minimal effective dose should be used to prevent adverse effects. Topical lidocaine is Pregnancy Category B. It should be used with caution in nursing mothers.

Adverse Drug Reactions

Adverse reactions are generally dose-related and usually result from high plasma levels of anesthetic due to excessive dosage or rapid absorption. The patient may experience local adverse effects, such as paleness of the area, erythema, and changes in temperature sensation.

Drug Interactions

Do not prescribe topical lidocaine products for use in children younger than 12 months who are concurrently taking methemoglobinemia-inducing drugs (acetaminophen, sulfonamides, nitrates, phenytoin, phenobarbital).

Class I antiarrhythmic agents (tocainide and mexiletine) may potentiate the toxicity of topical lidocaine products. See Table 23-12 for drug interactions.

Clinical Use and Dosing

Topical Anesthetic

To provide local anesthesia for minor procedures such as IV cannulation, venipuncture, or circumcision, the dose of EMLA varies by the age of the patient (Table 23-13). For adults and infants, cream is applied and occluded for 1 hour. If the patient is to self-administer the medication before a procedure, for ease of administration a 5 mg tube is dispensed and the patient instructed to apply half of the tube to the site or sites. For IV cannulation or venipuncture anesthesia, two sites may be treated. Dosing of cream for younger infants is determined by age, and the provider must refer to the dosing schedule for accurate dosing to prevent adverse effects. Higher dosing is used to harvest skin grafts, which is rarely done in primary care.

A Synera patch is applied to intact skin 20 to 30 minutes before venipuncture or 30 minutes before a dermatological procedure. Synera is approved for children age 3 years or older and adults. Patches are not to be cut. Synera patches contain iron powder and should be removed before a patient undergoes an MRI.

A Lidoderm patch is applied to intact skin at the most painful postherpetic neuralgia sites. Up to three patches may be applied at once for up to 12 hours of a 24-hour period. To adjust the dose, cut patches before release liner is removed. Do not apply to broken or inflamed skin. Avoid eyes and mucous membranes.

Monitoring

The patient being treated with topical lidocaine products should be monitored for adverse effects, such as methemoglobinemia.

Patient Education

Administration

Patients who are to self-administer topical lidocaine products should have clear instructions as to the correct use. The

Table 23–12 ⚏ **Drug Interactions: Miscellaneous Topical Medications**

Drug	Interacting Drug	Possible Effect	Implications
EMLA	Methemoglobinemia-inducing drugs: • Acetaminophen • Sulfonamides • Nitrates • Phenytoin • Phenobarbital	Methemoglobinemia	Methemoglobinemia can occur in very young (<12 mo) or patients with G6PD deficit, so do not use concurrently. Monitor other patients closely if using concurrently.
	Class I antiarrhythmic drugs: • Tocainide • Mexiletine	Additive toxic effects	Use concurrently with caution
Minoxidil	Topical steroids Topical retinoids Guanethidine Antihypertensives	Increased absorption of minoxidil Increased absorption of minoxidil Increased orthostatic hypertension Possible additive effect	Avoid concurrent use Avoid concurrent use Avoid concurrent use Monitor closely if using concurrently
Aluminum chloride (Drysol)	No known drug interactions		

Table 23–13 ⊗ **Dosage Schedule: Miscellaneous Topical Medications**

Drug	Indication	Dosage	Comments
Lidocaine 2.5% and prilocaine 2.5% (EMLA)	Topical anesthesia	Apply 2.5 g cream in a thick layer with occlusion over 20–25 cm² for 1 h	Apply to clean skin. Avoid eyes, mucous membranes, tympanic membrane, and application to large areas.
Lidocaine 70 mg and tetracaine 70 mg (Synera)	Topical analgesia	Children ≥3 yr and adults: apply patch 20 to 30 min before procedures.	Apply to intact skin. Remove before undergoing MRI (it contains iron powder). Do not cut patch.
Minoxidil (Rogaine for Women, Rogaine Extra Strength for Men)	Hair loss	Men: Use minoxidil 2% or 5%. Apply 1 mL topical 2×/d. Women: Use minoxidil 2%	Do not exceed recommended dose. Continue use or hair loss will begin again.
Aluminum chloride (Xerac 6.25% solution; Certain Dri 12% solution; Drysol 20% solution; Hypercare 20% solution)	Hyperhidrosis	Solution is applied once daily to the affected area at bedtime, then washed off in the morning. May decrease to 1–2×/wk once control is achieved.	Do not apply to recently shaven or broken skin
Eflornithine (Vaniqa)	Unwanted facial hair	Apply a thin layer to affected areas on the face and under the chin 2×/d, at least 8 h apart	For use by females only

patient should clearly understand how to apply the EMLA cream and occlude the area with the occlusive dressing or how to apply the Synera patch. If possible, the first dose should be applied by a health-care provider to demonstrate proper use.

MINOXIDIL

Topical minoxidil (Rogaine) is the first FDA-approved medication for stimulating hair growth. Alopecia androgenetica, also known as male pattern baldness, affects men and some women. It involves hair loss from the frontal, vertex, and occipital regions of the scalp in men and thinning of the hair in the frontoparietal area or diffuse hair loss in women.

Pharmacodynamics

The exact mechanism of action is unknown, but it does produce growth of epithelial cells near the base of the hair follicle. It may also induce vasodilatation of the scalp blood vessels, which also promotes hair growth. It does not appear to have an anti-androgen effect.

Pharmacokinetics

Absorption and Distribution

Topical minoxidil is poorly absorbed (2% of the dose) from an intact scalp. It is widely distributed in body tissues. It is not known whether minoxidil crosses the placenta or is distributed in breast milk.

Metabolism and Excretion

The small portion of topical minoxidil that is absorbed is extensively metabolized in the liver. Both the unchanged drug and the metabolites are excreted in the urine.

Pharmacotherapeutics

Precautions and Contraindications

Minoxidil topical solution used as directed has minimal cardiac effects, but if large amounts are applied, there is a potential for cardiac side effects, including hypotension.

Absorption of minoxidil is increased through abraded or irritated skin, leading to a slightly higher risk for cardiac side effects.

Minoxidil should not be used by pregnant patients (Pregnancy Category C) or by children younger than 18 years.

Adverse Drug Reactions

Minoxidil is generally well tolerated. The topical solution contains alcohol and therefore may be irritating upon application. Patients may be sensitive to minoxidil and develop contact dermatitis.

Drug Interactions

Topical steroids, retinoids, and other drugs that increase blood flow to the area may increase the absorption of minoxidil, leading to increased hypotension. Avoid using these topical medications concurrently on the scalp. There is a possible additive effect if minoxidil is used concurrently with antihypertensives.

Clinical Use and Dosing

Alopecia Androgenetica

Minoxidil is available OTC for the treatment of alopecia androgenetica (male pattern baldness). It is important to note that minoxidil does not treat balding of the frontoparietal areas in men; it only treats this in women. Minoxidil is effective in treating balding on the vertex of the scalp in men.

Minoxidil 2% topical solution is applied to the scalp twice daily for the entire length of treatment. Men may use the 5% solution if needed. The patient applies 1 mL directly to the affected area of the scalp (vertex area in men and frontoparietal area in women). The medication should be applied to a dry scalp. Patients should be instructed to wash their hands after using their fingers to rub medication into the scalp. Twice-daily application for at least 4 months may be needed to obtain observable hair growth. If the medication is discontinued, the hair in the treated area will shed in 3 to 4 months.

Monitoring

There is no specific laboratory monitoring needed when topical minoxidil is used.

Patient Education

Realistic expectations of therapy should be addressed. Minoxidil does not treat patients with predominantly frontal hair loss. It may take 3 to 4 months for the effects of treatment to be noticed. Treatment needs to be continued for there to be a continued effect, and the new hair will shed if the medication is discontinued. Effectiveness is variable among patients. New hair may initially be fine and almost colorless. With continued treatment, the hair should be the same color and thickness as the hair on the rest of the scalp.

Administration

Caution the patient to use the medication exactly as prescribed or, for OTC minoxidil, as the instructions indicate (see Table 23-13).

Adverse Reactions

Adverse effects of the medication should be discussed, and the patient instructed to use the medication exactly as recommended to decrease adverse effects.

MISCELLANEOUS TOPICAL MEDICATIONS

Bath Dermatologicals

Bath dermatologicals contain colloidal solids and oils that act as emollients. They are used to treat dry skin and the pruritus associated with dry skin and common dermatological conditions. Emollient baths that contain colloidal oatmeal solids (Aveeno) or oils (Alpha Keri Bath Oil, Lubriderm Bath Oil) can be used to provide relief from pruritus associated with contact dermatitis. These products are available OTC, and the patient should be instructed to use them according to the label instructions. Baths may be used as needed for comfort. Caution the patient to be careful when using bath oils to prevent slipping in the tub.

Astringents

Aluminum chloride hexahydrate (Drysol) is an astringent used for the management of hyperhidrosis (see Table 23-13). The solution is applied to the affected area at bedtime and then washed off in the morning. Excessive sweating may stop after two or more treatments. Once control of hyperhidrosis is achieved, the medication is applied once or twice weekly. Aluminum chloride hexahydrate solution should be applied to clean, completely dry skin to prevent irritation. Avoid use on broken, irritated, or recently shaved skin.

Hair-Growth Retardants

Eflornithine HCl (Vaniqa) is thought to inhibit hair growth by irreversibly inhibiting ornithine decarboxylase enzymes, which are necessary for the synthesis of polyamine. Polyamine inhibits cell division affecting the rate of hair growth. In clinical trials, 32% of women reported marked improvement in hair-growth reduction (SkinMedica, 2010). Adverse effects of eflornithine include acne, pseudofolliculitis barbae, stinging, burning, and rash. Vaniqa is Pregnancy Category C and is not recommended for use in children. It has been labeled for use in women. Vaniqa cream is applied twice a day (at least 8 hours apart) to affected areas of the face and adjacent areas under the chin. The medication is rubbed in thoroughly and the area should not be washed for at least 4 hours. Vaniqa works for most women within 8 weeks when used consistently twice a day. Women need to understand that this product only slows hair growth and they will need to continue to use other hair-removal methods (tweezing, shaving, etc.).

Sunscreens

Sunscreens provide either a chemical or physical barrier to sunlight. Chemical sunscreens are transparent and absorb portions of ultraviolet light. Some chemical sunscreens block UVA (avobenzone) and others UVB (PABA and others). Oxybenzone and dioxybenzone block both UVA and UVB light. Multiple-chemical sunscreens are usually combined in commercial products to provide broad-spectrum coverage. Physical barrier sunscreens contain large particulate ingredients (titanium dioxide, red petrolatum, or zinc oxide) that reflect and scatter UVA, UVB, and visible light.

The efficacy of sunscreens is determined by their sunscreen protective factor (SPF). Theoretically, a sunscreen with an SPF of 15 should allow the person to remain out in the sun 15 times longer before burning than if the skin is unprotected. According to the FDA (2012), sunscreen products labeled "broad-spectrum" sunscreens protect against both UVA and UVB rays. Sunscreens labeled "water resistant" sunscreens state whether the sunscreen remains effective for 40 minutes or 80 minutes when swimming or sweating. There is no longer a label of "waterproof" on sunscreen because eventually all sunscreens wash off. Sweating, reflection, and wind affect SPF.

Sunscreens must be applied liberally 15 to 30 minutes before sun exposure to allow penetration and binding to skin and must be reapplied after swimming.

Do not use sunscreens on children younger than 6 months. Sensitivity to sunscreen can occur. Contact dermatitis may occur with the use of PABA or its esters. PABA may permanently stain clothing yellow.

DRUGS USED IN TREATING INFECTIOUS DISEASES

Jennifer Jordan • R. Brigg Turner • Teri Moser Woo

In 1928, Alexander Fleming discovered the first antibiotic, penicillin. In the ensuing years, a wide variety of anti - biotic, antifungal, and antiviral classes and drugs have been developed. These anti-infective agents have made a significant difference in morbidity and mortality throughout the world. Many disease processes, once incurable, are now treatable with various agents.

ANTIMICROBIAL RESISTANCE

Within 10 years of Fleming's discovery, group A streptococci and pneumococci had developed modes of resistance (Schumann & Nollette, 2000). Antibiotic resistance has continued; widespread acquisition of penicillin resistance emerged in the 1950s and 1960s, and outbreaks of resistant gram-negative organisms and beta-lactamase-producing bacteria occurred in the 1970s. In the 1980s, new pathogens began to emerge, and organisms previously susceptible to therapy developed multidrug resistance (MDR). The first known penicillin-non-susceptible pneumococcus was identified in the 1960s; by the 1980s, there was a high prevalence of antibiotic-resistant pneumococci worldwide (Linares, Ardanuy, Pallares, & Fenoll, 2010). In the 1990s, vancomycin-resistance enterococci emerged. The World Health Organization (WHO) reported an estimated 630,000 cases (3.7%) of MDR tuberculosis in 2011 (WHO, 2013b).

Factors that contribute to this phenomenon include increasing populations of immunocompromised patients, increases in the number and complexity of invasive medical procedures, and increased survival of patients with chronic diseases. Spread of resistant organisms in the community has been associated with day care for young children, overcrowding, travel, and the use of antibiotics in agriculture (American Academy of Microbiology, 2009). The leading risk factors for having a drug-resistant pathogen include recent use of antibiotics, age younger than 2 years or older than 65 years, day-care center attendance, exposure to young children, multiple medical comorbidities, recent hospitalization, and immunosuppression (Chow et al, 2012).

Excessive and inappropriate use of antibiotic agents is a major factor in the development of drug resistance (Bishai, Morris, & Scanland, 2004; Centers for Disease Control and Prevention [CDC], 2011a; Linares et al, 2010). Examples of inappropriate use include prescribing antibiotics for viral infections, inadequate dosing, excessive duration of therapy, and increased empirical use of broad-spectrum antibiotics when not required (CDC, 2009b; Schumann & Nollette, 2000). To address the public health burden caused by overuse of antimicrobials, the CDC convened a meeting in December 2011 of international experts in clinical medicine, veterinary medicine, microbiology, public health and health policy, which led to the development of a Federal Action Plan titled *A Public Health Action Plan to Combat Antimicrobial Resistance* (CDC, 2011). In 2013, the CDC published a report outlining the burden and threats posed by antibiotic-resistant organisms and their impact on health in the United States, noting that 2 million people become infected with resis - tant bacteria and 23,000 people in the United States die annually from resistant bacteria (CDC, 2013a). Among the strategies proposed by the *Action Plan* were increased surveillance for emergence of antimicrobial organisms and the development, implementation, and evaluation of strategies to improve appropriate antimicrobial use. In 2015 the Obama Administration released a comprehensive national plan to combat antibiotic resistance that included doubling the budget for combating antibiotic resistance.

In the 21st century, resistance has developed to *every* antibiotic class. Unless novel drug mechanisms are developed, a prospect many experts find unlikely, providers will be dependent on the current classes of drugs to treat infectious diseases. Many health systems around the world are utilizing antimicrobial stewardship programs to preserve the current antibiotic armamentarium. These programs are helpful in combatting increasingly complex problems, are multidisciplinary, and promote using the most appropriate antibiotic with the best dose, route, and duration for a specific patient.

Stewardship strategies include treatment pathways for specific infectious diseases, formulary restrictions, dose optimization, prospective audits of prescribed antimicrobials, and continued education for prescribers.

This chapter focuses on the systemic administration of drugs that are active against bacterial, fungal, viral, and parasitic organisms. Topical applications associated with dermatological conditions are presented in Chapter 23. Although many of these drugs are available in IV formulations, oral (PO) and intramuscular (IM) formulations are more commonly used in primary care and are the focus of this chapter.

ANTIBIOTICS: BETA-LACTAMS

The discovery of penicillins initiated the antibiotic era. The active moiety of penicillins is a four-member ring known as the beta-lactam ring. Other antibiotics that contain the beta-lactam ring, mainly cephalosporins, carbapenems, and monobactams, have a similar mechanism of action and share clinical effects. Beta-lactam antibiotics are bactericidal when concentrations exceed the minimum inhibitory concentration (MIC) of the pathogen for approximately 50% of the dosing interval. Efficacy is affected by the organism's susceptibility, dose, tissue concentration, and rate of organism multiplication. They are most effective against rapidly growing organisms forming cell walls. Cephalosporins are discussed in the next section. Monobactams and carbapenems are used to treat serious infections in the hospital, which is outside the scope of this textbook. Beta-lactamase inhibitors are described with the penicillins because they are usually used together as combination products.

PENICILLINS

Penicillins are characterized chemically by the 6-aminopenicillanic acid joined to the beta-lactam ring. Attachment of different substitutes to 6-aminopenicillanic acid results in different pharmacological and antibacterial characteristics, which are the basis for four penicillin subclasses: (1) penicillinase-sensitive or natural penicillins, (2) aminopenicillins, (3) penicillinase-resistant or antistaphylococcal penicillins, and (4) anti-pseudomonal or extended-spectrum penicillins.

Pharmacodynamics

Penicillins hinder bacterial growth by inhibiting the biosynthesis of bacterial cell wall mucopeptide (also called murein or peptidoglycan). This action is dependent on the drug reaching the penicillin-binding proteins (PBPs), which include transpeptidase, carboxypeptidase, and endopeptidase enzymes involved in the terminal stages of forming the cell wall. When penicillins bind to the PBPs, the wall is weakened and lysis of the bacterial cell wall occurs. Because human cells lack a cell wall, there is virtually no action against host cells. Penicillins are bactericidal against sensitive organisms and are most effective during active cellular multiplication. Lower drug concentrations may result in bacteriostatic effects only.

Penicillin

The only natural penicillin commercially available is penicillin. Penicillin can be administered orally (Penicillin V, or oral Penicillin G which is no longer available in the United States), intramuscularly (procaine and benzathine penicillin), and intravenously (Penicillin G). This group is active against aerobic, gram-positive organisms, including *Streptococcus* species such as *S. pneumoniae* and group A beta-hemolytic *Streptococcus* (GABHS), some *Enterococcus* strains, and some non-penicillinase-producing staphylococci. Only about 5% to 15% of community-acquired *Staphylococcus aureus* remains susceptible to natural penicillins, principally because the majority of strains produce penicillinase.

The concern with penicillin-resistant *S. pneumoniae* has been somewhat decreased with less indiscriminate use of antibiotics and vaccination against pneumococcus. Resistant strains dropped from a high of 40% in 2000 to 20% by 2003 with the universal use of the PCV-7 vaccine (Thomas, 2005). Penicillin-resistant strains are also commonly resistant to cephalosporins, macrolides, and sulfonamides and, to a lesser extent, to clindamycin; they are commonly called drug-resistant *S. pneumoniae* (DRSP) (Thomas, 2005).

In addition to its bactericidal activity against most streptococcal and community-acquired enterococcal species, penicillin has reliable activity against *Pasteurella multocido*, *Actinomyces, Clostridium*, *Peptostreptococcus,* and *Treponema pallidum.* The American Academy of Pediatrics (AAP) *Red Book* recommends penicillin for Group A beta streptococci and for Group B beta streptococci due to low resistance (AAP, 2012a, 2012b). Penicillin G is reliable for treating *Listeria monocytogenes* but is no longer listed as active against *Neisseria gonorrhoeae* due to resistance that was first documented in 1976 (CDC, 2013b; see Chap. 44, Sexually Transmitted Infections) or against *Staphylococcus* species. Penicillinase-producing organisms have reduced the breadth of organisms that this group is used to treat.

Aminopenicillins

Like penicillin, aminopenicillins have reliable activity against gram-positive organisms, including *Streptococcus* and *Enterococcus* species. However, they have greater activity against gram-negative bacteria because of their enhanced ability to penetrate the outer membrane of these organisms. Ampicillin and amoxicillin are the only two available aminopenicillins. Because of the increasing beta-lactamase production among gram-negative pathogens and anaerobes, amoxicillin and ampicillin are often combined with beta-lactamase inhibitors, clavulanic acid, and sulbactam, respectively, for enhanced gram-negative and anaerobic activity. Beta-lactamase inhibitors prevent the destruction of beta-lactam antibiotics by serving as a competitive inhibitor of beta-lactamase. Although beta-lactamase inhibitors also contain a beta-lactam

ring, they have poor antimicrobial activity alone. As combination products, ampicillin/sulbactam and amoxicillin/clavulanate have excellent activity against methicillin-susceptible *Staphylococcus aureus* (MSSA), *Streptococcus* and *Enterococcus* species, *Moraxella catarrhalis, Haemophilus influenzae, Neisseria meningitidis, Escherichia coli, Klebsiella, Proteus mirabilis, Salmonella,* some *Shigella* species, *Pasteurella multocido, Actinomyces, Clostridium, Peptostreptococcus,* and *Bacteroides fragilis.*

Penicillinase-Resistant Penicillins

Nafcillin, oxacillin, cloxacillin, and dicloxacillin, also called the anti-staphylococcal penicillins, have a unique spectrum of activity. Chemical modifications of penicillin produced this class of antibiotics that is stable in the presence of penicillinase produced by staphylococci; however, activity was eliminated for *Enterococcus* species, *Listeria*, gram-negative bacteria, and most anaerobes. They are active against *Streptococcus* species, MSSA, some coagulase-negative staphylococci, and *Peptostreptococcus*. Resistance by staphylococci is mediated via the m*ecA* gene, which encodes the low-affinity PBP 2a. This will manifest as methicillin-resistant *S. aureus* (MRSA) and *Staphylococcus epidermidis* (MRSE). With the exception of ceftaroline, methicillin-resistant strains are resistant to all penicillins, cephalosporins, and carbapenems.

Anti-Pseudomonal Penicillins

The anti-pseudomonal penicillin group is comprised of piperacillin, ticarcillin, mezlocillin (discontinued in the United States), and carbenicillin (discontinued in the United States). Piperacillin and ticarcillin have enhanced activity against gram-negative bacilli, particularly *Pseudomonas aeruginosa, Enterobacter, Morganella,* and *Providencia* species. They retain activity against aminopenicillin-susceptible organisms, yet have less potency against streptococci and enterococci.

Piperacillin and ticarcillin are available as combination products with beta-lactamase inhibitors. Piperacillin/tazobactam and ticarcillin/clavulanate have a wider spectrum of activity that includes MSSA and anaerobes, including *Bacteroides* species. None of these agents is available for oral use in the United States.

Many texts and references, including the *Sanford Guide to Antimicrobial Therapy* (2012), have tables that list the organisms generally susceptible to various penicillins.

Resistance

Resistance to penicillins is due to (1) inactivation by beta-lactamases, (2) alteration in target PBPs on the bacterial cell wall, or (3) a permeability barrier preventing penetration of the antibiotic to the target cell. Beta-lactamase production is the most common mechanism. Beta-lactamases include a large group of enzymes called penicillinases, cephalosporinases, and carbapenemases. Beta-lactamases produced by *S. aureus, Haemophilus* species*,* and most *E. coli* have narrow specificity for penicillins. Beta-lactamase inhibitors (clavulanate, sulbactam, and tazobactam) have minimal antibacterial activity but irreversibly inactivate beta-lactamase

enzymes produced by bacteria by binding to their active site and protecting the antibiotic from inactivation. However, some *E. coli*, *Klebsiella* species, and *Enterobacter* species produce extended-spectrum beta-lactamases (ESBLs) that have broader specificity and will hydrolyze both penicillins and cephalosporins while sparing carbapenems. ESBLs are not inhibited by commercially available beta-lactamase inhibitors.

Alteration in PBPs is responsible for methicillin resistance in staphylococci and penicillin resistance in pneumococci . Drug penetration problems are associated with the cellular outer membrane, which is present in gram-negative but not gram-positive organisms.

Pharmacokinetics

Absorption and Distribution

The extent of oral absorption of penicillins is dependent on the specific penicillin agent, the pH of the stomach and intestine, and presence of food. Although oral penicillin formulations are generally well absorbed from the GI tract, use is limited to mild to moderate infections because higher-than-recommended doses cause GI distress and diarrhea. In addition, serum concentrations do not rise proportionately with increased doses.

Penicillin V has less individual variation in absorption than Penicillin G and is virtually the only oral natural penicillin in use. Nafcillin's oral absorption is so poor that the oral route is rarely used, whereas dicloxacillin is the best absorbed of the penicillinase-resistant group, producing blood levels twice that of orally administered oxacillin or cloxacillin. Amoxicillin is more completely absorbed than ampicillin and may be given without regard to food. Carbenicillin, the only oral anti-pseudomonal penicillin, is not adequately absorbed enough orally to attain blood levels effective for systemic infections, so it is indicated only for urinary tract and prostatic infections. It is not first-line treatment for this indication and not currently available in the United States.

All subclasses of penicillin have agents that can be given IM, but different penicillin salts have different absorption rates. The IM route is unreliable and erratic, as well as irritating to the tissue, and repeated dosing by this route should be avoided. Because the penicillin G procaine and penicillin G benzathine formulations are slowly absorbed, they are used as depot agents for deep IM use only. They are not to be injected near an artery or vein. IV injection of these depot formulations of penicillin may cause cardiac arrest and death.

Penicillins are bound to plasma proteins to varying degrees and are well distributed to most tissues and body fluids. Inflammation enhances penetration of the meninges, joints, and eye fluids, which are otherwise poorly penetrated. Penicillins cross the placenta and enter breast milk.

Metabolism and Excretion

Excluding nafcillin and oxacillin, penicillins undergo negligible metabolism and are excreted primarily as unchanged drugs in the urine, achieving high urinary concentrations.

Ninety percent of the renal excretion of penicillin is by active tubular secretion, and most other penicillins undergo extensive tubular secretion. Probenecid, which competes with penicillins for the tubular secretion carrier, will prolong the half-life and raise the peak plasma concentration of penicillins. Thus, concurrent administration of oral probenecid is used to treat some serious infections. Renal insufficiency prolongs the half-life and increases the risk for toxicity of penicillins. Table 24-1 shows the pharmacokinetic properties of each of the penicillin subclasses. Throughout this chapter, any change in dosing that is required based on renal impairment will be shown in the dosage schedule tables.

Pharmacotherapeutics

Precautions and Contraindications

Although less than 10% of patients taking these drugs have an allergic reaction, penicillins are the most likely antibiotics to cause an allergic reaction. A history of a serious hypersensitivity reaction (e.g., anaphylaxis, serum sickness, exfoliative dermatitis, hemolysis, or other blood dyscrasia) to a penicillin contraindicates the use of any penicillin on account of cross-reactivity. Severe, type I allergic reactions to cephalosporins, carbapenems, or beta-lactamase inhibitors may contraindicate use of penicillins. Although historically cross-sensitivity between penicillins and these other classes was thought to be much higher, recent data suggest that the rate is closer to 1% (Campagna, Bond, Schabelman, & Hayes, 2012; Frumin & Gallagher, 2009). Patients with a history of allergy to other substances (e.g., atopic skin conditions) should also use these drugs with caution.

Mezlocillin, carbenicillin (parenteral), and piperacillin may induce hemorrhagic manifestations, and they should be used with extreme caution by patients who have anemia, thrombocytopenia, granulocytopenia, or bone marrow depression, or who are receiving anticoagulants.

Penicillins are Pregnancy Category B, but there are not adequate and controlled studies in women. They should be used only when clearly indicated. They are excreted in low concentrations in breast milk and may cause diarrhea, candidiasis, or allergic response in the nursing infant.

The safety and efficacy of carbenicillin and the piperacillin-tazobactam combination have not been established for children younger than 12 years. Dosage adjustment of penicillins may be required for infants because of their undeveloped renal function (see the Clinical Use and Dosing section for further discussion).

Adverse Drug Reactions

Serious and occasionally fatal immediate hypersensitivity reactions (type I hypersensitivity) have occurred, with an incidence of anaphylactic shock of 0.015% to 0.04%. These reactions usually occur within 2 to 30 minutes after administration and are characterized by nausea, vomiting, urticaria, pruritus, tachycardia, severe dyspnea, diaphoresis, stridor, vertigo, and eventually loss of consciousness and circulatory collapse. Treatment is the same as for any anaphylactic reaction. Skin testing may be used to identify those at risk for penicillin allergy. A radioallergosorbent test (RAST), or a combination of RAST and minor determinant skin testing, may also be used. Patients should be referred to an allergist for skin testing. Patients with a known allergy or a positive skin test can be given desensitization therapy (Schafer, Mateo, Parlier, & Rotschafer, 2007). Other hypersensitivity reactions include skin rashes, a serum sickness–like reaction (skin rash, joint pain, fever), exfoliative dermatitis (red, scaly skin), and blood dyscrasias (hemolytic anemia, neutropenia, leukopenia).

A pruritic, maculopapular rash that does not represent a true allergy occasionally occurs with amoxicillin and ampicillin (9%). It is more common with patients who have mononucleosis (43% to 100%), chronic lymphocytic leukemia (90%), or concurrent allopurinol therapy (15% to 20%). This measles-like, pruritic, generalized rash typically appears 7 to 10 days after initiation of therapy and remains for a few days to a week after the drug is discontinued. This rash does not contraindicate subsequent use of aminopenicillins.

As with many antibiotics, common adverse reactions include GI symptoms such as nausea, vomiting, diarrhea, and epigastric distress. Amoxicillin produces these symptoms less often than ampicillin and can be taken with food, which will further decrease incidence of these adverse effects. Addition of clavulanate to amoxicillin doubles the incidence of diarrhea to 10%, but new formulations with lower concentrations of clavulanate have reduced this side effect. Although uncommon, the penicillinase-resistant penicillins are the most likely group to cause hepatotoxicity, especially when administered with other hepatotoxic drugs.

Use of broad-spectrum penicillins, or prolonged or repeat therapy with any broad-spectrum antibacterial, may result in bacterial or fungal overgrowth (i.e., superinfection) of non-susceptible organisms. The patient should be monitored for this possibility and treated with appropriate measures. *Clostridium difficile* infection (CDI) is a superinfection that manifests as diarrhea that may occur during therapy or up to several weeks after discontinuation of the antibiotic. CDI may present with watery or bloody diarrhea, accompanied by severe abdominal cramps and pain, fever, and pseudomembranous colitis. CDI is a serious sequela that may abate with supportive therapy and discontinuance of the antibiotic, but if definitive diagnosis is made, treatment with oral metronidazole, oral vancomycin, or fidaxomicin is required.

Patients who are HIV-positive are more susceptible to hepatotoxicity resulting from cloxacillin, dicloxacillin, and oxacillin than are HIV-negative patients. Although interstitial nephritis was commonly seen with methicillin, which is no longer used, it still occurs occasionally with oxacillin, nafcillin, or any other penicillin. High doses of procaine penicillin G can cause transient mental disturbances, including combativeness, irritability, and hallucinations. Platelet dysfunction is primarily associated with parenteral carbenicillin, piperacillin, and ticarcillin. Irritability and seizures have occurred with high doses of all penicillins, especially in patients with renal insufficiency.

Table 24–1 ❖ **Pharmacokinetics: Penicillins**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Penicillinase Resistance	Acid Stability	Elimination
Penicillinase Sensitive									
Penicillin G sodium (IM)	Rapid	0.5–3 h	4–6 h	60%	0	0.7 h	No	NA	70% unchanged by kidney
Penicillin G potassium (IM)	Rapid	15–30 min	4–6 h	UA	0	0.5–1 h	No	NA	70% unchanged by kidney
Penicillin G benzathine (IM)	Delayed	12–24 h	7–18 d	UA	0	0.5–1 h	No	NA	70% unchanged by kidney
Penicillin G procaine (IM)	Delayed	1–4 h	12 h	UA	0	0.5–1 h	No	NA	70% unchanged by kidney
Penicillin G potassium (PO)	1 h	1 h	4–6 h	UA	UA	0.5–1 h	No	No	70% unchanged by kidney
Penicillin V (PO)	Rapid	0.5–1 h	4–6 h	65%	60%	0.5 h	No	No	70% unchanged by kidney
Penicillinase Resistant									
Cloxacillin (PO)	30 min	1–2 h	6 h	93%–95%	50%–70%	0.5 h	Yes	Yes	30%–60% by liver; 40%–70% by kidney
Dicloxacillin (PO)	30 min	1–2 h	6 h	96%–98%	50%	0.8 h	Yes	Yes	6%–10% by liver; 50% unchanged in urine
Methicillin (IM)	Rapid	0.5–1 h	4–6 h	40%	Minimal	0.4 h	Yes	NA	Unchanged by kidney
Nafcillin (IM)	Rapid	30 min	1–2 h	80%–90%	NA	0.5–1.5 h	Yes	Yes	60% by liver; rest unchanged in urine
Oxacillin (IM)	Rapid	0.5–1 h	4–6 h	90%–94%	NA	0.5–1 h	Yes	Yes / Yes	49% by liver; rest unchanged in urine
Aminopenicillins									
Amoxicillin (PO)	30 min	1–2 h	8 h	20%	80%	1–1.5 h	No	Yes	30% by liver; 70% unchanged in urine
Ampicillin (PO)	Rapid	1–2 h	4–6 h	20%	50%	1–1.5 h	No	Yes	60% in urine
(IM)	Rapid	1 h	4–6 h	20%	NA	1–1.5 h	No	NA	50%–85% in urine
Anti-Pseudomonals									
Carbenicillin (PO)	Rapid	1 h	6 h	98%	30%–50%	1 h	No	Yes	85% unchanged in urine
Mezlocillin (IM)	Rapid	1–1.5 h	4–6 h	16%–42%	NA	0.7–1.3 h	No	NA	55%–60% unchanged in urine; up to 50% metabolized by liver
Piperacillin (IM)	Rapid	0.5–1 h	4–6 h	16%	NA	1h	No	NA	60%–80% unchanged in urine; 10% in bile
Combinations									
Amoxicillin/clavulanate (PO)	30 min	1–2 h	8 h	18%–25%	80%	1–1.3 h	Yes	Yes	30% by liver; 70% unchanged in urine
Ampicillin/sulbactam (IM)	Rapid	1 h	6–8 h	20%–38%	NA	1–1.3 h	Yes	NA	75% of ampicillin and sulbactam by kidney
Piperacillin/tazobactam (IM)	Rapid	0.5–1 h	4–6 h	16%–30%	NA	0.7–1.2 h	Yes	NA	Piperacillin 68% and tazobactam 80% by kidney

NA = not applicable; UA = information unavailable.

Drug Interactions

The main drug interactions with penicillins are shown in Table 24-2. Of interest is the potential for reduced efficacy of oral contraceptives (OCs), particularly with aminopenicillins. However, there are only a few case reports of such failures, which may be consistent with the normal failure rate of OCs. All antibiotics have been implicated in the failure of OCs; however, only rifampin and griseofulvin have been shown to alter serum levels of estrogen (Archer & Archer, 2002). Other proposed, but unproven, mechanisms of interaction between OCs and antibiotics include decreased absorption of OCs, decreased enterohepatic recirculation of OCs, and increased serum protein displacement by antibiotics. While potentially unnecessary, the most cautious approach is to recommend an additional form of contraception during the antibiotic course. For drug interactions specific to a particular penicillin, selecting a different penicillin may be acceptable, but selecting a different antibiotic class is preferable. Food and acidic juices decrease the oral absorption of penicillin V and the penicillinase-resistant penicillins.

Clinical Use and Dosing

A penicillin is usually the drug of choice for a susceptible organism because of limited toxicities. Amoxicillin is the top antibiotic prescribed to children and the second most prescribed antibiotic in adults (Kofke-Egger & Udow-Phillips, 2011). The most common infections treated with penicillins in ambulatory care are bacterial upper respiratory infections (URIs) (pharyngitis, otitis media, sinusitis), pneumonia, sexually transmitted infections, urinary tract infections, and wound infections. Other important indications for penicillins are endocarditis prophylaxis, eradication of *Helicobacter pylori* in gastritis and peptic ulcer disease, and Lyme disease.

Acute Bronchitis and Upper Respiratory Infection

Over the past 15 to 20 years, concern has been growing that overuse and misuse of antibiotics for URIs contribute to antibiotic resistance (AAP, 2012c; Bucher et al, 2003; Schumann & Nollette, 2000). In 1998, "Common Cold: Principles of Judicious Use of Antimicrobial Agents" was published in *Pediatrics* to begin a dialogue and recommendation for avoiding antibiotic prescriptions for the common cold (Rosenstein et al, 1998). In spite of recommendations not to prescribe antibiotics for the common cold, the CDC reported that up to 50% of patients treated for colds, bronchitis, and URIs received antibiotics inappropriately and launched a nationwide campaign called "Get Smart: Know When Antibiotics Work" (http://www.cdc.gov/getsmart) to educate providers and patients regarding the inappropriate use of antibiotics. In spite of almost 15 years of focusing on appropriate use of antibiotics, approximately 75% of antibiotic prescriptions written in pediatric practice are for otitis media, sinusitis, cough illness/bronchitis, pharyngitis, and the common cold (AAP, 2009). Because the common cold, URI, and acute bronchitis are seasonal, self-limiting illnesses usually caused by viruses, antibiotics have no role in management of uncomplicated cases (CDC, 2012c). Symptomatic treatment, rest, and proper nutrition should be mainstays of treatment; these are discussed in Chapter 46, Upper Respiratory Infections.

Table 24–2 ▦ **Drug Interactions: Penicillins**

Drug	Interacting Drug	Possible Effect	Implications
Penicillins	Diuretics	Potassium-wasting diuretics may have increased risk for hypokalemia; the reverse is true for potassium-sparing diuretics.	If they must be given together, monitor serum potassium levels and for indications of these electrolyte imbalances.
	Methotrexate	Increased levels of methotrexate.	Avoid concurrent administration.
	Oral contraceptives	Evidence is contradictory. The efficacy of oral contraceptives may be reduced, and increased breakthrough bleeding may occur. Although infrequently reported, contraceptive failure is possible.	It is difficult to tie contraceptive failure directly to penicillin use because no oral contraceptive is 100% efficacious. The use of an additional form of contraception during penicillin therapy should be considered.
	Probenecid	Delays renal elimination and increases blood levels.	Monitor for penicillin toxicity.
	Tetracyclines	Bacteriostatic action of tetracyclines may impair bactericidal effects of penicillins.	Rarely used therapeutically. Monitor for therapeutic efficacy.
	Warfarin	Increased effects of warfarin and risk of bleeding with penicillin, aminopenicillins, and antipseudomonal penicillins; however, decreased effects of warfarin with nafcillin, oxacillin, and dicloxacillin.	Monitor INR closely.
Ampicillin	Beta blockers	May reduce bioavailability of atenolol. Beta blockers may potentiate anaphylactic reactions of penicillin.	Select a different penicillin if patient is taking atenolol.
	Allopurinol	Higher incidence of ampicillin-induced rash.	Avoid coadministration.
Nafcillin	Cyclosporine	Concurrent administration produces subtherapeutic cyclosporine levels.	If they must be used concurrently, monitor cyclosporine levels more closely.
Penicillin G	Colestipol, cholestyramine	May decrease absorption of oral penicillin G.	Separate doses. Give penicillin G 1 h before or 4 h after colestipol or cholestyramine.

Cough of less than 3-weeks duration seldom requires treatment in adults or generally well-appearing children (CDC, 2012c). The American College of Chest Physicians produced an extensive guideline regarding the management of acute and chronic cough with clear guidelines recommending antibiotic avoidance coupled with patient education (Irwin et al, 2006). Bronchitis requires antimicrobial therapy only if there is prolonged cough with a diagnosed etiology of a specific infection, such as *Bordetella pertussis* or *Mycoplasma pneumoniae* (Irwin et al, 2006). Penicillins are generally not appropriate for the infecting organisms in these complicated cases of bronchitis. During the common cold, mucopurulent rhinitis (thick, opaque, or discolored nasal discharge) is not an indication for antimicrobials unless it persists without improvement for more than 10 days, at which point the symptoms meet the criteria for acute bacterial sinusitis, discussed in depth in Chapter 47 (Chow et al, 2012; Wald et al, 2013).

Chronic Bronchitis

It is important to distinguish acute bronchitis from an acute bacterial exacerbation of chronic bronchitis (ABECB). Chronic bronchitis, a condition largely confined to smokers, is defined as a recurrent daily cough with sputum production that persists for at least 3 months in at least 2 consecutive years (Irwin et al, 2006). Patients with underlying chronic bronchitis may periodically become infected with a wide variety of organisms. The common organisms found in the sputum of patients with chronic bronchitis are most commonly viruses, as well as *H. influenzae, S. pneumoniae, M. pneumoniae,* and *M. catarrhalis* (Rabe et al, 2007). Throat swab with Gram's stain and culture are unreliable in these patients because the respiratory tract is normally colonized below the vocal cords. The decision to use antimicrobial drugs may be based on the presence of at least two of the three cardinal symptoms: increased sputum volume, increased sputum purulence, and increased dyspnea. A radiograph of the chest may be required to rule out bronchopneumonia. Recovery usually begins 3 to 4 days after antibiotics are initiated. Amoxicillin/clavulanic acid, macrolides, and double-strength sulfamethoxazole/trimethoprim are all appropriate first-line choices (Rabe et al, 2007). Resistant organisms require selection of an antibiotic agent based on susceptibilities. Patients who don't respond to first-line therapy should be treated with a respiratory fluoroquinolone (levofloxacin, moxifloxacin, gemifloxacin). The length of treatment is 7 to 14 days.

Otitis Media

Acute otitis media (AOM) is the most common indication for antibiotic prescribing in the United States and accounts for nearly half of all pediatric diagnoses and office visits. In assessing middle-ear symptoms, it is important to distinguish between AOM and otitis media with effusion (OME). The AAP revised the AOM Clinical Practice Guideline in 2013 to define AOM as: "moderate to severe tympanic membrane (TM) bulging or new-onset otorrhea not caused by acute otitis externa; or mild bulging of the TM and recent (less than 48 hours) onset of ear pain (holding, tugging, rubbing of the ear in a nonverbal child) or intense erythema of the TM" (Lieberthal et al, 2013). The new AAP practice guidelines state that AOM should not be diagnosed in children without evidence of middle ear effusion based on pneumatic otoscopy or tympanometry (Lieberthal et al, 2013). OME is the presence of fluid in the middle ear in the absence of signs or symptoms of acute illness. OME often follows resolution of AOM and may not abate for several months after the infection. Chapter 47 discusses AOM in more depth. Observation without use of antibiotics in a child older than 24 months of age with nonsevere AOM is an option (see Chap. 47). Mixed bacterial-viral etiology may be dectected in up to 96% of AOM cases diagnosed using strict microbiologic testing (Lieberthal et al, 2013). The most common bacterial pathogens present in AOM are *S. pneumonia,* nontypeable *H. influenzae*, and *M. catarrhalis*. Because the culture of AOM requires tympanocentesis, AOM is usually treated empirically.

Amoxicillin is the first-line drug of choice for AOM with initial doses of 875 mg twice daily or 500 mg 3 times daily for adults. The pediatric dose is 80 to 90 mg/kg/d in two or three divided doses (Lieberthal et al, 2013). Recent studies indicate that 83% to 87% of *S. pneumoniae* and 58% to 82% of *H. influenzae* isolates are susceptible to high-dose amoxicillin (Lieberthal et al, 2013). Coverage for beta-lactamase is recommended for patients who have been prescribed amoxicillin in the past 30 days, have concurrent purulent conjunctivitis, or have a history of recurrent AOM unresponsive to amoxicillin. Amoxicillin/clavulanate (90 mg/kg/d of amoxicillin and 6.4 mg/kg/d of clavulanate in two divided doses) is the drug of choice (Leiberthal et al, 2013).

If symptoms worsen or there is a failure to respond to appropriate therapy within 48 to 72 hours, reassessment of the diagnosis is indicated to exclude other causes of the illness and decide if an antibiotic change is necessary. In general, if high-dose amoxicillin was the initial choice, then amoxicillin/clavulanate should be tried before moving to a different drug class. Almost 100% of *M. catarrhalis* strains produce beta-lactamase but remain susceptible to amoxicillin/clavulanate (Leiberthal et al, 2013). The AAP practice guidelines recommend the length of treatment in children under 2 years of age or with severe AOM to be 10 days (Leiberthal et al, 2013). Children 2 years to 5 years of age with mild or moderate symptoms may be treated for 7 days, and children age 6 years and older with mild to moderate disease may be treated with a 5 to 7 day course. Perforated tympanic membrane requires at least 10 days of treatment with a combination of topical and oral antibiotic therapy.

Persistent OME after therapy for AOM is expected and does not require treatment. OME should be treated with antimicrobials only if bilateral effusions, accompanied by documented hearing loss, persist for 3 or more months; however, insertion of tympanostomy tubes may be more effective.

Sinusitis

Sinus inflammation can be a response to viruses, allergy, pollution, or other irritants. Viral rhinosinusitis is 20 to 200 times

more common than bacterial sinusitis, which complicates 0.5% to 2% of cases of viral URI. Clinical diagnosis of acute bacterial sinusitis requires prolonged, nonspecific upper respiratory signs such as rhinosinusitis and cough without improvement for more than 10 days, or more severe upper respiratory signs and symptoms such as substantial fever, facial swelling, or maxillary tooth or facial pain (usually unilateral) (Chow et al, 2012; Wald et al, 2013). In children, the signs and symptoms are more subtle and difficult to diagnose. The CDC and AAP guidelines recommend not treating mucopurulent nasal discharge in children as a sinus infection until it has been present for at least 10 to 14 days, if there are severe symptoms such as fever great than 39°C, facial swelling, or pain (CDC, 2009a; Wald et al, 2013). Acute bacterial sinusitis is caused by the same pathogens as otitis media (*S. pneumoniae, H. influenzae, M. catarrhalis*) (Chow et al, 2012; Wald et al, 2013). Concerns with antibacterial resistance are similar to concerns with otitis media.

Amoxicillin is first-line therapy for sinusitis in children (Wald et al, 2013). Standard-dose (45 mg/kg/d divided in two doses) is first-line therapy for children 2 years or older who do not attend day care (Wald et al, 2013). In areas with greater than 10% pencillin-resistant *S. pneumoniae,* high-dose amoxicillin (80 to 90 mg/kg/d) is recommended (Wald et al, 2013). For children treated with antibiotics in the past 4 weeks, under 2 years of age, or with moderate to severe disease, high-dose amoxicillin-clavulanate (80 to 90 mg/kg/d of the amoxicillin component with 6.4 mg/kg/d of clavulanate in two divided doses with a maximum of 2 g per dose) is recommended for 10 days or until symptom-free for 7 days (Wald et al, 2013). Failure to respond within 72 hours to first-line therapy should prompt reassessment and a change in therapy should be considered. If amoxicillin was used, high-dose amoxicillin/clavulanate should be considered (Wald et al, 2013). Treatment of sinusitis in children is more fully described in Chapter 46.

First-line treatment for sinusitis in adults at low risk for resistance is amoxicillin/clavulanate (875 mg amoxicillin/ 125 mg clavulanate) for 5 to 7 days (Chow et al, 2012). In areas with greater than 10% pencillin-resistant *S. pneumoniae,* then high-dose amoxicillin/clavulanate (2 g orally twice daily) is recommended (Chow et al, 2012). Failure to respond within 3 to 5 days should prompt reassessment and a change in therapy should be considered. Antimicrobial drugs have little efficacy in treatment of chronic sinusitis. Sinusitis treatment is discussed in depth in Chapter 46.

Pharyngitis

Pharyngitis is usually caused by a virus, and concurrent rhinorrhea, cough, hoarseness, conjunctivitis, and diarrhea strongly suggest this etiology. Most bacterial pharyngitis is self-limiting and will subside without sequelae (AAP, 2012a; Shulman et al, 2012). The exception is that caused by group A beta-hemolytic streptococci (GABHS; *Streptococcus pyogenes*), which is associated with rheumatic fever if not treated (Shulman et al, 2012). The risk of rheumatic fever is now so rare in the United States that 3,000 to 4,000 patients with GABHS would need to be treated to prevent a single case

(Thomas, 2005). An antigen detection ("rapid strep") test should be used to confirm the diagnosis, with negative results confirmed by throat culture. Antibiotics have no effect on the clinical course of patients with negative cultures. Antibiotic therapy started within 9 days of onset will prevent rheumatic fever (AAP, 2012a; Shulman et al, 2012).

Treatment for GABHS pharyngitis is best managed with narrow-spectrum agents. Due to consistent susceptibility, penidcillin remains the first choice in both adults and children (AAP, 2012a; Shulman et al, 2012). Penicillin V 250 mg 2 to 3 times a day for children weighing less than 27 kg (60 lb) and 500 mg 2 to 3 times a day for patients weighing more than 27 kg, including adolescents and adults, is recommended (AAP, 2012a; Shulman et al, 2012). To prevent acute rheumatic fever, penicillin should be given for 10 days, even if the patient is afebrile and asymptomatic (AAP, 2012a). Treatment failure is more likely with oral penicillin than IM penicillin G benzathine (AAP, 2012a). Due to the poor taste of the oral penicillin V solution, amoxicillin 50 mg/kg/d in one dose (maximum 1,000 mg/d) for 10 days may be used in children. If nonadherence is anticipated, penicillin G benzathine as a single IM dose of 1.2 million U for patients weighing greater than 27 kg, or 600,000 U for those under 27 kg, is recommended (AAP, 2012a; Shulman et al, 2012). For patients who are allergic to penicillin, first-generation cephalosporins (cephalexin) or a macrolide (clarithromycin, azithromycin) may be substituted.

Urinary Tract Infections

Urinary tract infections (UTIs) are responsible for 8.27 million (1.41 million men; 6.86 million women) office visits per year (Litwin & Saigal, 2007). *E. coli* is responsible for 85% of community-acquired UTIs and 50% of hospital-acquired UTIs. Empirical treatment with trimethoprim/sulfamethoxazole (TMP/SMX, Septra, Bactrim) or nitrofurantoin are the first-line choice when no complicating factors are present (Gupta et al, 2011). Amoxicillin-clavulanate for 3 to 7 days can be prescribed as therapy to patients who are allergic to first-line drugs (Gupta et al, 2011). Because of its safety profile, amoxicillin/clavulanate 500 mg twice daily for 3 to 5 days is an acceptable therapy for treating asymptomatic bacteriuria or UTI during pregnancy (Hooton & Stamm, 2010). Up to 25% to 70% of *E. coli* is resistant to amoxicillin; therefore, it should not be used as first-line therapy unless patient factors warrant its use.

Sexually Transmitted Infections

Because of beta-lactamase production by many strains of *N. gonorrhoeae,* penicillins no longer have a role in the treatment of gonococcal infections. However, *T. pallidum* retains susceptibility to natural penicillins, so recommended treatment for adults with primary, secondary, or latent syphilis of less than 1-year duration is one 2.4 million U dose of penicillin G benzathine IM (CDC, 2010e). If latent syphilis is over 1-year duration or of indeterminate duration, three doses at weekly intervals are required (CDC, 2010e). Because penicillin G benzathine does not attain adequate concentrations in the brain, neurosyphilis and congenital syphilis are treated with

IV penicillin G or IM penicillin G procaine (2.4 million U daily for 10 d) plus oral probenecid (1 g daily for 10 d). Pregnant women with chlamydial infections unable to tolerate erythromycin may be treated with amoxicillin (CDC, 2010e).

Skin and Tissue Infections

Amoxicillin/clavulanate is indicated as first-line therapy for prophylaxis of infection following animal bites, including cats, dogs, and humans (AAP, 2012d). It may also be used for infected post-operative or post-traumatic wounds. Oral penicillinase-resistant penicillins (dicloxacillin) are indicated for bullous impetigo caused by *S. aureus* and erysipelas of the extremities (Stevens et al, 2014). Penicillin V and penicillin G benzathine are used in the treatment of impetigo caused by group A streptococci. Wounds accompanied by sepsis and severe tissue involvement require hospitalization and IV treatment.

Pneumonia

Although the pattern of causal organisms in pneumonia varies by age and other risk factors (e.g., smoking, HIV, alcohol abuse, IV drug abuse, airway obstruction, use of cortico-steroids), the most common pathogens in community-acquired pneumonia (CAP) are *S. pneumoniae, M. pneumoniae, Chlamydia pneumoniae, H. influenzae,* and *M. catarrhalis. M. pneumoniae* lack a cell wall and are naturally resistant to penicillins. Acquired resistance is common in strains of the other organisms that cause pneumonia, so oral or IM penicillin has a minimal role in the empirical treatment of pneumonia. High-dose amoxicillin (80 to 90 mg/kg/d) is recommended for previously healthy and immunized infants as well as preschool and older children with mild to moderate CAP (Bradley et al, 2011). Amoxicillin can be combined with a macrolide as an alternative to respiratory fluoroquinolones for CAP in adults. Management of pneumonia is fully described in Chapter 42.

Helicobacter Pylori Eradication

Antral gastritis and peptic ulcer of the stomach or duodenum are associated with colonization of *H. pylori;* 95% to 100% of duodenal ulcers are colonized by this organism. Once colonized, it remains in the body for life unless eradicated by antibiotics. Eradication of the organism decreases recurrence of ulcer and promotes resolution of gastritis. Although there are many treatment regimens for *H. pylori* eradication, treatment with amoxicillin 1 g given twice daily for 10 to 14 days in combination with two other drugs is standard therapy (Lew, 2009). Because there is greater than 90% eradication with 7-day therapy with these combinations, selective pressure for resistance and adverse effects are reduced by limiting therapy to 1 week. Other antimicrobials used in *H. pylori* eradication include clarithromycin, metronidazole, tetracycline, and bismuth subsalicylate. Some experts recommend *H. pylori* eradication prior to initiation of NSAIDs to prevent NSAID-induced peptic ulcers, but further research is needed to confirm the efficacy of this strategy. Further discussion of *H. pylori* eradication is found in Chapter 34, and four treatment protocols are found in Table 34-6.

Lyme Disease

Lyme disease is caused by *Borrelia burgdorferi* and other *Borrelia* species and is transmitted by tick bite. Diagnosis is primarily clinical, although serological testing of positive findings with an enzyme-linked immunosorbent assay (ELISA) and Western blot provide confirmatory evidence. According to the Infectious Disease Society of America (IDSA) guidelines, amoxicillin 500 mg 3 times daily for 14 to 21 days may be used in early stages of the disease, characterized by erythema chronicum migrans, isolated facial nerve paralysis, or arthritis (Wormser et al, 2006). Children younger than 8 years of age are treated with amoxicillin 50 mg/kg/d (maximum 500 mg/dose) for 14 to 21 days (Wormser et al, 2006; AAP, 2012e). Alternative treatments for the early stage include doxycycline, clarithromycin, or cefuroxime axetil.

Bacterial Endocarditis Prophylaxis

Antibiotic administration has traditionally been recommended for susceptible patients prior to certain oral, GI, and pulmonary invasive procedures when bacteria may be released into the circulation. A joint task force from the American College of Cardiology and the American Heart Association recently published a document that currently recommends therapy only for those with prosthetic heart valves, previous infective endocarditis, certain patients with congenital heart disease, and cardiac transplant patients with valve regurgitation who are undergoing dental procedures that involve manipulation of either gingival tissue or the periapical region of the teeth (Nishimura et al, 2008). Patients with congenital heart disease (CHD) who require prophylaxis include those with unrepaired cyanotic CHD, completely repaired CHD repaired with prosthetic material or device during the first 6 months after repair, and repaired CHD with residual effects at the site of the prosthetic patch or device (Nishimura et al, 2008). Amoxicillin (adults 2 g and children 50 mg/kg orally 1 h before procedure) and ampicillin (adults 2 g and children 50 mg/kg IM or IV within 30 min before procedure) should be used as first-line therapy. Penicillin-allergic patients should use cephalosporins (cefazolin, ceftriaxone, cephalexin), clindamycin, or the newer macrolides (azithromycin, clarithromycin) for prophylaxis (Nishimura et al, 2008).

Group B Streptococcal Disease Prevention

Sepsis caused by group B streptococci (GBS) is the leading cause of neonatal morbidity and mortality within the United States (AAP, 2012f; CDC, 2010d). The CDC guidelines recommend all pregnant women be screened for GBS vaginal and rectal colonization at 35 to 37 weeks of gestation (CDC, 2010d). Women who have had previous GBS isolation either via urine screen or who had a previous infant with invasive GBS do not need screening; they receive intrapartum antibiotic prophylaxis. At the time of labor or rupture of membranes, intrapartum antibiotic prophylaxis is given to all women who test positive for GBS and those with unknown culture results who have one or more risk factors (less than 37 weeks' gestation, rupture of membranes greater than 18 hours, intrapartum temperature, or intrapartum testing

positive for GBS) (CDC, 2010d). For women undergoing testing while in preterm labor, prophylactic antibiotics are started while awaiting results. Prophylaxis is IV aqueous crystalline penicillin G 5 million U loading dose and 2.5 to 3 million U every 4 hours until delivery or IV ampicillin 2 g loading dose and then 1 g every 4 hours until delivery (CDC, 2010d). Table 24-3 presents the dosage schedule of penicillins for their common indications.

Rational Drug Selection

Indication

The first consideration in drug selection is whether antimicrobial therapy is indicated. Antibiotic therapy is indicated only when the benefits of therapy outweigh the costs and risks of treatment. For self-limiting infections, symptomatic and

supportive treatment, rather than antibiotic therapy, is recommended. If antibiotics are deemed necessary, empirical selection or definitive, culture-derived selection are both appropriate strategies (Table 24-4).

The first step with either method is identifying a clinical diagnosis. Collection of specimens for culture or laboratory testing follows the clinical diagnosis. For some infections, such as otitis media or pelvic inflammatory disease, specimens are not available without invasive procedures, so they are not usually obtained. Additionally, specimens for culture are not helpful if the site is commonly colonized, such as in acute exacerbation of chronic bronchitis. Microbiological testing is an important tool in the rational prescribing of antibiotics, although delay in obtaining results, misinterpretation of colonization as infection, quality control (mislabeling

Table 24–3 ⚕ Dosage Schedule: Penicillins

Drug	Indications	Dosage Forms	Initial Dose	Maximal Dose and Maintanence Dose
Amoxicillin (Amoxil, Trimox, Polymox, Wymox, generic)	Antibacterial	Tablets: 500, 875 mg Tablets (chewable): 125, 200, 250 mg Capsules: 250, 500 mg Powder for oral suspension: 50 mg/mL (drops), 125 mg/5 mL, 250 mg/5 mL, 400 mg/5 mL	*Adults:* PO: 250–500 mg q8h, 875 mg q12h *Children >3 mo:* 25–50 mg/kg/d in divided doses *Children high dose:* 80–90 mg/kg/d in two divided doses	Maximal daily dose 4.5 g Duration of therapy depends on site of infection Continue treatment 5–14 d, depending on site of infection Suspensions retain potency after reconstitution for up to 14 d at room temperature or refrigerated, depending on manufacturer
	Exacerbation of chronic bronchitis		*Adults:* 500 mg tid	Usual duration of therapy 3–10 d
	Acute otitis media		*Adults:* 500 mg tid or 875 mg bid *Children:* 80–90 mg/kg/d in 2–3 divided doses	Usual duration of therapy 5–7 d Usual duration of therapy 10 d
	Chlamydia and non-gonococcal urethritis or cervicitis		*Adults:* 500 mg tid	Usual duration of therapy 7 d
	H. pylori eradication in peptic ulcer disease		*Adults:* 1 g bid *Children:* 90 mg/kg/d in 2 divided doses	Given as part of three-drug regimen for 10–14 d
	Sinusitis		*Adults:* 500 mg tid or 875 mg bid *Children:* 80–90 mg/kg/d in 2–3 divided doses	4 g/d in divided doses for patients at risk for DRSP
	Suspected resistant *S. pneumoniae* (DRSP)		*Children:* PO: 80–90 mg/kg/d divided into 2–3 doses	90 mg/kg/d doses for patients at risk for DRSP
	Endocarditis prophylaxis, preprocedural		*Adults:* 2 g 1 h before procedure *Children:* 50 mg/kg 1 h before procedure	
	Lyme disease		*Adults:* 500 mg tid for 14–21 d *Children:* 50 mg/kg/d for 14–21 d	
	Urinary tract infections, uncomplicated		*Pregnant women:* 500 mg tid for 7 d

Table 24–3 � Dosage Schedule: Penicillins—cont'd

Drug	Indications	Dosage Forms	Initial Dose	Maximal Dose and Maintanence Dose
Amoxicillin and potassium clavulanate (Augmentin)	*Antibacterial*	Tablets: 250 mg amoxicillin/ 125 mg clavulanate 500 mg amoxicillin/125 mg clavulanate 875 mg amoxicillin/125 mg clavulanate Tablets (chewable): 125 mg amoxicillin/31.25 mg clavulanate (chewable): 200 mg amoxicillin/28.5 mg clavulanate (chewable): 250 mg amoxicillin/62.5 mg clavulanate (chewable): 400 mg amoxicillin/57 mg clavulanate	*Children >40 kg and adults:* PO: 250 mg amoxicillin and 62.5 mg clavulanate q8h for 7–10 d *Children <40 kg:* PO: 20–40 mg/kg/d amoxicillin component q8h for 7–10 d *or* 25 to 45 mg/kg/d amoxicillin component q12h. Use 200 mg/5mL or 400 mg/5 mL amoxicillin formulation or 200 mg or 400 mg chewable	Suspensions maintain potency after reconstitution for 10 d if refrigerated Less diarrhea if daily dose in bid therapy because of lower amount of clavulanate.
	Antibacterial, pneumonia, serious or resistant infections	Tablet, extended-release: 1,000 mg amoxicillin/ 62.5 mg clavulanate (Augmentin XR) Powder for oral suspension: 125 mg amoxicillin/ 31.25 mg clavulanate per 5 mL 200 mg amoxicillin/28.5 mg clavulanate per 5 mL 250 mg amoxicillin/62.5 mg clavulanate per 5 mL 400 mg amoxicillin/57 mg clavulanate per 5 mL Powder for oral suspension: 600 mg amoxicillin and 42.9 mg clavulanate (Augmentin ES)	*Children >40 kg and adults:* PO: 500 mg amoxicillin and 125 mg clavulanate q8h *or* 875 mg amoxicillin and 125 mg clavulanate q12h *Children ≥16 yr and adults:* Extended-release tablet = 2,000 mg q12h *Children <40 kg:* PO: 80–90 mg/kg/d of amoxicillin component, 7:1 bid formulation or ES-600 suspension	Pediatric dose equivalent to 70–90 mg/kg amoxicillin/d in 2–3 divided doses. Using 600 mg amoxicillin and 42.9 mg clavulanate/5 mL formulation bid decreases clavulanate-related diarrhea. NOTE: Children <40 kg should not receive the 250 mg film-coated tablets, which contain a higher dose of clavulanic acid than the 250 mg chewable tablets.
	Acute exacerbation of chronic bronchitis		*Adults:* 875/125 mg bid	Usual duration of therapy 10 d.
	Acute otitis media and sinusitis		*Adults:* 875/125 mg bid *Children:* 80–90 mg/kg/d of amoxicillin component with 6.4 mg of clavulanate	Usual duration of therapy 5–7 d. Do not exceed 6.4 mg clavulanate.
	Animal bites (excluding spider)		*Adults:* 875/125 mg bid or 500/125 mg tid	Usual duration of therapy 5 d. For penicillin allergy, clindamycin may be substituted.
Ampicillin (Polycillin, Principen, Totacillin)	Antibacterial	Capsules: 250, 500 mg Powder for oral suspension: 125 mg/5 mL (reconstituted), 250 mg/5 mL (reconstituted) Powder for injection: 125, 250, 500 mg, 1 g, 2 g	*Children ≥20 kg and adults:* PO: 250–500 mg q6h *Children <20 kg:* PO: 12.5–25 mg/kg q6h *or* 16.7– 33.3 mg/kg q8h	Maximum dose: parenteral 14 g/d; oral 4 g/d Take on empty stomach Suspensions retain their potency after reconstitution for 7 d at room temperature or 14 d in refrigerator, depending on manufacturer
Ampicillin and sulbactam (Unasyn)	Antibacterial	Powder for injection: 1.5 g (1 g ampicillin/ 0.5 g sulbactam) 3 g (2 g ampicillin/1 g sulbactam)	*Adults:* IM: 1.5–3 g q6h *Children <12 yr:* IM: 300–600 mg/kg/d divided into three–four doses	After reconstitution, the IM solution loses potency in 1 h Equivalent to 1–2 g amoxicillin and 0.5–1 g sulbactam Off-label dosage for children. Equivalent to 200–400 mg/kg/d amoxicillin and 100–200 mg/kg/d sulbactam

Table 24–3 ⊗ Dosage Schedule: Penicillins—cont'd

Drug	Indications	Dosage Forms	Initial Dose	Maximal Dose and Maintanence Dose
Carbenicillin indanyl sodium (Geocillin)	UTI and prostatitis	Tablets: 382 mg	*Adults:* PO: 500–1,000 mg q6h	Not effective in severe renal impairment (creatinine clearance [CCr] <10 mL/min)
Cloxacillin sodium (Cloxapen)	Antibacterial	Capsules: 250, 500 mg Powder for oral solution: 125 mg/5 mL	*Children ≥20 kg and adults:* PO: 250–500 mg (base) q6h *Children <20 kg:* PO: 6.25–12.5 mg/kg (base) q6h	Maximum 6 g (base)/d Suspension stable 14 d in refrigerator. Shake suspension well before measuring. Take on empty stomach, preferably 1 h before meals.
Dicloxacillin sodium (Dynapen, Dycill, Pathocil)	Antibacterial Infections in cystic fibrosis patients	Capsules: 250, 500 mg	*Children ≥40 kg and adults:* PO: 125–500 mg q6h *Children <40 kg:* PO: 3.125–6.25 mg/kg (base) q6h *Children <40 kg:* PO: 12.5–25 mg/kg (base) q6h	Maximum adult dose 6 g (base)/d Shake suspension well before measuring Take on empty stomach, preferably 1 h before meals
Oxacillin (Bactocill, Prostaphlin)	Antibacterial	Capsules: 250, 500 mg Powder for oral solution: 250 mg/5 mL (reconstituted) Powder for injection: 250, 500 mg, 1 g, 2 g, 4 g	*Children ≥40 kg and adults:* PO: 500 mg–1 g (base) q4–6h IM: 250 mg–1 g (base) q4–6h *Children <40 kg:* PO: 12.5–25 mg/kg (base) q6h IM: 12.5–25 mg/kg (base) q6h *or* 16.7 mg/kg q4h	Maximum adult daily dose 6 g Take oral forms on empty stomach, preferably 1 h before meals After reconstitution, IM solution retains potency for 4 d at room temperature or 7 d if refrigerated After reconstitution, oral solution retains potency for 7 d at room temperature or 14 d if refrigerated
Penicillin G, benzathine (Bicillin L-A)	Prophylaxis for streptococcal infections in patient with rheumatic fever history	Injection: 300,000 U per mL in 10 mL vials 600,000 U per dose in 1 mL Tubex 1,200,000 U per dose in 2 mL Tubex 2,400,000 U per dose in 4 mL syringe	*Adults:* IM: 1,200,000 U q3–4wk *Children: >27 kg:* IM: 1,200,000 U q2–3wk *Children <27 kg:* 600,000 U q2–3wk	For deep IM use only into large muscle mass.
	Pharyngitis, group A streptococci		*Adolescents and adults:* IM: 1,200,000 U as single dose *Children >27 kg:* IM: 1.2 million U as single dose *Children <27 kg:* IM: 600,000 U as single dose	IV injection causes embolic or toxic reaction. Intra-arterial injection causes necrosis of extremity or organ, especially in children. Maximum daily adult dose 2,400,000 U. Inject at slow, steady rate to avoid blockage of the needle.
	Syphilis (primary, secondary, early latent)		*Adolescents and adults:* IM: 2,400,000 U as single dose *Children:* IM: 50,000 U/kg up to 2,400,000 units as single dose	
	Syphilis (late latent or latent of unknown duration)		*Adolescents and adults:* IM: 2,400,000 U weekly for 3 wk	

Continued

Table 24–3 ⊗ **Dosage Schedule: Penicillins—cont'd**

Drug	Indications	Dosage Forms	Initial Dose	Maximal Dose and Maintanence Dose
			Children: IM: 50,000 U/kg weekly up to 2,400,000 U as single dose for 3 wk	
Penicillin G, procaine	*Antibacterial* *Neurosyphilis* Congenital syphilis Diphtheria Rat bite fever	Injection: 600,000 U per dose in 1 mL Tubex 1,200,000 U per dose in 2 mL Tubex 2,400,000 U per dose in 4 mL disposable syringe	*Adults:* IM: 600,000–1,200,000 U/d *Adults:* IM: 2,400,000 U and 500 mg probenecid qid for 10–14 d *Children:* 50,000 U/kg/d for 10–14 d *Adults:* IM: 300,000–600,000 U/d as adjunct to diphtheria antitoxin *Adults:* IM: 600,000 U every 12 h	For deep IM use only into large muscle mass. After large doses, some patients may experience a CNS syndrome of transient anxiety, confusion, agitation, combativeness, depression, seizures, hallucinations, expressed fear of impending death.
Penicillin G benzathine and procaine combined (Bicillin-CR)	Antibacterial Pneumococcal infections (excluding meningitis)	Injectable: 300,000 U (150,000 U of each) per dose in 10 mL vials 600,000 U (300,000 U of each) per dose in 1 mL Tubex 1,200,000 U (600,000 U of each) in 2 mL Tubex 2,400,000 U (1,200,000 U of each) in 4 mL syringe 1,200,000 U (900,000 U of benzathine and 300,000 U of procaine) per dose in 2 mL Tubex	*Children >27 kg and adults:* IM: 2,400,000 U as single dose *Children 14–27 kg:* IM: 900,000–1,200,000 U as single dose *Children <14 kg:* IM: 600,000 U as single dose *Adults:* IM: 1,200,000 U every 2–3 d *Children:* IM: 600,000 U every 2–3 d	See comments for penicillin G benzathine and penicillin G procaine May be dosed with half of dose on day 1 and half on day 3 *For deep IM use only into large muscle mass* Continue until afebrile for 48 h
Penicillin V (Beepen-VK, Betapen-VK, Ledercillin-VK, Pen Vee K, Veetids, V-Cillin K, generic)	Antibacterial Continuous prophylaxis of streptococcal infection in patients with history of rheumatic heart disease Pharyngitis (GABHS)	Tablets: 250, 500 mg Powder for oral solution: 125 mg/5 mL (reconstituted) 250 mg/5 mL (reconstituted)	*Adults and children >12 yr:* 125–500 mg q6h *Children <12 yr:* 2.5–8.3 mg/kg q6h *or* 5–16.7 mg/kg q8h *Children >12 yr and adults:* 125–250 mg q12h *Adults and children >27 kg:* 500 mg PO 2 to 3 times/d for 10 d *<27 kg (60 lb):* 250 mg PO 2 to 3 times/d for 10 d	Use higher doses for moderate-severe infections and obese patients. Maximum adult dose 7.5 g/d. Solution retains potency for 14 d if refrigerated. Shake solution well before measuring. Duration dependent on response. Treatment failures have occurred and retreatment may be necessary.
Piperacillin (Pipracil)	Antibacterial Urinary tract infection, uncomplicated		*Children >12 yr and adults:* IM: 3–4 g q4–6h *Adults:* IM: 1.5–2 g q6h or 3–4 g q12h	Maximum adult daily dose 24 g. CCr <40 mL/min requires reduced dosage and/or frequency. IM injection should not exceed 2 g per site.

DRSP = drug-resistant *Streptococcus pneumoniae*; GABHS = Group A beta hemolytic streptococcus.

Table 24–4   Steps in Antimicrobial Drug Selection

Step 1	Make clinical diagnosis
Step 2	Obtain cultures and/or specimens
Step 3	Make microbial diagnosis Results of culture and/or lab test *or* most likely pathogen, references
Step 4	Select drug Results of sensitivity *or* usual susceptibility

of the specimen or using the wrong procedure), and cost are disadvantages of routine culture and sensitivity (Kolmos & Little, 1999). Procedures such as the group A streptococci antigen test, urine dipsticks, and microscopy are widely used and have the advantages of moderate cost and immediate results. However, these rapid tests are rarely definitive and require confirmatory testing for a definitive diagnosis. With the empirical method, culture results can confirm the diagnosis and allow for adjustment of therapy.

The final two steps, making the microbial diagnosis and drug selection, differ for definitive and empirical therapy. In definitive therapy, the microbial diagnosis is based on valid and reliable tests such as culture or antigen assays, and drug selection is based on laboratory and susceptibility results. The goal of susceptibility testing is to identify susceptible antibiotics.

Susceptibility tests measure the in vitro concentration of the drug required to inhibit the growth of the organism (called the minimum inhibitory concentration [MIC]) or the concentration required to kill the organism (minimum bactericidal concentration [MBC]). The MBC is rarely used clinically. The MIC can be correlated with achievable concentrations at the site of infection (e.g. middle-ear fluid, serum, cerebrospinal fluid [CSF]).

The gold standard technique for susceptibility testing is the broth dilution method. This method consists of inoculating the organism into a series of liquid media containing increasing concentrations of the antibiotic. The MIC is the lowest concentration that inhibits growth. This technique is not widely used clinically and is usually reserved for reference laboratories or in research. The most common methods used clinically include the automated and disk diffusion methods. In the disk diffusion method, fibrous disks or strips containing specific drug concentrations are placed on agar plates incubated with the organism (Kirby-Bauer or E-test). After incubation, susceptibility is determined by the diameter of the visible area of growth inhibition around the disk or strip. In the automated method, a standardized inoculum of organism is placed into a machine that performs a technique similar to that of broth dilution described above. Sensitivity and resistance represent a continuum rather than a dichotomy. For example, *S. pneumoniae* strains are defined as penicillin-susceptible if the MIC is less than 0.1 mcg/mL, intermediate if the MIC is 0.1 mcg/mL to 1 mcg/mL, and resistant if the MIC is greater than 2 mcg/mL.

In empirical testing, the microbial diagnosis and drug regimen are determined based on epidemiological studies. References that compile and update these data annually or biannually include the *Sanford Guide to Antimicrobial Therapy,* the *Handbook of Antimicrobial Therapy*, periodic updates given in the biweekly *Medical Letter on Drugs and Therapeutics,* and material available on the CDC Web site at http://www.cdc.gov. These references identify the drug with the narrowest spectrum that covers the most likely microbiological pathogens for a specific clinical diagnosis. Clinicians should also consult local sources for local trends in susceptibility.

Allergy History

Allergy history may limit antimicrobial selection. References and guidelines usually provide alternative therapies when first-line therapies cannot be used.

Age, Pregnancy, and Genetic Factors

Age is important when using penicillins because most are renally eliminated. Neonates and elderly patients often have poor renal function and are more prone to drug toxicity. Highly protein-bound drugs such as sulfonamides and the penicillinase-resistant penicillins should be avoided in late pregnancy and neonates because these agents may displace bilirubin from plasma proteins of the newborn, causing kernicterus, a central nervous system (CNS) disorder.

Pregnancy contraindicates several classes of antibiotics, such as tetracyclines and fluoroquinolones, so aminopenicillins may be used for gravid women, even though another agent is the drug of choice.

For some drugs, genetic factors predispose patients to adverse effects. Pharmacogenomics are discussed in Chapter 8.

Site of Infection

The anatomical site of the infection affects drug selection, as well as dose, route, and duration of therapy. For example, penicillins enter CSF poorly, so a CNS infection may require a different agent, higher doses, IV and/or intraventricular administration, or prolonged therapy. When the meninges are inflamed, as in meningitis, penicillin attains higher concentrations in the CSF. By contrast, penicillins enter the respiratory tract in high concentrations, permitting single-dose or short-course therapy for susceptible organisms.

Immunocompromised Status

Bactericidal drugs, such as penicillins, may be preferred to bacteriostatic drugs in immunocompromised patients.

Affordability

Affordability is another consideration in drug selection. One reason amoxicillin is the preferred drug of choice for several common infections is its low cost combined with its high efficacy and long history of safe use. Oral amoxicillin and penicillin are on most $4 or reduced-cost generic plans at pharmacies.

Taste and Convenience

Taste is a significant factor in patient acceptance of a liquid product, affecting adherence to the prescribed regimen

(Steele, Thomas, & Begue, 2001). The use of amoxicillin suspension rather than penicillin V suspension for group A streptococcal infections is an example of drug selection based on taste and convenience. Steele and colleagues (2001) provide comparative ratings on antibiotic suspensions based on overall taste and adjusts them for cost. In all categories in this study, no antibiotic scored significantly higher than amoxicillin.

Convenience is largely a matter of the number of times per day that a drug must be taken. Amoxicillin requires two or three doses daily, whereas penicillin V requires two to four doses per day. Frequent dosing decreases compliance and may be particularly problematic when the patient is away from home, such as at work or in day care, especially when the drug requires refrigeration or cannot be taken with food.

Monitoring

Both microbiological and clinical responses are used to evaluate the therapeutic outcome of antimicrobial therapy. Serial cultures of specimens from infected sites become sterile with successful treatment. Follow-up cultures may detect superinfection or development of resistance. All patients with early or congenital syphilis should have a quantitative Venereal Disease Research Laboratory (VDRL) test at 6 and 12 months after therapy.

For most infections treated in outpatient settings, it is sufficient to monitor clinical response alone. Local signs of heat, redness, swelling, tenderness, or discharge usually abate after 48 to 72 hours. Specific indicators of improvement such as the resolution of pulmonary infiltrates and normalization of pulse oximetry in pneumonia are important outcomes to monitor. Systemic signs such as fever, malaise, and leukocytosis also improve. The patient should be advised to call the prescriber if there is no improvement in 48 to 72 hours, when consideration should be given to adjusting the treatment; alternatively, the provider can initiate telephone contact to evaluate progress and improvement. Compliance is monitored throughout the course of therapy, particularly if there is therapeutic failure, as well as after symptoms resolve and the patient is less motivated to complete the therapy.

Signs of allergic reactions may occur from minutes to weeks after the antibiotic is initiated and even after the course of therapy is completed. Although immediate hypersensitivity reactions are more likely to be life-threatening, delayed reactions can also be serious. Superinfection often presents with subtle and nonspecific symptoms such as mouth or throat pain (oral candidiasis) or perineal itching or discharge (vaginal candidiasis), so it is important to attend to these minor complaints. Distinguishing between antibiotic-associated diarrhea and CDI is at times difficult, but more than three watery, unformed stools per day or blood in the stool warrant stool testing to detect *C. difficile* toxin.

Other adverse effects are almost exclusively associated with high-dose parenteral therapy, protracted oral therapy, or impaired renal function. During parenteral therapy, periodic blood urea nitrogen (BUN) and creatinine determinations should be performed, especially with agents from the penicillinase-resistant group or the anti-pseudomonal group. However, many of the penicillins, especially amoxicillin, have a wide range of tolerance for renal impairment. Amoxicillin is an especially safe drug for the elderly, who commonly have decreased renal function. When amoxicillin is combined with a beta-lactamase inhibitor, closer monitoring is appropriate. Monitor serum potassium in patients receiving piperacillin, potassium penicillin G, or other parenteral agents. Patients with low potassium, especially if they are taking cytotoxic drugs or diuretics, can develop hypokalemia. Hyperkalemia has occurred with high doses of potassium penicillin G in patients with impaired renal function. The partial thromboplastin time (PTT) and prothrombin time (PT) should be assessed at baseline and during therapy with parenteral carbenicillin, piperacillin, or ticarcillin, particularly for patients with renal impairment.

Patient Education

Administration

The most critical information to provide to patients who will self-administer antibiotics is the importance of completing the full course of therapy. They should understand that failure to complete therapy may result in resistant infections that can be passed on to family and friends or cause the patient to become more seriously ill. Doses of the medication should be spaced as evenly as possible without sleep disruption throughout the 24 hours of a day. Missed doses should be taken as soon as they are remembered, but the dose should not be doubled.

Oral penicillins that should be taken on an empty stomach, 1 hour before a meal or 2 hours after meals, include ampicillin, carbenicillin, cloxacillin, oxacillin, nafcillin, and dicloxacillin. Chewable tablets must be crushed or chewed or the drug may not absorb adequately. Oral tablets and chewable tablets of amoxicillin/clavulanate have different clavulanate content and should not be considered interchangeable.

Many penicillins are available as solutions or suspensions. Suspensions must be shaken to disperse the particles of drug immediately before measurement. Refrigerated liquid formulations maintain full activity for 14 days after reconstitution, except amoxicillin/clavulanate suspension, which lasts for 10 days in the refrigerator. Amoxicillin suspension maintains full activity for 14 days whether refrigerated or not, although some manufacturers specify refrigerated storage. Instruct patients not to use antibiotics beyond the expiration date. Liquid formulations should always be dispensed with a calibrated measuring device. Because household teaspoons vary from 2 mL to 10 mL in volume, they are unreliable for medication measurement. Clinicians should tell the patient whether there will be liquid remaining at the end of the course of therapy and urge disposal of unused medication.

Very concentrated oral forms of amoxicillin (50 mg/mL) or ampicillin (100 mg/mL) in suspension are called antibiotic drops. It is important to explain that the drops are for oral use, describe how to measure and administer the medication

appropriate to the patient's developmental and physical capabilities, and specify that an appropriate measuring device be used.

Medications mixed for injection also lose potency with time, although refrigeration after reconstitution will extend the period of full potency. Consult the package insert for proper mixing and storage of reconstituted parenteral penicillins. Some of these agents (e.g., piperacillin) can be prepared with lidocaine to decrease pain on IM injection. Adhere to the manufacturer's limits on volume of injection at one site. IM injection should be slow and steady, extended over 12 to 15 seconds to minimize pain and avoid blockage of the needle, especially with procaine and benzathine preparations that are very thick. Because IV extravasation of nafcillin causes tissue necrosis, IM injection should be avoided and a Z-track injection technique used if this route is unavoidable.

Adverse Reactions

Patients should be taught to distinguish allergic reactions from other adverse effects so that they can provide an accurate drug allergy history. Many patients claim penicillin allergy because they experienced diarrhea during therapy. Patients with immediate or type 1 allergies of the anaphylactic type should wear an identification bracelet.

If severe diarrhea occurs, the patient should contact the prescriber before initiating any treatment. For mild diarrhea, they can use adsorbent antidiarrheal agents containing attapulgite (e.g., Donnagel) but should avoid antiperistaltic agents that promote the retention of toxins.

Aminopenicillins and clavulanate cause false positives on glucose urine testing by the copper sulfate technique (Clinitest). Diabetics on these penicillins should use blood glucose monitoring or urine testing based on glucose enzymatic tests (Clinstix, TesTape).

Lifestyle Management

Mild infections, especially upper-respiratory tract infections, are often self-limiting and resolve with symptomatic treatment, rest, fluids, and nutritious diet. Prevention of infection by good hand washing, shunning crowded environments, avoiding cigarette smoke including passive smoke, practicing safe sex, and maintaining a generally healthy lifestyle will limit the need for antibiotics. Other risk-reduction counseling specific to otitis media includes breastfeeding of infants, avoidance of passive smoke, enrollment in day care with a small class size if day care is unavoidable, and pneumococcal and influenza vaccine (Lieberthal et al, 2013). Because pain has been shown to inhibit the immune system, comfort measures and pain management of patients with infections will promote the antibiotic action.

CEPHALOSPORINS

Cephalosporins are beta-lactam antibiotics, structurally and chemically related to the penicillins. Cefoxitin and cefotetan are actually cephamycins, and loracarbef (no longer available in the United States) is a carbacephem, but they are usually included with the cephalosporins because of their clinical and chemical similarity. The cephalosporin class of drugs is divided into five generations, based on the order of development and spectrum of antibacterial activity.

Pharmacodynamics

Spectrum of Activity

Cephalosporins inhibit mucopeptide synthesis in the bacterial cell wall, making the bacterium osmotically unstable. As with penicillins, cephalosporins inhibit PBPs involved in the cross-linking of peptidoglycans in the cell wall. Cephalosporins are usually bactericidal, depending on organism susceptibility, dose, tissue concentration, and the rate of organism multiplication. They are most effective against rapidly growing organisms forming cell walls and when antibiotic concentrations exceed the pathogen's MIC for at least 50% of the dosing interval.

First-Generation Cephalosporins

First-generation cephalosporins are active against grampositive cocci, including *S. aureus* and *S. epidermidis* (excluding methicillin-resistant strains), and most streptococci; however, *Enterococcus* species are intrinsically resistant to cephalosporins. First-generation cephalosporins have limited activity against aerobic gram-negative organisms, such as *E. coli, P. mirabilis,* and *Klebsiella pneumonia.* In addition, they do not readily enter the CSF.

Second-Generation Cephalosporins and Cephamycins

Examples of second-generation cephalosporins include cefaclor, cefprozil, and cefuroxime. These are active against the same organisms as the first generation but with increased activity against *H. influenzae.* The cephamycins include cefotetan and cefoxitin. These antibiotics are unique: they have a similar spectrum of activity as first-generation cephalosporins, while adding limited activity against anaerobes, including *Bacteroides fragilis.* Each of the drugs listed as a second-generation cephalosporin has a slightly different spectrum of activity, so susceptibility tests for each must be performed, rather than assuming consistency within the group.

Third-Generation Cephalosporins

Third-generation cephalosporins have activity against streptococcal species, *Streptococcus pneumoniae,* MSSA, *H. influenzae* (including beta-lactamase producing strains), *Moraxella, N. gonorrhoeae, N. meningitidis, E. coli, Klebsiella, Proteus,* and *Salmonella*. Oral and IV agents have a similar spectrum; however, cefdinir and cefpodoxime have the best gram-positive activity. Parenteral third-generation cephalosporins available in the United States include cefotaxime, ceftazidime, and ceftriaxone. With the exception of ceftazidime, their spectrum of activity is similar. Ceftazidime has reduced gram-positive potency but has increased gram-negative activity to include *Pseudomonas aeruginosa*. Historically, third-generation cephalosporins

have been active against uncommon gram-negative pathogens like *Serratia, Citrobacter,* and *Enterobacter*; however, the use of third-generation cephalosporins for these pathogens is discouraged secondary to the poor ability to detect inducible beta-lactamases that are capable of inactivating these cephalosporins. None of the third-generation cephalosporins have reliable activity against anaerobes, other than *Peptostreptococcus.*

Fourth-Generation Cephalosporin

The fourth-generation cephalosporin, cefepime (Maxipime), has a broader spectrum of activity and is more resistant to beta-lactamases that inactivate many third-generation agents. Cefepime is active against both gram-positive and gram-negative organisms, including *Pseudomonas* and extended-spectrum beta-lactamase producing strains of *Enterobacter, E. coli,* and *Klebsiella.*

Resistance

The most common mechanisms of resistance that bacteria express against cephalosporins are beta-lactamase production and altered target sites. All cephalosporins are stable in the presence of penicillinases produced by *S. aureus*. Most beta-lactamases produced by *Haemophilus* and *Moraxella* only affect the first-generation cephalosporins. Third- and fourth-generation cephalosporins are generally the most stable in the presence of most beta-lactamases produced by enteric gram-negative bacteria. Emergence of cephalosporinases and carbapenemases are of great concern.

Changes of PBPs that prevent all cephalosporins from binding to receptors are accountable for the resistance of MRSA, DRSP, *E. faecalis,* and *E. faecium*. Cefepime is active against most gram-positive and gram-negative pathogens, including resistant strains, with the exception of those listed previously (see Box 24-1).

Pharmacokinetics

Absorption and Distribution

Cephalosporins that have oral formulations are well absorbed from the GI tract. Except for cefadroxil and cefprozil, absorption is delayed by food, but the amount absorbed is not affected. The absorption of the oral ester prodrugs cefpodoxime proxetil and cefuroxime axetil is increased when given with food. All IM formulations are well absorbed from muscle tissue. Differences in bioavailability exist for the suspension and tablet formulations of both cefpodoxime proxetil and cefixime, so the formulations should not be substituted.

All cephalosporins are widely distributed to most tissues and fluids. Protein binding varies, but ceftriaxone is so highly bound to albumin that it should be avoided in neonates at risk for hyperbilirubinemia, especially preterm infants. The penetration of CSF varies by generation. Except for cefuroxime, first- and second-generation drugs do not readily enter the CSF, even when the meninges are inflamed. Third- and fourth-generation drugs and cefuroxime readily enter the CSF in the presence of meningeal inflammation. Therapeutic levels are reached in bone at usual doses for most cephalosporins, and they are used prophylactically and therapeutically in orthopedic disorders.

High concentrations of ceftriaxone are found in bile. Bile levels of cefazolin can exceed serum levels by up to 5 times in patients with obstructive biliary disease.

Metabolism and Excretion

In general, hepatic metabolism is not significant for cephalosporin drug elimination. A metabolite of cefotaxime increases its spectrum of activity and extends the dosing interval because of its prolonged metabolic half-life. Cefuroxime and cefpodoxime are prodrugs metabolized to active metabolites.

Most cephalosporins are excreted via the kidney in varying degrees as unchanged drug. Increased cephalosporin plasma concentrations may occur when probenecid blocks renal tubular secretion of cephalosporins. The combination of oral probenecid and cephalosporins is used in serious infections and single-dose therapy of sexually transmitted infections. Renal impairment significantly extends the half-life of these drugs. Ceftriaxone elimination is mainly extra-renal, making its half-life stable to changes in renal function. In hepatic dysfunction, the half-life and urinary excretion of ceftriaxone are increased.

Changes Related to Pregnancy and in Children

The pharmacokinetic properties of cephalosporins change during pregnancy, tending toward shorter half-lives, lower serum levels, larger volumes of distribution, and increased clearance.

In neonates, accumulation of these drugs because of immature renal function results in prolonged half-lives. Ceftriaxone is contraindicated in neonates younger than 28 days of age with hyperbilirubinemia because of the displacement of bilirubin from plasma albumin, leading to more free bilirubin and possible bilirubin encephalopathy. In children older than 3 months, higher doses of cefoxitin have been associated with increased incidence of eosinophilia and elevated AST. In children older than 6 months, ceftizoxime has been associated with transient elevated levels of AST, ALT, and CPK.

BOX 24–1 ANTI-MRSA CEPHALOSPORINS

Ceftaroline (Teflaro) is an injectable cephalosporin approved for complicated skin and soft tissue infections and CAP. Ceftaroline inhibits cell wall synthesis by binding to the modified PBP sites expressed by MRSA and penicillin-resistant *S. pneumoniae*. Gram-negative activity is similar to third-generation cephalosporins but does not include *Pseudomonas*. Ceftobiprole is an injectable cephalosporin that has activity against MRSA and pseudomonal species. Ceftobiprole was rejected by the FDA in 2009; however, clinical investigations continue.

Table 24-5 presents the pharmacokinetics of selected cephalosporins. Half-life alterations associated with end-stage renal disease are included.

Pharmacotherapeutics

Precautions and Contraindications

Like the penicillins, cephalosporins may produce hypersensitivity reactions in a small percentage of patients. Cross-sensitivity with penicillins increases the risk and occurs in 5% to 16% of patients. Cephalosporins are generally not recommended for those who have had a type 1 (immediate, anaphylactic) reaction to any penicillin. Skin testing is not helpful for identifying individuals likely to experience anaphylactic reactions to cephalosporins.

Renal function impairment significantly affects the half-life of most cephalosporins, and they may also be nephrotoxic. Use in the presence of markedly impaired renal function (creatinine clearance [CCr] 10 to 50 mL/min) is undertaken with extreme caution. Older adults and patients with known or suspected renal impairment are monitored carefully prior to and during therapy. Dosage adjustments of 50% are recommended for oral agents only after the glomerular filtration rate (GFR) reaches less than 10 mL/minute, a condition not usually seen in primary care patients. *Drug Facts and Comparisons* (2010) recommends titrated dosage adjustments for some cephalosporins for CCr less than 30 mL/minute. Dosage adjustments are usually not required based on renal function at higher levels.

Hepatic impairment is a concern for ceftriaxone. Caution is advised if daily doses exceed 4 g.

Cephalosporins are Pregnancy Category B; however, their use during pregnancy should always be based on a risk/benefit determination because relatively few controlled studies exist. All of these drugs cross the placenta, with maternal to fetal serum ratios of 0.16 to 1. Cefotetan, however, reaches therapeutic levels in cord blood (see discussion about pharmacokinetic changes in pregnancy).

Table 24–5 ✂ Pharmacokinetics: Cephalosporins

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life NRF/ESRD*	Elimination (% unchanged in urine)
First Generation							
Cefadroxil (PO)	Rapid	1.5–2 h	12–24 h	20%	90%	78–96 min/20–25 h	>80%
Cefazolin (IM)	Rapid	1–2 h	6–12 h	80%–86%	NA	90–120 min/3–7 h	60%–80%
Cephalexin (PO)	15–30 min	1 h	6–12 h	10%	UA	50–80 min/19–22 h	>95%
Second Generation							
Cefaclor (PO)	15 min	0.5–1 h	6–12 h	25%	>90%	35–54 min/2–3 h	60%–85%
Cefotetan (IM)	Rapid	1–3 h	12 h	88%–90%	0NA	180–276 min/13–35 h	51%–81%
Cefoxitin (IM)	Rapid	0.5 h	4–8 h	73%	NA	40–60 min/20 h	85%
Cefprozil (PO)	Rapid	1–2 h	12–24 h	36%	95%	78 min/5.2–5.9 h	60%
Cefuroxime (PO)	2–3 h	2 h	8–12 h	50%	40–50%	80 min/16–22 h	66%–100%
(IM)	Rapid	15–60 min	6–12 h	50%	NA	80 min/16–22 h	66%–100%
Loracarbef (PO)	Rapid	0.5–1.2 h	12 h	25%	79%	60 min/32 h	>90%
Third Generation							
Cefdinir (PO)	Slow	2–4 h	UA	60%–70%	20–25%	100 min/16 h	12%–18%
Cefixime (PO)	15–30 min	2–6 h	25 h	65%	30–50%	180–240 min/11.5 h	85%
Cefotaxime (IM)	Rapid	0.5 h	4–12 h	30%–40%	NA	60 min/3–11 h	60%
Cefpodoxime (PO)	Rapid	1 h	12 h	21%–29%	50%	120–180 min/9.8 h	85%
Ceftazidime (IM)	Rapid	1 h	6–12 h	<10%	NA	114–120 min/14–30 h	80%–90%
Ceftibuten (PO)	Rapid	2–3 h	24 h	65%	UA	144 min/13.4–22.3 h	70%
Ceftriaxone (IM)	Rapid	1–2 h	12–24 h	85%–95%	NA	348–522 min/15.7 h	33%–67%
Fourth Generation							
Cefepime (IM)	30 min	1–2 h	12 h	20%	NA	102–138 min/17–21 h	85%

ESRD = end-stage renal disease; NRF = normal renal function; UA = information unavailable; NA = not applicable.

Most cephalosporins are excreted in breast milk in small quantities. The average breast milk plasma ratio is 0.01 to 0.5 after 500 mg to 2 g doses. Cefdinir has not been detected in breast milk and ceftibuten has not been studied.

The safety and efficacy in children vary by drug. Safety and efficacy have not been established for children younger than 1 month for cefazolin, cefotaxime, and cefaclor; younger than 2 months for cefpodoxime; younger than 3 months for cefuroxime, cephapirin, and cefoxitin; younger than 6 months for cefdinir, loracarbef, cefixime, ceftizoxime, and cefprozil; younger than 9 months for oral cephradine; and younger than 1 year for cefepime and parenteral cephradine. Cefditoren is not approved for use in children younger than 12 years.

Adverse Drug Reactions

In addition to type I allergic reactions (see the Precautions and Contraindications section), serum sickness–like reactions, consisting of erythema multiforme, other skin rashes, arthralgia, and fever, have been reported. This type III delayed reaction usually occurs following a second course of therapy and may be delayed up to 10 or more days after initiation of the drug. Between 0.1% and 1% of patients who receive cefaclor have this reaction. Antihistamines and corticosteroids may help to manage symptoms.

Several parenteral cephalosporins have been associated with induction of seizure activity, especially in the presence of renal impairment when the dose was not adjusted. Discontinuance of the drug resolved the problem in most cases.

Coagulation abnormalities have occurred in conjunction with administration of parenteral cephalosporins containing a particular chemical group and include cefotetan. Patients at risk appear to be those with renal impairment, cancer, impaired vitamin K synthesis, low vitamin K stores, or malnutrition. These cephalosporins are also associated with a disulfiram-like reaction in patients who consume or, less frequently, inhale alcohol (such as aftershave or alcohol swabs).

Immune hemolytic anemia has also been observed with cephalosporins in rare instances. Patients who develop anemia within 2 to 3 weeks of the initiation of cephalosporin therapy should be evaluated for the role the cephalosporin may play in this disorder, and the drug should be stopped until the etiology is determined.

As with almost all antibiotics, CDI is a potentially serious adverse reaction to cephalosporins. Detection and management were described earlier. Use of cephalosporins, especially prolonged or repeated therapy, may result in bacterial or fungal overgrowth of nonsusceptible organisms. The patient should be monitored for this superinfection and treated with appropriate measures.

Incidence of non–*C. difficile* diarrhea is high with some oral cephalosporins, including cefdinir (16%), cefixime (16%), and cefpodoxime (7%). There have been reports with cefpodoxime of acute liver injury, bloody diarrhea, and pulmonary infiltrates with eosinophilia. Ceftriaxone has caused accumulation of biliary sludge or pseudolithiasis, which clears on discontinuation of the drug.

Drug Interactions

Table 24-6 shows specific drugs and their interactions. Drugs that interact with all cephalosporins include probenecid,

Table 24–6 ▦ Drug Interactions: Cephalosporins

Drug	Interacting Drug	Possible Effect	Implications
All cephalosporins	Probenecid	Probenecid may increase and prolong cephalosporin plasma levels by competitively inhibiting renal tubular secretion.	Avoid concurrent administration unless planned for therapeutic reasons.
	Loop diuretics	Increased risk of nephrotoxicity.	Use with caution and monitor renal function.
	Warfarin	May increase effects of warfarin and increase bleeding risk.	Monitor INR.
Cefotetan	Ethanol Anticoagulants	Alcoholic beverages consumed concurrently or within 72 h after cefotetan may produce an acute disulfiram-like reaction within 30 min of alcohol ingestion. This reaction may occur ≤3 d after last antibiotic dose. Effects of anticoagulants may be increased. Bleeding complications may occur. This interaction is also reported with some other cephalosporins.	Warn patients to avoid concurrent ingestion of alcohol. Select a different antibiotic class for patients taking anticoagulants. If they must be given together, monitor PT more closely.
Cefaclor, cefdinir, cefpodoxime	Antacids	Extended-release tablets may have reduced plasma concentration when given with antacids.	If both must be given, separate administration by at least 2 h. Cefprozil and ceftibuten do not appear to be affected by antacids and may be substituted if appropriate.
Cefpodoxime, cefuroxime	Histamine₂ blockers	Plasma concentrations of the cephalosporin may be reduced by coadministration.	Cefaclor does not appear to be affected and may be substituted if appropriate.
Cefdinir	Iron supplements	Iron supplements and foods fortified with iron reduce absorption of cefdinir by 80% and 30%, respectively.	If iron must be taken, separate administration by 2 h. Iron-fortified infant formula has no effect.

which increases plasma levels of cephalosporins, and loop diuretics, which increase the risk for nephrotoxicity.

Clinical Use and Dosing

Exacerbation of Chronic Bronchitis

The common organisms found in the sputum of patients with COPD with acute exacerbation of chronic bronchitis are viruses—*H. influenzae, S. pneumoniae, M. pneumoniae,* and *M. catarrhalis.* The most common organism is *S. pneumoniae* (Rabe et al, 2007). Although penicillins are among the first-line agents to treat this disorder, oral cephalosporins are also useful in mild to moderate disease based on their activity against *S. pneumoniae, H. influenzae,* and *M. catarrhalis.* For severe disease, macrolides or respiratory fluoroquinolones have a broader spectrum that includes the likely organisms and is more effective against DRSP. When cephalosporins are used, treatment is continued for 5 to 10 days at dosages shown in Table 24-7.

Acute Otitis Media

Although amoxicillin is the recognized first-line drug of choice for otitis media (see discussion in the Clinical Use and Indications section for penicillins), cephalosporins play an important role in the management of this common infection. For therapeutic failures of amoxicillin, the AAP guidelines recommend amoxicillin/clavulanate and then ceftriaxone 50 mg/kg IM or IV once daily for 3 days (Lieberthal et al, 2013). For penicillin-allergic children, cefdinir (14 mg/kg/d in one or two doses), cefuroxime axetil (30 mg/kg/d in two divided doses), or high-dose cefpodoxime (10 mg/kg/d as one or two doses) may be prescribed (Lieberthal et al, 2013). The duration of therapy is 10 days for children younger than 2 years, and 7 days for children 2 to 5 years, and 5 to 7 days in children age 6 years or older with mild to moderate symptoms (Lieberthal et al, 2013). Ceftriaxone 50 mg/kg as a daily IM dose can be given (Lieberthal et al, 2013). Ceftriaxone is approved as a single injection for first-line therapy, but three daily doses are recommended for children who have recently failed therapy with another antimicrobial.

Sinusitis

The primary organisms involved in acute sinusitis are *S. pneumoniae* (31%), *H. influenzae* (21%), viruses (15%), anaerobes (6%), *S. aureus* (4%), *M. catarrhalis* (2%), and

Table 24–7 ⊗ Dosage Schedule Cephalosporins

Drug	Indications	Dosage Forms	Initial Dose	Maximal Dose and Comments
First Generation				
Cefadroxil (Duricef)*	Endocarditis prophylaxis	Capsules: 500 mg Tablets: 1 g Powder for oral suspension: 125 mg/5 mL, 250 mg/5 mL, 500 mg/5 mL	*Adults:* PO: 2 g 1 h prior to surgery *Children:* PO: 50 mg/kg 1 h prior to surgery	Maximum adult daily dose 4 g. Decrease dose frequency if CCr <25 mL/min.
	Pharyngitis/tonsillitis, impetigo (children)		*Adults:* PO: 500 mg q12h *or* 1 g once daily for 10 d *Children:* PO: 15 mg/kg q12h *or* 30 mg/kg once/d for 10 d	
	Skin and soft tissue infection		*Adults:* PO: 500 mg q12h *or* 1 g once daily *Children:* PO: 15 mg/kg q12h	
	Urinary tract infection, uncomplicated		*Adults:* PO: 500 mg–1 g q12h *or* 1–2 g once daily *Children:* PO: 15 mg/kg q12h	
Cefazolin (Kefzol, Ancef)*	Endocarditis prophylaxis	Powder for injection: 250 mg, 500 mg, 1 g	*Adults:* IM: 1 g 30 min prior to surgery *Children:* IM: 25 mg/kg 30 min prior to surgery	Maximum adult daily dose 6 g, although up to 12 g/d have been used in rare instances. Reconstituted IM solution stable for 24 h at room temperature and 10 d if refrigerated.
	Urinary tract infection, uncomplicated		*Adults:* IM: 1 g q12h	
	Antibacterial, mild to moderate infections		*Adults:* IM: 250 mg–1 g q6–8h *Children:* IM: 6.25–25 mg/kg q6h *or* 8.3–33.3 mg/kg q8h

Table 24–7 ⊗ **Dosage Schedule Cephalosporins—cont'd**

Drug	Indications	Dosage Forms	Initial Dose	Maximal Dose and Comments
First Generation				
Cephalexin (Keftab, Keflex)	Antibacterial, mild to moderate infection	Capsules: 250 mg, 500 mg Tablets: 250 mg, 500 mg, 1 g	*Children: >40 kg and adults:* PO: 250–500 mg q6h *Children* PO: 25–50 mg/kg/d divided q6–8h	Adult maximum daily dose 4 g. If adult dose >4 g/d is needed, substitute parenteral therapy.
	Antibacterial, severe infection	Powder for oral suspension: 125 mg/5 mL, 250 mg/5 mL	*Children >40 kg and adults:* PO: 1 g q6h *Children:* 50–100 mg/kg/d divided q6–8 h	Shake suspension well before measuring.
	Endocarditis prophylaxis (off-label use)		*Children >40 kg and adults:* PO: 2 g as single dose 1 h prior to surgery *Children ≥1 yr:* PO: 50 mg/kg as single dose 1 h prior to surgery	Potency of suspension maintained after reconstitution for 14 d if refrigerated.
	Streptococcal pharyngitis, tonsillitis		*Children > 40 kg and adults:* PO: 500 mg q12h *Children ≥1 yr:* PO: 25–50 mg/kg/d divided q12 h	Dose adjustments may be necessary if CCl <50 mL/min.
	Cystitis, uncomplicated		*Adolescents >15 yr and adults:* 50 mg q12h for 7–14 d	Dose on higher range if patient is obese.
Second Generation				
Cefaclor (Ceclor)	Bacterial infections, pharyngitis, pneumonia, skin infections due to *S. aureus* or *S. pyogenes,* tonsillitis, or urinary tract infection	Capsules: 250 mg, 500 mg Tablets, extended-release: 500 mg Powder for oral suspension: 125 mg/5 mL, 187 mg/5 mL, 250 mg/5 mL, 375 mg/5 mL	*Adults:* PO: 250–500 mg q8h *or* 375–500 mg extended-release tablet q12h *Infants >1 mo:* PO: 6.7–13.4 mg/kg q8h *or* 10–20 mg/kg q12h 500 mg q8h or 500 mg q12h for extended-release form	Adult maximum dose 2 g/d, although 4 g/d have been used in rare cases. Dose adjustments for CCl <10 mL/min. Extended-release formulation should be taken with food and not crushed or chewed. Cefaclor extended-release 500 mg bid is equivalent to capsules 250 mg tid, but not to other formulations at doses of 500 mg tid. Shake suspension well before measuring. After reconstitution, the suspension maintains potency for 14 d if refrigerated.
	Acute exacerbation of chronic bronchitis			
Cefprozil (Cefzil)	Pharyngitis, tonsillitis	Tablets: 250 mg, 500 mg Powder for oral suspension: 125 mg/5 mL, 250 mg/5 mL	*Children >12 yr and adults:* PO: 500 mg q24h for 10 d *Children 2–12 yr:* PO: 15 mg/kg/d divided q12h	
	Sinusitis, acute pneumonia		*Children >12 yr and adults:* PO: 250–500 mg q12h for 10 d	

Table 24–7 ⚗ **Dosage Schedule Cephalosporins—cont'd**

Drug	Indications	Dosage Forms	Initial Dose	Maximal Dose and Comments
Second Generation				
	Skin and soft tissue infections Otitis media		*Children 6 mo–12 yr:* PO: 7.5–15 mg/kg q12h for 10 d *Children >12 yr and adults:* PO: 500 mg q12–24h for 10 d *Children 2–12 yr:* PO: 20 mg/kg q24h for 10 d *Children 6 mo–12 yr:* PO: 30 mg/kg q12h for 10 d *Children >12 yr and adults:* PO: 500 mg q24h for 10 d	
	Urinary tract infection			
Cefotetan (Cefotan)*	Bacterial infections, mild to moderate Urinary tract infections	Powder for injection: 1 g, 2 g	*Adults:* IM: 1–2 g q12h for 5–10 d *Adults:* IM: 500 mg q12h *or* 1–2 g q12–24h for 5–10 d	Lidocaine (0.5%–1%) without epinephrine can be used as diluent for preparing IM injection. Solutions maintain potency 24 h at room temperature, 96 h if refrigerated, and 1 wk if frozen. Dosage should be decreased if CCr <30 mL/min.
Cefuroxime axetil (Ceftin, Kefurox, Zinacef)*	Pharyngitis, sinusitis, tonsillitis	Tablets: 125, 250, 500 mg Suspension: 125 mg/5 mL, 250 mg/5 mL Powder for injection: 750 mg, 1.5 g	*Children >12 yr and adults:* PO: 250 mg bid for 10 d *Children 3 mo–12 yr:* PO: 10 mg/kg q12h for 10 d *Children 3 mo–12 yr:* PO: 30 mg/kg/d divided q12h up to 1,000 mg/d for 10 d *Children >12 yr and adults:* PO: 250–500 mg bid for 10 d 250 to 500 mg q12h *Children >12 yr and adults:* PO: 500 mg bid for 20 d 500 mg bid *Adults:* 125–250 mg for 7–10 d	Studies indicate 4- to 6-day treatment effective for group A streptococcal pharyngitis. Suspension is not as well absorbed as tablets. Oral forms should be taken with food to increase absorption. Suspension does not require refrigeration and maintains potency for 10 d after reconstitution. Single-dose packets for suspension can be mixed with 10 mL or more cold water; apple, grape, or orange juice; or lemonade. Mix and consume entire volume immediately. Low rating for palatability of suspension.
	Otitis media or impetigo			
	Bronchitis, skin and soft tissue infections			
	ABECB Lyme disease, early Pneumonia Urinary tract infection, uncomplicated

Table 24–7 �֎ Dosage Schedule Cephalosporins—cont'd

Drug	Indications	Dosage Forms	Initial Dose	Maximal Dose and Comments
Second Generation				
Cefdinir (Omnicef)	Sinusitis, otitis media	Capsules: 300 mg Oral suspension: 125 mg/5 mL	*Adults:* PO: 300 mg q12h *or* 600 mg q24h for 10 d *Children:* PO: 7 mg/kg q12h *or* 14 mg/kg q24h for 5–10 d	Dose reduction if CCl <30 mL/min
	Community-acquired pneumonia, skin and soft tissue infections		*Adults:* PO: 300 mg q12h *or* 600 mg q24h for 10 d *Children:* PO: 7 mg/kg q12h for 10 d	
	Pharyngitis, tonsillitis		*Adults:* PO: 300 mg q12h for 5–10 d *or* 600 mg q24h for 10 d *Children:* PO: 7 mg/kg q12h for 5–10 d *or* 14 mg/kg q24h for 10 d	
Third Generation				
Cefixime (Suprax)*	Bronchitis, exacerbation; pharyngitis; tonsillitis; or urinary tract infection	Tablets: 200 mg, 400 mg Powder for oral suspension: 100 g/5 mL	*Children >50 kg and adults:* PO: 400 mg q24h *Children 6 mo–12 yr, <50 kg:* PO: 4 mg/kg q12h *or* 8 mg/kg q24h *Adults:* PO: 400 mg as a single dose	Palatability of suspension rated high. Oral suspension results in higher blood level than tablets, so do not substitute tablets for suspension in otitis media. Shake suspension well before measuring. Refrigeration not required. After reconstitution, it maintains potency for 14 d at room temperature. Dosage reduction required if CCr <60 mL/min.
	Gonorrhea, cervical, urethral, rectum			
Cefotaxime (Claforan)*	Antibacterial, uncomplicated infection	Powder for injection: 500 mg, 1 g, 2 g	*Children >50 kg and adults:* IM: 1 g q12h *Children >1 mo <50 kg:* IM: 8.3–30 mg/kg q4h *or* 12.5–45 mg/kg q6h	After preparation, the solution retains potency for 12 h at room temperature and 5 d if refrigerated in syringe and 7 d if refrigerated in original container For pneumonia, only if MIC = 2 mcg/mL

Table 24–7 ⊗ Dosage Schedule Cephalosporins—cont'd

Drug	Indications	Dosage Forms	Initial Dose	Maximal Dose and Comments
Third Generation				
Cefpodoxime proxetil (Vantin)	ABECB	Tablets: 100 mg, 200 mg Granules for suspension: 50 mg/5 mL, 100 mg/5 mL	*Adolescents and adults:* 200 mg q12h *Infants >6 mo and children:* 10 mg/kg/d divided q12h max 200 mg/dose	Palatability of suspension rated low. Shake suspension well before measuring. Take suspension with food or alone. Tablets should be taken with food. After reconstitution, maintains potency for 14 d if refrigerated.
	Sinusitis		*Adults:* PO: 100 mg q12h for 7 d *Children >12 yr and adults:* PO: 100 mg q12h for 5–10 d *Children 2 mo–12 yr:* PO: 5 mg/kg, up to 400 mg, q12h for 10 d	
	Urinary tract infection Pharyngitis, tonsillitis Otitis media Pneumonia, community acquired Skin and soft tissue infection		*Children 2 mo–12 yr:* PO: 10 mg/kg, up to 400 mg, q24h for 10 d *or* 5 mg/kg, up to 200 mg, q12h for 10 d *Children >12 yr and adults:* PO: 200 mg q12h for 14 d PO: 400 mg q12h for 7–14 d	
Ceftibuten (Cedax)*	Pharyngitis, tonsillitis	Capsules: 400 mg Powder for oral suspension: 90 mg/5 mL, 180 mg/5 mL	*Children >12 yr and adults:* PO: 400 mg q24h for 10 d *Children 6 mo–12 yr:* PO: 9 mg/kg q24h for 10 d	Maximal daily adult dose 400 mg. Renal impairment (CCr <50 mL/min) requires dosage decrease. Shake suspension well before measuring. Maintains potency for up to 14 d if refrigerated.
Ceftriaxone (Rocephin)	Gonorrhea, uncomplicated; chancroid Syphilis, early Pelvic inflammatory disease Epididymo-orchitis Gonococcal conjunctivitis Otitis media Skin and soft tissue infections All other serious infections Febrile neutropenia	Powder for injection: 250 mg, 500 mg, 1 g, 2 g	*Adolescents and adults:* IM: 250 mg as a single dose 1 g daily IM or IV for 10 d to 14 d 250 mg IM as a single dose 250 mg IM as a single dose 1 g IM as a single dose *Children:* IM: 50 mg/kg, up to 1 g, daily × 3 d *Children:* IM: 50–75 mg/kg q24h or 25–37.5 mg/kg q12h, up to 2 g/d	Maximal daily dose is 4 g for adults and 2 g for children (except meningitis is 4 g). Dose should not exceed 2 g/d in patients with both hepatic and renal impairment. After reconstitution, IM solution retains potency for 24 h at room temperature and 48–96 h if refrigerated. Yellow to amber discoloration does not affect potency. Must give with doxycycline 100 mg/d for 14 d. Must give with doxycycline 100 mg/d for 10 d. Adults only. Also saline lavage of eye.

Table 24–7 ⊗ Dosage Schedule Cephalosporins—cont'd

Drug	Indications	Dosage Forms	Initial Dose	Maximal Dose and Comments
		Fourth Generation		
Cefepime (Maxipime)	Complicated intra-abdominal infections	Injectable: 500 mg/ 15 mL vial, 1 g/15 mL vial, 2 g/15 mL vial	*Adults:* IM: 1–2 g q24h or 500 mg–1 g q12h *Children:* 80–100 mg/kg/d in 1–2 divided doses (max 4 g/d) *Children:* IM: 25–37.5 mg/kg q12h up to 2 g/d	Combine with metronidazole.
	Pneumonia		*Adults:* 2 g IV q8h *Children:* 50 mg/kg/dose q8h	
	Skin and skin structure infections, uncomplicated		*Adults:* 2 g IV q8–12h for 4 to 7 d *Adults:* 1–2 g q8–12h *Children:* 50 mg/kg/dose q12h for 10 d	
	Urinary tract infections		*Children:* 50 mg/kg/dose q12h for 10 d *Adults:* Mild to moderate 0.5 to 1 g q12h for 7 to 10 d Severe 2 g q12h for 10 d	

*Required dosage adjustments for renal impairment. Frequently it means extending the time between doses. If a drug must be used in the presence of renal impairment because there is no alternative, consult the package insert for specific dosage data.

group A streptococci (2%). Second- and third-generation cephalosporins are no longer recommended for empiric sinusitis due to variable rates of resistance (Chow et al, 2012). Children with type I penicillin allergy with severe sinusitis may be treated with a combination of cefixime and clindamycin (Wald et al, 2013).

Pharyngitis

Penicillin V is the drug of choice for treatment of pharyngitis caused by group A streptococci (AAP, 2012a). A narrow-spectrum first-generation cephalosporin (cephalexin or cefadroxil) is indicated as an alternative for this infection as a 10-day course of treatment (Shulman et al, 2012). The recommended pediatric dosage of cephalexin for this indication is 40 to 50 mg/kg/d divided every 12 hours. Adult dosage for cephalexin for streptococcal pharyngitis is 500 mg every 12 hours. Cefadroxil 30 mg/kg once daily may also be prescribed (Shulman et al, 2012). A small percentage (5% to 10%) of patients allergic to penicillins may also be allergic to cephalosporins (AAP, 2012a).

Urinary Tract Infection

The cephalosporins (cephalexin, cefpodoxime, cefixime) can be prescribed as second-line therapy to patients who are allergic to sulfa drugs or fluoroquinolones or as first-line treatment for women who are pregnant. Duration of therapy for cystitis-urethritis in adults is 3 days; uncomplicated pyelonephritis requires 14 days of treatment. Children require 10 days of therapy for UTI because it is difficult to distinguish cystitis and

pyelonephritis in young children. Cefpodoxime proxetil is used in adult dosages of 100 mg twice daily for urethritis-cystitis, 200 mg twice daily for pyelonephritis, and pediatric dosages of 10 mg/kg/day divided into two doses. Cefixime is used in adult dosages of 400 mg once daily for urethritis-cystitis and pyelonephritis; pediatric dosages are 8 mg/kg/d divided into two doses. Dosages of other agents for adults and children are listed in Table 24-7.

UTI is a common cause of unexplained fever in infants and young children aged 2 months to 2 years. In this population, diagnosis requires a culture obtained by catheterization. Febrile UTI is treated aggressively in infants and children, because fever is often an indication of pyelonephritis (Gaylord & Starr, 2009). Infants and children with febrile UTI should receive parenteral antibiotics for the first 24 hours or until afebrile. Ceftriaxone 50 to 75 mg/kg/day divided every 12 to 24 hours IV/IM is often used because of the convenience of 24-hour dosing. Another appropriate parenteral antibiotic choice is cefotaxime (50 to 200 mg/kg/d in divided doses every 6 to 8 hours). The treatment of UTIs is discussed in depth in Chapter 47.

Sexually Transmitted Infections

Ceftriaxone and cefixime are the recommended antibiotics for the treatment of cervicitis, urethritis, pharyngitis, and proctitis due to *N. gonorrhoeae* (CDC, 2007). Recommended adult dosages are ceftriaxone 250 mg IM or cefixime 400 mg orally, both as single doses (CDC, 2010e). Acceptable alternative parenteral treatments include ceftizoxime 500 mg IM;

or cefoxitin 2 g IM, administered with probenecid 1 g orally; or cefotaxime 500 mg IM (CDC, 2010e). An acceptable alternative single-dose oral therapy is cefpodoxime 400 mg or cefuroxime axetil 1 g (CDC, 2010e). Ceftriaxone 1 g IM or IV every 24 hours is used for disseminated gonococcal infections with cefotaxime (1 g IV every 8 h) or ceftizoxime (1 g IV every 8 h) as alternative regimens (CDC, 2010e). Because chlamydia is commonly associated with genital gonorrhea, azithromycin 1 g as a single dose or doxycycline 100 mg twice daily for 10 days should be prescribed concurrently (CDC, 2006a). Ceftriaxone is also used in the treatment of chancroid (250 mg as a single IM dose); early primary, secondary, or latent syphilis (1 g daily IM for 8 to 10 d); pelvic inflammatory disease (250 mg IM as a single dose plus doxycycline 100 mg daily for 14 d); epididymo-orchitis (250 mg IM as a single dose plus doxycycline 100 mg daily for 10 d); and gonococcal conjunctivitis in the adult (1 g IM as single dose plus saline lavage of eye) (CDC, 2006a, 2007). Treatment of STIs is discussed in depth in Chapter 44.

Skin and Tissue Infections

First-generation cephalosporins are first-line agents in the treatment of primary and secondary skin infections, including cellulitis, erysipelas, impetigo, traumatic wound infection, and surgical incision infection. The most commonly used drug is cephalexin (Stephens et al, 2014). Other first-line drugs include dicloxacillin, amoxicillin/clavulanate, and clindamycin (Stephens et al, 2014). Dosages are listed in Table 24-7.

Coverage for MRSA is indicated in areas of high prevalence or with high clinical suspicion. Antibiotics appropriate for MRSA include TMP-SMZ, doxycycline, or clindamycin, depending on local resistance patterns (Stephens et al, 2014). Cat bites, 80% of which become infected with *Pasteurella multocida* and/or *S. aureus,* can be treated with amoxicillin/clavulanate or cefuroxime axetil 500 mg twice daily. Cephalexin and other first-generation cephalosporins should not be used for cat bite infections.

Community-Acquired Pneumonia

Macrolides are the first-line treatment for CAP in adults (Mandell et al, 2007) and high-dose amoxicillin is the first-line treatment for CAP in children under age 5 years (Bradley et al, 2011). Cephalosporins (cefpodoxime, cefuroxime, or parenteral ceftriaxone followed by oral cefpodoxime) combined with a macrolide are used as alternative therapy to respiratory fluoroquinolones in adults with CAP (Mandell et al, 2007). Ceftriaxone (50 mg/kg in one daily dose) is appropriate therapy for 1 to 2 days in toxic-appearing children who may not be able to take oral antibiotics. Treatment of pneumonia is discussed in Chapter 42.

Other Uses

Although an off-label use, oral and parenteral first-generation cephalosporins are effective in dosages listed in Table 24-7 for endocarditis prophylaxis prior to surgery for patients with a history of rheumatic heart disease. Cefuroxime axetil in adult doses of 500 mg twice a day for 21 days is used in early Lyme disease characterized by erythema migrans. Ceftriaxone in adult doses of 2 g daily for 14 to 28 days has been used for facial nerve involvement and arthritis of Lyme disease.

Rational Drug Selection

The general principles of rational antimicrobial selection, using the definitive and empirical approaches, are presented in the section on penicillins. Because there is so much variability within each generation of the cephalosporins, sensitivity testing is valuable in drug selection. Selection of cephalosporins, like selection of any antimicrobial, is based on the organism that is present (in the definitive approach) or most likely present (in the empirical approach), site of infection, resistance patterns, adverse effects, pharmacokinetics, cost, and convenience.

The oral first-generation cephalosporins are interchangeable in terms of efficacy and safety. Parenteral cefazolin has good tissue penetration and is the drug of choice for surgical prophylaxis. Oral first-generation agents are good alternatives to penicillinase-resistant penicillins in the penicillin-allergic patient, unless the allergy is a type I hypersensitivity reaction. First-generation cephalosporins have the advantage of a fairly narrow spectrum and may be used by most penicillin-allergic individuals. An off-label use is endocarditis prophylaxis prior to surgical procedures.

Second-generation oral cephalosporins are slightly less active against gram-positive cocci than first-generation oral cephalosporins, so the latter are the preferred empirical treatment for skin and tissue infections. Cefaclor is more susceptible to beta-lactamases than other oral second-generation cephalosporins and is not recommended for the treatment of otitis media in current guidelines. Cefuroxime axetil has the most consistent activity of the second-generation cephalosporins against penicillin intermediate-resistant pneumococci and *H. influenzae.* Consequently, although all second-generation oral cephalosporins are approved for URIs, the resistance pattern favors cefuroxime axetil for oral therapy for otitis media unresponsive to amoxicillin, for sinusitis, and for pneumonia if *S. pneumoniae* is suspected. For other indications including UTIs, all second-generation agents have comparable efficacy.

Generic cefuroxime axetil is among the less expensive oral second-generation cephalosporins, but the suspension formulation has been rated one of the least palatable liquid preparations (Steele et al, 2001). Cefixime suspension was

On The Horizon **CEFTOBIPROLE**

Ceftobiprole is a new fifth-generation cephalosporin active against MRSA, DRSP, and *Pseudomonas aeruginosa*. It is intended for use with skin and skin structure infection and for nosocomial pneumonia. It was originally submitted to the FDA in May 2007 for the treatment of complicated skin and skin structure infections. In 2010, the FDA requested further information and studies before approving **ceftobiprole**.

also low in cost and rated as moderate to high on palatability. With the exception of cefaclor, which requires three doses daily, the oral second-generation agents are dosed twice daily. Extended-release cefaclor (Ceclor-CD) has the advantages of twice-daily dosing and daily cost comparable to other second-generation cephalosporins. Cephalexin oral formulations are on most $4 or reduced-cost generic plans at pharmacies that offer these services.

Because of the enhanced beta-lactamase resistance and extended gram-negative spectrum of third-generation cephalosporins, agents in this class are indicated for infections where resistance is a major consideration, such as gonorrhea infections and resistant otitis media. Although the incidence of GI intolerance would be expected to be lower with single-dose IM ceftriaxone, diarrhea has been observed in up to 25% of patients who receive ceftriaxone for otitis media. Additionally, IM injections may be poorly accepted by children and their parents, so the convenience and improved compliance expected with ceftriaxone may be offset by these liabilities. Cefdinir and cefpodoxime proxetil are oral agents that share similar antibacterial activity. Cefixime and ceftibuten are much less active than cefpodoxime proxetil against pneumococci, are completely inactive against penicillin-resistant pneumococcal strains, and have poor activity against *S. aureus.* Cefixime and cefpodoxime proxetil are the most active oral agents against *N. gonorrhoeae.* Parenteral ceftriaxone and cefotaxime are effective against most resistant strains of pneumococcus and are used empirically in serious infections presumed to be caused by these strains. Because they cross the blood–brain barrier, third-generation parenteral cephalosporins are used to treat meningitis. Unfortunately, this class of drugs is commonly misused for infections that could be treated by a narrower-spectrum agent. Because of long half-lives, ceftriaxone, ceftibuten, and cefixime can be dosed once daily for most infections; cefpodoxime proxetil and cefdinir require two doses daily. Third-generation cephalosporins are expensive relative to other antimicrobials. The palatability of cefixime suspension was rated moderate to high, whereas cefpodoxime proxetil suspension had one of the lowest ratings of all suspensions tested (Steele et al, 2001).

Monitoring

Monitoring for therapeutic and adverse responses to antimicrobials requires clinical, microbiological, and laboratory data (see the Monitoring section for the penicillins).

Because the cephalosporins have a broad spectrum, signs and symptoms of *C. difficile* infection (CDI), as well as other superinfections, should be noted. Diarrhea is common with some cephalosporins and must be distinguished from CDI. Perform *C. difficile* testing if there are more than three watery, unformed stools per day or if there is blood in the stool. Although hemolytic anemia is rare with the cephalosporins, signs of tiredness or weakness, yellow skin, or yellow eyes require a red blood cell (RBC) count with indices. During prolonged therapy, periodic BUN and CCr determinations should be performed to evaluate renal

function. If the CCr indicates renal impairment, dosage should be decreased according to the schedule in the package insert or drug reference. Many older patients require dosage adjustment because of age-related decrements in renal function. Patients who are receiving protracted courses of cefotetan, a parenteral cephalosporin that may affect clotting, require baseline and periodic assessment of PT. Administation of exogenous vitamin K (phytonadione; AquaMephyton) may be necessary if the PT is prolonged. Patients receiving cefotetan should also be observed for disulfiram reaction (abdominal cramping, facial flushing, headache, hypotension, palpitations, shortness of breath, sweating, tachycardia, vomiting) if exposed to alcohol.

Patient Education

Administration

Emphasize to the patient or caregiver the importance of completing the entire course of antibiotic therapy. IM cephalosporins may be irritating and painful. Inject the medication deep into a large muscle mass and avoid repeated injection by initiating IV access for therapy requiring more than a few injections. Medications mixed for injection will lose potency with time, although refrigeration after reconstitution will usually extend the period of full potency. Consult the package insert for proper mixing and storage of reconstituted parenteral cephalosporins. Adhere to the manufacturers' limits on volume of injection at one site (see also Table 24-7).

Usually, oral cephalosporins can be taken with food or milk if they cause stomach irritation. Ceftibuten is the exception because it is poorly absorbed unless taken on an empty stomach; it should be taken 1 hour before or 2 hours after meals. Cefuroxime axetil, particularly the suspension formulation, and cefpodoxime proxetil should be taken with food to enhance absorption. Tablets and suspension formulations of cefuroxime axetil and cefixime should not be used interchangeably because they have different bioavailability. Cefuroxime tablets are more completely absorbed than the suspension; however, the suspension of cefixime is better absorbed than the tablets. Cefdinir must be taken 2 hours before or 1 hour after antacids that contain magnesium or aluminum, which impairs its absorption. Patients with phenylketonuria should avoid cefprozil, which contains phenylalanine.

Suspensions and antibiotic solutions must be shaken to disperse or dissolve particles of drug immediately before measurement. Adhere to the manufacturer's specifications for storage after reconstitution and advise the patient not to use the drug after the expiration date. Describe to the patient whether there will be liquid remaining at the end of the course of therapy and urge disposal of unused medication. Ask the pharmacist to dispense a measuring device with every liquid preparation.

Adverse Reactions

If severe diarrhea occurs, the patient should contact the prescriber before initiating any treatment. For mild diarrhea,

adsorbent antidiarrheal agents containing attapulgite can be used, but antiperistaltic agents that would promote the retention of *C. difficile* toxins must be avoided.

Other signs and symptoms of adverse effects that patients should be advised to report include vaginal itching or discharge, sore mouth or throat, white patches on mucous membranes of the mouth, easy bruising or bleeding, altered urine output, yellow skin or eyes, or unusual lethargy commencing after the drug is started. Development of skin rash, aching joints, hives, or respiratory problems may signal allergic response and should also be reported. Cephalosporins cause false positives on urine testing for glucose when the copper sulfate technique (Clinitest) is used. Diabetics taking cephalosporins should use blood glucose monitoring or urine testing based on the glucose enzymatic tests (e.g., Clinstix, TesTape). Anorexia, epigastric pain, nausea, and vomiting in a patient taking a course of ceftriaxone may indicate development of biliary sludge or pseudolithiasis, which abates when the drug is discontinued.

Lifestyle Management

Practicing infection control and good health hygiene, such as safe sex practices and a healthy lifestyle, helps to prevent infections. Supportive nutrition, adequate rest, appropriate fluids, and comfort measures promote recovery from an infection. Maintaining a clean, dry wound site free of excess necrotic tissue and foreign bodies is essential to resolution of a wound infection and wound healing.

FLUOROQUINOLONES

The fluoroquinolones are synthetic, broad-spectrum antibiotics chemically related to the quinolone nalidixic acid (NegGram), a narrow-spectrum antibiotic used to treat UTIs. Fluoroquinolones are a newer class of antibiotics introduced in the 1980s. The fluoroquinolones are divided into the older group (ciprofloxacin [Cipro], norfloxacin [Noroxin], ofloxacin [Floxin]) and the newer group (gemifloxacin [Factive], levofloxacin [Levaquin], and moxifloxacin [Avelox]). The newer fluoroquinolones are often referred to as the respiratory fluoroquinolones, which is a reference to their activity against *S. pneumoniae*, not to drug distribution or limited treatment indications. Two newer fluoroquinolones have been withdrawn from the market because of adverse effects: trovafloxacin (Trovan) because of liver toxicity and gatifloxacin (Tequin) because of hypoglycemia and hyperglycemia. Sparfloxacin is no longer available in the United States. An ophthalmic solution of gatifloxacin (Zymar) is still available.

Pharmacodynamics

Fluoroquinolones are bactericidal through interference with enzymes required for the synthesis and repair of bacterial DNA. The addition of two chemical moieties, including a fluorine-containing group and a piperazine group, to the structure of the quinolone nalidixic acid resulted in the greatly enhanced antimicrobial efficacy of the fluoroquinolones. The fluorine molecule added to create the fluoroquinolones provides increased potency against gram-negative organisms and broadens the spectrum to include gram-positive organisms as well. The added piperazine moiety is responsible for the anti-pseudomonal activity of fluoroquinolones. Levofloxacin, the pure L-isomer of racemic ofloxacin, has a broader gram-positive spectrum than the racemate.

Fluoroquinolones inhibit bacterial topoisomerase II (DNA gyrase) and topoisomerase IV. Inhibition of DNA gyrase prevents the relaxation of positively supercoiled DNA that is required for normal transcription and replication. Inhibition of topoisomerase IV probably interferes with separation of replicated DNA into the daughter cells during replication.

Fluoroquinolones exhibit concentration-dependent killing, with the best predictor for clinical efficacy being the ratio of exposure to the drug, expressed as AUC to MIC. Achieving an AUC:MIC of less than 125 for gram-negative bacteria and less than 30 for gram-positive bacteria has been associated with clinical failures and the development of resistance.

Spectrum of Activity

Fluoroquinolones are notable for their extensive gram-negative activity against *E. coli, Klebsiella, Enterobacter, Campylobacter, Salmonella, Shigella, Proteus, Serratia, Haemophilus, N. gonorrhoeae, N. meningitidis, M. catarrhalis,* and many others. Only ciprofloxacin and levofloxacin have full activity against *P. aeruginosa*. All fluoroquinolones have some activity against gram-positive organisms; however, only the newer fluoroquinolones (gemifloxacin, levofloxacin, and moxifloxacin) have significantly more potent activity against *Staphylococcus*, *Enterococcus*, and *Streptococcus*, including DRSP. The fluoroquinolones are active against atypical organisms such as *Chlamydia, Legionella,* and *Mycoplasma* species. They have varying activity against *Mycobacterium* species. Moxifloxacin is the only fluoroquinolone with significant activity against anaerobic organisms.

Resistance

Resistance is mediated by mutations in the quinolone-binding region of the target enzyme or by a change in the permeability of the organism (Piddock, 1999). Many scientists and clinicians are concerned that overuse of these agents has already eroded the utility of this group of drugs. Resistance has been documented in community-acquired isolates of *Staphylococcus, Enterococcus, E. coli,* and *Pseudomonas.* The CDC no longer recommends fluoroquinolones in the treatment of gonorrhea because of resistance (CDC, 2007). Many areas can no longer use fluoroquinolones as empiric therapy for uncomplicated cystitis since *E. coli* resistance rates exceed 20%. Fluoroquinolone-resistant tuberculosis is associated with previous exposure to fluoroquinolones (Devasia et al, 2009). To prevent increased resistance, fluoroquinolones should not be used for upper and lower respiratory infections, skin and soft tissue infections, or urinary tract infections for which other inexpensive, safe, and

narrower-spectrum drugs are still effective. Rather, fluoro-quinolones should be reserved for use when alternatives are costlier and more hazardous.

Pharmacokinetics

Absorption and Distribution

All drugs in this class are well absorbed after oral administration. Recommended dosing of intravenous and oral formulations typically yields similar serum concentrations, making oral therapy attractive for those patients with a functional GI tract. Food only marginally affects absorption of fluoroquinolones; however, norfloxacin is best absorbed on an empty stomach and ciprofloxacin absorption may be decreased when administered with dairy products. Divalent (calcium, magnesium, zinc) and trivalent (aluminum, iron) cations can bind to fluoroquinolones in the GI tract and significantly decrease drug absorption.

All drugs in this class are widely distributed, with high tissue and urinary levels. For most fluoroquinolones, tissue concentrations are usually higher than plasma concentrations. Plasma protein binding is variable. Fluoroquinolones are also found in saliva, nasal and bronchial secretions, sputum, bile, lymph, and peritoneal fluid. They cross the blood–brain barrier poorly into uninflamed meninges, but ciprofloxacin, levofloxacin, moxifloxacin, and ofloxacin penetrate to a moderate extent in the presence of inflammation. All appear to cross the placenta. Although ciprofloxacin and ofloxacin are known to enter breast milk, this property has not been adequately studied for other fluoroquinolones.

Metabolism and Excretion

The predominant route of elimination varies widely between fluoroquinolones. Ofloxacin and levofloxacin have predominant renal excretion with minimal (less than 10%) metabolism. In contrast, nalidixic acid and moxifloxacin undergo extensive metabolism (greater than 35%). The other drugs undergo modest metabolism but have significant renal excretion as well. A few of them are also excreted in feces. Renal impairment results in increased half-lives of those patients with substantial excretion of unchanged drug. For patients with CCr of 50 mL/min or less, dosage adjustments are necessary for all fluoroquinolones, except for moxifloxacin. This is especially of concern with older adults, who are likely to have some degree of reduced renal function. Table 24-8 lists the pharmacokinetics of selected oral fluoroquinolones.

Pharmacotherapeutics

Precautions and Contraindications

All of the fluoroquinolones have a Black-Box Warning regarding the risk of tendon rupture and tendonitis. The risk is increased in older patients; in patients taking cortico-steroids; and patients with a heart, kidney, or lung transplant. An additional Black-Box Warning has been issued for all fluoroquinolones to avoid this class in patients with myasthenia gravis.

All fluoroquinolones produce a slight prolongation of the QTc interval. The increase is not considered to be clinically significant and is rarely reported in ciprofloxacin and levofloxacin. Preexisting QTc prolongation or concurrent use

Table 24–8 ◫ **Pharmacokinetics: Fluoroquinolones**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life*	Elimination
Ciprofloxacin	1 h	1–2 h	12–24 h	20%–40%	70%	3–6 h	40%–50% unchanged in urine; remainder in feces
Gemifloxacin	Rapid	0.5–2 h	24 h	60%–70%	71%	7 h	36% unchanged in urine; 61% in feces
Levofloxacin	Rapid	1–2 h	24 h	24%–38%	99%	6–8 h	87% unchanged in urine; eliminated by tubular secretion
Lomefloxacin	Rapid	1.5 h	12–24 h	10%	95%–98%	6–8 h	60%–80% unchanged in urine; 5% metabolized; 28%–30% biliary excretion
Moxifloxacin	Rapid	1–3 h	24 h	30%–50%	90%	11–16 h	20% unchanged in urine; 52% hepatically cleared, and 25% in feces
Norfloxacin	Rapid	2–3 h	12 h	10%–15%	30%–40%	6.5 h	30% unchanged in urine; 30% in feces; 10% metabolized by liver
Ofloxacin	Rapid	1–2 h	12 h	20%–25%	89%	5–7 h	70%–80% unchanged in urine

*Half-life is increased in renal impairment and dosage adjustments may be needed.

of other drugs producing this cardiac conduction change produces additive effects with the fluoroquinolones.

Cautious use is required for patients with renal impairment. Dosage adjustments of all fluoroquinolones except moxifloxacin are needed for patients with impaired renal function. Seizures, increased intracranial pressure, and toxic psychoses have occurred with fluoroquinolones. CNS stimulation, including tremors, restlessness, sleeplessness, tiredness, dizziness, light-headedness, bad dreams, confusion, and hallucinations, may also occur. These symptoms are dose-dependent and tend to resolve with continued use. Some studies indicate fluoroquinolones inhibit bonding of gamma-aminobutyric acid (GABA) to its receptor, which may be the mechanism of CNS stimulation. Slight decreases in magnesium concentration amplify the effect (*Sanford Guide,* 2010). Patients with known or suspected CNS disorders and other factors that predispose to seizures should use these agents with caution and careful monitoring.

Older adults and dialysis patients have increased risk of tendon rupture and adverse CNS reactions. Use fluoroquinolones cautiously with these populations.

Hepatitis, hepatonecrosis, and liver failure have been observed with fluoroquinolones. Drug discontinuation should occur at the first sign of jaundice.

Fluoroquinolones are Pregnancy Category C. Use is not recommended in pregnant women because there are no adequate, well-controlled studies in this population, and teratogenesis has been demonstrated in animals. Use during pregnancy only if there is a clear benefit that justifies the risk to the fetus.

Norfloxacin is not detected in breast milk following a 20 mg dose to nursing mothers; however, this dose is much lower than recommended. Ciprofloxacin is excreted in breast milk, but the dose ingested by the infant is small. Concentration of ofloxacin in breast milk is similar to maternal plasma, and it is presumed that its L-isomer, levofloxacin, also enters breast milk. Moxifloxacin is excreted in the breast milk of rats, but the drug has not been studied in humans. Because fluoroquinolones have caused cartilage lesions on weight-bearing joints in young animals, lactating women should use fluoroquinolones only if there is no safer alternative.

Fluoroquinolones are not recommended for children younger than 18 years. Arthropathy and osteochondrosis have been demonstrated in all species of immature animals tested. Nalidixic acid, norfloxacin, and ciprofloxacin have been used in children without evidence of arthropathy or osteochondrosis, but these three agents have poorer tissue penetration than other fluoroquinolones.

The only indications for which a fluoroquinolone is licensed by the FDA for use in patients younger than 18 years are complicated urinary tract infections, pyelonephritis, and post-exposure treatment for inhalation anthrax. The AAP (2006) recommends that the systemic use of fluoroquinolones in children should be restricted to situations in which there is no safe and effective alternative to treat an infection caused by multidrug-resistant bacteria or to provide oral therapy when parenteral therapy is not feasible and no other effective oral agent is available.

Adverse Drug Reactions

CDI has been reported with nearly all antibacterial agents, including fluoroquinolones, and may be mild to life-threatening. It is important to consider this diagnosis in patients who present with diarrhea subsequent to administration of fluoroquinolones, especially if this diarrhea contains blood, pus, or mucus. Other common GI adverse reactions include abdominal pain, nausea, and altered taste, which are the most frequent adverse drug reactions.

Serious and occasionally fatal hypersensitivity reactions, including Stevens–Johnson syndrome, have occurred with fluoroquinolones. Some of the reactions occur following the first dose, presumably due to cross-allergy with other chemicals in the environment. Reactions that are anaphylactic in nature have also occurred.

Phototoxicity has been observed with all fluoroquinolones. Clinical manifestations range from mild erythema to severe bullous eruptions in the sun-exposed areas.

Use of fluoroquinolones, especially in prolonged or repeated therapy, may result in bacterial or fungal overgrowth of nonsusceptible organisms. The patient should be monitored for this superinfection and treated with appropriate measures.

Cardiovascular adverse reactions, including angina, atrial flutter, cardiopulmonary arrest, cerebral thrombosis, myocardial infarction, and ventricular ectopy, have rarely been reported. CNS symptoms such as sleep disorders, nervousness, and vertigo have also been observed uncommonly for this drug class. Fluoroquinolones have increased or decreased blood sugar in diabetics.

Rarely, fluoroquinolones are associated with acute renal failure, typically acute interstitial nephritis. Crystalluria has been reported with ciprofloxacin and other fluoroquinolones, especially in patients with alkaline urine (pH greater than 7). Ciprofloxacin has been associated with acidosis, polyuria, urinary retention, and renal calculi.

Fluoroquinolone tendinitis begins with inflammatory edema that manifests as painful and swollen tendons that are bilateral in 50% of cases. Failure to take appropriate measures to rest the tendon can result in rupture. The time from initiation of the drug to onset of tendinitis has varied from 1 week up to months after treatment (Stahlmann & Lode, 2010). The elderly are at high risk of developing tendon rupture (Stahlmann & Lode, 2010). This condition has led to a Black-Box Warning regarding the risk of tendonitis and tendon rupture with the use of fluoroquinolones.

Ophthalmological abnormalities are extremely rare but include cataracts and multiple punctate lenticular opacities. A causal relationship has not been clearly established.

Additional adverse reactions are listed in the Precautions and Contraindications section.

Drug Interactions

Table 24-9 shows the various drug interactions. Several drugs interact with this class to decrease their absorption. Some

Table 24–9 Drug Interactions: Fluoroquinolones

Drug	Interacting Drug	Possible Effect	Implications
All fluoroquinolones	Antacids, bismuth subsalicylate, calcium, iron salts, magnesium, sucralfate, sevalamer, zinc salts	Interfere with GI absorption of the fluoroquinolone, resulting in decreased serum levels	Avoid simultaneous use; administer antacids 2–4 h before or after the fluoroquinolone
	Antidiabetic drugs	Increase or decrease blood sugar	Carefully monitor blood sugar
	Class 1 and 3 antiarrhythmics: Amiodarone, disopyramide, quinidine, bepridil, sotalol, all drugs that cause QT prolongation	Increased risk of serious adverse cardiovascular effects and fatal arrhythmias	Select different antibiotic
	Glucocorticoids	Concurrent use may increase risk for tendon rupture	Select different antibiotic
	Warfarin	Effects of anticoagulant may be increased	Monitor PT/INR
Ciprofloxacin	Caffeine	Total body clearance of caffeine reduced, with possible increased pharmacological effects	Monitor for increased blood pressure or CNS excitability
	Phenytoin	Phenytoin levels may be increased or decreased	Monitor phenytoin levels
	Probenecid	Renal clearance of ciprofloxacin reduced 50%; serum concentrations increased 50%	Avoid concurrent use
	Theophylline	Decreased clearance, increased plasma levels, and toxicity of theophylline have occurred with concurrent use of ciprofloxacin and enoxacin	Select different antibiotic or monitor theophylline levels
Levofloxacin	NSAIDs	Concurrent use increases CNS stimulation and seizures	Avoid concurrent use
Moxifloxacin	Rifampin	Rifampin may decrease moxifloxacin exposure by 31%	Use with caution
Norfloxacin	Caffeine	Total body clearance of caffeine reduced, with possible increased pharmacological effects	Ofloxacin does not appear to affect caffeine
	Cyclosporine	Nephrotoxic effects increased	Monitor renal function
	Nitrofurantoin	Antibacterial effect of norfloxacin in urinary tract may be antagonized	Avoid concurrent use

INR = international normalized ratio; PT = prothrombin time.

fluoroquinolones weakly inhibit drug metabolism by cytochrome P450 (CYP) 3A4, one of the most important enzymes in hepatic drug metabolism. Ciprofloxacin inhibits drug metabolism by CYP 1A2, which increases drug levels of caffeine, zolpidem, olanzapine, clozapine, and several other drugs. Cyclosporine's nephrotoxic effects are increased by concurrent administration with norfloxacin. Warfarin has increased effects when administered to a patient receiving a fluoroquinolone.

Food may decrease the absorption of norfloxacin. Food delays the absorption of ciprofloxacin, although total absorption is not changed. Dairy products reduce the absorption of ciprofloxacin and should not be used concurrently. Antacids, bismuth subsalicylate, iron salts, sevalamer, sucralfate, and zinc salts form an insoluble chelate with fluoroquinolones, preventing the absorption of the antimicrobial drug.

Clinical Use and Dosing

Exacerbations of Chronic Bronchitis

Because culture and sensitivity in patients with chronic bronchitis are unreliable due to bronchial colonization, empirical therapy is selected to cover the most likely pathogens. The primary organisms are viruses (20% to 50%), *C. pneumoniae* (5%), and *M. pneumoniae* (less than 1%). The treatment of

ABECB is described in the Clinical Use and Indications section for penicillins. Patients with moderate exacerbation who may require hospitalization or who do not respond to first-line therapy should be treated with a respiratory fluoroquinolone (levofloxacin, moxifloxacin, gemifloxacin), using dosages summarized in Table 24-10. Treatment of ABECB is discussed in Chapter 30.

Community-Acquired Pneumonia

In dosages listed in Table 24-10, fluoroquinolones with enhanced gram-positive activity, such as levofloxacin, moxifloxacin, and gemifloxacin, are active against strains of *S. pneumoniae.* In addition, fluoroquinolones cover *Legionella,* as well as *M. pneumoniae* and *C. pneumoniae,* which are the most common pathogens in patients with CAP without comorbidity. These atypical organisms are resistant to beta-lactam antibiotics but susceptible to macrolides. A respiratory fluoroquinolone such as moxifloxacin, gemifloxacin, or levofloxacin is used as first-line therapy when there are comorbidities, such as chronic heart, lung, liver, or renal disease; diabetes mellitus; alcoholism; malignancies; asplenia; immunosuppressing conditions or use of immunosuppressing drugs; or other risk for DRSP infection, such as use of antimicrobials within the

Table 24–10 ✖ Dosage Schedule: Fluoroquinolones

Drug	Indications	Dosage Forms	Initial Adult Dose	Maintanence Dose
Ciprofloxacin (Cipro)	Bone and joint infections Bacterial diarrhea Inhalation anthrax Intra-abdominal infections Meningococcal carrier Prostatitis Sinusitis Typhoid fever Skin and soft tissue infections Urinary tract infection: acute, uncomplicated cystitis, severe or complicated	Tablets: 100, 250, 500, 750 mg, Tablets: 500 mg extended-release Powder for oral suspension: 250 mg/5 mL, 500 mg/ 5 mL	PO: 500–750 mg q12h for at least 4–6 wk PO: 500 mg q12h for 1–3 days *Adults:* PO 500 mg q12h × 60 d post-exposure *Children:* PO 15 mg/kg/dose q12h × 60 d post-exposure PO: 500–750 mg q12h for 7–14 d in combination with oral metronidazole 500 mg as a single dose 500 mg q12h for 28 d PO: 500 mg q12h 10 d PO: 500 mg q12h for 10 d 500–750 mg q12h for 7–14 d 250–500 mg q12h for 3 d *Adults:* 500 mg q12h for 7–14 d *Children:* 20–40 mg/kg/d divided q12h (max 2 g/d)	Maximal adult daily dose 1.5 g Renal impairment (CCr <50 mL/min) requires dosage reduction Use higher range of dosing for severely ill or obese patients Not recommended for children, but doses of 10–20 mg/kg q12h have been used where no alternative existed Oral suspension stable for 14 d at room temperature or in refrigerator Shake suspension well before measuring Take with full glass of water Oral and parenteral routes are bioequivalent
(Ciloxan)	Bacterial conjunctivitis		Ophthalmic solution: >1 yr: 1–2 drops every 2 h while awake for 2 d, then 1–2 drops qid while awake for 5 d	
Gemifloxacin (Factive)	Bronchitis, acute exacerbation of chronic Community-acquired pneumonia	Tablet: 320 mg	PO: 320 mg q 24 h for 5 d	Not studied in ages less than 18 yr
Gatifloxacin (Zymar)	Bacterial conjunctivitis		Ophthalmic solution: >1 yr: 1 drop every 2 h while awake for 2 d, then 1 drop qid while awake for 5 d	
Levofloxacin (Levaquin)	Bronchitis, acute exacerbation of chronic Community-acquired pneumonia Sinusitis Skin and soft tissue infection Urinary tract infection: uncomplicated cystitis, complicated or pyelonephritis prostatitis	Tablets: 250, 500, 750 mg	500 mg q24h for 7 d 750 mg q24h for 5 d 750 mg q24h for 5 d 500 mg q24h for 7–10 d 250 mg q 24 h for 3 d 750 mg q 24 h for 5–14 d 750 mg q24h for 4 wk	Not recommended for use by children Renal impairment (CCr <50 mL/min) requires dosage reduction Take with full glass of water Oral and parenteral routes are bioequivalent and interchangeable Can use oral or injectable form
(Quixin)	Bacterial conjunctivitis		Ophthalmic solution: >1 yr: 1 drop every 2 h while awake for 2 d, then 1 drop qid while awake for 5 d	
Lomefloxacin (Maxaquin)	Bronchitis, bacterial exacerbation Urinary tract infection, complicated; uncomplicated due to *E. coli,* uncomplicated due to *P. mirabilis, K. pneumoniae, S. saprophyticus*	Tablets: 400 mg	400 mg daily for 10 d 400 mg daily for 14 d 400 mg daily for 3 d 400 mg daily for 10 d	Not recommended for use by children Renal impairment (CCr <40 mL/min) requires dosage reduction Take with full glass of water with or without food
Moxifloxacin (Avelox)	Acute sinusitis Acute exacerbation of chronic bronchitis Community-acquired pneumonia	Tablets: 400 mg	400 mg daily for 10 d 400 mg daily for 5 d 400 mg daily for 10 d	Not for use by children Duration dependent on organism

Continued

Table 24–10 ⊗ Dosage Schedule: Fluoroquinolones—cont'd

Drug	Indications	Dosage Forms	Initial Adult Dose	Maintanence Dose
(Vigamox or Moxeza)	Bacterial conjunctivitis		Ophthalmic solution: >1 yr: 1 drop tid for 7 d	
Norfloxacin (Noroxin)	Gastroenteritis (off-label) Prostatitis Urinary tract infection, uncomplicated, due to *E. coli, K. pneumoniae, P. mirabilis* uncomplicated, due to other organisms	Tablets: 400 mg	400 mg q8–12h for 5 d 400 mg q12h for 28 d 400 mg q12h for 3 d 400 mg q12h for 7–10 d	Maximal adult daily dose 800 mg (1.2 g infectious diarrhea) Take on empty stomach with full glass of water (1 h before or 2 h after food or milk) Not recommended for use by children
Ofloxacin (Floxin)	Bronchitis, bacterial exacerbations or community-acquired pneumonia Skin and soft tissue infections *Chlamydia*, endocervical or urethral Uncomplicated; nongonococcal urethritis Pelvic inflammatory disease, acute Prostatitis Urinary tract infection, complicated Cystitis due to *E. coli, K. pneumoniae* Cystitis due to other organisms	Tablets: 200, 300, 400 mg	400 mg q12h for 10 d 400 mg q12h for 7–10 d 300 mg q12h for 7 d 300 mg q12h for 7 d 400 mg q12h for 10–14 d 200 mg q12h for 10 d 200 mg q12h for 3 d 200 mg q12h for 7 d	Maximal adult daily dose 400 mg. Not recommended for use by children Renal impairment (CCr <50 mL/min) requires dosage reduction Take with a full glass of water
(Ocuflox)	Bacterial conjunctivitis		Ophthalmic solution: >1 yr: 1–2 drops every 2–4 h while awake for 2 d, then 1 drop qid while awake for 5 d	

previous 3 months (Mandell et al, 2007). For older patients or those with underlying disease, levofloxacin may be the best choice. The usual duration of therapy for CAP is 7 to 14 days. Higher dosages of some fluoroquinolones are required for more serious infections. Pneumonia treatment is discussed in depth in Chapter 42.

Urinary Tract Infection

Although empirical first-line treatment for a UTI is trimethoprim/sulfamethoxazole (TMP/SMX, Septra, Bactrim) or nitrofurantoin, an alternative treatment in patients who are not able to take or tolerate first-line therapy is the the fluoroquinolones ofloxacin, ciprofloxacin, and levofloxacin (Gupta et al, 2011). Moxifloxacin and gemifloxacin are not approved for use with UTIs because they have poor concentration in the urine. Cross-resistance occurs with the fluoroquinolones. Fluoroquinolone resistance has been steadily increasing, with 24.2% of *E. coli* resistant to ciprofloxacin and 24% resistant to levofloxacin (Kashanian et al, 2008). Fluoroquinolones are not prescribed to children or pregnant women because of concern for adverse effects on joints and cartilage, which have been found in animal studies. The exception is ciprofloxacin, which has FDA approval as second-line therapy in complicated UTI or pyelonephritis in children.

Uncomplicated cystitis and urethritis are treated with oral fluoroquinolones for 3 days. Complicated UTI and pyelonephritis require 7 to 14 days of therapy. Dosages of some fluoroquinolones for acute cystitis are lower than dosages for more serious urinary tract and kidney infections. Treatment of UTIs is discussed in Chapter 47.

Sexually Transmitted Infections and Genital Infections

Previously, the fluoroquinolones were recommended for treatment of uncomplicated gonorrhea manifested as cervicitis, urethritis, pharyngitis, or proctitis. Unfortunately, strains of gonococci resistant to fluoroquinolones have been identified worldwide and the CDC treatment guidelines no longer recommend the use of ciprofloxacin or other fluoroquinolones (CDC, 2007).

Oflaxacin or levofloxacin are recommended by the CDC as second-line therapy for chlamydia (CDC, 2010e). The first-line therapy is azithromycin or doxycycline. If treating with a fluoroquinolone, oflaxacin 300 mg twice a day or levofloxacin 500 mg daily for 7 days is prescribed (CDC, 2010e).

The fluoroquinolones, ofloxacin and levofloxacin, are recommended for the treatment of acute epididymitis most likely caused by enteric organisms or with a negative gonococcal culture or nucleic acid amplification test (CDC, 2010e).

Dosing for the treatment of epididymitis with ofloxacin is 300 mg orally twice a day for 10 days, and with levofloxacin it is 500 mg orally once daily for 10 days.

Detailed discussion of treatment of sexually transmitted infections is found in Chapter 44.

Skin and Tissue Infections

Although approved for skin and tissue infections, use of fluoroquinolones in these infections should be avoided to decrease selection pressure for bacterial resistance. Most skin and tissue infections treated in outpatient settings respond to beta-lactam antibiotics, except wounds that have been exposed to fresh water, such as ponds, lakes, and swimming pools, which may be infected with *Pseudomonas* and *Aeromonas* species.

Infectious Diarrhea

Fluoroquinolones are first-line therapy in treatment of traveler's diarrhea and severe diarrhea not associated with antibiotic therapy. Recommended self-treatment for traveler's diarrhea is 3 days of twice-daily therapy with oral ciprofloxacin (500 mg), norfloxacin (400 mg), or ofloxacin (300 mg), combined with loperamide 4 mg initially and 2 mg after each stool (Conner, 2013). Growing resistance may limit the use of fluoroquinolones in some countries.

For mild bacterial diarrhea not associated with antibiotics, characterized by three or fewer stools per day and minimal associated symptomatology, supportive therapy is usually adequate. For moderate infectious diarrhea, evidenced by four or more stools per day or fewer stools with systemic symptoms, an antiperistaltic drug (e.g., loperamide) may be added to supportive therapy. Severe infectious diarrhea not associated with antibiotics is manifested by six or more unformed stools per day and/or a temperature of 38.8%C or more, tenesmus, blood, or fecal leukocytes. Presence of blood may be indicative of *E. coli* O157:H7 infection, which has serious sequelae and requires hospitalization. Most common pathogens in severe infectious diarrhea not associated with antibiotics are *Shigella, Salmonella, Campylobacter jejuni,* and *E. coli* (O157:H7 strains). Drugs of choice for severe bacterial diarrhea (not associated with antibiotics) are ciprofloxacin 500 mg every 12 hours or norfloxacin 400 mg every 12 hours. Therapy is continued for 3 to 5 days.

Sinusitis

The Infectious Diseases Society of America (ISDA) published updated guidelines for the treatment of sinusitis in adults and children in 2012 (Chow et al, 2012). The fluorquinolones levofloxacin (500 mg PO daily) or moxifloxacin (400 mg PO daily) may be prescribed for adult patients who are allergic to beta-lactam antibiotics, although the ISDA cautions against the use due to higher cost and increasing rsistance (Chow et al, 2012). The ISDA guidelines recommend levofloxacin (10–20 mg/kg/d PO every 12–24 h) for treatment of sinusitis in children with a type 1 allergy to beta-lactams (Chow et al, 2012), although this is an off-label indication. The AAP issued a clinical practice guideline for sinusitis management soon after the ISDA guidelines that cautions

against the use of levofloxacin due to cost, toxicity, and emerging resistance (Wald et al, 2013). The AAP guidelines state levofloxacin can be used as therapy in penicillin-allergic pediatric patients but recommends a combination of clindamycin and cefixime to be prescribed first.

Other Uses

Ciprofloxacin is approved for bone and joint infections, but many typical pathogens (*Staphylococci* and *Streptococci*) are no longer susceptible to this drug. Use should be reserved for proven susceptibility on culture and sensitivity. Ciprofloxacin may be used off-label as a single 500 mg dose as chemoprophylaxis for high-risk adult (18 years of age or older) contacts of persons with invasive meningococcal disease (MacNeil & Cohn, 2011). The CDC notes ciprofloxacin should be avoided in areas where ciprofloxacin-resistant strains of *N. meningitidis* have been detected. Ciprofloxacin should not be used as chemoprophylaxis in pregnant women or children younger than age 18, with safer options of ceftriaxone or azithromycin available (McNeil & Cohn, 2011). Ciprofloxacin is also a first-line treatment for typhoid fever in doses of 500 mg twice daily for 10 days, although resistance is increasing, especially in the Indian subcontinent (Newton & Mintz, 2013).

Rational Drug Selection

Both definitive drug selection and empirical drug selection follow the same principles described in the Rational Drug Selection section for the penicillins. Specific implications to consider in selecting fluoroquinolones are cost, resistance, pharmacodynamics parameters, and adverse effect profile. Brand-name fluoroquinolones are relatively high-cost agents. Ciprofloxacin is on multiple $4 or reduced-cost generic lists, making it a cost-effective choice if appropriate. Levofloxacin is available as a generic product. The cost of fluoroquinolones is comparable to other, newer, broad-spectrum agents, such as amoxicillin/clavulanate, clarithromycin, and cefuroxime axetil (see the available dosage forms table for these drug classes).

Another reason to use fluoroquinolones judiciously is to prevent resistance. Ciprofloxacin and levofloxacin are unique as oral agents effective for *P. aeruginosa.* In addition, the agents with enhanced gram-positive activity (levofloxacin, gemifloxacin, moxifloxacin) retain susceptibility to highly penicillin-resistant strains of *S. pneumoniae* that are also resistant to cephalosporins, tetracyclines, macrolides, and sulfonamides. Moxifloxacin and gemifloxacin achieve much higher AUC:MIC ratios than levofloxacin and ciprofloxacin, making them more desirable for the treatment of upper respiratory infections. It behooves us to guard these susceptibilities as long as possible by using definitive drug selection based on culture and sensitivity and by selecting agents with the narrowest spectrum.

Selection between agents with similar spectrums of bacterial activity may depend on the comparative adverse effects and drug interactions. Norfloxacin has much less effect on caffeine metabolism; lomefloxacin and ofloxacin appear devoid of effects on caffeine metabolism. Treated diabetics and patients with a prolonged QTc interval or taking drugs that

increase the QTc interval should avoid fluoroquinolones if other equally effective antimicrobial drugs are available. Unless there are compelling reasons, fluoroquinolones should not be used by children and pregnant women. Renal impairment requires decreased dosage of all agents except moxifloxacin. Other antibacterial drugs are also preferable for patients with severe cerebral arteriosclerosis or who are otherwise seizure-prone (e.g., epilepsy, alcohol abuse, theophylline or antipsychotic drug use).

Monitoring

Monitoring for therapeutic response to antimicrobial drugs is described in the Monitoring section for penicillins. Patients on prolonged therapy with fluoroquinolones should have periodic assessment of organ function, including renal, hepatic, and hematopoietic function. Renal function should be measured or estimated with standard formulas prior to initiation of a fluoroquinolone. It is prudent to obtain a baseline electrocardiogram (ECG) prior to prescription of moxifloxacin. The drugs should be withheld and the ECG repeated if syncope occurs, which may indicate development of torsades de pointes, a potentially lethal arrhythmia. Patients taking theophylline and cyclosporine should have determinations of the plasma concentrations ("blood levels") of these agents, which are metabolized by CYP3A4, a hepatic drug-metabolizing enzyme inhibited by fluoroquinolones. Patients on warfarin who are started on fluoroquinolones should have their INR monitored closely. When either ofloxacin or levofloxacin is administered for gonorrhea, it may mask, but not cure, coexisting syphilis. Obtain serological testing for syphilis whenever a diagnosis of gonorrhea is made, with repeat testing at 3 months after treatment. Patients with epilepsy, alcohol abuse, or concurrent theophylline use should be monitored for CNS irritability (agitation, irritability) and seizure activity.

Patient Education

Administration

As with all antimicrobial drugs, the patient must understand the significance of taking all doses and completing the full course of therapy. Although the effect of food on absorption is unknown, the manufacturer suggests that the optimal time for administration of ciprofloxacin is 2 hours after meals. All fluoroquinolones should be taken with a full glass of water to help avoid dehydration, which can lead to crystalluria. Fluoroquinolones should not be taken within 2 to 6 hours of drugs that may chelate them (including antacids, sucralfate, iron preparations, sevalamer, and zinc salts) and prevent absorption. Dairy products hamper absorption of norfloxacin.

Adverse Reactions

Fluoroquinolones can cause photosensitivity or phototoxicity; therefore, all patients should be taught to avoid direct sunlight, sun lamps, and tanning beds from the first dose until several days after therapy is completed. They should withhold the drug and report any blister, rash, or itching that occurs. Recovery is prolonged and the reaction tends to recur

if the patient is exposed to sunlight again before recovery. Sunscreens, hats, and long-sleeved clothing should be suggested for even short-term exposure.

Fluoroquinolones often cause dizziness or light-headedness, so driving and hazardous activities should be avoided until a patient's reaction is known. Adequate fluid intake to maintain urine output of 1,500 mL per day will avoid crystalluria. Minimize use of urinary alkalinizers such as citrus drinks and avoid baking soda and antacids. If tenderness or inflammation occurs in any tendon, the patient should immediately discontinue the fluoroquinolone, notify the prescriber, rest, and refrain from exercise of the affected joint. Diabetics should immediately report any signs or symptoms of hypoglycemia and should perform home blood glucose testing regularly. The drug should be discontinued at any sign of an allergic reaction (hives, itching, dyspnea) because serious anaphylactic reactions have occurred during first exposure to a fluoroquinolone.

Lifestyle Management

See the Lifestyle Modification section for the penicillins.

LINCOSAMIDES

The original drug in this class was lincomycin. Although structurally different from erythromycin, lincomycin resembled it in activity. Unfortunately, it was too toxic and is rarely used; therefore, it will not be discussed in this chapter. Clindamycin (Cleocin) is a chlorine-substituted derivative of lincomycin and the only other drug in the class. Although less toxic, its indications are still limited because of its potential to cause severe diarrhea and CDI.

Pharmacodynamics

Clindamycin binds to the 50S subunit of the bacterial ribosome and suppresses protein synthesis. This is the same as the receptor for macrolides, so combined use with erythromycin and related drugs may decrease the effectiveness of both drugs. The action of clindamycin is usually bacteriostatic, but it may produce bactericidal effects if the pathogen is especially sensitive.

Spectrum of Activity

Susceptible organisms are primarily gram-positive, including *S. pneumoniae, S. pyogenes, Streptococcus viridans, S. aureus, Corynebacterium diphtheria,* and *Corynebacterium acnes.* It is also effective against selected anaerobic pathogens: *Bacteroides, Fusobacterium, Actinomyces, Peptococcus, Prevotella, C. perfringens,* and *C.tetani.* It is also effective against *Campylobacter jejuni* and *Gardnerella vaginalis,* and is used for treatment of bacterial vaginosis. In primary care, clindamycin is used for infections associated with anaerobic pathogens as well as gram-positive cocci. Clindamycin plays a significant role in treating infections secondary to staphylococcal or streptococcal species in penicillin-allergic patients. In addition, because of its inhibition of protein

synthesis, clindamycin is able to decrease toxin production in the setting of septic shock caused by *Streptococcus*, susceptible *Staphylococcus*, and *Clostridium*. Clindamycin lacks clinically relevant activity against enterococci and gram-negative aerobic organisms. *C. difficile* is resistant to clindamycin, which explains the prevalence of CDI as an adverse effect of the drug.

Resistance

Mechanisms of resistance include mutation or modification of the ribosomal receptor site and enzymatic inactivation of clindamycin. Resistance to clindamycin commonly confers cross-resistance to macrolides.

Pharmacokinetics

Absorption and Distribution

Oral administration of clindamycin results in complete absorption, and it is not affected by gastric acid or food. It distributes to pleural and peritoneal fluids, with high concentrations in bile and bone but poor CSF penetration.

Plasma protein binding is high. It readily crosses the placenta and is found in breast milk at 0.7 to 3.8 mcg/mL following doses of 150 to 600 mg.

Metabolism and Excretion

Clindamycin is metabolized by the liver to active and inactive metabolites. Both the parent drug and its metabolites are excreted in the bile and in urine. Approximately 10% of the drug is eliminated in the urine. Dosage modification is not usually required for renal or hepatic impairment unless it is very severe. Table 24-11 shows the pharmacokinetics of this drug.

Pharmacotherapeutics

Precautions and Contraindications

Use with caution in patients with a history of asthma or significant allergies. Hypersensitivity may occur. Cautious use is also recommended for the patient with severe renal or hepatic impairment accompanied by severe metabolic aberrations. The routes of excretion include both hepatic and renal.

Clindamycin is Pregnancy Category B. However, it crosses the placenta in amounts approximating 50% of maternal serum levels. It also appears in breast milk. According to LactMed, the National Institutes of Health Drug and Lactation Database, if clindamycin is required by a nursing mother, breastfeeding may continue, but an alternative drug may be a better choice in breastfeeding women.

Dosages are given for infants and children. Yet clindamycin should be used only for serious infections and when other, less toxic, alternatives are not appropriate.

Adverse Drug Reactions

The main adverse reactions with this drug are GI-related, including nausea, vomiting, and a bitter or metallic taste. GI intolerance may be dose-limiting. The most serious is the risk for CDI. The provider should consider CDI in patients who present with diarrhea subsequent to administration of clindamycin, especially if the diarrhea involves three or more unformed stools per day and contains blood, pus, or mucus. Older adults are less likely to tolerate any diarrhea, and the drug should be used cautiously with that population.

Other adverse effects include dizziness, vertigo, headache, hypotension, and rare cardiac arrhythmias. Indicators of hepatic and renal dysfunction occasionally occur.

Drug Interactions

There are few drug interactions with clindamycin. Table 24-12 lists them.

Clinical Use and Dosing

Because of its anaerobic activity, clindamycin is a first-line therapy for several serious infections treated parenterally in the hospital. Clindamycin is appropriate first-line therapy for MRSA in areas of the country where resistance is low; however, these areas are very limited and may only apply to the

Table 24–11 ⚏ Pharmacokinetics: Lincosamides

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Clindamycin	Rapid	45 min	6–8 h	93%	>90%	2–3 h	>90% hepatic; 10% unchanged in urine; 3.6% in feces

Table 24–12 ⚏ Drug Interactions: Lincosamides

Drug	Interacting Drug	Possible Effect	Implications
Clindamycin	Erythromycin	Antagonistic effects have occurred for both oral and topical formulations	Avoid concurrent use
	Kaolin-pectin	GI absorption is delayed when coadministered	Give 2 h before or 3–4 h after clindamycin, or avoid concurrent use
	Neuromuscular blockers	Enhanced neuromuscular blockade that may cause severe respiratory depression	Use with caution

pediatric population. Providers will need to know their local susceptibilities to make an informed prescribing decision. Other uses of clindamycin in primary care are limited to second-line treatment of gram-positive cocci. Despite the controversy about whether clindamycin causes a higher incidence of CDI than other antimicrobials, research shows that limiting its use decreases the prevalence of CDI and decreases clindamycin resistance.

Infections in Penicillin-Allergic Patients

Clindamycin is used for bacterial endocarditis prophylaxis as an alternative to penicillins in individuals allergic to penicillin. It also can be substituted for penicillin in treatment of pneumococcal pneumonia and skin and tissue infections, although there are other effective agents.

Drug-Resistant Pneumococcal Infections

Although many strains of *S. pneumoniae* are resistant to penicillins, cephalosporins, macrolides, tetracyclines, and sulfonamides, clindamycin retains good activity. Clindamycin is recommended for second- or third-line therapy for upper and lower respiratory infections (pneumonia, sinusitis, otitis media) due to DRSP. Because it does not cover other common pathogens (*H. influenzae* and *M. catarrhalis*), clindamycin should be reserved for definitive therapy for DRSP or in otitis media nonresponders after at least 72 hours of therapy with a drug that covers *H. influenzae.*

Infections in Special Populations

Clindamycin is indicated for pregnant women and children to treat infections when first-line agents may be harmful or not tolerated. For example, clindamycin has been used for bacterial vaginosis in pregnancy in doses of 300 mg twice daily for 7 days. However, because metronidazole is now recognized as safe for use in pregnancy, the use of clindamycin is limited for this indication. Clindamycin is also used in treatment of malaria and other protozoal infections in pregnant women, children, and in patients unable to tolerate first-line therapy.

Odontogenic (Dental) Infections

Clindamycin 300 to 450 mg given every 6 hours for 3 to 5 days is first-line therapy to treat odontogenic infections because of consistent activity against oral organisms. Pediatric dosing of clindamycin for dental infections is 10 to 20 mg/kg/d in three to four divided doses. It is especially helpful in dental abscesses. Table 24-13 presents the dosage schedules of lincosamides.

Rational Drug Selection

Both definitive drug selection and empirical drug selection follow the same principles described in the Rational Drug Selection section for the penicillins. Specific implications for selection of clindamycin are spectrum of activity and adverse effects. Because clindamycin has a narrow spectrum of aerobic activity and lacks activity against *H. influenzae,* it cannot

Table 24–13 ⊗ Dosage Schedule: Lincosamides

Drug	Indication	Dosage Forms	Initial Dose	Maintanence Dose
Clindamycin (Cleocin)	Mild-moderate bacterial infections	Capsules: 75, 150, 300 mg Injection, solution: 150 mg/mL	*Adults:* PO: 150–300 mg q6h *Children:* PO: 8–20 mg/kg/d in 3–4 equal doses	Maximal daily adult dose is 1.8 g orally and 2.7 g parenterally.
	Severe bacterial infections	Topical: 1% lotion 1% gel 1% solution	*Adults:* PO: 300–450 mg q6h *Children:* PO: 16–40 mg/kg/d in 3–4 equal doses	Take with food and a full glass of water to decrease esophageal irritation. Sit or stand for 30 min after dose.
	Endocarditis prophylaxis (off-label)	1% swab	*Adults:* PO: 600 mg 1 h before procedure *Children:* PO: 20 mg/kg 1 h before procedure	Dosing for clindamycin palmitate HCl (Cleocin Pediatric) oral solution varies slightly from tablets for children.
	Malaria treatment		*Adults:* PO: 900 mg tid for 7 d with quinine *Children:* PO: 20 mg/kg divided in 3 equal doses for 7 d with quinine	Shake solution well before measuring. Shake solution well before measuring.
	Bacterial vaginosis in pregnancy (off-label)		*Adults:* PO: 300 mg bid for 7 d	Dispense with calibrated measuring device. Do not refrigerate solution because it will become thick and hard to pour.
	Pneumocystis carinii pneumonia (off-label)		*Adults:* PO: 1,200–1,800 mg/d in divided doses with 15–30 mg primaquine daily for 21 d	
	Toxoplasmosis of CNS treatment (off-label)		*Adults:* PO: 600 mg tid with pyrimethamine and leucovorin	No dosage adjustments required for renal or liver impairment.
	Odontogenic (dental) infections		*Adults:* 300–450 mg q6h for 3–5 d *Children:* 10–20 mg/kg/d divided in 3–4 doses	

be substituted for other agents typically used to treat URIs but must be used when there is reasonable certainty that the organisms are susceptible to clindamycin. Because of the high incidence of CDI associated with clindamycin, patients with a history of colitis and older patients who poorly tolerate colitis should probably not receive this agent. Severe hepatic impairment requires careful monitoring of drug response.

Monitoring

Monitoring for therapeutic response to antibiotics is described in the Monitoring section for penicillins. If significant diarrhea occurs (six or more stools daily and/or blood, mucus, or watery diarrhea), the drug should be discontinued. Cytotoxin assays or PCR testing may be used to detect the presence of *C. difficile* and its toxin. If the original infection for which clindamycin was prescribed is severe and alternative antibiotics cannot be used, therapy can continue with close observation. Hospitalization may be warranted. CDI requires treatment with metronidazole, oral vancomycin, or fidaxomicin.

Prolonged therapy with clindamycin requires assessment of liver and renal function and blood counts. Because some oral clindamycin formulations contain tartrazine, patients with asthma or aspirin allergy are at risk to develop an allergic response and should be carefully monitored.

Patient Education

Administration

The patient should be advised of the necessity of completing the full course of therapy. Because clindamycin requires multiple daily doses, the patient should be guided in planning mnemonic or other strategies to promote adherence. The drug can be taken without regard to meals, but taking the drug with food and a full glass of water will avoid esophageal irritation. Sitting or standing for a full 30 minutes after the dose will also decrease the risk of esophageal irritation.

Adverse Reactions

If severe diarrhea develops, the patient should check with the prescriber before initiating any antidiarrheal treatment. Antiperistaltic agents, which may worsen the symptoms, should not be used. For mild diarrhea, the patient may use an attapulgite-containing antidiarrheal (e.g., Kaopectate, Donnagel) at least 2 hours before or 3 to 4 hours after the clindamycin. If surgery or general anesthesia is planned during or within a day or so after therapy, the anesthetist or anesthesiologist must be advised because clindamycin can intensify neuromuscular blockade.

Lifestyle Management

See the Lifestyle Management section for the penicillins.

MACROLIDES, AZALIDES, AND KETOLIDES

The macrolides are another early antibiotic group. The prototype drug in this group, erythromycin, was discovered in 1952. The drugs in the class (erythromycin, clarithromycin [Biaxin], dirithromycin [Dynabac]) are compounds characterized by a macrocyclic lactone ring with deoxy sugars attached. A closely related drug, azithromycin (Zithromax), is chemically an azalide derived from erythromycin by the addition of a methylated nitrogen to the lactone ring. The latest addition to this group is telithromycin (Ketek), which is chemically a ketolide derived from erythromycin by the lack of alpha-L-cladinose at position 3 on the erythronolide A ring. They are generally included with the macrolide group and are discussed in the same section here. In addition to their antibiotic activity, macrolides exhibit immunomodulating properties, which increase their usefulness in infectious diseases and cystic fibrosis.

Pharmacodynamics

This group of drugs reversibly binds to the P site of the 50S ribosome subunit of susceptible organisms and may inhibit RNA-dependent protein synthesis by stimulating the dissociation of peptidyl-tRNA from ribosomes. These drugs are typically bacteriostatic but may be bactericidal depending on drug concentrations and the bacterial species tested. Macrolides are weak bases, and their activity increases in alkaline media.

Erythromycin is inactivated by acid, and erythromycin base is marketed in acid-resistant, enteric-coated form to retard gastric inactivation. Erythromycin is also formulated as acid-stable salts and esters to improve bioavailability. These salts include erythromycin ethylsuccinate, erythromycin estolate, and erythromycin stearate. Dirithromycin is a prodrug that is converted nonenzymatically during intestinal absorption into a form of erythromycin. Azithromycin, telithromycin, and clarithromycin are semisynthetic derivatives of erythromycin.

Spectrum of Activity

Macrolides are active against gram-positive organisms such as pneumococci and other *Streptococcus* species, MSSA, and *Corynebacterium.* The gram-negative spectrum of the oral macrolides includes *H. influenzae, M. catarrhalis, Neisseria* species, *B. pertussis, Bartonella quintana,* some *Rickettsia* species, *T. pallidum,* and *Campylobacter* species. Atypical and intracellular organisms commonly resistant to beta-lactam antibiotics are also susceptible, such as *Mycoplasma, Legionella, Chlamydia, Helicobacter, Listeria,* and certain strains of *Mycobacterium.*

Among the macrolides, there is some variability of spectrum. Azithromycin has the greatest activity of the macrolides against gram-negative organisms such as *H. influenzae* and *M. catarrhalis.* It is more active than erythromycin against anaerobes and has activity similar to erythromycin against gram-positive organisms. Clarithromycin has some anaerobic activity and greater activity than erythromycin or azithromycin against gram-positive organisms such as *Streptococcus* species and MSSA. Its activity against *H. influenzae* is greater than that of erythromycin but less than that of azithromycin.

Telithromycin is also effective against DRSP, including those resistant to penicillin, cephalosporins, tetracycline, trimethoprim/sulfamethoxazole, and other macrolides. Dirithromycin has the narrowest spectrum of the macrolides. The single best use for all these drugs is in treating highly intracellular organisms.

Resistance

Resistance to erythromycin is a result of (1) reduced permeability of the cell membrane or active efflux, (2) modification of the ribosomal binding site by chromosomal mutation, or (3) production of esterase by *Enterobacteriaceae* that hydrolyze macrolides. Cross-resistance is nearly complete between erythromycin and the other macrolides. Cross-resistance may also develop with other antibiotics that share the same ribosomal binding site, such as clindamycin. The prevalence of macrolide-resistant pneumococci in the United States reported in the 2011 Active Bacterial Core Surveillance was 26.2% (CDC, 2012). Telithromycin is newer but resistance has developed to *S. pyogenes* (Richter et al, 2008).

Pharmacokinetics

Absorption and Distribution

The macrolides, azalides, and ketolides are all well absorbed from the duodenum following oral administration. Food decreases the amount of absorption of azithromycin tablets by 23% and the suspension by 56%. These formulations should be taken on an empty stomach. Food does not affect the absorption of telithromycin. Absorption of enteric-coated erythromycin is delayed by food. Food also delays the absorption of clarithromycin, although bioavailability is not affected, so this drug may be taken without regard to meals. Dirithromycin is best absorbed when taken with food or within an hour of having eaten. Erythromycin base or stearate must be taken on an empty stomach, but the absorption of the estolate and ethylsuccinate forms are not affected by food intake. Minimal absorption occurs after topical or ophthalmic use. Macrolides distribute readily to body tissues and enter pleural fluid, ascitic fluid, middle-ear exudates, and sputum. When meninges are inflamed, macrolides enter the CSF. Because of high intracellular concentrations, particularly in phagocytic cells, tissue levels are higher than serum levels and concentrations in white blood cells may remain high for many hours after the last dose of the drug.

Metabolism and Excretion

Macrolides, azalides, and ketolides are partially metabolized by the liver, and clarithromycin, dirithromycin, and telithromycin are converted to active metabolites. This class of drugs is excreted mainly unchanged in bile; the drug is also excreted unchanged in urine in varying degrees. Clarithromycin and its active metabolite are substantially eliminated by the kidneys. Because older adults often have renal impairment, dosage adjustment should be considered for this population.

Erythromycin is heavily metabolized by CYP 3A4, which explains many of its drug interactions. Telithromycin is 50% metabolized by CYP 3A4, but the remaining 50% is CYP450 independent, so dosage adjustments are not required for hepatic dysfunction. Table 24-14 presents the pharmacokinetics.

Pharmacotherapeutics

Precautions and Contraindications

Hypersensitivity to any of the macrolides and patients' use of pimozide contraindicate use of macrolides. The removal

Table 24–14 Pharmacokinetics: Macrolides, Azalides, and Ketolides

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Azithromycin	Rapid	2.5–3.2 h	24 h	7%–50%	40%	11–14 h after single dose; 68 h after multiple doses	6% unchanged in urine; remainder unchanged in bile
Clarithromycin	UA	2 h	12 h	40%–70%	55%	3–4 h for 250 mg dose; 5–7 h or 500 mg dose	20%–30% unchanged in urine
Dirithromycin	UA	2–4 h	6–8 h	15%–30%	10%	2–36 h	81%–97% fecal/hepatic
Erythromycin	1 h	1–4 h	UA	7%–90%	35–60%	1.4–2 h	5% unchanged in urine; remainder largely in bile
Telithromycin	Rapid	0.5–4 h	24 h	60%–70%	57%	7.16 h after single dose; 9.81 h after doses	7% unchanged in feces; 13% unchanged in multiple urine; 37% metabolized by liver

UA = information unavailable.

of terfenadine and cisapride from the market was related to serious dysrhythmic reactions that frequently were triggered by inhibition of CYP 3A4 by erythromycin and other drugs. QT prolongation has been observed with erythromycin, azithromycin, clarithromycin, and telithromycin. These drugs should be avoided if possible in patients at risk for torsades de pointes or when receiving other medications that could prolong the QT interval.

The FDA issued a Drug Safety Communication in March 2013 regarding cardiac arrhythmias associated with azithromycin use. The label was changed to reflect a risk of prolonged QT interval and torsades de pointes. Groups at higher risk of cardiac rhythm disturbance with azithromycin include: patients with known prolongation of the QT interval, a history of torsades de pointes, congenital long QT syndrome, bradyarrhythmias, uncompensated heart failure, and patients on drugs known to prolong the QT interval. Patients with ongoing proarrhythmic conditions such as uncorrected hypokalemia or hypomagnesemia or clinically significant bradycardia and patients receiving Class IA (quinidine, procainamide) or Class III (dofetilide, amiodarone, sotalol) antiarrhythmic agents should be prescribed azithromycin with caution.

Telithromycin has been associated with fatal hepatotoxicity, potentially fatal exacerbations of myasthenia gravis, and visual disturbances. The FDA issued a warning in 2007 that telithromycin should not be used for minor illnesses such as upper respiratory illnesses. Erythromycin should also be avoided in patients with myasthenia gravis, because it may aggravate the condition.

Known, suspected, or potential bacteremia contraindicates use of dirithromycin because serum levels are inadequate to provide antibacterial coverage of the plasma.

Patients with Renal and Hepatic Impairment

Azithromycin is principally excreted via the liver. Patients with impaired hepatic function require cautious use of this drug. There are no data about use with renal impairment, so cautious use is also recommended in decreased renal function.

Clarithromycin is excreted via the liver and the kidney. Dosage adjustments are not required for hepatic impairment in the presence of normal renal function. Renal impairment with CCr less than 30 mL/min with or without hepatic impairment requires that dosages be halved or the dosing interval doubled.

Erythromycin is contraindicated for patients with preexisting liver disease. Erythromycin estolate has been associated with the infrequent (1 case per 1,000 patients) occurrence of cholestatis hepatitis. This has also occurred with other erythromycin salts but is rarer in children. Laboratory findings include abnormal liver function tests, peripheral eosinophilia, and leukocytosis. Symptoms include malaise, nausea, vomiting, abdominal cramps, and fever. Jaundice may or may not be present. These symptoms tend to occur after 1 to 2 weeks of continuous therapy, disappear if the drug is discontinued, and reappear within 48 hours if the drug is readministered.

Telithromycin has not shown altered AUC for patients with hepatic impairment. In severe renal impairment (CCr less than 30 mL/min), AUC was increased. To date, no dosage adjustments are recommended.

Older Adults

Although maximum plasma concentrations and AUC of clarithromycin and dirithromycin increase in older adults, no specific dosage adjustments or precautions are recommended for older adults with normal renal and hepatic function. Older adults with impaired renal function should be treated as any patient with that impairment. Younger and older adults appear to have the same pharmacokinetics for azithromycin and telithromycin.

Pregnant Women

Azithromycin and erythromycin are Pregnancy Category B and are considered safe to use during pregnancy. Clarithromycin, dirithromycin, and telithromycin are Pregnancy Category C. Animal studies with clarithromycin have shown adverse effects on pregnancy outcome and on fetal development. Animal studies with dirithromycin have shown significantly decreased fetal weight and incomplete ossification of fetal bone. These latter two drugs should not be used during pregnancy except in clinical circumstances in which no alternative therapy is appropriate. Telithromycin was not teratogenic in animals, but there are no adequate, well-controlled studies in pregnant women.

Azithromycin, clarithromycin, and erythromycin are compatible with breastfeeding. Telithromycin is excreted in the breast milk of rats and probably in human breast milk. Data are not available for the other drugs in this class, and they should be used with caution in nursing mothers.

Pediatric Patients

Erythromycin has been used extensively in infants and children and is considered safe. Azithromycin was studied and relabeled in 2008 for safety and efficacy for children as young as 6 months for otitis media, sinusitis, and CAP. Efficacy has been established for children older than 2 years for pharyngitis-tonsillitis. Clarithromycin has established safety and efficacy for children older than 6 months. The safety and efficacy of dirithromycin have not been established for children younger than 12 years. The safety and efficacy of telithromycin in children have not been established.

Adverse Drug Reactions

The most common adverse reactions to macrolides are dose-related GI symptoms, including nausea, vomiting, abdominal pain, cramping, and diarrhea. Taste disturbances have been reported with clarithromycin. In general, these reactions are transient, mild to moderate in severity, and reversible when the drug is discontinued. Erythromycin is most likely to cause GI symptoms whether given orally or parenterally because it stimulates the motilin receptor in the GI tract. An off-label use of erythromycin for the treatment of gastroparesis derives from this receptor activity. Diarrhea may also be secondary to CDI.

Azithromycin, erythromycin, and telithromycin have been associated with liver abnormalities, including hepatitis, cholestatic jaundice, and hepatic failure. Erythromycin has been associated with urticaria, bullous eruptions, eczema, and Stevens–Johnson syndrome. Allergic reactions have been reported with all available macrolides. Isolated cases of reversible hearing loss have also been reported with erythromycin, clarithromycin, and azithromycin, particularly with parenteral administration or high doses.

Hyperkinesia, dizziness, and agitation have occurred in fewer than 1% of children taking azithromycin. Stomatitis, dry mouth, and dysphagia have occurred in a small number of adults for all macrolides. Laboratory abnormalities include elevated liver function studies (azithromycin), increased platelet counts (dirithromycin and erythromycin) and elevated potassium levels (dirithromycin). In each case, less than 6% of patients were affected.

Drug Interactions

Clarithromycin, erythromycin, and telithromycin have more drug interactions than the other two drugs in this class because they are strong inhibitors of the CYP450 enzymes, particularly CYP 3A4. Object drugs in these interactions include such common drugs as cyclosporine, most statins, rivaroxaban, theophylline, carbamazepine, and select benzodiazepines. Other drug effects that will be increased with concomitant use of macrolides include colchicine, digoxin, and warfarin. The combination of most macrolides with pimozide (Orap), a drug used to treat Tourette syndrome, can result in serious dysrhythmia; the inhibited metabolism causes prolonged QT interval of the cardiac cycle, predisposing to potentially fatal cardiac dysrhythmias. Table 24-15 lists the various drug interactions by specific drug. Although azithromycin has fewer drug interactions, confirmed interactions with drugs with narrow therapeutic margins have been observed in clinical practice.

Drugs inducing CYP 3A4, such as efavirenz, rifampin, rifapentine, and rifabutin, may significantly increase the metabolism of clarithromycin and decrease effectiveness. Alternative therapy should be considered.

Caution should be used when administering any additional medications that may prolong the cardiac QT interval. These may include, but are not limited to, Class 1a and Class 3 antiarrhythmic agents, fluconazole, and promethazine.

In addition, antacids containing aluminum or magnesium slow absorption of macrolides and azalides, so they should be taken 1 hour before or 2 hours after the antimicrobial drug, particularly with azithromycin. Drug interaction testing with telithromycin indicated that no significant interactions exist with antacids, grapefruit juice, digoxin, warfarin, or the anti-ovulatory effects of oral contraceptives.

Clinical Use and Dosing

Macrolides are drugs of choice for empirical treatment of CAP due to the prevalence of intracellular organisms and the presence of other resistant strains. Relative safety in children and convenient dosing schedules have made the newer macrolides, azithromycin and clarithromycin, popular in primary care practice. In particular, azithromycin has both a 3-day dosing schedule and a 5-day dosing schedule. Clarithromycin usually requires twice-daily dosing but is available in a delayed-release formulation that can be administered once daily. Although bioavailability varies by erythromycin salt, the dosages of base, stearate, and estolate salts are the same for any indication. The dosage of erythromycin ethylsuccinate is higher because of the mass of the ethylsuccinate component. The equivalent of 250 mg base is 400 mg ethylsuccinate. Specific dosages are included in Table 24-16.

Community-Acquired Pneumonia

Pathogens in CAP that are naturally resistant to beta-lactam antibiotics are the atypical organisms *C. pneumoniae, M. pneumoniae,* and *Legionella pneumophila.* Other common pathogens in CAP are *S. pneumoniae, H. influenzae,* and *M. catarrhalis,* some of which are increasingly resistant to many antibiotics. *S. aureus* is occasionally the pathogen in postbronchitic pneumonia.

Initial empirical therapy to treat CAP in the previously healthy older child (older than age 5 years), adolescent, or

Table 24–15 ▦ Drug Interactions: Macrolides and Azalides

Drug	Interacting Drug	Possible Effect	Implications
All macrolides	Ergot alkaloids	Acute ergot toxicity, characterized by severe peripheral vasospasm and dysesthesia, has occurred	Use with caution, avoid concurrent use if possible
	Methadone	Additive effects on QT interval prolongation, possibly leading to torsades de pointes	Avoid concurrent use if possible
	Pimozide	Two sudden deaths occurred when clarithromycin was added to ongoing pimozide therapy	Coadministration is contraindicated
Azithromycin, dirithromycin, erythromycin	Antacids	Aluminum- and magnesium-based antacids reduce peak serum levels but not extent of absorption of azithromycin; when given immediately following antacids, dirithromycin absorption is slightly enhanced; when given immediately prior to antacids, elimination rate of erythromycin may be slightly decreased	Consider outcomes in patient education

Table 24–15 ▦ **Drug Interactions: Macrolides and Azalides—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
Azithromycin, clarithromycin, erythromycin	Cyclosporine, Tacrolimus	Elevated cyclosporine or tacrolimus concentration with increased risk for toxicity	Monitor drug levels; azithromycin may be preferred
	Digoxin	Digoxin levels may be elevated based on effect of macrolide on gut flora that metabolizes digoxin in 10% of patients	Carefully monitor for signs and symptoms of digoxin toxicity
Clarithromycin, erythromycin	Rifabutin, rifampin	Antibiotic effects of macrolide reduced; increased rifabutin levels and risk of adverse effects of rifabutin	Select different macrolide; decrease dose of rifabutin when used with clarithromycin
	Alprazolam, diazepam, midazolam, triazolam	Plasma levels of benzodiazepine elevated, increasing and prolonging CNS depression effects	Azithromycin and dirithromycin not expected to react; select benzodiazepine not strongly metabolized by CYP 3A4
	Amlodipine, diltiazem, felodipine, verapamil	Calcium channel blocker levels and effects increased	Monitor closely. Azithromycin and dirithromycin not expected to react
	Buspirone	Plasma levels of buspirone elevated, increasing pharmacological and adverse effects	Azithromycin and dirithromycin not expected to react
	Carbamazepine	Increased concentration of carbamazepine	Azithromycin and dirithromycin not expected to react
	Colchicine	Increased colchicine levels	Reduce colchicine dose; concurrent use contraindicated if patient has renal or hepatic impairment
	Disopyramide	Plasma levels of disopyramide increased. Arrhythmias and prolonged QTc have occurred.	Avoid concurrent administration Carefully monitor any patient receiving both drugs
	Fluconazole, Posaconazole, Voriconazole	Increased serum concentrations of macrolide	Use caution or select a different drug combination
	HMG-CoA reductase inhibitors	Increased risk of severe myopathy or rhabdomyolysis	
	Oral anticoagulants	Potentiates anticoagulant effects	Avoid concurrent use
	Theophylline	Concurrent use associated with increased serum theophylline levels	Carefully monitor anticoagulant effects for patients receiving any macrolide Avoid concurrent use Azithromycin and dirithromycin not expected to interact
Clarithromycin	Atazanavir, Ritonavir	Increased clarithromycin levels	Decrease clarithromycin dose by 50%–75% if concurrent renal impairment
	Sildenafil, Vardenafil	Increased levels and effects of phosphodiesterase inhibitor	Coadministration not recommended
Dirithromycin	H$_2$ blockers	Dirithromycin absorption slightly enhanced when given immediately after H$_2$ blocker	Separate doses by at least 1 h or select different macrolide
Erythromycin	Alfentanil	Alfentanil clearance decreased and elimination half-life increased	Select different macrolide
	Bromocriptine	Bromocriptine levels increased; increased pharmacological and adverse effects	Select different macrolide
	Clindamycin	Potential antagonistic effects	Select a different antimicrobial regimen if possible
	Methylprednisolone	Clearance of methylprednisolone greatly reduced	Monitor for adverse effects or select a different macrolide
Telithromycin	Itraconazole, ketoconazole	Significant increase in telithromycin AUC	Select different antifungal
	Simvastatin; possibly atorvastatin and lovastatin	Significant increase in simvastatin AUC; possible increased risk for rhabdomyopathy	Avoid concurrent use
	Midazolam; BDZs metabolized by CYP3A4	Increased risk for sedation and adverse effects of midazolam and BDZs	Adjust dose of interacting drug if concurrent use cannot be avoided
	Digoxin	Peak and trough levels of digoxin increased by 73% and 21%, respectively. No increased risk for digoxin toxicity seen in research.	Monitor digoxin level closely
	Rifampin, phenytoin, carbamazepine, phenobarbital	Decreased levels of telithromycin and loss of effect	Avoid concurrent use

Table 24–16 ⊗ Dosage Schedule: Macrolides, Azalides, and Ketolides

Drug	Indication	Dosage Form	Dose	Comments
Azithromycin (Zithromax)	Community-acquired pneumonia, otitis media, uncomplicated skin and soft tissue infections, acute bacterial exacerbation of chronic bronchitis	Tablets: 250, 500, 600 mg Powder for oral suspension: 100 mg/5 mL, 200 mg/5 mL Extended-release oral suspension: 2 g single-dose cup	*Adults:* 500 mg as single dose on day 1, followed by 250 mg daily on days 2–5; or 500 mg daily for 3 d *Children:* 10 mg/kg as a single dose on day 1 (not to exceed 500 mg/d), followed by 5 mg/kg as a single dose on days 2–5	Take capsules and pediatric suspension on empty stomach. Tablets and adult single-dose packets may be taken without regard to meals. Store pediatric oral suspension at room temperature after reconstitution. Stable for 10 d. Discard excess after dosing is complete. Shake suspension before measurement, using calibrated dosing device. Pediatric dosing limits: 500 mg daily for pharyngitis, tonsillitis, and first day of dosing for otitis media and pneumonia; 250 mg daily for days 2–5 for otitis media and pneumonia.
	Pharyngitis/tonsillitis		*Adults:* Same as community-acquired pneumonia *Children:* 12 mg/kg daily for 5 d (not to exceed 500 mg daily)	
	Chancroid, genital ulcer disease, nongonococcal urethritis caused by *Chlamydia trachomatis*		*Adults:* Single 2 g dose, or 1 g if combined with ceftriaxone	Do not use adult single-dose packet formulation for doses >1,000 mg. As above
	M. avium complex (MAC) prophylaxis Endocarditis prophylaxis		*Adults:* 1.2 g/wk *Adults:* 500 mg *Children:* 15 mg/kg	As above As above. Also safe for use in pregnancy. As above 30–60 min prior to procedure
Clarithromycin (Biaxin)	Pharyngitis, tonsillitis, otitis media, or skin and soft tissue infections	Tablets: 250 mg, 500 mg Granules for oral suspension: reconstituted 125 mg/5 mL, 250 mg/5 mL Extended-release: 500 mg tablet	*Adults:* 250 mg bid for 10 d *Children:* 15 mg/kg/d in 2 divided doses	May be given without regard to food. If CCr <30 mL/min, dose should be halved or dosing interval doubled.. Store suspension at room temperature after reconstitution. Stable for 14 d. Do not refrigerate. Shake suspension well before measurement with calibrated measuring device.
	Acute maxillary sinusitis		*Adults:* 500 mg bid for 14 d, 1,000 mg once daily of extended-release *Children:* Same as above for 10–14 d	As above Take extended-release formulation with food
	Acute exacerbation of chronic bronchitis caused by *S. pneumoniae, H. influenzae,* or *M. catarrhalis*		*Adults:* 500 mg q12h for 7 d or ER formulation 1 g daily for 7 d	As above
	Community-acquired pneumonia		*Adults:* 250 mg q12h for 7–14 d or ER formulation of 1 g daily for 7 d	As above

Table 24–16 ⊗ **Dosage Schedule: Macrolides, Azalides, and Ketolides—cont'd**

Drug	Indication	Dosage Form	Dose	Comments
	M. avium complex (MAC) treatment		*Adults:* 500 mg twice daily *Children:* 7.5 mg/kg up to 500 mg bid; give in conjunction with other antimycobacterial drugs	As above
	MAC prophylaxis		*Adults:* 500 mg bid	As above
	Active duodenal ulcer associated with H. pylori infection in combination with bismuth citrate		*Adults:* 500 mg bid–tid with ranitidine bismuth citrate 400 mg bid for days 1–14; followed by bismuth citrate 400 mg/d for days 15–28	As above
	Active duodenal ulcer associated with H. pylori infection in combination with omeprazole		*Adults:* 500 mg tid with omeprazole 40 mg bid for 4 d	As above
	Active duodenal ulcer associated with H. pylori infection, in combination with amoxicillin and lansoprazole		*Adults:* 500 mg clarithromycin, 1,000 mg amoxicillin, and 30 mg lansoprazole q12h for 7 d	As above
Dirithromycin (Dynabac)	Acute bacterial exacerbations of chronic bronchitis; uncomplicated skin and soft tissue infections due to methicillin-sensitive S. aureus	Tablets: 250 mg	*Adults:* 500 mg/d for 7 d	Take with food or within 1 h of eating. Do not crush or chew tablets.
	Community-acquired pneumonia caused by M. catarrhalis or S. pneumoniae (not for empirical therapy)		*Adults:* 500 mg/d for 14 d	As above
	Pharyngitis/tonsillitis caused by S. pyogenes		*Adults:* 500 mg/d for 10 d	
Erythromycin dose in mg erythromycin base	Antibacterial, mild infection, usual dose	Tablets: 250, 333, 500 mg Capsules: 250 mg		
Estolate (Ilosone)		Tablets: 500 mg Capsules: 250 mg Suspension: 125 mg/5 mL, 250 mg/5 mL	*Adults:* 250 mg base (400 mg ethylsuccinate) q6h; or 500 mg (800 mg ethylsuccinate) q12h; or 333 mg q8h	Take with 180–240 mL of water Maximum adult daily dose is 4 g
Ethylsuccinate (EryPed, E.E.S.)		Tablets: 400 mg Suspension: 200 mg/5 mL, 400 mg/5 mL		
Base (E-Mycin, E-Base, Ery-Tab, Eryc) Stearate (Erythrocin Stearate)		Tablets: 250 mg, 333 mg Tablets: 250 mg, 500 mg	*Children:* 30–50 mg/kg/d of base in divided doses (or 50–80 mg/kg/d ethylsuccinate)	Taking with food may decrease effectiveness of erythromycin stearate and certain formulations of erythromycin base. Check package insert for erythromycin base. Take erythromycin stearate and most erythromycin base at least 2 h before or after a meal.

Continued

Table 24–16 ⊗ Dosage Schedule: Macrolides, Azalides, and Ketolides—cont'd

Drug	Indication	Dosage Form	Dose	Comments
				Erythromycin estolate, erythromycin ethylsuccinate, and some enteric-coated formulations of base can be taken without regard to meals. Should be taken with meals if GI upset occurs. Do not chew or crush erythromycin base. Suspensions should be shaken before measurement, using a calibrated dispensing spoon.
	Erysipelas or nonbullous impetigo due to *S. pyogenes*		*Adults:* 250–500 mg qid for 10 d *Children:* 20–50 mg/kg/d in divided doses for 10 d	As above
	Bullous impetigo or cellulitis due to *S. aureus*		*Adults:* 250 mg q6h or 500 mg q12h to maximum of 4 g/d *Children:* 20–50 mg/kg/d in divided doses	As above
	Community-acquired pneumonia, mild to moderate		*Adults:* 250–500 mg q6h for 10–14 d; treat severe mycoplasma pneumonia with higher dose up to 21 d *Children:* 20–50 mg/kg/d in divided doses for 10–14 d	As above
	Upper respiratory tract infection, mild to moderate, due to *S. pyogenes* or *S. pneumoniae*		*Adults:* 250–500 mg qid for 10 d *Children:* 20–50 mg/kg/d in divided doses for 10 d	As above
	Pertussis (whooping cough) due to *Bordetella pertussis*		*Adults:* 500 mg qid for 10 d *Children:* 40–50 mg/kg/d in divided doses for 10 d	As above
	Newborn conjunctivitis, pneumonia of infancy due to *C. trachomatis*		*Children:* 50 mg/kg/d in 4 divided doses for 14 d (conjunctivitis) or 21 d (pneumonia)	As above
	Urethral, endocervical, or rectal infections due to *C. trachomatis*		*Adults:* 500 mg qid for 7 d or 250 mg qid for 14 d (in pregnancy)	As above
	Nongonococcal urethritis; urethral, endocervical, or rectal infections due to *N. gonorrhoeae*		*Adults:* 500 mg qid for at least 7 d	As above

Table 24–16 ⊗ **Dosage Schedule: Macrolides, Azalides, and Ketolides—cont'd**

Drug	Indication	Dosage Form	Dose	Comments
	Primary syphilis		*Adults:* 20 g in divided doses over 10 d or 500 mg qid for 14 d	As above
	Endocarditis prophylaxis		*Adults:* 1 g 2 h before procedure, 500 mg 6 h after procedure *Children:* 20 mg/kg 2 h before procedure, 10 mg/kg 6 h after procedure	As above
Erythromycin ethylsuccinate and sulfisoxazole (Pediazole, Eryzole)	Acute otitis media	Granules for oral suspension: 200 mg erythromycin base activity and 600 mg ulfisoxazole/ 5 mL	*Children:* 50 mg/kg/d erythromycin and 150 mg/kg/d (to a maximum of 6 g/d) sulfisoxazole in four evenly divided doses for 10 d	May be taken without regard to meals. Not for use in infants <2 mo.
Telithromycin (Ketek)	Community-acquired pneumonia	Tablets: 400 mg	800 mg daily for 7–10 d	Tablets should be swallowed whole and may be taken with or without food.

adult outpatient with no cardiopulmonary disease, no antibiotics in the past 3 months (no risk for DRSP), and no modifying factors is to treat with an advanced-generation macrolide (level I evidence), such as azithromycin or clarithromycin (Mandell et al, 2007). Usual dosages are azithromycin 500 mg once on day 1, followed by 250 mg daily on days 2 to 5, or 500 mg daily for 3 days (for children, 10 mg/kg on day 1, then 5 mg/kg on days 2 to 5); or clarithromycin 500 mg twice daily for 7 to 14 days (for children, clarithromycin 7.5 mg/kg twice daily). Outpatient treatment of infants and children for CAP may also be erythromycin 10 mg/kg orally 4 times daily (Bradley et al, 2011).

It is desirable to obtain sputum for culture and Gram's stain so that the treatment may be more directed, but it is impossible to identify a pathogen in up to 50% of patients with CAP. Consequently, treatment often proceeds empirically. Macrolides have high cross-resistance (50%) for highly penicillin-resistant *S. pneumoniae* strains. If the adult patient's condition deteriorates or is not improving by 48 to 72 hours, a switch to a respiratory fluoroquinolone with extended gram-positive spectrum (e.g., levofloxacin) is indicated. Detailed discussion of pneumonia and its management is found in Chapter 42.

Sexually Transmitted Infections

Nongonococcal and postgonococcal urethritis or cervicitis is most commonly caused by *C. trachomatis* (50%) or *M. hominis.* Other etiologies such as *Ureaplasma, Trichomonas, M. genitalium,* and viruses account for 10% to

15% of cases. Azithromycin 1 g as a single oral dose is a drug of choice for nongonococcal urethritis and cervicitis (CDC, 2010e). If the urethritis is recurrent or persistent, therapy includes metronidazole 2 g as a single oral dose to cover *Trichomonas,* plus azithromycin 1 g as a single dose if not used for the initial episode. If cervicitis is recurrent or persistent, the woman should be reevaluated for possible reexposure to a STI (CDC, 2010e).

Azithromycin is also first-line treatment of chancroid as a single oral dose of 1 g. An alternative is erythromycin base 500 mg orally 4 times daily for 7 days (CDC, 2010e). Azithromycin is commonly prescribed as part of the treatment of gonococcal urethritis and cervicitis as a 1 g oral dose to cover the chlamydial infections that often coexist with gonorrhea. Azithromycin is no longer indicated in the treatment of pelvic inflammatory disease due to *C. trachomatis, M. hominis,* or *N. gonorrhoeae* because of resistance (CDC, 2010e). Azithromycin 2 g as a single dose may be used as a second-line therapy for penicillin-allergic patients with early syphilis, although this has not been well studied and treatment failure has been noted (CDC, 2010e). Sexually transmitted infections are discussed in more detail in Chapter 44, Sexually Transmitted Infections.

Mycobacterium avium Complex

Infections with the nontuberculous mycobacterial organism *Mycobacterium avium* complex (MAC) occur in up to 40% of patients with AIDS. Advanced immunosuppression is the major risk factor for MAC. Patients with AIDS are thought

to acquire this organism, usually resident in water and soil, by respiratory or GI routes. The syndrome presents with high fever, diarrhea, night sweats, weight loss, anemia, and neutropenia. Diagnosis is usually based on blood culture, although it is sometimes identified on biopsy of the liver, bone marrow, or lymph nodes. MAC prophylaxis is now strongly recommended for HIV-infected adults with a mean CD4 lymphocyte count of fewer than 50 cells/mL.

The first-line drug is clarithromycin at dosages listed in Table 24-16. An alternative treatment is azithromycin if clarithromycin is not tolerated (Benson, Kaplan, Masur, Pau, & Holms, 2004). Before prophylaxis is initiated, patients should be evaluated to assure they do not have active MAC or *Mycobacterium tuberculosis.* National guidelines indicate that treatment of MAC should include at least two antimicrobials to prevent or delay resistance, one of which should be either clarithromycin or azithromycin (Benson et al, 2004). Of these, clarithromycin, 500 mg twice daily, has the greatest evidence for efficacy (Benson et al, 2004). HIV infection and its management are discussed in Chapter 37.

Peptic Ulcer Disease

Most patients with peptic ulcers who are or are not taking NSAIDs have evidence of *H. pylori.* Eradication of *H. pylori* is recommended for all peptic ulcer patients with an active ulcer, a history of ulcer complications, or a need for maintenance therapy. Duodenal and gastric ulcers recur in up to 80% of patients treated with drugs to reduce gastric acid but not treated for eradication of *H. pylori* infection. Multiple treatment regimens for *H. pylori* eradication are available, including combining a proton pump inhibitor (PPI) and two antibiotics for 14 days (Lew, 2009). Antimicrobial agents used include clarithromycin, tetracycline, amoxicillin, levofloxacin, and metronidazole. They are given in three or four drug regimens with PPIs and bismuth subsalicylate. Approved combinations are included in Table 34-8 (Chap. 34). Two regimens include the macrolide antibiotic clarithromycin (500 mg twice daily).

Endocarditis Prophylaxis

The American Heart Association and the American College of Cardiology published joint updated guidelines for endocarditis prophylaxis in 2008, narrowing the recommendation for therapy to only those with prosthetic heart valves, previous infective endocarditis, certain patients with congenital heart disease, and cardiac transplant patients with valve regurgitation who are undergoing dental procedures that involve manipulation of either gingival tissue or the periapical region of the teeth (Nishimura et al, 2008). For patients who can take oral medications but are allergic to penicillins, a single dose of 500 mg of azithromycin or clarithromycin for adults or 15 mg/kg for children is indicated for endocarditis prophylaxis 1 hour before the procedure.

Exacerbations of Chronic Bronchitis

In patients with chronic obstructive pulmonary disease (COPD), presence of at least two of the three cardinal symptoms warrants treatment with antibiotics: increased sputum volume, increased sputum purulence, and increased dyspnea. Any of the macrolides are active against the most common pathogens (see the discussion in the penicillin section for a list of pathogens) and are appropriate first-line choices (Rabe et al, 2007). Length of treatment is 7 to 14 days. Asthma and bronchitis and their management are discussed in Chapter 30.

Upper Respiratory Infections

The common bacterial infections in the upper respiratory tract include acute otitis media (AOM), sinusitis, and pharyngitis. *S. pneumoniae, H. influenzae,* and *M. catarrhalis* are the most common pathogens found in both children and adults. Amoxicillin or amoxicillin-clavulnate is the recommended first-line treatment for both AOM and sinusitis. *S. pneumoniae* is resistant to the common macrolides erythromycin (35.3% resistance), azithromycin (35.3% resistance), and clarithromycin (35.2% resistance) (Jenkins & Farrell, 2009). A meta-analysis of 10 trials indicated greater likelihood of clinical failure if macrolides were prescribed, specifically azithromycin or clarithromycin (Courter et al, 2010). Thus the macrolides are no longer considered agents for AOM or sinusitis. The macrolides are also used for treatment of GABHS pharyngitis in penicillin-allergic patients. Dosages are shown in Table 24-16.

Skin or Soft Tissue Infections

Macrolides are primarily indicated for skin and soft tissue infections in penicillin-allergic patients, although they are not first-line treatment because of resistance. Oral and topical erythromycin has been used in the treatment of acne (see Chap. 32).

Other Uses

An accepted off-label use for erythromycin is Lyme disease in individuals who are allergic to penicillin and in children younger than age 9. However, erythromycin may be less effective than amoxicillin or doxycycline, possibly because of erratic absorption. Other accepted off-label uses for erythromycin include treatment of actinomycoses, anthrax, lymphogranuloma venereum, and relapsing fever caused by *Borrelia* species. Erythromycin and azithromycin are considered drugs of first choice for *C. jejuni.* Erythromycin is indicated in the treatment of listeriosis caused by *L. monocytogenes* and in diphtheria prophylaxis and treatment. It has been used in conjunction with oral neomycin for preoperative preparation of the bowel. Erythromycin is also approved for treatment of erythrasma caused by *Corynebacterium minutissimum.* Erythromycin is an agonist at the motilin receptor and has been effective in the treatment of gastroparesis.

Erythromycin ophthalmic ointment 0.5% is administered to all newborns to prevent ophthalmic neonatorum. During a shortage of erythromycin ointment in 2009, the CDC recommended azithromycin ophthalmic drops as an alternative, off-label treatment, but when the shortage ended the CDC issued a statement that alternatives to erythromycin ointment should no longer be used (CDC,

2010a). Erythromycin is indicated in chlamydial conjunctivitis in newborns and chlamydial pneumonia in infants caused by *C. trachomatis.* There are limited studies regarding the use of azithromycin for chlamydial pneumonia in infants, dosed at 20 mg/kg/day for 3 days (AAP, 2012f).

Rational Drug Selection

Both definitive drug selection and empirical drug selection follow the same principles described in the Rational Drug Selection section for the penicillins. Macrolides, azalides, or ketolides are often selected for susceptible organisms as alternatives in penicillin-allergic patients. Azithromycin and clarithromycin have a slightly broader spectrum than erythromycin and additional indications, such as MAC and *H. pylori.* Because of its long history, erythromycin has accumulated indications for which the newer agents have not been tested.

Increasing resistance of *H. influenzae, Staphylococcus,* and *S. pneumoniae* may increasingly limit the utility of macrolides for common bacterial infections. After consideration of antimicrobial activity and the disease state being treated, the selection of a specific macrolide may be based on cost, convenience, and adverse effect profile. Erythromycin salts are substantially less expensive than the newer drugs but have more adverse GI effects. The improved bioavailability and milder GI effects of the erythromycin estolate salt are offset by the risk of cholestatic jaundice in adults. This agent should not be prescribed for individuals with liver impairment. Patients with a history of cardiac arrhythmia or QT prolongation should avoid erythromycin or be carefully monitored. Azithromycin may be selected over erythromycin, clarithromycin, or telithromycin if the patient is taking interacting drugs whose hepatic metabolism is subject to inhibition.

Erythromycin is generally preferred over the newer agents during pregnancy and for very young infants because of greater accumulated clinical experience. A major reason for selection of azithromycin over other drugs is the enhanced compliance caused by its convenient dosing schedule. However, with its once-per-day dosing and short duration of 3 to 5 days, a single missed dose could jeopardize the successful outcome. There are no indications for dirithromycin over other drugs.

Monitoring

Monitoring for therapeutic response to antibiotics is described in the Monitoring section for penicillins. Because erythromycin, clarithromycin, and telithromycin inhibit the metabolism of many drugs, observation for altered response to concurrent medications metabolized by CYP 3A4 is essential, beginning with the first dose and continuing for several half-lives of the drugs after it is discontinued. Patients taking drugs with narrow therapeutic margins require extra scrutiny if they are taking any macrolide.

Individuals with a history of hearing loss may be at increased risk for further hearing loss, especially if they have hepatic or renal impairment and are taking high doses (more than 4 g/d) of erythromycin. These risk factors may indicate audiometric testing at baseline and whenever there is clinical evidence of hearing loss (e.g., dizziness, fullness in the ears). The hearing loss is usually reversible; it occurs from 36 hours to 8 days after treatment is initiated and begins to recover 1 to 14 days after the drug is discontinued.

ECG monitoring of QT interval is particularly recommended for patients at high risk for torsades de pointes. If the patient develops malaise, nausea, vomiting, skin rash, abdominal pain, or jaundice within 1 to 2 weeks after therapy is initiated, the drug should be discontinued and liver function tests initiated to assess for cholestatic jaundice.

Patient Education

Administration

Doses of macrolides should be evenly spaced for the best effect. Azithromycin and telithromycin are given once daily. Suspensions must be shaken thoroughly before administration, and excess medication should be discarded after the prescribed therapy is administered and never used by another individual or by the same patient for a different episode. Because it is irritating to the GI mucosa, erythromycin should be taken with a full 8 oz glass of water by adults and with at least 4 to 6 oz by children.

Food interactions are complex for these drugs. Azithromycin tablets, the adult single-dose azithromycin packet, clarithromycin, erythromycin estolate, and telithromycin can be taken without regard to meals. Erythromycin stearate, most brands of erythromycin base, erythromycin ethylsuccinate, azithromycin capsules, and azithromycin suspension must be taken on an empty stomach 1 hour before or 2 hours after eating. Dirithromycin should be taken with food or within an hour of a meal. Erythromycin ethylsuccinate has improved bioavailability if taken with food.

Because the requirements for administration with respect to food may vary by brand, the package insert is the best guide for erythromycin base. Tablets of erythromycin base, erythromycin stearate, and dirithromycin should not be chewed or crushed. If chewable tablets of erythromycin ethylsuccinate are prescribed, the necessity for chewing the dosage form should be stressed. If pediatric drops of erythromycin estolate (100 mg/mL) or erythromycin ethylsuccinate are prescribed, the prescription should specify dispensing a calibrated dropper, and the parent should be instructed on proper measurement and oral administration technique; parents have occasionally assumed drops were meant to be administered in the ear. The adult single-dose azithromycin packet should be thoroughly mixed with 2 oz (60 mL) of water and consumed immediately. An additional 2 oz of water should be added to the container, mixed, and ingested to ensure consumption of the entire dose. This form should not be used for doses greater than 1,000 mg.

Adverse Reactions

Taking erythromycin with a full glass of water decreases the GI symptoms that are the most common adverse effects. Because patients often discontinue the medication if adverse

effects are intolerable, they should be urged to call the prescriber if GI distress becomes severe so that an alternative drug can be prescribed. Patients who experience signs of liver impairment (malaise, nausea, vomiting, abdominal cramps, skin rash, fever, or jaundice) should discontinue the macrolide and call the prescriber immediately. Syncope may indicate torsades de pointes related to cardiac QT interval prolongation and should also be reported. Other patient education includes information about symptoms of superinfection that is part of the education for all antibacterial drugs.

Lifestyle Management

See the Lifestyle Management section for the penicillins.

FIDAXOMICIN

Fidaxomicin (Dificid) is a macrocyclic antibiotic, currently classified as an 18-ring macrolide, which was approved by the FDA in 2011 for the treatment of *C. difficile* infection (CDI). It is not discussed in the macrolide section of this chapter because its mechanism of action, spectrum of antimicrobial activity, pharmacokinetics, and use are very different than those of the typical macrolides.

Pharmacodynamics

Fidaxomicin binds to RNA polymerase and thus inhibits RNA synthesis. Fidaxomicin is bactericidal, as is its active metabolite OP-1118.

Spectrum of Activity

Fidaxomicin has activity primarily against *Clostridium* species, *C. difficile* in particular. Minimal activity was found for staphylococci, enterococci, or *Bacteroides* spp. (Biedenbach, Ross, Putnam, & Jones, 2010; Finegold et al, 2004).

Resistance

Resistance to fidaxomicin is rare and is not related to resis - tance with other macrolides or other antibiotic classes.

Pharmacokinetics

Absorption and Distribution

Fidaxomicin is administered orally, but minimal amounts of drug are absorbed. Maximum plasma concentrations occur 1 to 5 hours after an oral dose. Plasma concentrations are higher in patients diagnosed with CDI than in healthy adults and range from 2 to 179 ng/mL. Fidaxomicin may be taken with or without food.

Metabolism and Excretion

Fidaxomicin is metabolized in the intestine primarily through hydrolysis. It does not undergo metabolism through CYP450 enzymes. Greater than 92% of fidaxomicin is excreted in feces, and 0.59% is excreted in the urine. Serum levels were not impacted by renal impairment.

Pharmacotherapeutics

Precautions and Contraindications

The only contraindication listed by the manufacturer is a preexisting allergy to fidaxomicin or any components of the product. Use caution if a patient has a macrolide allergy. Althought the impact of hepatic impairment on dosing has not been fully evaluated, dosage adjustments are not recommended by the manufacturer.

Fidaxomicin is Pregnancy Category B, but clinical trials in humans have not been conducted. It is unknown if fidaxomicin is excreted in human breast milk; therefore, caution is advised. Safety has not been evaluated in persons under 18 years of age.

Adverse Drug Reactions

Allergic reactions including acute dyspnea, angioedema, rash, and pruritis have been observed. In clinical trials, GI disturbances were reported in less than 6% of patients; however, these findings were consistent with CDI symptoms and had similar rates to the comparator.

Drug Interactions

Fidaxomicin may have synergistic effects with rifampin or rifaximin. No antagonistic or enhanced effects have been noted with other medications.

Clinical Use and Dosing

Fidaxomicin should only be used for CDI. In clinical trials comparing fidaxomicin to oral vancomycin, noninferiority was achieved for clinical cure. However, for non-NAP1 strains, recurrent CDI was reduced in the fidaxomicin group (Golan & Epstein, 2012). The dose of fidaxomicin for CDI is 200 mg orally twice daily for 10 days. Fidaxomicin is only available as a 200 mg tablet.

Rational Drug Selection

Fidaxomicin treatment should only be initiated for documented or highly suspected CDI. Although fidaxomicin is highly effective, safe, and has the least impact on gastrointestinal microbes, its cost has severely limited its use. Because of cost, fidaxomicin use may be limited to patients at high risk for recurrent CDI.

Monitoring

Monitoring for therapeutic response to antimicrobial drugs is described in the Monitoring section for penicillins.

Patient Education

Fidaxomicin should be taken twice daily with doses evenly spaced. It can be taken with or without food. The full course of prescribed therapy should be completed. Patients should consult their health-care provider if diarrhea does not resolve or worsens. Patients should also contact their health-care provider if a rash or other allergic symptoms develop.

OXAZOLIDINONES

Linezolid (Zyvox), approved in the United States in 2000, is the first drug in a new class of antibiotics, the oxazolidinones. Each antibiotic developed within the past 60 years has seen the emergence of resistant organisms. Recently, there has been a specific need to develop drugs effective against methicillin-resistant, penicillin-resistant, and vancomycin-resistant strains of bacteria that have produced serious illness. Unfortunately, although new variants of drugs within a class have created subclasses (e.g., azalides and ketolides), no entirely new class of antibiotics has been developed since the 1980s (Mollering, 2003). The oxazolidinones represent a unique class of totally synthetic antibiotics that make the development of naturally occurring resistance mechanism less likely.

Pharmacodynamics

The oxazolidinones are inhibitors of bacterial ribosomal protein synthesis, but unlike other antibiotics they stop the first step in synthesis in which bacteria assemble ribosomes from their dissociated subunits. Linezolid does this by binding to the 50S ribosomal subunit, thus preventing the formation of a 70S initiation complex required for protein synthesis. No other known antibiotic uses this process, so there is no cross-resistance.

Spectrum of Activity

Linezolid is bacteriostatic against most organisms, including staphylococci and enterococci, and bactericidal against others. It is most effective against aerobic gram-positive bacteria. The in vitro spectrum of activity also includes a small number of gram-negative and anaerobic bacteria. The main susceptible organisms include group A and B *Streptococcus, S. pneumoniae, E. faecalis, E. faecium, S. aureus* (both MSSA and MRSA), *S. epidermidis, C. perfringens, Peptostreptococcus* spp., *Corynebacterium jeikeium,* and *L. monocytogenes.* It is weakly effective against *H. influenzae* and *M. catarrhalis.* Linezolid also exhibits some activity against *M. tuberculosis.*

Resistance

Although linezolid resistance is not widespread and considered uncommon, reports of resistance emerged as early as 2002 (Auckland et al, 2002; Bersos, Maniati, Kontos, Petinaki, & Maniatis, 2004). Resistance has been reported in enterococci (*E. faecalis* and *E. faecium*) (Kainer et al, 2007). Linezolid resistance in *S. aureus* is associated with previous linezolid exposure, and linezolid-resistant *S. aureus* outbreaks have been reported in the hospital setting. (Sanchez Garcia et al, 2010)

Pharmacokinetics

Absorption and Distribution

Linezolid is rapidly and completely absorbed after oral administration. Food slightly delays its uptake but does not affect the total amount of drug absorbed. Linezolid may be taken without regard to meals. It is only 31% protein bound and the binding is concentration-dependent. High drug concentrations are found in the skin and other well-perfused tissues. Breast milk concentrations are similar to those in the maternal plasma.

Metabolism and Excretion

There are two inactive metabolites of linezolid created by oxidation of the morpholine ring. Because this is a nonenzymatic oxidation, this drug does not induce the CYP450 system. Nonrenal excretion accounts for 65% of the total clearance; of the remainder, 30% is excreted unchanged in urine. A small degree of nonlinearity in clearance is observed with increasing doses; however, the difference is small and not clinically significant. No dosage adjustments are required for impaired hepatic or renal function.

Clearance is altered by age; it is most rapid in the youngest age group (age 1 week to 11 years). As the age of the child increases, the clearance decreases and reaches that of the adult population during adolescence. Once again, no dosage adjustments are required, except for preterm neonates younger than 7 days because they have lower clearance values. Table 24-17 presents the pharmacokinetics of this drug.

Pharmacotherapeutics

Precautions and Contraindications

Concomitant use or use within 2 weeks of a monoamine oxidase inhibitor (MAOI) with linezolid is contraindicated. Linezolid should be used with caution with other drugs that interact with MAOIs because this may result in serotonin syndrome or increased blood pressure.

Myelosuppression (anemia, leucopenia, pancytopenia, and thrombocytopenia) has been reported in patients receiving linezolid; however, blood counts return to normal after linezolid is discontinued. Complete blood counts should be monitored weekly if a patient is on linezolid for longer than 2 weeks.

Lactic acidosis has been reported with the use of linezolid. Patients with recurrent nausea or vomiting, unexplained acidosis, or low bicarbonate level should be evaluated.

Use of linezolid for periods longer than 28 days has been associated with peripheral neuropathy and optic neuropathy.

Table 24–17 ❖ Pharmacokinetics: Oxazolidinones

Drug	Onset (h)	Peak (h)	Duration (h)	Protein Binding	Bioavailability	Half-Life (h)	Elimination
Linezolid	Rapid	1–2	12	31%	100%	4.4–5.5	30%–35% in urine; 65% nonrenal elimination

Linezolid is Pregnancy Category C. In animal studies, fetal toxicities were seen only at ranges that produced maternal toxicity. There are no adequate, well-controlled studies in pregnant women, so use during pregnancy only if the potential benefit clearly outweighs the potential risk to the fetus. Because this drug is excreted in breast milk in concentrations similar to those in maternal plasma, consider the benefit to the mother in choosing to continue the drug and/or to discontinue breastfeeding.

Linezolid is approved for use in children from birth. Preterm infants and neonates require reduced dosing per 24 hours because of reduced clearance.

Adverse Drug Reactions

The most common adverse reactions reported were diarrhea (2.8% to 11%), headache (0.5% to 11.3%), and nausea (3.4% to 9.6%). Although uncomfortable, none created serious medical consequences. CDI has been reported with nearly all antibiotics. Detection and management of CDI were described earlier. Myelosuppression has been reported, but it resolves with discontinuance of the drug. This adverse event seems to be related to duration of therapy (longer than 2 weeks). Consider discontinuing the drug if the patient develops or has worsening myelosuppression.

Drug Interactions

Linezolid was originally developed as a monoamine oxidase inhibitor (MAOI) and has properties of that inhibition. Indirect-acting sympathomimetics, vasopressors, or dopaminergic drugs may have increased effects when given concurrently, requiring decreased doses of these drugs. Because linezolid is a reversible, nonselective inhibitor of monoamine oxidase, it also has potential interactions with serotonergics such as SSRIs, tricyclic antidepressants, ondansetron, meperidine, buspirone, methadone, and tramadol. Signs and symptoms of serotonin syndrome (e.g., hyperpyrexia and cognitive dysfunction) should be watched for if concomitant therapy is required. There is also potential interaction with tyramine-rich foods and beverages. They do not need to be eliminated entirely but should not be eaten in large quantities (Table 24-18).

Clinical Use and Dosing

Pneumonia and Complicated Skin and Skin Structure Infections

The adult dose is 600 mg every 12 hours for 10 to 14 days. In pediatric patients (birth to 11 years), the dose is 10 mg/kg every 8 hours for 10 to 14 days. In each case linezolid is useful only for susceptible bacteria and only after older, less expensive agents have been tried and are found to be ineffective. The goal is to keep any new antibiotic free from resistant strains of bacteria as long as possible. It should be remembered that linezolid has poor activity against *H. influenzae* and none against *M. pneumoniae,* two common pneumonia organisms. The FDA approval for CAP is for susceptible strains of *S. pneumoniae* or *S. aureus* only.

Uncomplicated Skin and Skin-Structure Infections

The dosage is less for these uncomplicated infections and it varies with age. For adults, linezolid is approved for 400 mg every 12 hours; however, this strength is no longer available in the United States so 600 mg every 12 hours is typically prescribed. For adolescents, the recommended dose is 600 mg every 12 hours; for children aged 5 to 11 years, it is 10 mg/kg every 12 hours; and for young children (younger than 5 years), the dose is 10 mg/kg every 8 hours due to the renal clearance issues discussed above. Once again, it is not first-line therapy and is intended for resistant organisms.

Vancomycin-Resistant *Enterococcus faecium* Infections

A very useful indication for linezolid is the treatment of infections caused by vancomycin-resistant *Enterococcus*. The dose for this indication is 600 mg every 12 hours for adults and 10 mg/kg every 12 hours for children from birth to 11 years. The duration of therapy should be determined by the disease state being treated and patient response. Because these infections may include infected hardware, bone, or other deep-seated infections, long durations may be warranted. It should be noted that 28-day treatment is the outer limit of duration that has been evaluated in clinical trials and has been associated with more adverse effects, including lactic acidosis and neuropathies. Dosage schedules are found in Table 24-19.

Table 24–18 ⋙ Drug Interactions: Oxazolidinones

Drug	Interacting Drug	Possible Effect	Implications
Linezolid	Adrenergic (sympathomimetic) drugs (e.g., dopamine and epinephrine)	Increased action of the interacting drug	Reduce and titrate initial doses of interacting drug, monitor blood pressure
	Monoamine oxidase inhibitors	Increased risk of serotonin syndrome	Discontinue interacting drug 2 weeks before starting linezolid
	Serotonergics (e.g., SSRIs)	Development of serotonin syndrome	Watch for serotonin syndrome indications. Avoid concurrent use unless no appropriate alternative
	FOOD INTERACTIONS Tyramine-rich foods and drinks	Significantly increased blood pressure	No need to delete entirely from diet, but quantities of tyramine eaten should not exceed 100 mg/meal

Table 24–19 ⊗ **Dosage Schedules: Oxazolidinones**

Drug	Indication	Available Dosage Forms	Dose	Comments
Linezolid (Zyvox)	Community-acquired pneumonia and complicated skin and skin-structure infections	Tablets: 600 mg Powder for oral suspension: 100 mg/5 mL	*Adults:* 600 mg q12h for 10–14 d *Children birth–11 yr:* 10 mg/kg q8h for 10–14 d	May be administered without regard to food, but amount of tyramine-rich food in any meal should be kept low (<100 mg/meal)
	Uncomplicated skin and skin-structure infections		*Adults:* 600 mg q12h for 10–14 d *Adolescents:* 600 mg q12h for 10–14 d *Children 5–11 yr:* 10 mg/kg q12h	Oral suspensions should be gently inverted 3–5 times to mix; do not shake
			Children <5 yr: 10 mg/kg q8h	Store at room temperature
	Vancomycin-resistant *Enterococcus faecium* infections		*Adults:* 600 mg q12h for duration as indicated by site of infection *Children birth–11 yr:* 10 mg/kg q8h	Duration of therapy beyond 14 d is associated with more adverse effects

Note: Most preterm neonates <7 d of age (gestational age <34 wk) have lower systemic linezolid clearance values and larger AUC values than many full-term neonates and older infants. These neonates should be initiated with a dosing regimen of 10 mg/kg q12h. Consideration may be given to the use of 10 mg/kg q8h regimen in neonates with a suboptimal clinical response. All neonatal patients should receive 10 mg/kg q8h by 7 days of life (Zyvox label).

Rational Drug Selection

Although very effective for the treatment of infections caused by MRSA and VRE, linezolid's prohibitive cost, potential for drug interactions, and adverse effects associated with long-term administration have severely limited its use in the ambulatory care setting. However, with increased MRSA infections in the community, a new focus on reducing hospital admissions and length of stays, and an oral generic formulation expected in 2015, linezolid use will likely increase. Linezolid's high oral bioavailability allows for a cost-advantageous alternative to intravenous vancomycin for the treatment of complicated skin and skin-structure infections (Barron, Turner, Jaeger, Adamson, & Singer, 2012). Linezolid's use should be reserved for moderate to severe infections in which alternative antibiotics are less desirable secondary to efficacy, resistance, safety, route, or cost.

Monitoring

Because of the risk for myelosuppression, a complete blood count should be done prior to therapy at baseline and weekly if therapy exceeds 14 days.

Patient Education

Administration

Patient counseling for all antibiotics includes advice to complete the entire course of therapy, take the drug as prescribed on an evenly spaced schedule, and not double missed doses. Linezolid may be taken with or without food but should be taken with a full glass of water. Because significantly elevated blood pressure may occur if taken with tyramine-rich foods, the amount of tyramine consumed at any one meal should be limited (less than 100 mg/meal). Oral suspensions should be gently inverted 3 to 5 times to mix; do not shake. The drug should be stored at room temperature.

Adverse Reactions

The main adverse reactions are diarrhea, headache, and nausea. Diarrhea should be reported to the health-care provider. Blood, pus, or mucus in the stool may indicate a serious problem that requires treatment. Otherwise, an antidiarrheal medication may be suggested by the provider. Patients should be instructed to consult their health-care provider if any of the following occur: visual changes; severe nausea or vomiting, or unusual bruising or bleeding.

Lifestyle Management

Lifestyle management is the same as discussed in the section on penicillins.

On The Horizon **TEDIZOLID**

Tedizolid is a next-generation oxazolidinone in development. It has greater potency than linezolid and a similar antimicrobial spectrum, including but not limited to MRSA, VRE, streptococci, and *M. tuberculosis*. Clinical trials with up to 21 days of therapy have not demonstrated myelosuppression. Preliminary testing suggests that tedizolid has lower potential than linezolid for MAOI drug and food interactions (Flanagan, Bartizal, Minassian, Fang, & Prokocimer, 2013). Like linezolid, tedizolid has excellent oral bioavailability and tissue penetration (Urbina et al, 2013).

SULFONAMIDES, TRIMETHOPRIM, NITROFURANTOIN, AND FOSFOMYCIN

The sulfonamides were once major antibacterials, but the development of resistant strains of bacteria and the incidence of allergic reactions to sulfa drugs resulted in their largely being relegated to treatment of UTIs, alternative therapy options for drug-resistant organisms, and treatment of specific infections in immunocompromised hosts, like nocardiosis and toxoplasmosis. Sulfasalazine (Azulfidine) is used in the treatment of ulcerative colitis and rheumatoid arthritis for its anti-inflammatory properties rather than for treatment of infection. Mafenide (Sulfamylon) and silver sulfadiazine (Silvadene) are used to prevent infection in patients with burns. Topical applications such as those for burns are not discussed in this chapter. Included in this section are drugs commonly used in combination with sulfonamides, such as trimethoprim (Proloprim, Trimpex), and agents used to treat UTIs, such as nitrofurantoin (Furadantin, Macrodantin) and fosfomycin (Monurol). The combination formulation trimethoprim-sulfamethoxazole (Bactrim, Septra, TMP-SMZ) is also considered in this section.

Pharmacodynamics

Sulfonamides and trimethoprim both have distinctive pharmacodynamic properties that are enhanced when combined.

Sulfonamides

Sulfonamides exert their bacteriostatic action by competitive inhibition of dihydrofolate synthetase, which is necessary for the conversion of para-aminobenzoic acid (PABA) to dihydrofolic acid. Inhibition of this pathway prevents folic acid synthesis, which is required by susceptible organisms for production of purines and nucleic acids. Microorganisms that use exogenous folic acid or do not synthesize folic acid are not susceptible to sulfonamides. Clinical use of sulfonamides as monotherapy is uncommon. Sulfamethoxazole is combined with trimethoprim, as described below with trimethoprim.

Spectrum of Activity

Sulfonamides inhibit both gram-positive and gram-negative bacteria. Susceptible organisms include *E. coli, Enterobacter, Klebsiella, Salmonella, S. pyogenes, S. pneumoniae, H. influenzae, Nocardia,, N. gonorrhoeae,* and some protozoa (*Pneumocystis jiroveci* and toxoplasmosis).

Resistance

The increasing frequency of resistant organisms limits the use of sulfonamides in chronic and recurrent UTI. In addition, resistance has increased in streptococci and limited their role in skin (other than MRSA infections) and upper respiratory tract infections. Mutations that result in excessive production of PABA cause organisms to develop resistance.

Dihydropteroate synthetase with a low sulfonamide affinity may be encoded on a plasmid that is transmissible and can be disseminated rapidly and widely. Cross-resistance between sulfonamides is common.

Trimethoprim

Trimethoprim inhibits bacterial dihydrofolic acid reductase. Dihydrofolic acid reductases convert dihydrofolic acid to tetrahydrofolic acid, a stage leading to the synthesis of purines and ultimately to DNA. When given with a sulfonamide, it produces a sequential blocking in the metabolic sequence, resulting in synergistic activity of both drugs. This combination is often bactericidal. The widely used formulation trimethoprim-sulfamethoxazole (TMP-SMZ) illustrates the synergy of the combination.

Spectrum of Activity

Trimethoprim is active against both gram-positive and gram-negative organisms. Gram-positive organisms include *S. pneumoniae,* and staphylococci. Its spectrum of gram-negative organisms includes *Citrobacter, Enterobacter, E. coli, K. pneumoniae, P. mirabilis, Stenotrophomonas, H. influenzae, B. pertussis, Nocardia, Salmonella,* and *Shigella.* Some *Serratia* and the protozoan *P. carinii* are also susceptible. Although enterococci may be susceptible to TMP/SMZ in vitro, these agents may not be effective because enterococci have the ability to utilize extrinsic folic acid.

Resistance

Resistance results from reduced cell permeability, overproduction of dihydrofolate reductase, or production of an altered reductase with less drug-binding ability. Mutation is possible, but the most common cause is plasmid-encoded resistant reductases. As with the sulfonamides, dissemination of resistance is rapid and widespread.

Nitrofurantoin

Nitrofurantoin is a synthetic nitrofuran that is activated by bacteria to reactive intermediates that inactivate or alter bacterial ribosomes and other macromolecules. Ultimately, protein synthesis, aerobic energy metabolism, DNA and RNA synthesis, and cell wall synthesis are inhibited. Nitrofurantoin is bacteriostatic in low concentrations and bactericidal in high concentrations in the urine.

Spectrum of Activity

Nitrofurantoin is active against most gram-positive cocci and gram-negative bacilli that cause UTIs. These include *Staphylococcus saprophyticus* and other *Staphylococcal* spp.*, Enterococcus* spp.*, E. coli, Klebsiella,* and *Citrobacter* spp. Most strains of *Enterobacter, Proteus,* and *Serratia* are resistant. It has no activity against *Pseudomonas* species.

Resistance

Among susceptible organisms, resistant mutants are rare. Some plasmid-mediated resistance transferable to susceptible organisms has been demonstrated. There is no cross-resistance between this drug and other antibacterial agents.

Fosfomycin

Fosfomycin is a bactericidal antibiotic available in the United States only as an oral formulation for the treatment of urinary tract infections. Fosfomycin inactivates the enzyme enolpyruvyl transferase, which ultimately leads to inhibition of cell wall synthesis. It is beneficial in the treatment of urinary tract infections because it reduces adherence of bacteria to the epithelial cells in the urinary tract.

Spectrum of Activity

Fosfomycin has clinical activity against most urinary pathogens, including *S. saprophyticus*, *Enterococcus*, *E. coli, Citrobacter, Enterobacter, Klebsiella*, indole-negative *Proteus, Serratia*, and some strains of *Pseudomonas*.

Resistance

Resistance to fosfomycin is uncommon but has been reported. The bacterial mechanisms of resistance most commonly described are enzymatic modification of fosfomycin.

Pharmacokinetics

Absorption and Distribution

Oral sulfonamides are absorbed readily from the GI tract. They are distributed widely throughout the body and found in all body tissues. They readily enter the CSF, pleura, synovial fluids, and the eye. They cross the placenta and enter breast milk. They are bound to plasma proteins in varying degrees. "Free" serum levels of 5 to 15 mg/dL are therapeutically effective for most infections.

Trimethoprim is also well absorbed following oral administration. It is widely distributed in body tissues, including prostatic tissues, and crosses the placenta. Distribution into breast milk occurs with high concentrations.

Nitrofurantoin is readily absorbed via oral administration. The macrocrystalline form is absorbed more slowly than the microcrystalline form, causing less GI distress. The monohydrate crystals are so slowly absorbed that twice-daily dosing is effective. Bioavailability is enhanced by taking nitrofurantoin with food. Because it undergoes rapid tubular secretion, therapeutic serum and tissue concentrations are achieved only in the urinary tract at usual oral doses. It is not effective in patients with severe renal impairment.

Fosfomycin has an oral bioavailability of 34% to 58%, which is not affected by food. Very little drug is protein bound. Fosfomycin distributes into the kidneys, bladder wall, prostate, and CSF fluid if the meninges are inflamed.

Metabolism and Excretion

Metabolism of sulfonamides occurs in the liver by conjugation and acetylation to inactive metabolites. Patients who are slow acetylators have increased risk for toxicity.

Renal excretion is mainly by glomerular filtration, with some acetylated metabolites being less soluble. Acetylated metabolites may produce crystalluria unless the urine is sufficiently alkaline and adequate fluid intake (more than 2,500 mL/d) is maintained. Sulfadiazine is especially prone

to this problem. Small amounts are excreted in feces, bile, breast milk, and other secretions.

Liver metabolism of trimethoprim is less than 20%. Eighty percent of this drug is excreted unchanged in the urine. Because it is so dependent on the kidney for excretion, elimination is delayed and its half-life is increased in patients with renal impairment.

Approximately 50% to 70% of nitrofurantoin is rapidly metabolized by body tissues to inactive metabolites. Plasma concentrations are low and prostatic fluid concentrations are negligible. However, nitrofurantoin crosses the placenta and enters breast milk. Renal excretion is via glomerular filtration and tubular secretion. Acidic urine enhances antibacterial activity and enhances tubular reabsorption, which increases its activity in renal tissues. Serum half-life is increased in patients with severe renal impairment. Usual doses produce therapeutic urinary levels in patients with normal renal function. If CCr is less than 40 mL/minute, urinary concentrations are not therapeutic, and the increased serum levels may produce toxicity.

Fosfomycin is eliminated as unchanged drug primarily through renal excretion (up to 60% of an oral dose) and in feces (18%). Therapeutic drug levels of fosfomycin are present at 48 hours after the initial dose. The half-life of fosfomycin is increased in the setting of renal impairment; however, urinary drug concentrations may be decreased.

Table 24-20 presents the pharmacokinetics of sulfonamides, trimethoprim, nitrofurantoin, and fosfomycin.

Pharmacotherapeutics

Precautions and Contraindications

There are a number of patients in which the sulfonamides, trimethoprim, and nitrofurantoin should be used cautiously. Such patients include those with glucose-6-phosphate dehydrogenase (G6PD) deficiency, renal impairment, and folate deficiency. Neither nitrofurantoin nor fosfomycin are indicated for the treatment of pyelonephritis or perinephric abscess.

Blood Dyscrasias or Glucose-6-Phosphate Dehydrogenase Deficiency

Sulfonamides should be used with caution in patients who have blood dyscrasias or G6PD deficiency. Serious adverse reactions secondary to direct toxic effects on the bone marrow have sometimes resulted in death. They include agranulocytosis, aplastic anemia, and other blood dyscrasias. Acute hemolytic anemia resulting in increased destruction of RBCs has resulted, usually with G6PD deficiency. Sore throat, fever, pallor, purpura, or jaundice may be early indications of these serious blood disorders. These problems occur only rarely with trimethoprim and with nitrofurantoin in conjunction with G6PD deficiency.

Renal Impairment

Sulfonamides should be used cautiously for patients with renal impairment. The more soluble drugs in this class (sulfisoxazole and sulfamethoxazole) are less likely to result

Table 24–20 ❖ **Pharmacokinetics: Sulfonamides, Trimethoprim, Nitrofurantoin, and Fosfomycin**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Nitrofurantoin	2.5–4.5 h	0.5 h	6–12 h	90%	87%–94%	20 min*	30%–50% unchanged in urine
Sulfadiazine	Varies	3–6 h	6–12 h	32%–56%	70%–100%	13 h	Mainly in urine; small amount in feces
Sulfamethoxazole	1 h	2–4 h	12 h	65%	90%–100%	7–12 h	Mostly by liver with 80%–100% excreted in the urine as metabolites or unchanged drug (20%)
Sulfamethoxazole/ trimethoprim	Rapid	2–4 h	6–12 h	65%/50%	80%/90%–100%	8–13 h	
Sulfisoxazole	1 h	2–4 h	4–6 h	90%	70%–100%	5–8 h	Mostly by liver
Trimethoprim	Rapid	1–4 h	12–24 h	50%	80%	8–11 h	80% unchanged in urine; 20% by liver
Fosfomycin	2–4 h	2 h	48 h	<10%	34%–58%	5.7 h	38% in the urine, 18% excreted in feces

UA = information not available.
   *Increased in renal impairment.

in renal complications. Adequate hydration (more than 2,500 mL/d) helps to prevent crystalluria and stone formation. Cautious use of trimethoprim is recommended for patients with renal impairment. Nitrofurantoin is contraindicated in patients with CCr less than 60 mL/min. Nitrofurantoin is not effective in severe renal impairment and patients are at increased risk of toxicity.

Folate Deficiency

Because of its effect on folic acid synthesis, trimethoprim should be used with caution for patients with folate deficiency. Folate supplementation may be administered concomitantly without interfering with antibacterial action.

Pregnancy

Sulfonamides are Pregnancy Category C. These drugs cross the placenta, and fetal levels average 70% to 90% of maternal serum levels. Significant levels may persist if they are given near-term. Sulfonamides are highly bound to plasma albumin and compete for binding sites with bilirubin, resulting in increased free bilirubin concentrations. In utero, the fetus clears free bilirubin through the placental circulation. After birth, this route is no longer available and unbound bilirubin may cross the blood–brain barrier. Do not use near-term. Jaundice, hemolytic anemia, and kernicterus have occurred. Teratogenicity has occurred in animal studies.

Trimethoprim is also Pregnancy Category C. It crosses the placenta, producing similar levels in fetal and maternal plasma. Teratogenicity has occurred in animal studies. Because it may interfere with folic acid metabolism, it should be used only when its benefits clearly outweigh fetal risks. The combination product, TMP/SMZ, is Pregnancy Category D for all trimesters.

Nitrofurantoin is Pregnancy Category B. Use for women of childbearing potential only when it is clearly needed. The

incidence of fetal changes in animal studies was low and the alterations minor. It should not be given, however, to pregnant patients at term, during labor and delivery, or when the onset of labor is imminent; it may induce hemolytic anemia in the newborn because of immature enzyme systems. For this reason, nitrofurantoin is contraindicated in infants younger than 1 month.

Fosfomycin is Pregnancy Category B, but limited safety information and the fact that fosfomycin crosses the placenta indicate caution in its use.

Lactation

Because sulfonamides are excreted in breast milk in low concentrations and milk to plasma ratios are as low as 0.5 to 0.6, the American Academy of Pediatrics considers breastfeeding safe during administration of sulfonamides. However, premature infants or those with hyperbilirubinemia or G6PD deficiency should not be breastfed while the mother is taking the drugs. Trimethoprim milk:plasma ratios are 1.25, indicating the drug concentrates in breast milk. Because it may interfere with folic acid metabolism, it should be used cautiously for nursing women. Nitrofurantoin is excreted in breast milk in very low concentrations. Infants with G6PD deficiency, however, should not nurse while the mother is receiving this drug. It is unknown if fosfomycin is excreted in breast milk. Its use during lactation cannot be recommended at this time due to lack of safety information.

Children

Sulfonamides are contraindicated in infants less than 2 months of age (except as adjunctive therapy with pyrimethamine for congenital toxoplasmosis). Insufficient clinical data are available on prolonged or recurrent therapy with sulfamethoxazole in children under 6 years with chronic renal disease. It is best to avoid its use in these patients.

Safety for use in infants younger than 2 months has not been established for trimethoprim. Nitrofurantoin is contraindicated in infants younger than 1 month.

Safety and effectiveness of fosfomycin in children under 12 years of age have not been well studied. In addition, the clinical studies for fosfomycin did not have sufficient numbers of patients over the age of 65 to detect a difference in therapeutic response as compared to younger patients.

Adverse Drug Reactions

As with most antibiotics, the most common adverse reactions for all these drugs are in the GI tract. Anorexia, nausea, vomiting, diarrhea, stomatitis, and abdominal pain are the main adverse reactions. CDI has been reported with all of these agents.

Rashes and generalized skin eruptions are also common adverse reactions for sulfonamides and trimethoprim. The incidence may be dose-related and is more prevalent in HIV-infected patients. Skin eruptions may include erythema multiforme, exfoliative dermatitis, toxic epidermal necrolysis, and Stevens–Johnson syndrome. Cholestatic jaundice, hepatitis, and hepatonecrosis, as a result of direct toxicity or hypersensitivity reactions, may occur with sulfonamides and nitrofurantoin. These drugs should be discontinued at the first sign of rash or jaundice. For the sulfonamides, cross-hypersensitivity occurs within the sulfonamide antimicrobial class and with dapsone. However, minimal data exist to suggest that other sulfonamide-containing compounds that lack the arylamine group or a substituted aromatic ring (sulfonylureas, thiazide and loop diuretics, carbonic anhydrase inhibitors, and sunscreens with PABA) cross-react (Brackett, Singh, & Block, 2004; Slatore & Tilles, 2004).

Photosensitivity reactions can occur with sulfonamides. Measures such as sunscreens and protective clothing may reduce these problems.

Trimethoprim is an inhibitor of the sodium channel in the renal distal tubules of the kidney, resulting in decreased urinary excretion of potassium. This has led to clinically significant hyperkalemia.

Peripheral neuropathy may develop and become severe and irreversible with nitrofurantoin. Predisposing conditions include renal impairment, anemia, diabetes, electrolyte imbalances, vitamin B deficiency, and debilitating disease. Less severe peripheral neuropathy has also occurred with sulfonamides. CNS adverse effects, including headache, dizziness, and drowsiness, have occurred with both of these drug classes. Aseptic meningitis has been associated with TMP/SMZ therapy.

Nitrofurantoin has also been associated with acute, subacute, and chronic pulmonary reactions. Pulmonary toxicity, including pulmonary fibrosis, typically occurs when nitrofurantoin treatment lasts longer than 6 months,

Other serious adverse reactions are discussed in the Precautions and Contraindications section.

Drug Interactions

Trimethoprim and nitrofurantoin have very few drug interactions. Sulfonamides interact with several commonly used drugs, including salicylates, warfarin, and hydantoins. In addition, sulfamethoxazole and trimethoprim may increase the cardiac QT interval, so they should not be used with other agents that could exacerbate this effect. Specific drug interactions are listed in Table 24-21.

Clinical Use and Dosing

Urinary Tract Infections

Lower-tract UTIs are most commonly caused by gram-negative bacteria (95%), with *E. coli* the most prevalent organism ((75% to 95%) (Gupta et al, 2011). Among community-acquired infections, *S. saprophyticus, Klebsiella,* and gram-negative enteric bacilli cause almost all UTIs not caused by *E. coli.* In children, additional organisms include *Klebsiella* in neonates and *Proteus* in boys. All of the antibiotics mentioned have a spectrum of activity that covers these organisms.

Trimethoprim-sulfamethoxazole is the most effective drug when no complicating factors are present; the recommended dose for adults is one double-strength tablet twice daily for 3 days if local *E. coli* resistance is less than 20% (Griebling, 2007; Gupta et al, 2011). If 3-day empirical therapy fails, urine should be sent for culture and subsequent therapy continued for 14 days. The recommended dosage of TMP-SMZ in children is 6 to 12 mg trimethoprim and 30 to 60 mg sulfamethoxazole per kg/d in two divided doses (1 mL suspension per kg/d). Children should be treated with a 10-day regimen. Resistance to TMP-SMZ is seen in patients who have had antibiotic therapy for any reason in the past 3 months or if they have been hospitalized recently.

Nitrofurantoin is an effective treatment for UTIs, with a low *E. coli* resistance rate of 2.1% in a recent study comparing it to TMP-SMZ, ciprofloxacin, and levofloxacin (Kashanian et al, 2008). The dose of nitrofurantoin is 50 to 100 mg twice a day. This drug can also be used prophylactically in adults and children who have recurrent UTIs more often than 3 times per year. Nitrofurantoin is useful in pregnant women because it is Pregnancy Category B. During pregnancy, the dose must be given for 7 days. Nitrofurantoin should be avoided in pregnancy near-term, in labor, and during lactation when the infant is less than 1 month of age because of the risk of the infant's developing hemolytic anemia. The pediatric dose is 5 to 7 mg/kg/d divided every 6 hours for 7 to 10 days. Shortened therapy should not be used in children.

Recurrent infections (more than three infections in 1 year) may be treated with prophylactic antibiotics. Low-dose nitrofurantoin at bedtime (50 to 100 mg) or TMP-SMZ (40 mg TMP and 200 mg SMZ or 1 single-strength tablet) at bedtime and postcoitally to prevent recurrent UTIs in women.

Pregnant women with asymptomatic bacteriuria detected during routine screening during the first trimester can be treated with TMP-SMZ, nitrofurantoin, or trimethoprim, as well as amoxicillin or oral cephalosporins. Other genitourinary indications for TMP-SMZ are treatment of acute prostatitis in men older than 35 years, chronic prostatitis, recurrent UTI (more than three in a year), and prophylaxis before and after invasive urological procedures. Although

Table 24–21 ▦ Drug Interactions: Sulfonamides, Trimethoprim, Nitrofurantoin, and Fosfomycin

Drug	Interacting Drug	Possible Effect	Implications
Nitrofurantoin	Anticholinergics Magnesium salts Probenecid	Increase nitrofurantoin bioavailability by delaying gastric emptying and increasing absorption. May delay or decrease nitrofurantoin absorption. High doses decrease renal clearance and increase serum levels of nitrofurantoin.	Monitor for adverse reactions and toxicity. Avoid concurrent administration. Monitor for increased risk for toxicity.
All sulfonamides	Cyclosporine Hydantoins Methotrexate Probenecid and other uricosurics, salicylates, indomethacin Sulfonylureas Thiazide diuretics Warfarin	Increased cyclosporine concentration and risk of nephrotoxicity. Increased serum hydantoin levels. Enhanced adverse effects of methotrexate, including bone marrow suppression. Increased sulfonylureas half-life and risk of hypoglycemia. Sulfonamides may be displaced from plasma albumin resting in increased free drug. Sulfonamides may potentiate action ofuricosurics. May cause increased incidence of thrombocytopenia with purpura. Enhanced action of warfarin.	Select different antibacterial. Monitor serum levels closely. Avoid concurrent use. Unless planned for therapeutic reasons, avoid concurrent administration. Avoid concurrent use or monitor blood glucose closely. Avoid coadministration. Monitor PT/INR closely.
Trimethoprim	ACE inhibitors and Angiotensin II receptor blockers	Enhanced hyperkalemic effects.	Monitor closely.
	Phenytoin	Inhibition of hepatic metabolism may result in increased effects of phenytoin.	Avoid concurrent administration or monitor phenytoin levels closely.
Fosfomycin	Metoclopramide	Decreased fosfomycin serum and urinary concentrations.	Monitor for clinical response or select a different antibiotic.

INR = international normalized ratio; PT = prothrombin time.

infrequently used, the sulfonamides sulfadiazine, sulfamethizole, sulfamethoxazole, and sulfisoxazole are approved for treatment of cystitis and uncomplicated pyelonephritis. A more detailed discussion of UTI and its management is found in Chapter 47. For dosage schedules see Table 24-22.

Upper Respiratory Infection

TMP-SMZ is no longer recommended in patients with sinusitis or AOM due to high rates of resistance to *S. pneumoniae* and *H. influenza* (Chow et al, 2012; Lieberthal et al, 2013). Although TMP-SMZ is effective in vitro against group A beta-hemolytic *S. pyogenes,* it does not eradicate the organism or protect against rheumatic fever. Thus, it should not be used to treat streptococcal pharyngitis.

Exacerbations of Chronic Bronchitis

Although treatment of ABECB is controversial, TMP-SMZ may be a good choice for patients who have not taken anti - biotics recently and therefore are less likely to be infected with a resistant strain and for those with a persistent cough (Rabe et al, 2007). Treatment is one DS tablet twice daily for 14 days. Another advantage of this formulation is low cost. However, with repeated use of TMP-SMZ, resistant organisms are likely to prevail and it is not first-line therapy.

MRSA

Methicillin-resistant *S. aureus* (MRSA) has emerged as a common pathogen in both hospital-acquired and community-acquired infections. Depending on local resistance patterns,

TMP-SMZ is an inexpensive treatment for community-acquired MRSA (CA-MRSA) (Liu et al, 2011; Stevens et al, 2014).

Other

TMP-SMZ will slightly shorten the duration of symptoms and carrier state if given for the treatment of shigellosis enteritis in adults and children (Heiman & Bowen, 2013). It also is used for the prevention and treatment of pneumonia caused by the protozoon *Pneumocystis jiroveci* (PCP) in immunocompromised patients, particularly HIV patients (Mofeson et al, 2009), although TMP-SMZ may be associated with up to 35.3% treatment failure (Rabodonirina et al, 2013). Sulfonamides are inexpensive agents used primarily outside North America to treat trachoma, inclusion conjunctivitis, toxoplasmosis, chancroid, and meningitis.

Rational Drug Selection

Both definitive drug selection and empirical drug selection follow the same principles described in the Rational Drug Selection section for the penicillins. Although no longer primary agents for upper respiratory tract infections, the sulfonamides and trimethoprim are useful, low-cost agents for proven-susceptible urinary tract infections.

Trimethoprim/sulfamethoxazole plays a key role as affordable and effective therapy to treat MRSA infections as compared to intravenous vancomycin or oral linezolid. Nitrofurantoin and fosfomycin play an important role

Table 24–22 ⊗ **Dosage Schedule: Sulfonamides, Trimethoprim, Nitrofurantoin, and Fosfomycin**

Drug	Indication	Available Dosage Forms	Dose	Comments
Nitrofurantoin (Furadantin) Nitrofurantoin macrocrystals (Macrodantin)	Urinary tract infection	Oral suspension: 25 mg/5 mL Capsules: 25, 50, 100 mg	*Adults:* 50–100 mg qid with meals and at bedtime for 3–7 d or more	Maximum daily dose 600 mg for adults or 10 mg/kg for children. Take all nitrofurantoins with food or milk to decrease GI distress.
			Children: 5–7 mg/kg/d in 4 divided doses for at least 7 d	All nitrofurantoins are contraindicated in infants under age 1 mo. Suspension should be shaken well before measurement, using a calibrated measuring device. Store at room temperature. The oral suspension can be mixed with water, milk, fruit juice, or infant formula, although it may discolor.
	Long-term suppression of urinary tract infection		*Adults:* 50–100 mg at bedtime *Children:* 1 mg/kg/24 h in 1 or 2 divided doses	As above
Monohydrate macrocrystals (Macrobid)	Urinary tract infections	Capsule: 100 mg	*Adults:* 100 mg q12h for 3–7 d	As above
Sulfadiazine	Antibacterial or antiprotozoal	Tablets: 500 mg	*Adults:* 2–4 g as initial dose, then 1 g q4–6h *Children:* 75 mg/kg as initial dose, then 37.5 mg/kg q6h or 25 mg/kg q4h	Take with a full glass of water.
Sulfamethoxazole (Gantanol)	Antibacterial or antiprotozoal, mild to moderate infections	Tablets: 500 mg	*Adults:* Initial dose of 2 g, followed by 1 g q8–10h *Children >2 mo:* 50–60 mg/kg to maximum of 2 g initially, followed by 25–30 mg/kg q12h	Maximum dose for children is 75 mg/kg. Fluid intake should be sufficient to maintain urine output of at least 1,200 mL/d. Most crystalluria-prone sulfonamide. Take with full glass of water.
Sulfisoxazole (Gantrisin)	Recurrent acute otitis media	Suspension: 500 mg/5 mL	*Children:* 50 mg/kg/d in 2 divided doses q12h	Maximum adult daily dose 8 g; maximum daily pediatric dose 6 g. Take with full glass of water. Fluid intake should be sufficient to maintain urine output of at least 1,200 mL/d. Shake suspension well before measurement, using calibrated dosing device. Store at room temperature.
	Rheumatic fever prophylaxis (secondary) Antibacterial or antiprotozoal		*Adults:* With carditis, 1 g/d for 10 yr or until age 25 Without carditis, 1 g/d for 5 yr or until age 18 *Adults:* 2–4 g initially, then 750 mg–1.5 g q4h; 1–2 g q6h *Children >2 mo:* 75 mg/kg or 2 g/m^2 initially, followed by 25 mg/kg q4h or 37.5 mg/kg q6h	As above As above

Continued

Table 24–22 ⊗ Dosage Schedule: Sulfonamides, Trimethoprim, Nitrofurantoin, and Fosfomycin—cont'd

Drug	Indication	Available Dosage Forms	Dose	Comments
Trimethoprim (Polytrim, Trimpex, Triprim, Primsol)	Urinary tract infection, treatment	Tablet: 100 mg, 300 mg Oral solution: 50 mg/5 mL	*Adults:* 100 mg q12h for 3–10 d or 200 mg daily	May be taken on an empty stomach or with food to decrease GI distress.
	Urinary tract infection, prophylaxis		*Children >2 mo:* 3 mg/kg bid for 10 d *Adults:* 100 mg/d	As above
Trimethoprim (TMP)/ Sulfamethoxazole (SMZ) (Bactrim, Septra)	Urinary tract infection	Tablets: 400 mg (SMZ)/ 80 mg (TMP) 800 mg (SMZ)/160 mg (TMP) Oral suspension: 200 mg (SMZ)/40 mg (TMP)/ 5 mL	*Adults:* 160 mg TMP/800 mg SMZ bid for 3 d *Children >2 mo:* 6–12 mg TMP/30–60 mg SMZ per kg/d in 2 divided doses × 10 d	If empirical 3 d treatment fails, culture urine for treatment decision. For pyelonephritis; duration of therapy is 7–14 d; in pregnancy, duration of therapy is 7 d. For prostatitis, duration of therapy is 4–6 wk.
	MRSA		*Adults:* 160 mg TMP/800 mg SMZ bid for 7 to 10 d *Children >2 mo:* 4–6 mg TMP mg 1 kg/dose TMP/20–30 mg/kg/dose SMZ for 7–10 d	Dose is ½ of a single-strength tablet. Not first-line therapy. Only for penicillin allergy. As above As above
	Chronic suppression of urinary tract infection in women		*Adults:* 40 mg TMP/200 mg SMZ at bedtime a minimum of 3 times wk and postcoitally	
	Acute exacerbation of chronic bronchitis		*Adults:* 160 mg TMP and 800 mg SMZ q12h for 14 d	
	P. carinii pneumonia prophylaxis		*Adults:* 160 TMP and 800 SMZ orally q24h or thrice weekly *Children:* 150 mg/m² TMP and 750 mg/m² SMZ/d in 2 divided doses on 3 consecutive d	
	P. carinii pneumonia treatment		*Adults and Children:* 15–20 mg/kg/d of trimethoprim component, in divided daily doses for 14–21 d	
Fosfomycin (Monurol)	Uncomplicated urinary tract infections (acute cystitis)	3 g sachet	One sachet	Mix sachet with 3 to 4 oz water and stir to dissolve. Do not use hot water. Fosomycin is not indicated for the treatment of pyelonephritis or perinephric abscess

in the empiric treatment of cystitis, especially in the setting of high community TMP/SMZ and fluoroquinolone resistance. Because trimethoprim and nitrofurantoin are indicated as monotherapy only for UTI, use of these agents does not contribute as much to selection pressure that promotes resistance to drugs used for other infections. A single dose of fosfomycin is an attractive option for uncomplicated cystitis, especially when medication adherence may be an issue. However, nitrofurantoin is significantly less expensive than fosfomycin and may be preferred in patients without renal dysfunction. Sulfamethoxazole/

trimethoprim oral formulations are on multiple $4 or reduced-cost generic lists, making it a cost-effective choice if appropriate.

Nitrofurantoin is available as microcrystals, macrocrystals, and monohydrate macrocrystals. Microcrystals (Furadantin) cause excessive GI irritation and should not be used. Monohydrate macrocrystals (Macrobid) form a gel that gradually releases the drug, requiring only twice-daily dosing, whereas macrocrystals (Macrodantin) require administration every 6 hours. Nitrofurantoin should be used with caution in those predisposed to its adverse effects: older patients and patients

with anemia, renal impairment, electrolyte imbalance, diabetes, vitamin B deficiency, and debilitating diseases.

Monitoring

Monitoring for therapeutic response to antibiotics is described in the Monitoring section for penicillins. Culture of the urine to follow up a UTI will verify eradication of the infection. If a patient is on long-term therapy of nitrofurantoin, trimethoprim, or a sulfonamide, periodic assessment of the complete blood cell (CBC) count, hepatic function, and renal function should be conducted. For nitrofurantoin, there should also be periodic evaluation of pulmonary function for signs of fibrosis, physical examination for indications of peripheral neuropathy, and urine culture; superinfections with *Pseudomonas* or *Candida* sometimes occur with chronic therapy. Elderly patients on nitrofurantoin should be monitored closely because serious adverse effects such as acute pneumonitis and peripheral neuropathy occur more commonly in this population. Any patient on nitrofurantoin who develops cough, dyspnea, chest pain, or fever should receive a chest x-ray, sedimentation rate, and CBC to detect the signs of hypersensitivity and pulmonary fibrosis. Patients on long-term sulfonamide therapy should also have periodic urinalysis to check for crystalluria or urinary calculi formation. Patients with AIDS are prone to adverse effects of sulfonamides.

Patient Education

Administration

Patient counseling for all antimicrobials includes advice to complete the entire course of therapy, take the medications as prescribed on a regular schedule, and abstain from sharing medications with others. Sulfonamides and solid or liquid forms of trimethoprim-sulfamethoxazole should be taken with a full glass of water and sufficient daily fluid intake to maintain 1,200 mL urine output in the adult. Nitrofurantoin causes less GI distress and is better absorbed if taken with food or milk. Suspensions should be shaken before measurement and taken with a specially marked measuring spoon or comparable device. Patients receiving fosfomycin should be advised on proper preparation and administration of the sachet packet and drinking extra fluids to increase urination.

Adverse Reactions

Patients taking sulfonamides and trimethoprim or combinations containing these agents should be counseled to avoid photosensitivity or photoallergy by wearing protective clothing and sunscreens. They should not expose their skin to ultraviolet light from the sun or tanning lamps more than a few minutes until tolerance is determined. The patient who develops a rash while taking these agents should discontinue the drug and contact the health-care provider; rash may develop into Stevens–Johnson syndrome. Patients on sulfonamides should also report signs of crystalluria (blood in urine) and blood dyscrasias (sore throat, fever, chills, pale skin, unusual bleeding or bruising). Sulfonamides may cause

dizziness that can make operation of machinery and automobiles dangerous.

Counseling for patients on nitrofurantoin includes similar cautions for signs of blood dyscrasias (sore throat, fever, chills, pale skin, unusual bleeding or bruising). Patients should know that the drug may cause brownish discoloration of the urine and elicit a false positive on copper sulfate urine tests for glucose. Patients should call the health-care provider if there are signs of acute pulmonary fibrosis (sudden onset of chest pain, dyspnea, cough, fever) or subacute pulmonary fibrosis (dyspnea, nonproductive cough, malaise after 1 to 6 months of therapy). Because rechallenge with nitrofurantoin could cause rapid return of the pulmonary condition, the patient should be provided with written information to warn future health-care providers of the reaction. Other symptoms to report are signs of peripheral neuropathy (numbness, tingling, pain in extremities) and intolerable GI upset.

Lifestyle Management

See the Lifestyle Management section for the penicillins.

TETRACYCLINES

Tetracyclines are broad-spectrum antibiotics that are used extensively throughout the world. Originally introduced in 1948, they are used in the United States for a variety of bacterial, *Rickettsiae*, and spirochete infections; malaria prophylaxis for certain travel destinations; and acne vulgaris. Included in this class are oxytetracycline, tetracycline, demeclocycline, doxycycline (Doxy, Doxychel, Vibramycin), and minocycline (Minocin). Tigecycline, a glycylcycline that has an extended spectrum of activity, is only available as an intravenous formulation and is reserved for very resistant organisms due to tolerability and safety concerns. Demeclocycline is used primarily for syndrome of inappropriate antidiuretic hormone secretion (SIADH). Due to the uncommon usage of tigecycline and demeclocycline, these drugs will not be discussed further in this chapter. The second-generation drug doxycycline is the most commonly prescribed tetracycline. It has fewer problems with drug–food interactions, is dosed less frequently than tetracycline, and is generally less expensive than minocycline. Tetracycline is used both topically and orally to treat acne and is one of four drugs in the combination treatment of *H. pylori* infection. Topical application is discussed in Chapters 23 and 32.

Pharmacodynamics

Tetracyclines include a group of drugs with a common tetracycline nucleus structure and similar spectrum of activity. Tetracyclines inhibit protein synthesis by reversibly binding to the 30S subunit of the bacterial ribosome and preventing the addition of amino acids to growing peptides. The class is typically bacteriostatic but may be bactericidal against highly susceptible organisms. In addition to their

antibacterial properties, tetracyclines have other anti-inflammatory mechanisms that are useful for the treatment of acne vulgaris. Tetracyclines chelate with divalent and trivalent cations, which can interfere with their absorption and activity.

Spectrum of Activity

Tetracyclines have good activity against gram-positive organisms such as *S. aureus* (including MRSA), *S. pneumoniae*, *Bacillus anthracis*, *Actinomyces* spp., *C. perfringes*, *L. monocytogenes*, *Nocardia*, and *Propionibacterium acnes*. Activity against *Enterococcus* spp. is variable.

Gram-negative organisms that tetracyclines are effective against include *Haemophilus ducreyi* (chancroid), *Yersinia pestis, Francisella tularensis, Bartonella bacilliformis, Vibrio cholerae,* and *Brucella.* Although not first-line therapy, they also are active against *H. influenzae, E. coli, Shigella,* and *Klebsiella* spp. Tetracyclines, particularly minocycline and tigecycline may have a role in the treatment of infections due to *Bacteroides* spp. or *Acinetobacter*. None of the tetracyclines have reliable activity against *Proteus* spp.

Tetracyclines also have activity against intracellular organisms such as *Chlamydia*, *Mycoplasma pneumoniae*, *Ureaplasma urealyticum*, and *Legionella*. This class is active against *Rickettsia* (Rocky Mountain spotted fever, typhus, Q fever, rickettsial pox, and tick fever)and spirochetes such as *Borrelia recurrentis* (relapsing fever), *Treponema pallidum*, and *Leptospira*. Tetracycline has demonstrated activity against *H. pylori*. Doxycycline is a blood schizonticidal agent and is active against the asexual erythrocytic forms of *P. falciparum*.

Resistance

The mechanisms of resistance to tetracyclines are (1) decreased intracellular accumulation due to impaired influx or increased efflux of an active transport protein pump, (2) ribosome protection by proteins that interfere with drug binding, and (3) enzymatic inactivation. Resistance to tetracycline generally predicts resistance to the entire class. For the treatment of gram-positive and gram-negative bacterial infections, susceptibilities should be verified because resistance may be an issue. For example, in the United States, up to 13% of *S. pneumoniae* and 21.6% of *N. gonorrhea* are resistant (CDC 2012).

Pharmacokinetics
Absorption and Distribution

Tetracyclines are adequately but incompletely absorbed in the fasting state. The percentage of oral dose absorbed is highest for doxycycline and minocycline (95% to 100%) and intermediate for oxytetracycline and tetracycline (60% to 70%). Achlorhydria has no effect on absorption of tetracyclines. Food and polyvalent cations (Ca^{2+}, Mg^{2+}, Zn^{2+}, Fe^{3+}, and Al^{3+}) decrease absorption of tetracyclines. Doxycycline is the least affected by food and divalent cations.

Doxycycline and minocycline are highly lipid soluble and readily penetrate body tissues and fluids, including pleural fluid, eye, and prostate, and cross placental membranes. Fetal plasma concentrations reach 60% of maternal serum levels. Minocycline displays good penetration of saliva. Tetracycline has intermediate lipid solubility, and oxytetracycline has the least. Oxytetracycline readily diffuses across the placenta into fetal circulation and into pleural fluid.

Metabolism and Excretion

Tetracyclines are eliminated by the kidney via glomerular filtration and by liver metabolism and undergo enterohepatic recirculation with excretion in the bile and feces. Dosage adjustments of tetracycline and oxytetracycline are required for renal impairment; however, doxycycline and minocycline do not significantly accumulate or require dosage reductions. Minocycline is metabolized by the liver and its half-life is prolonged in oliguria. Because it also uses nonrenal routes of excretion, dosage adjustments are not required in renal impairment. Table 24-23 describes the pharmacokinetics of selected tetracyclines.

Table 24–23 **Pharmacokinetics: Tetracyclines**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Doxycycline	1–2 h	1.5–4 h	12 h	80%–95%	93%	18–22 h	30%–42% unchanged in urine; some inactivation in intestine; remainder excreted in bile and feces
Minocycline	Rapid	2–3 h	6–12 h	70%–80%	90%	11–22 h	5%–10% unchanged in urine; some metabolism by liver; remainder excreted in bile and feces
Oxytetracycline	1–2 h	2–4 h	6–12 h	20%–40%	60%	6–12 h	10%–35% unchanged in urine
Tetracycline	1–2 h	2–4 h	6–12 h	65%	60%–80%	6–12 h	20%–55% unchanged in urine

Pharmacotherapeutics

Precautions and Contraindications

There are a number of patients for whom the tetracyclines should be prescribed cautiously; such patients include those with renal impairment, those with hepatic impairment, pregnant women, lactating women, and children under 8 years of age. In addition, outdated tetracyclines should not be administered. Historically, the degradation products of these drugs were highly nephrotoxic, and reversible nephrotoxicity, including a Fanconi-like syndrome, has been reported. However, current formulations do not include citric acid as an excipient, which may have eliminated this possible adverse effect.

Renal Impairment

Extreme caution should be used in the presence of renal impairment. Usual doses of tetracyclines (except doxycycline and minocycline) may lead to excessive accumulation of the drugs and possible hepatotoxicity. The antianabolic activity of tetracyclines may be seen with renal impairment and include an increased BUN, azotemia, hyperphosphatemia, and acidosis. Therefore, lower-than-normal doses are recommended for tetracycline and oxytetracycline in renal impairment. If therapy is prolonged, an assay of drug serum concentrations may be advisable.

Hepatic Impairment

There are serious concerns related to hepatotoxicity for IV forms of tetracycline. This is not a major concern with oral administration, but liver function studies are advisable during long-term management with doxycycline or minocycline. Hepatotoxicity has been reported with minocycline, and it should be used with caution in patients with hepatic dysfunction.

Pregnancy

Doxycycline is Pregnancy Category D. Others are Pregnancy Category X and should not be used during pregnancy. They readily cross the placenta in concentrations up to 60% of maternal plasma. Tetracyclines are found in fetal tissue and can produce retardation of skeletal development in the fetus and staining of deciduous teeth.

Lactation

Tetracycline is excreted in breast milk; however, the AAP considers tetracycline to be compatible with breastfeeding because the serum concentrations of infants in the study were below detectable levels and there was no evidence of teeth staining (AAP, 2001). Doxycycline is also excreted into breast milk; however, because milk levels are low and absorption is inhibited by the calcium in breast milk, a short course is considered safe during lactation (LactMed, 2014). Minocycline may affect milk production or composition.

Children

Children younger than 8 years generally should not use any tetracycline. These drugs form a stable calcium complex in any bone-forming tissue, decreasing bone growth. They also may cause permanent yellow/gray/brown discoloration of deciduous and permanent teeth. Enamel hypoplasia has also been reported. Doxycycline is less likely to produce these problems, but the risk outweighs any potential benefit for most indications.

Adverse Drug Reactions

As with other antibiotics, the most common adverse reactions are associated with the GI tract. Anorexia, nausea, vomiting, and diarrhea are caused by direct irritation of the intestinal mucosa. Taking the drug with food (note food interactions above) or reducing the dose usually alleviates GI complaints. Esophageal ulcers have occasionally occurred but can be avoided by taking the drug with a full glass of water and remaining upright after taking the drug. As broad-spectrum antibiotics, tetracyclines can cause CDI, previously discussed in the sections on penicillins, cephalosporins, and clindamycin.

Light-headedness, dizziness, and vertigo have been reported in up to 9% of patients taking minocycline and in some patients taking doxycycline. Pseudotremor cerebri (benign intracranial hypertension) has also been associated with tetracyclines. Symptoms are headache and blurred vision. Discontinuing the drug usually resolves these problems, but the possibility for permanent sequelae exists.

Dermatological adverse reactions include photosensitivity manifested by an exaggerated sunburn reaction, as well as maculopapular and erythematous rashes. Severe skin reactions, including Stevens–Johnson syndrome and toxic epidermal necrolysis, have been reported with tetracyclines. Blue-gray pigmentation of skin and mucosa has been reported with minocycline.

Drug Interactions

The main drug–drug interactions associated with tetracyclines are with divalent and trivalent cations that are found in antacids, iron salts, sevalemer, magnesium-containing laxatives, and zinc supplements. Concurrent administration leads to the formation of poorly soluble chelated compounds, resulting in decreased antibiotic activity. Separation of these products from the administration of tetracyclines by at least 2 hours is recommended. Doxycycline and minocycline have less affinity for calcium and zinc and are not significantly affected. Tetracyclines increase the anticoagulant effects of warfarin.

Whether tetracyclines cause a decrease in efficacy of oral contraceptives is controversial, but the alleged mechanism is related to the enterohepatic recirculation of tetracycline and oral contraceptives. It seems prudent to suggest the use of a barrier contraceptive method while the patient is taking the tetracycline and until the next menses. These and other interactions of the tetracyclines are shown in Table 24-24.

Clinical Use and Dosing

The tetracyclines are prescribed for sexually transmitted infections, acne, *H. pylori,* and other less common infections.

Table 24–24 ▦ Drug Interactions: Tetracyclines

Drug	Interacting Drug	Possible Effects	Implications
Tetracyclines	Antacids, dairy foods, iron salts, and sodium bicarbonate	Impair absorption because of formation of a poorly soluble chelate	Take on empty stomach or separate doses by 2 h and take tetracycline first. Doxycycline and minocycline have lower affinity for divalent cations and are not significantly affected by food or dairy products.
	Warfarin	Tetracyclines may increase warfarin effects	Choose a different antibiotic or monitor PT/INR closely.
	Barbiturates, carba-mazepine, hydantoins	Increase metabolism and decrease half-life and serum levels of doxycycline	Antibacterial activity decreased. Avoid concurrent administration.
	Cimetidine	Decreased GI absorption of tetracyclines because of pH-dependent inhibition of dissolution	Antibacterial activity decreased. May be true for other H_2 blockers. Avoid concurrent administration.
	Digoxin	Serum levels of digoxin increased in 10% of patients with risk for toxicity	Effects last for months after tetracycline discontinued. Select different antibiotic class.
	Insulin	May reduce insulin requirements	Further study needed. Monitor blood glucose closely.
	Lithium	May increase or decrease lithium levels	Monitor serum levels closely.
	Oral contraceptives	May decrease effectiveness; breakthrough bleeding may occur	Controversial. Suggest barrier method for women taking tetracyclines.
	Penicillin	May interfere with bactericidal action of penicillins	Avoid concomitant administration.

INR = international normalized ratio; PT = prothrombin time.

Genitourinary Infections

One of the most important indications for doxycycline is treatment of genital *C. trachomatis* infections and nongonococcal urethritis and cervicitis. Doxycycline in doses of 100 mg twice daily for 7 days is a first-line agent because of its low cost, but it may have lower compliance than the more expensive azithromycin, which requires a single dose in these infections (CDC, 2010e). Sexual partners should be evaluated and treated. Doxycycline is contraindicated in pregnancy; the drug of choice for pregnant women is amoxicillin or azithromycin (CDC, 2010e). In penicillin-allergic patients, doxycycline (100 mg orally twice daily) or tetracycline (500 mg orally 4 times daily) for 14 days is the only recommended alternative treatment of early primary, secondary, or latent syphilis of less than 1 year's duration (CDC, 2010e). For latent syphilis of more than 1 year's duration without neurosyphilis, a longer course of treatment (28 days) is required.

Doxycycline (100 mg twice daily for 10 days) combined with ceftriaxone (250 mg IM) is indicated for empirical treatment of epididymo-orchitis in heterosexual men less than 35 years of age where the likely pathogens are *C. trachomatis* or *N. gonorrhoeae* (CDC, 2010e).

Men with acute proctitis who practice receptive anal sex should be treated with a combination of antibiotics that cover for *N. gonorrhoeae* and *C. trachomatis*. The CDC guidelines (2010e) recommend ceftriaxone 250 mg IM combined with doxycycline 100 mg twice daily for 7 days. Chronic prostatitis, the most common form, is a chronic pain syndrome of unknown etiology. Studies suggest it may have a microbial etiology, and doxycycline (100 mg twice daily for 14 days) is used empirically for treatment.

Acne

Patients with moderate, inflammatory acne who show no improvement with 6 to 8 weeks of topical therapy may be treated with oral antibiotics to treat the *P. acnes* that cause inflammatory papules and pustules. Treatment is tetracycline (Achromycin) 500 mg twice daily for 1 to 2 months; then, when acne control is achieved, the dose is lowered to 500 mg per day for 1 to 2 months, after which a maintenance dose of 125 to 500 mg daily is taken. Minocycline is an alternative, although more expensive, treatment. Dosing of minocycline is 100 mg twice daily; then the patient is weaned to 50 mg daily. Doxycycline is an oral alternative to topical metronidazole in the treatment of acne rosacea.

Peptic Ulcer Disease

Tetracycline is one component of the quadruple drug regimen used for the eradication of *H. pylori* associated with peptic ulcer disease (PUD). Tetracycline 500 mg 4 times a day is combined with metronidazole 250 mg 4 times a day, bismuth subsalicylate 525 mg 4 times a day, and a proton pump inhibitor. The quadruple drug therapy is more complex than the triple drug therapy. Full prescribing information for PUD is found in Chapter 34.

Lyme Disease

The International Lyme and Associated Diseases Society (ILADS) has released evidence-based guidelines recommending

early and aggressive antibiotic treatment to prevent Lyme disease from becoming persistent or recurrent (Cameron et al, 2006). Doxycycline, 100 mg twice daily, is the first-line drug of choice for early treatment of Lyme disease, a tick-borne infection caused by *B. burgdorferi* (CDC, 2013c). Children age 8 years or older are treated with doxycycline 4 mg/kg/d divided into twice daily doses (maximum 100 mg twice daily). The duration of oral treatment varies by the presenting signs: early erythema migrans (14 to 21 days), mild cardiac involvement (21 days), arthritis (28 days), and isolated facial paralysis (21 to 28 days). Amoxicillin is the alternative for pregnant women and children younger than 8 years, for whom doxycycline is contraindicated (CDC, 2013c). The ILADS recommends early empirical treatment for patients with a likely diagnosis of Lyme disease while waiting for laboratory confirmation (Cameron et al, 2006).

Other

Doxycycline is an alternative for penicillin-allergic patients for prophylaxis of rat, bat, raccoon, and skunk bites (AAP,

2012g). The primary drug of choice for ehrlichiosis and rickettsial infections (e.g., Rocky Mountain spotted fever, typhus, Q fever, trench fever caused by *B. quintana*) is doxycycline (AAP, 2012h). Minocycline, 100 mg twice daily for 6 to 8 weeks, is the drug of first choice for infections by *Mycobacterium marinum,* an infection associated with contamination by water from aquariums. Minocycline may be used as an alternative to sulfonamides in nocardiosis. Tetracyclines are first-line therapy for a number of diseases rarely seen in North America, including trachoma, cholera, and granuloma inguinale. Doxycycline 100 mg twice daily for 6 days is an alternative therapy for post-exposure prophylaxis to anthrax (Hendricks et al, 2014). Doxycycline is also used in prophylaxis and treatment of falciparum malaria and as an adjunct in treatment of intestinal amebiasis. Table 24-25 presents the dosage schedule of tetracyclines.

Rational Drug Selection

Both definitive drug selection and empirical drug selection follow the same principles described in the Rational Drug

Table 24–25 ⊗ Dosage Schedule: Tetracyclines

Drug	Indication	Dosage Form	Dose	Comments
Doxycycline (Doxy Caps, Vibramycin)	Antibacterial	Capsules: 25, 50, 100 mg Tablets: 100 mg Syspension: 25 mg/5 mL Syrup: 50 mg/5mL	*Adults:* 50–100 mg q12h	Maximal daily adult dose 500 mg for 5 d for acute gonococcal infection; 300 mg for all other infections.
	Community-acquired MRSA		*Children >8 yr:* 2.2–4.4 mg/kg/d divided into 2 doses q12h *Adults:* 100 mg q 12h for 5 to 10 d *Children >45 kg:* 100 mg q 12 h for 5 to 10 d *Children ≤45 kg:* 2 mg/kg/dose q12 h for 5 to 10 d	Shake suspension well before measurement with calibrated device. Store at room temperature for up to 14 d. Do not take this drug within 1 h of other medicines; separation of 3 h preferable. May be administered without regard to meals.
	Anthrax (post-exposure prophylaxis)		*Children <8 yr:* 2.2 mg/kg q12h (max 100 mg/dose) *Children ≥8 yr and adults:* 2.2 mg/kg q12h (max 100 mg/dose)	
	Endocervical, rectal, or urethral infection caused by *C. trachomatis*		*Adults:* 100 mg q12h for 7 d	As above
	Epididymo-orchitis caused by *C. trachomatis* or *N. gonorrhoeae;* nongonococcal urethritis		*Adults:* 100 mg q12h for 10 d combined with ceftriaxone 250 mg IM	As above
	Gonococcal infections, uncomplicated		*Adults:* 100 mg q12h for 7 d combined with ceftriaxone 250 mg IM	Ceftriaxone is first-line treatment
	Lyme disease		*Adults and children >8 yr:* 100 mg q12h for 14 to 21 d	As above

Continued

Table 24–25 ⊗ **Dosage Schedule: Tetracyclines—cont'd**

Drug	Indication	Dosage Form	Dose	Comments
	Malaria prophylaxis		*Adults:* 100 mg daily beginning 1–2 days before travel, continued through visit and for 4 wk after traveler leaves the malarious area *Children >8 yr:* 2.2 mg/kg daily, up to 100 mg daily on same schedule as adult	As above
	Acne vulgaris		*Adolescents and adults:* 100 mg bid for inflammatory form	May wean
(Oracea)	Acne rosacea	Capsule: 40 mg	*Adults:* 40 mg daily in the a.m.	As above
	Acute exacerbation of chronic bronchitis		*Adults:* 100 mg q12h for 5–10 d	As above
	Bite of rat, bat, raccoon (prophylaxis)		*Adolescents and adults:* 100 mg q12h	As above
Minocycline (Dynacin, Minocin)	Antibacterial, other infections	Capsules: 50 mg, 100 mg Oral suspension: 50 mg/5 mL	*Adults:* 200 mg base initially, then 100 mg q12h; *or* 100–200 mg initially, then 50 mg q6h *Children >8 yr:* 4 mg base/kg initially, then 2 mg/kg q12h	As above
	Acne		*Adolescents ≥12 yr:* 100 mg daily for 1 to 2 mo then wean to 50 mg/d	Treat for at least 12 wk. May need to increase to 150 mg to 200 mg/day in some patients.
Oxytetracycline (Terramycin)	Brucellosis	Capsules: 250 mg	*Adults:* 500 mg q6h for 3 wk, given concurrently with 1 g streptomycin IM q12h the first wk and once/d the second wk	Maximum daily adult dose 4 g; maximum daily pediatric dose 250 mg. Take with full glass of water. Keep container tightly closed in a dry place. Store at room temperature. Parenteral dose must be given by deep IM injection; do not administer IV. Change to oral form as soon as possible.
Tetracycline (Achromycin V, Sumycin)	Acne	Oral suspension: 125 mg/5 mL Capsules: 100, 250, 500 mg Tablets: 250 mg, 500 mg	*Adults:* 1 g/d in divided doses (q 6 to 12 h) for severe cases; gradually reduce to maintenance dose of 125 mg– 500 mg/d in divided doses. Alternate-day dosing or intermittent therapy possible if in remission.	Shake suspension well before measurement with calibrated device. Not for children <8 yr. Keep container tightly closed in a dry place. Store at room temperature. Heed expiration date. Dispose of excess or leftover drug. Do not take within 1–3 h of other drugs. Take with full 8 oz glass of water, and stand for at least 90 sec after swallowing. Take drug at least 1 h before bedtime.
	Brucellosis		*Adults:* 500 mg qid for 3 wk in combination with streptomycin 1 g bid for the first wk and 1 g/d for second wk	As above
	Other bacterial infections		*Adults:* 250–500 q6h to q12h *Children >8 yr:* 25 to 50 mg/kg q6h	As above

Selection section for the penicillins. When a patient with renal impairment requires a tetracycline, doxycycline is preferred; it does not require dosage adjustment and lacks the antianabolic effects that increase azotemia when other tetracyclines are used. Another advantage of doxycycline and minocycline is decreased chelation with divalent cations, which allows them to be taken with meals if necessary. Additionally, these two agents also require fewer daily doses than other tetracyclines. Unfortunately, tetracyclines are contraindicated in children younger than 8 years and during pregnancy because of the risk of bone and teeth abnormalities in the fetus and young child, as well as increased risk of hepatotoxicity during pregnancy. Besides age and pregnancy, reasons to choose alternative agents over tetracyclines are concurrent administration of other hepatotoxic drugs and risk of noncompliance with the complex scheduling required to avoid drug–food interactions. Doxycycline is on multiple $4 or reduced-cost generic lists, making it a cost-effective choice if appropriate.

Monitoring

Monitoring for therapeutic response to antimicrobial drugs is described in the Monitoring section for penicillins. Long-term therapy with tetracyclines exceeding several weeks requires periodic hematopoietic, hepatic, and renal function tests. Because doxycycline is metabolized by the liver, other drugs can induce or inhibit its metabolism. Patients should be assessed for potential interactions of other drugs with doxycycline, particularly inducers such as rifampin, phenytoin, carbamazepine, and barbiturates that accelerate doxycycline metabolism and may result in therapeutic failure. Additionally, digoxin assays should be obtained when a patient takes broad-spectrum antibiotics concurrent with digoxin.

Patient Education

Administration

Oral solid dosing forms of tetracyclines should be stored in a tightly closed container in a dry environment to avoid accelerated decomposition that might result in toxic constituents. The patient should note the expiration date and dispose of outdated tetracycline, which can cause serious toxicity. The entire prescription should be taken, with doses evenly spaced.

Suspension products should be shaken before measurement of the dose with a calibrated dosing device. Although some tetracyclines come in liquid formulations for use by adult patients who cannot swallow solids, it should not be assumed they are indicated for children younger than 8 years. Administer tetracyclines 1 hour before or 2 hours after meals and give tetracyclines 2 hours before antacids. However, doxycycline and minocycline can be taken with meals if they cause GI upset when taken on an empty stomach. To avoid esophageal irritation, do not take tetracyclines at bedtime and administer with a full 8 oz glass of water.

Tetracyclines should not be used during pregnancy and should be avoided in children younger than 8 years.

Adverse Reactions

Tetracyclines can cause phototoxicity, so sunlight and tanning lights should be avoided. Wear sunscreen, hats, and protective clothing if it is necessary to be in the sun for more than a few minutes. Avoid hazardous activities and driving if dizziness, light-headedness, or unsteadiness develops, which is most common with minocycline. Contact the prescriber if these symptoms interfere with activities of daily living. The patient should stop taking the tetracycline and contact a health-care provider if headache and blurred vision develop; these are the symptoms of pseudotumor cerebri.

Signs of superinfection that should be reported to the prescriber include hoarseness, glossitis, sore throat, dysphagia, or vaginal itching and discharge. The patient should also report symptoms of hepatotoxicity, which include upper abdominal pain, nausea, vomiting, dark urine, clay-colored stools, or yellowing of skin or eyes. Diarrhea involving three or more unformed stools per day and blood or mucus in the stool could indicate CDI. Detection and management of CDI were described earlier.

Women of childbearing age would be prudent to use a backup barrier method of contraception during tetracycline therapy and until the next menses. Women on hormone replacement should know that broad-spectrum antibiotics can cause exacerbation of hot flashes and menopausal symptoms during therapy.

Tetracyclines can cause reversible pigmentation of skin and mucous membranes, which is more common with minocycline.

Lifestyle Management

See the Lifestyle Management section for the penicillins.

GLYCOPEPTIDES

The glycopeptide class consists of vancomycin (Vancocin) and the structurally similar lipoglycopeptides, which include telavancin (Vibativ) and a drug in phase III trials, dalbavancin (Zeven). This group of antibiotics is used for gram-positive infections that are resistant to first-line antibiotics.

Vancomycin is a narrow-spectrum antibiotic. Use of vancomycin has increased because of the development of organisms resistant to other drugs, such as MRSA. Unfortunately, its widespread use led to the development of strains of vancomycin-resistant *Enterococcus* (VRE) and *S. aureus* with reduced susceptibility, including vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant *S. aureus* (VRSA). The decreased susceptibility of *S. aureus* and *E. faecium* has greatly reduced treatment options for some infections, especially nosocomial infections in hospitals and hemodialysis centers.

Telavancin was approved in 2009 for use in complicated skin and skin-structure infections (cSSSI) caused by susceptible gram-positive bacteria. Although telavancin does not require therapeutic drug monitoring, its use has been limited

by adverse effects and lack of demonstrated superiority over vancomycin.

Pharmacodynamics

Vancomycin is a tricyclic glycopeptide antibiotic that inhibits cell wall synthesis by binding firmly to the D-A1a-D-A1a terminus of nascent peptidoglycan pentapeptide. The end result is a weakened cell wall susceptible to lysis. The cell membrane is also damaged, contributing to the antibacterial effects.

Telavancin is a lipoglycopeptide antibacterial that is a synthetic derivative of vancomycin. Telavancin inhibits cell wall synthesis by binding the bacterial membrane and disrupting the membrane barrier function.

Spectrum of Activity

Vancomycin is bactericidal for gram-positive organisms, including staphylococci, streptococci, pneumococci, *Corynebacterium, Listeria, Lactobacillus, Actinomyces,* and *Clostridium.* It kills staphylococci relatively slowly and only if cells are actively dividing.

Telavancin is active against gram-positive organisms including *S. aureus* (including MRSA), *S. pyogenes, Enterococcus* spp. (vancomycin-susceptible isolates only), *Streptococcus agalactiae,* and *Streptococcus anginosus* group (includes *S. anginosus, S. intermedius,* and *S. constellatus*). Additionally, *E. faecium* (vancomycin-susceptible isolates only), *Staphylococcus haemolyticus,* and *Staphylococcus epidermidis* are more than 90% susceptible to telavancin.

Resistance

Resistance is due to a modification of the binding site of the peptidoglycan building block. This results in loss of a critical hydrogen bond that facilitates high-affinity binding of vancomycin to the target organism. To reduce the development of resistant strains, it is recommended to limit vancomycin use to situations in which drug resistance is suspected or documented or when severe drug allergies preclude the use of beta-lactam or other preferred therapies. There is some cross-resistance between VRE strains with a high vancomycin MIC and telavancin.

Pharmacokinetics

Absorption and Distribution

Absorption of vancomycin from the GI tract is poor, although clinically significant serum concentrations have occurred. When administered intravenously, onset of action is rapid, with peak concentrations in 1 hour and a duration of effect of approximately 12 hours, depending on renal clearance. It is 52% to 56% protein bound and has less than 1% bioavailability by the oral route. Its half-life is 4 to 6 hours in adults and 2 to 3 hours in children. Distribution is wide, with 20% to 30% penetration of the CSF. The drug crosses the placenta.

Telavancin is administered IV and is 90% protein bound. Its single-dose half-life is 8 hours. Concentrations of telavancin in skin blister fluid were 40% of those in plasma.

On The Horizon **DALBAVANCIN**

A new glycopeptide antibiotic, dalbavancin (Zeven), is in phase III trials. The only other drug structurally related to dalbavancin is vancomycin. This once-weekly antibiotic is effective against MRSA and MRSE. In 2008, Pfizer withdrew its global applications to conduct further studies on dalbavancin. In 2010, Pfizer out-licensed dalbavancin to Durata Therapeutics, which will continue phase III trials.

Metabolism and Excretion

Because minimal oral absorption occurs, the majority of oral doses of vancomycin are excreted in feces. Intravenously administered vancomycin is eliminated renally, with more than 90% via glomerular filtration.

Telavancin is primarily excreted in the urine (76%). Clearance is decreased in patients with renal impairment.

Pharmacotherapeutics

Precautions and Contraindications

Because of poor oral absorption, oral forms of vancomycin should not be used to treat systemic infections. Oral formulations are unlikely to cause systemic adverse effects. However, clinically significant serum concentrations may occur in some patients who have inflammatory conditions of the intestinal mucosa. Care should be taken if this drug must be administered to these patients. Intramuscular administration should be avoided.

Vancomycin is nephrotoxic and should be used with caution in patients with impaired renal function or patients receiving other nephrotoxic agents. Vancomycin may be ototoxic, with increased risk for these problems when coadministered with other ototoxic agents or in older adults, who may have an underlying hearing loss. It should be used with caution in the elderly. Red man syndrome, including potentially severe hypotension, has been associated with rapid intravenous administration of vancomycin.

Oral vancomycin is listed as Pregnancy Category B, and IV forms are Pregnancy Category C. Telavancin is Pregnancy Category C; there are no data on the use of telavancin in pregnant women. A pregnancy test should be performed before telavancin therapy, with use avoided in pregnant females. The VIBATIV pregnancy registry at 1-888-658-4228 should be contacted to monitor outcomes of telavancin exposure during pregnancy.

Vancomycin is excreted in breast milk, although concentrations in breast milk during oral administration are low. It is unknown whether telavancin is excreted in human milk. Exercise caution when giving either drug to a nursing mother. Vancomycin has been used in serious infections in neonates and children and there are published doses for neonates, infants, and children. Vancomycin use in children is best confined to serious infections during which the child

is hospitalized. Telavancin has not been studied and is not approved for children younger than age 18.

Adverse Drug Reactions

Vancomycin therapy has been associated with nephrotoxicity, presenting with increased serum creatinine and BUN. Risk factors for nephrotoxicity include the use of high-dose, prolonged therapy, preexisting renal dysfunction, and concomitant use of other nephrotoxins. Vancomycin has rarely been associated with serious ototoxicity that may be transient or permanent. It has occurred most often in patients with high IV doses, who have underlying hearing loss, or who are receiving concomitant therapy with another ototoxic drug. Serial tests of auditory function may be helpful to minimize this adverse reaction. Hematological effects include reversible neutropenia, eosinophilia, and thrombocytopenia. Skin rash is the most common adverse effect with oral therapy.

The significant adverse reaction to telavancin is nephrotoxicity, especially in patients who are at risk for decreased renal function (preexisting renal disease, diabetes mellitus, congestive heart failure) and those with CDI. Other adverse effects associated with telavancin include QT interval prolongation, GI disturbances, and hypersensitivity reactions.

If telavancin or vancomycin is infused too fast, the patient may develop red man syndrome, a flushing of the upper body, urticaria, pruritus, or rash. Stopping or slowing the infusion usually leads to resolution of the rash. Slow infusion over 60 minutes or more per gram of vancomycin may decrease the likelihood of this reaction.

Drug Interactions

The only significant interaction between vancomycin and drugs used in primary care occur with drugs that also have ototoxic or nephrotoxic effects (aminoglycosides). The concomitant administration increases the risk and should be avoided if possible.

The adverse effects of telavancin may be increased by drugs that may affect renal function, such as ACE inhibitors, loop diuretics, and NSAIDS. Renal function should be monitored and the patient observed for adverse effects.

Clinical Use and Dosing

Vancomycin (Vancocin) is used to treat CDI; however, it is recommended that metronidazole be tried first in mild to moderate cases. It is also used to treat staphylococcal enterocolitis. It is not effective in any other intestinal infections, especially when gram-negative pathogens are present. Adult dosages are 125 to 500 mg orally every 6 hours for 7 to 10 days. The maximum oral daily adult dosage is 2 g. Studies have indicated that higher dosages result in fecal concentrations far in excess of the MIC and that the 125 mg dose is as effective as higher doses. Dosage for children is 10 mg/kg, up to 125 mg, every 6 hours. Recurrences, which develop in approximately 25% of treated patients, may be treated with a second course of oral vancomycin.

Vancomycin is available for oral administration in pulvules at 125 mg and 250 mg formulations. It is also available as a powder for reconstitution as a solution of 250 mg/5 mL or 500 mg/6 mL. The more concentrated solution contains ethanol. The solution must be refrigerated after reconstitution and will maintain potency for 14 days. It should be dispensed with a calibrated measuring device.

The intravenous dose of vancomycin is 2 to 3 g per day (30 to 60 mg/kg/d) in divided doses every 8 to 12 hours, with a dosage adjustment for decreased renal function and maintainance of troughs of 10 to 20 mg/L. The usual dose for infants older than 1 month and children is 10 to 15 mg/kg every 6 hours.

The telavancin dose for complicated skin and skin structure infections is 10 mg/kg IV every 24 hours for 7 to 14 days. Infuse over 60 minutes. In patients with renal function impairment, dosing is adjusted accordingly: for CrCl 30 to 50 mL/min, give 7.5 mg/kg every 24 hours; for CrCl 30 to 10 mL/min, give 10 mg/kg every 48 hours.

Monitoring

For oral vancomycin, positive response to therapy will be manifested in cessation of diarrhea and associated symptoms. Proctosigmoidoscopy and/or colonoscopy may be useful to document the presence of pseudomembranous colitis or relapse in patients with persistent symptoms. Enzyme immunoassay of stool samples for the presence of *C. difficile* toxins may remain positive after treatment, so follow-up cultures and toxin assays are not recommended. Renal function determinations are warranted periodically during either oral or IV vancomycin therapy, especially in patients receiving high doses of vancomycin, receiving other nephrotoxins, and those with renal function impairment or severe CDI. Vancomycin troughs should be performed during intravenous therapy. The white blood cell (WBC) count or audiometry may also be monitored during extended or repeat therapy.

Renal function should be measured prior to starting telavancin and during treatment at 48 to 72 hour intervals. Pregnancy testing should be done on all women of childbearing age before the start of therapy.

Patient Education

Administration

If cholestyramine is used in conjunction with oral vancomycin, the medications should be administered several hours apart because cholestyramine binds oral vancomycin and prevents its effectiveness. The oral solution can cause a bitter or unpleasant taste and mouth irritation and should be followed by a full glass of water. Oral vancomycin can be taken without regard to meals. If the patient is too ill for oral therapy, vancomycin solution may be administered by nasogastric tube, enema, long intestinal tube, or directly into a colostomy or ileostomy.

Adverse Reactions

Skin rashes may occur and, if serious, should be reported to the health-care provider. Patients should report evidence of ototoxicity (loss of hearing; ringing, buzzing, or fullness in

ears; dizziness), neutropenia (chills, coughing, difficult breathing, sore throat, fever), or nephrotoxicity (altered frequency or amount of urine, nausea or vomiting, increased thirst, difficulty breathing, weakness).

Lifestyle Management

Detection and management of CDI were described earlier. If diarrhea is present, administration of an antiperistaltic antidiarrheal (e.g., atropine and diphenoxylate, loperamide, opioids) is contraindicated because it may delay the elimination of toxins from the colon, thereby prolonging or worsening the condition. Good perianal hygiene will improve patient comfort during this illness.

Patients should be educated about how to prevent the spread of skin infections, including hand washing and covering open skin lesions.

ANTIMYCOBACTERIALS

Mycobacterial infections are among the most difficult to cure because mycobacteria (1) grow slowly and are relatively resistant to drugs that are largely dependent on how rapidly cells are dividing, (2) have a lipid-rich cell wall relatively impermeable to many drugs, (3) are usually intracellular and inaccessible to drugs that do not have good intracellular penetration, (4) have the ability to go into a dormant state, and (5) easily develop resistance to any single drug. Tuberculosis, an example of a mycobacterial infection, is a worldwide public health issue. In addition to drug–organism issues, adherence is often poor to treatment regimens that include multiple drugs and last for months.

Despite these problems, drug combinations have proved effective in the treatment of mycobacterial disease. Drugs used to treat tuberculosis include first-line drugs (isoniazid [INH], rifampin [RIF, Rifadin, Rimactane], ethambutol [EMB, Myambutol], pyrazinamide [PZA], and streptomycin) and second-line drugs used for drug-resistant or recurrent disease (para-aminosalicylic acid [PASA], ethionamide [Trecator-SC], capreomycin [Capastat], cycloserine [Seromycin], kanamycin [Kantrex], ofloxacin [Floxin], levofloxacin [Levaquin], moxifloxacin [Avelox], and bedaquiline [Sirturo]). Rifabutin (Mycobutin) is used mainly to treat or prevent *Mycobacterium avium* complex (MAC) and may be the preferred rifamycin for HIV patients when specific drug–drug interactions exist. Management of tuberculosis is further discussed in Chapter 45, and HIV infection is discussed in Chapter 37.

Pharmacodynamics

Spectrum of Activity

Isoniazid is the most active drug for the treatment of tuberculosis. It interferes with lipid and nucleic acid biosynthesis in growing organisms. It is also thought that isoniazid and ethambutol inhibit synthesis of mycolic acids. These acids are important constituents for mycobacteria cell walls and are not found in mammalian cells. Isoniazid is bactericidal against susceptible mycobacteria, including intracellular and extracellular organisms.

Rifamycins (rifampin, rifabutin, and rifapentine) bind to the beta subunit of mycobacteria DNA-dependent RNA polymerase and inhibit RNA synthesis. Antimycobacterial action results in destruction of both multiplying and inactive bacilli. These drugs readily penetrate most tissues and can kill bacteria that are poorly accessible to many other drugs. Rifamycins are bactericidal against susceptible mycobacteria. Rifampin and rifabutin also have activity against *N. gonorrhoeae,* staphylococci, streptococci, *Mycobacterium leprae* (the cause of leprosy), MAC, and *H. influenzae* type b. Rifabutin is active against most *Mycobacterium* spp. Rifampin resistance develops rapidly when used as monotherapy; therefore, it should be combined with another active antibiotic for treatment of established infections.

Ethambutol inhibits synthesis of arabinogalactan, an essential component of mycobacteria cell walls. It also arrests cell multiplication, causing cell death. Ethambutol enhances the activity of lipophilic drugs such as rifampin and ofloxacin that cross the mycobacteria cell wall primarily in lipid portions of this wall. It is bacteriostatic against susceptible mycobacteria, including *M. tuberculosis*, *M. avium*, and *M. kansasii.*

Pyrazinamide, an analogue of nicotinamide, is bactericidal against *M. tuberculosis* in an acidic environment (pH less than 5.6). Pyrazinamide therapy is especially useful in the treatment of tuberculosis; it exhibits good activity within macrophages and plays a key role in killing intracellular organisms. This may be especially important in shortening therapy and preventing relapses. The exact mechanism of action of pyrazinamide is unknown.

Streptomycin is an aminoglycoside used now almost exclusively to treat *M. tuberculosis* infections. It is added as a fourth drug to the treatment regimen because up to 80% of patients treated with this drug harbor resistant bacilli after 4 months of treatment. Other mycobacteria except *M. avium* and *M. kansasii* are resistant to streptomycin. This drug is an irreversible inhibitor of protein synthesis. It penetrates cells poorly but is bactericidal in an alkaline extracellular environment.

Ethionamide, a thioamide with a similar binding site and mechanism of action as isoniazid, ultimately blocks the synthesis of mycolic acids. It is bacteriostatic against *M. tuberculosis,* and this drug also inhibits some other *Mycobacterium* species.

Capreomycin, a peptide antibiotic, inhibits RNA synthesis, thereby decreasing the replication of *M. tuberculosis.* Because resistance easily develops when it is given alone, it is given as part of a multidrug regimen. It is bactericidal to susceptible mycobacteria.

Bedaquiline is a unique antimycobacterial that was approved by the FDA in December 2012 specifically for the treatment of pulmonary multidrug-resistant tuberculosis. Bedaquiline inhibits mycobacterial adenosine triphosphate (ATP) synthesis and is active against replicating and dormant mycobacteria. The role of bedaquiline in the treatment

of tuberculosis therapy has yet to be fully defined. The FDA issued a Black-Box Warning that bedaquiline is associated with increased mortality as compared with a placebo treatment group. Bedaquiline should therefore only be used when an effective treatment regimen cannot otherwise be provided. Bedaquiline will not be discussed further.

Para-aminosalicylic acid, structurally similar to para-aminobenzoic acid (PABA) and the sulfonamides, is a folate synthesis antagonist that is active almost exclusively against *M. tuberculosis.* It is bacteriostatic. It is not used frequently because primary resistance is common and other drugs are better tolerated and less expensive. It will not be discussed further.

Resistance

Resistance to isoniazid is mediated through the *inhA* gene or through mutation or deletion of *katG,* which encodes mycobacterium catalase. *InhA* mutants have low-level resistance and cross-resistance to ethionamide. The *katG* mutants have high-level resistance but no cross-resistance. Resistant mutants occur with a frequency of about 1 per 10^6 bacilli and are selected out if isoniazid is given alone. Globally, 3.6% of new and 20.2% of previously treated cases of tuberculosis are resistant to both isoniazid and rifampin. In the United States, only 1% of new cases and approximately 3% of retreatment cases are resistant to isoniazid and rifampin (WHO, 2013c).

Resistance to rifamycins results from point mutations that prevent binding to RNA polymerase. Cross-resistance often exists between the rifamycins. The mechanism of resistance is unknown for ethambutol, but it develops rapidly when ethambutol is used as monotherapy. Resistance to ethionamide also develops rapidly when it is used as monotherapy.

Resistance also develops rapidly to pyrazinamide, but there is no cross-resistance to other antimycobacterial drugs so that it can be given to patients exposed to a case of multidrug-resistant tuberculosis. Capreomycin is also useful for treatment of drug-resistant tuberculosis because of its lack of cross-resistance to first-line drugs. A point mutation that alters the ribosomal binding site is the mechanism of resistance for streptomycin.

Pharmacokinetics

Absorption and Distribution

All oral antimycobacterials are rapidly and well absorbed in the GI tract after oral administration.

Isoniazid is 90% bioavailable but should be taken on an empty stomach because food decreases the peak and extent of absorption. It readily diffuses into all body fluids, including CSF (90% of serum levels), pleural, and ascitic fluids; tissues; organs; and saliva, sputum, and feces. It also crosses the placenta and enters breast milk.

Meals slow the rate of absorption of rifamycins but not the extent of absorption. These drugs may be taken with or without food. Bioavailability of the oral formulations vary between 20% for rifabutin in an HIV-positive person to over 90% for rifampin. Therapeutic concentrations are achieved

for all rifamycins at recommended doses. Rifamycins and ethambutol also penetrate and concentrate in most body fluids. Adequate penetration of CSF occurs only in the presence of inflamed meninges. They both cross the placenta and enter breast milk.

Pyrazinamide is widely distributed in body tissues and fluids including the liver and lung, and it reaches high concentrations in CSF. It enters breast milk.

Streptomycin and capreomycin are widely distributed through extracellular fluid, cross the placenta, and enter breast milk in small amounts. They have poor CSF penetration except in the presence of inflamed meninges.

Ethionamide is widely distributed to body tissues and fluids. CSF concentrations are equal to those in the serum.

Metabolism and Excretion

The metabolism of isoniazid is extensive and highly variable and dependent on acetylator status. The liver, in a process that is genetically controlled, primarily acetylates it. Fast acetylators metabolize this drug 5 to 6 times faster than slow acetylators do. Approximately 50% of both blacks and whites are slow acetylators, and the rest are rapid acetylators. The majority of Alaskan natives and Asians are rapid acetylators. The rate of acetylation does not alter effectiveness but may increase the risk for toxic reactions in slow acetylators. Rapid clearance is of no consequence when the drug is given daily but may result in subtherapeutic doses when given once weekly. Isoniazid metabolites and unchanged drug are excreted in the urine. Elimination is largely independent of renal function.

Rifampin and rifapentine are also metabolized in the liver by deacetylation, with metabolites also active against *M. tuberculosis.* Rifamycins are potent inducers of liver metabolism. With repeated administration, the half-lives of rifampin and rifapentine decrease. They are excreted mainly in bile; then, through enterohepatic recirculation, the remainder is excreted in feces, with a small amount excreted in urine. Hepatic insufficiency or the age of the patient alters the pharmacokinetics of rifabutin only slightly. Somewhat reduced drug distribution and faster drug elimination are seen in renal insufficiency and may result in decreased drug concentrations.

Ethambutol is mainly excreted as unchanged drug in the urine. However, about 20% of ethambutol is metabolized by oxidation in the liver. Marked accumulation may occur in renal failure.

Approximately 70% of a pyrazinamide dose is excreted in urine by glomerular filtration. Pyrazinamide is hydrolyzed by the liver to a metabolite that also has antimycobacterial activity. Its half-life may be significantly prolonged in the presence of impaired renal or hepatic function. Streptomycin and capreomycin are excreted almost exclusively by the kidney.

Approximately 35% of ethionamide is metabolized by the liver, and the majority of the drug is excreted in urine as inactive metabolites. Less than 1% is excreted as unchanged drug.

Table 24-26 presents the pharmacokinetics of selected antimycobacterials.

Table 24–26 ⊞ **Pharmacokinetics: Selected Antimycobacterials**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Capreomycin (IM)	Rapid	1–2 h	UA	UA	UA	4–6 h	52% unchanged in urine within 12 h
Ethambutol	Rapid	2–4 h	24 h	UA	69%–85%	3–4 h*	20%–50% metabolized by liver; 50% unchanged in urine
Ethionamide	Rapid	3 h	UA	10%	100%	2–3 h	Metabolized by liver; <1% unchanged in urine
Isoniazid (PO/IM)	Rapid	1–2 h	24 h	40%–30%	90%	1–4 h	Extensively metabolized by liver; up to 66% unchanged in urine, dependent on acetylator status
Pyrazinamide	Rapid	2 h	UA	5%–10%	Nearly complete	9–10 h*	Metbolized via hydrolysis, 70% excreted in urine
Rifampin	Rapid	2–4 h	24 h	88%–90%	90%–95%	1–5 h†	40%–60% in bile and by enterohepatic circulation
Rifabutin	Rapid	2–4 h	24 h	85%	20%–53%	45 h	30% in feces; 53% as metabolites in urine
Rifapentine	Rapid	5–6 h	UA	98%	70%	13–14 h	70% in feces, 17% in urine
Streptomycin (IM)	Rapid	0.5–1.5 h	UA	0%–10%	UA	2–3 h*	>90% in urine

UA = information unavailable.
  *Increased in renal or hepatic impairment.
  †Varies by dose and averages 2–3 h after repeated doses.

Pharmacotherapeutics

Precautions and Contraindications

Isoniazid should be used cautiously and with careful monitoring for hepatotoxity, especially for those patients who drink alcohol daily, who have active chronic liver disease or severe renal dysfunction, who are over 35 years of age, use drugs of abuse, are pregnant or immediately postpartum. Peripheral neuropathy and other neurotoxicities may occur with isoniazid use. Special caution should be used with patients with preexisting peripheral neuropathy and those who are pregnant or are HIV-positive.

Cautious use in renal impairment is recommended for ethambutol, streptomycin, and capreomycin. Dosage adjustments may be required and are discussed in the Clinical Use and Dosing section.

Cautious use in the presence of hepatic impairment is recommended for isoniazid, rifamycins (hepatotoxic), pyrazinamide, and ethionamide (hepatotoxic). Black and Hispanic women, women postpartum, and patients older than 50 years are at special risk for development of hepatitis while taking isoniazid.

Ethionamide should be given cautiously to patients with diabetes mellitus. Management may be more difficult and hepatitis is more likely in these patients.

Hematologic alterations including various anemias and thrombocytopenia have been seen with the use of isoniazid and rifampin. Ethambutol and pyrazinamide each may precipitate gouty arthritis attacks and should be used cautiously in the presence of this disorder.

Rifamycins are potent inducers of liver metabolism. These agents may lead to subtherapeutic concentrations of other medications metabolized by CYP enzymes. Treatment failures may occur.

See Table 24-27 for specific drug–drug interactions.

Ethambutol has caused visual disturbances, including irreversible blindness. Cautious use is advised in patients with inability to appreciate or report visual changes or with preexisting optic neuritis, cataracts, or diabetic retinopathy.

Pyrazinamide should not be used during acute gout attacks.

Pregnancy categories vary by drug and country. Isoniazid is Pregnancy Category A; most other antimycobacterials are Category C. Use of antimycobacterials, particularly isoniazid and rifampin, with ethambutol added if drug resistance is a possibility, is recommended because the risk of losing the fetus is secondary to tuberculosis infection or because congenital tuberculosis poses a higher risk than the observed risks of adverse effects of the treatment. The exception is streptomycin. Streptomycin, Pregnancy Category D, may cause congenital deafness if given to pregnant women.

The infant should be observed for any evidence of adverse effects from drugs that appear in breast milk. Discontinuing the drug must take into account the importance of the drug for the mother. The drugs that enter breast milk in smaller amounts include rifampin, ethambutol, and pyrazinamide.

Table 24–27 ⬛ **Drug Interactions: Selected Antimycobacterials**

Drug	Interacting Drug	Possible Effect	Implications
Capreomycin	Aminoglycosides and other ototoxic and nephrotoxic drugs Isoniazid, ethionamide Phenytoin	Additive ototoxicity and nephrotoxicity Additive CNS effects; increased risk for peripheral neuropathy Inhibition of phenytoin metabolism; increased toxicity risk	Avoid concurrent use If symptoms occur, discontinue one of the drugs Monitor serum levels of phenytoin
Ethambutol	Aluminum salts	Reduced absorption of ethambutol	Administer ethambutol 1–2 h before aluminum salt
Isoniazid	Alcohol	Daily ingestion increases risk for hepatitis	Avoid concurrent use
	Aluminum salts	Reduced oral absorption of isoniazid	Administer isoniazid 1–2 h before aluminum salts
	Oral anticoagulants	Enhanced anticoagulant activity	Avoid concurrent use or monitor PT/INR
	Benzodiazepines (BDZs)	Isoniazid may inhibit metabolic clearance of BDZs that undergo oxidative metabolism (e.g., diazepam, triazolam)	Avoid concurrent use
	Carbamazepine	Toxicity or hepatotoxicity may occur	Monitor carbamazepine drug levels and liver function
	Cyclosporine	Increased risk of neurotoxicity	Use with caution
	Disulfiram	Acute behavioral and coordination changes	Avoid coadministration
	Hydantoins	Increased serum hydantoin levels because of inhibition of CYP-450 enzymes. Most significant in slow acetylators	Monitor hydantoin levels and adjust doses as needed
	Itraconazole and ketoconazole	Decreased serum antifungal levels; decreased antifungal activity	Select different antifungal
	Rifampin	Increased risk for hepatotoxicity	If alterations in liver function tests, discontinue one of these drugs
	Theophylline	Increased or decreased theophylline levels	Monitor theophylline levels
	Warfarin	Increased warfarin effects and risk of bleeding	Monitor closely
	Tyramine-containing foods	Isoniazid has slight monoamine oxidase inhibition activity	Teach patient foods to avoid
	Histamine-containing foods	Diamine oxidase may be inhibited	Teach patient foods to avoid (e.g., tuna, sauerkraut, yeast extract)
Pyrazinamide	Laboratory interactions	Has been reported to interfere with Acetest and Ketostix urine tests to produce a pink/brown color	Select different method of determining ketoacidosis
Rifamycins (rifampin, rifapentine, rifabutin)	Oral anticoagulants, azole antifungals, barbiturates, BDZs, beta blockers, chloramphenicol, clofibrate, oral contraceptives, corticosteroids, cyclosporine, digitoxin, disopyramide, efavirenz, elvitegravir, etravirine, estrogens, hydantoins, methadone, mexiletine, miraviroc, nevirapine, quinidine, sildenafil, sulfonylureas, tacrolimus, tamoxifen, theophylline, tocainide, verapamil	Rifampin induces CYP-450 enzyme systems that metabolize these drugs. Therapeutic effects of these drugs may be significantly decreased. Treatment failure may occur.	Select alternative therapy

Continued

Table 24–27 ⚎ **Drug Interactions: Selected Antimycobacterials—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
	Digoxin	Decreased serum levels of digoxin	Monitor serum levels or select different antimycobacterial
	Isoniazid	Increased risk for hepatotoxicity	See isoniazid above
	Protease inhibitors	Significant decrease in protease inhibitor concentrations, increased risk of HIV or hepatitis C treatment failure	Avoid concurrent use
	Laboratory interactions	Therapeutic levels of rifampin interfere with standard assays of serum folate and B_{12}	Consider alternative methods for determining concentrations
Rifabutin	Clarithromycin	Increased rifabutin levels, decreased clarithromycin levels. Increased risk of neutropenia, rash, GI disturbances.	Monitor for toxicity; select a different macrolide if possible
	Efavirenz	Decreased rifabutin levels	Increase rifabutin dose
	Fluconazole	Up to 80% increase in rifabutin levels, increased risk of rifabutin toxicity, including uveitis	Use with caution; monitor for toxicity
Streptomycin	Cephalosporins, vancomycin	Increased risk of nephrotoxicity	Monitor renal function
	Loop diuretics	Increased risk for ototoxicity. Hearing loss may be irreversible.	Avoid concurrent use

CNS = central nervous system; INR = international normalized ratio; PT = prothrombin time.

Capreomycin is excreted in such small amounts as to be undetectable in some women. Isoniazid is distributed into breast milk but is considered safe during breastfeeding.

Use in children varies by drug. Pediatric doses are listed for all of these drugs, but the age under which they should not be used varies. No age restrictions are provided for isoniazid, rifampin, and pyrazinamide. The safety and efficacy of rifabutin or rifapentine have not been established in children. Ethambutol is not FDA approved for use by children younger than 13 years. Safety and optimal dosage have not been determined for children for ethionamide and capreomycin. Ototoxicity risk precludes use of streptomycin in neonates and in older adults or patients with diminished hearing.

Adverse Drug Reactions

All of the antimycobacterial drugs have risks for hypersensitivity reactions, some of which may be severe. The usual management associated with these reactions applies here as well.

Peripheral neuropathy is the most common adverse reaction with isoniazid. It occurs in about 2% of patients taking 5 mg/kg/d. Prevalence is higher for patients taking higher doses, up to about 44% for patients taking 16 mg/kg/d. The symptoms include symmetrical numbness and tingling in the extremities. Patients predisposed to this adverse reaction include the malnourished, slow acetylators, pregnant women, older adults, diabetics, and patients with chronic liver disease, including alcoholics. Pyridoxine (B_6) prevents the development of peripheral neuropathy and is recommended for patients in these at-risk categories. Some providers use

pyridoxine for all patients on isoniazid. Recommended prophylactic doses range from 10 to 50 mg daily. Treatment of established neuropathy requires 50 to 200 mg daily.

Elevated serum transaminases (AST/ALT) are observed in 10% to 20% of patients taking isoniazid. Patients at risk were discussed previously. This condition typically occurs in the first 3 months of therapy, is asymptomatic, and will return to normal with continued isoniazid therapy. However, a small portion of patients (0.4%) may progress to hepatic failure or necrosis. The symptoms are those usually associated with the development of hepatitis, including abnormal liver function studies, jaundice, and fatigue. The frequency of progressive liver damage increases with age. Concurrent alcohol use increases the risk. When rifampin is given concurrently, the risk is increased 4-fold. Other adverse reactions associated with isoniazid include blood dyscrasias, metabolic acidosis, drug fever, and gynecomastia.

The most common adverse reactions associated with rifamycins are GI in nature: anorexia, nausea, vomiting, diarrhea, flatulence, and abdominal pain. Although hepatotoxicity is less common than it is with isoniazid, hepatotoxicity leading to hepatitis occurs with rifampin. Transient elevations of AST/ALT are seen in the first 8 weeks of therapy in 10% to 15% of patients. However, less than 1% of patients have progressive hepatotoxicity. A harmless orange-red discoloration of body fluids, including tears, saliva, urine, sweat, CSF, and feces, also occurs. Hematuria should not be confused with this discoloration because hematuria may be an indication of a hypersensitivity reaction.

Other adverse reactions associated with rifamycins include blood dyscrasias, headache, drowsiness and inability

to concentrate, a pruritic rash (1% to 11% of patients), visual disturbances, lupus erythematosus, and exudative conjunctivitis. Thrombocytopenia and neutropenia have been observed with rifabutin.

Ethambutol also has the usual GI disturbances, but the most serious adverse reaction is optic neuritis, which appears to be dose-related. Signs and symptoms include decreased visual acuity, red-green color blindness, diminished visual fields, and sometimes loss of vision. These adverse reactions are generally reversible when the drug is discontinued promptly. In rare cases, recovery may take up to 1 year. Vision testing should be done before and throughout therapy. Other adverse reactions associated with ethambutol include precipitation of gouty arthritis related to elevated uric acid levels, transient impairment of liver function, and infrequent peripheral neuropathy.

The principal adverse reaction with pyrazinamide is dose-related hepatotoxicity that may appear any time during therapy. Patients at risk for this adverse reaction are the same ones mentioned in the Precautions and Contraindications section. Discontinuing the drug may be required. Because this drug inhibits the renal excretion of urates, hyperuricemia also often occurs. It is often asymptomatic but may precipitate acute gouty arthritis or arthralgias. Baseline serum uric acid levels should be drawn.

The most serious adverse effect associated with streptomycin and capreomycin is ototoxicity. Damage to the eighth cranial nerve results in vertigo, nausea, vomiting, and loss of hearing. The risk is increased with higher doses and longer duration of therapy. Nephrotoxicity is also a serious risk for patients on any aminoglycoside. Risk for this adverse reaction increases for patients with renal insufficiency and for older adults with age-related decreased renal function. Dosage adjustments are made based on renal function studies to reduce the risk for this adverse reaction. Doses taken 2 or 3 times weekly rather than daily also reduce the risk for toxicity.

Ethionamide has few adverse reactions, but it is often poorly tolerated because of its most common adverse reaction, GI distress, including nausea and diarrhea. Some patients develop a metallic taste in their mouth. Other common adverse reactions include hepatitis (rare), optic neuritis, and peripheral neuritis (common). Neurological symptoms can be alleviated by pyridoxine.

Cycloserine is associated with neurological effects, such as somnolence, psychosis, and suicidal ideation.

Drug Interactions

Drug interactions and drug–food interactions vary by drug. Many are associated with increased incidence of the common adverse reactions for the particular antimycobacterial. Some are associated with reduced effectiveness of the interacting drug. Rifamycins are potent inducers of the CYP450 enzyme system and speed the metabolism of many drugs, resulting in therapeutic failure.

Antimycobacterial agents may reduce the effectiveness of the live Bacillus Calmette Guerin (BCG) vaccine

and intravesical treatment regimens. Concomittant use should be avoided. Table 24-27 provides a list of the drug interactions.

Clinical Use and Dosing

Resistance to antimycobacterial drugs has a frequency of about 1 in 10^6 bacilli. However, with 10^8 bacilli lesions in an infected person, resistant mutants are selected out when only one drug is given. Because of the relatively high proportion of adult patients with tuberculosis caused by organisms that are resistant to isoniazid, four drugs are necessary in the initial phase of therapy for the 6-month regimen to be maximally effective (CDC, 2003). Multiple drugs with independent actions lower the prevalence of resistance. Patients with HIV infection are especially at risk for tuberculosis and resistance development. Treatment regimens include initial phase and continuation phases. Initial phases have four drugs (isoniazid [INH], rifampin [RIF], pyrazinamid [PZA], and ethambutol [EMB]) given for 2 months followed by continuation phases, usually with two drugs (INH and another drug, most often RIF) given for 4 to 7 months.

The first-line antimycobacterial drugs should be administered together; split dosing should be avoided. Fixed-dose combination preparations may be more easily administered than single-drug tablets and may decrease the risk for acquired drug resistance and drug errors. Two combination formulations have been approved for use in the United States: INH/RIF (Rifamate) and INH/RIF/PZA (Rifater). It should be noted that for patients weighing more than 90 kg, the dose of PZA in the three-drug combination is insufficient and additional PZA tablets are necessary.

Some continuation phase protocols are designed for HIV-infected individuals. These combinations are discussed in Chapter 37. Initial phase and continuation phase drug combinations and dosing for tuberculosis are discussed in Chapter 45.

Table 24-28 presents the dosage schedule for selected antimycobacterials.

Rational Drug Selection

Rifampin is also used to treat several nonmycobacterialinfections. It is used as prophylaxis for close contacts of people with meningococcal infections caused by *N. meningitidis,* including household members, children and personnel in nurseries and day-care centers, and closed populations such as in college dormitories and military barracks. Health-care personnel with intimate exposure to index cases (such as mouth-to-mouth resuscitation) should receive prophylactic therapy. Prophylaxis for adults is oral rifampin 600 mg every 12 hours for four doses (two days). The dose for children is 10 mg/kg every 12 hours for four doses (two days).

Rifampin is also indicated for prophylaxis for close contacts of people with actual or suspected infections with *H. influenzae* type b. If one of the contacts in a household is an unvaccinated child 4 years or younger, it is recommended that all contacts in the household except pregnant

Table 24–28 ⚛ Dosage Schedule: Selected Antimycobacterials

Drug	Indication	Dosage Form	Initial Dose	Comments
(Capastat)	Tuberculosis, as part of combined drug therapy when first-line therapy ineffective or caused toxicity or resistance	Powder for injection: 1 g	1 g IM/IV daily for 60–120 d, then 1 g 2–3 times/wk	Maximum adult daily dose 20 mg/kg. Monitor renal function tests, audiograms, vestibular function, and sites of injection at baseline and at least weekly. Serum potassium should be measured at baseline and monthly during daily therapy. Administer deep IM into large muscle mass because superficial injections are associated with pain and sterile abscess. Administer within 24 h of reconstitution. Store in refrigerator after reconstitution. Darkening of reconstituted drug from initial nearly colorless or straw color does not affect potency. Renal impairment requires decreased dose (see package insert). Educate patients to report altered hearing, dizziness, imbalance; altered urination, nausea, vomiting, or thirst. Patients should advise prescribers they are taking capreomycin because of its potential for drug interactions.
Ethambutol (Myambutol)	Tuberculosis, as part of combined drug therapy	Tablets: 100 mg, 400 mg	*Adults:* Orally 15–25 mg/kg/d, maximum 1,500 mg/d; *or* 50 mg/kg up to 2,500 mg twice/wk; *or* 25–30 mg/kg 3 times/wk *Children <13 yr:* HIV negative: 15–20 mg/kg/d *or* 50 mg/kg twice weekly HIV exposed/infected: 15–20 mg/kg/d Not recommended for children <6 yr in whom visual acuity cannot be monitored	Maximum adult daily dose 1.5 g. Impairment of renal function may require a decreased dosage. Monitor visual fields and red and green discrimination prior to and monthly during treatment, especially for prolonged therapy or >15 mg/kg daily. Periodic uric acid and renal function tests.
	Atypical mycobacterial infections (off-label)		Orally 15–25 mg/kg/d	Educate about importance of vision monitoring. Blurred vision, eye pain, vision loss, or problems with red and green discrimination should be reported. Other reportable symptoms include evidence of peripheral neuropathy (numbness, tingling, burning pain, weakness in hands or feet), gout (chills, pain and swelling of joints, hot skin over affected joints), and hypersensitivity (rash, fever, joint aches). Take drug with food if GI irritation occurs.
Ethionamide (Trecator)	Tuberculosis, as part of combined drug therapy	Tablets: 250 mg	*Adults:* 250 mg q8–12h for 1–2 yr or more *Children:* 15–20 mg/kg/d divided into 2 or 3 doses *or* 15 mg/kg as 1 dose daily	Administer with meals to minimize GI distress. Maximal daily adult dose 1 g. In order to minimize the risk of resistance to the drug, give the highest tolerated dose (based on gastrointestinal intolerance). Monitor liver function tests periodically. Ophthalmic examinations if symptoms of visual impairment. Orthostatic blood pressure checks. Thyroid function tests if signs of hypothyroidism; serum glucose if signs of hypoglycemia. Neurological exam for peripheral neuritis.

Table 24–28 ⚛ **Dosage Schedule: Selected Antimycobacterials—cont'd**

Drug	Indication	Dosage Form	Initial Dose	Comments
				Pyridoxine decreases risk of peripheral neuropathy. Report signs of hepatitis (yellow eyes or skin, upper abdominal pain, malaise), peripheral neuritis (numbness, tingling, burning pain, weakness in hands or feet), optic neuritis (blurred vision, eye pain), hypoglycemia (poor concentration, tachycardia, hunger, shakiness), or hypothyroidism (weight gain; dry, puffy skin; coldness; irregular menses). Administer with or after meals if GI irritation occurs. Usually administered after evening meal or at bedtime as a single dose. Serum concentrations may be higher with divided doses, but GI irritation may worsen.
Isoniazid (Laniazid) (Nydrazid) Isoniazid combinations (Rifater) (Rifamate)	Inactive or latent tuberculosis	Tablets: 100 mg, 300 mg Syrup: 50 mg/5 mL Injection: 100 mg/mL Injection: 100 mg/mL Tablets: 120 mg rifampin, 50 mg isoniazid, 300 mg pyrazinamide Capsules: 150 mg isoniazid, 300 mg rifampin	*Adults:* PO or IM 5 mg/kg up to 300 mg/d *or* 15 mg/kg up to 900 mg 2 or 3 times/wk *Children:* 10–15 mg/kg, up to 300 mg, once daily *or* 20–40 mg/kg up to 900 mg/day 2 or 3 times/wk	Renal impairment does not usually require dosage adjustment if serum creatinine is <6 mcg/dL and patient is fast acetylator. For slow acetylators, adjust dose to maintain plasma concentration <1 mcg/mL at 24 h after last dose. Monitor liver function tests monthly or more often if liver impairment or clinical signs of hepatitis or prodromal symptoms. CBC and platelet count periodically or at signs of blood dyscrasia (fever, sore throat, bleeding or bruising, tiredness). Ophthalmic exam if signs of optic neuritis. Educate to report signs of clinical hepatitis (dark urine, yellow eyes or skin), hepatitis prodromal symptoms (anorexia, nausea and vomiting, unusual tiredness), optic neuritis (blurred vision or loss of vision, with or without eye pain), or peripheral neuropathy (numbness, clumsiness, burning pain of hands or feet). High risk for peripheral neuropathy (pregnant, high alcohol use, taking anticonvulsants, poor diet, malnourished, history of neuritis, chronic renal failure, diabetes, and over 65) should be prescribed 25 mg pyridoxine/d. May be taken with meals or antacids if GI irritation occurs, but do not take within 1 h of aluminum-containing antacid. Measure syrup with calibrated measuring device. Crystals may form at low temperatures, but they redissolve upon warming to room temperature.
	Tuberculosis, as part of combined drug therapy Prophylaxis or preventive TB therapy		*Adults:* PO or IM 300 mg once daily *or* 15 mg/kg, up to 900 mg, given 2–3 times/wk *Children:* 10 mg/kg, up to 300 mg, once daily, *or* 20–40 mg/kg, up to 900 mg, given 2–3 times/wk	As above. Directly observed therapy (DOT) may be administered twice weekly The following contacts with TB infection should be given prophylaxis INH therapy for 8–12 wk after exposure and until they have a negative PPD: (1) children aged <5 years; (2) contacts with HIV infection; (3) other contacts with risk factors for progression to TB disease (4); (4) contacts with documented skin test conversion; and (5) contacts of patients with positive sputum AFB smear results and cavities on chest radiography (www.CDC.gov/TB)

Continued

Table 24–28 ⊗ **Dosage Schedule: Selected Antimycobacterials—cont'd**

Drug	Indication	Dosage Form	Initial Dose	Comments
Pyrazinamide	Tuberculosis, as part of combined drug therapy	Tablets: 500 mg	*Adults and children:* 15–30 mg/kg once daily or 50–70 mg/kg 2–3 times/wk; patients with HIV take 20–30 mg/kg/d for first 2 mo DOT: 50 mg/kg/dose twice weekly	Maximal adult and pediatric daily dosage is 2 g when taken daily, 3 g when taken 3 times/wk, 4 g when taken twice/wk. Monitor liver function tests prior to and every 2–4 wk during treatment. Uric acid determinations may be needed. Educate that arthralgia is usually mild and self-limiting and to report signs of hepatotoxicity (dark urine, anorexia, nausea, vomiting, yellow skin or eyes) and gout (pain, swelling, heat over joints). May be taken without regard to meals.
Rifampin (Rifadin, Rimactane)	Tuberculosis, as part of combined drug therapy	Capsules: 150, 300 mg	*Adults:* 600 mg PO once daily *or* 10 mg/kg up to 600 mg 2–3 times/wk *Infants <1 mo:* 10–20 mg/kg PO once daily *or* 10–20 mg/kg 2–3 times/wk	Maximum adult or pediatric daily oral dose should not exceed 600 mg. Severe hepatic impairment requires 50% reduction in dosages. Monitor hepatic function prior to and at least monthly during treatment; CBC if signs of blood dyscrasia (sore throat, bleeding, bruising). Advise patients to report signs of hepatotoxicity (dark urine, anorexia, nausea, vomiting, yellow skin or eyes), flu-like syndrome, or blood dyscrasias. Reddish orange or reddish brown discoloration may stain clothes or soft contact lenses but is harmless. Avoid alcohol, which can increase hepatotoxicity. Advise healthcare providers of rifampin use because of high risk of drug interactions. May be taken without regard to meals. Shake suspension before measurement, using calibrated dosing device. Store suspension at controlled room temperature and discard remaining liquid 30 d after reconstitution.
	Meningococcal meningitis prophylaxis		*Adults:* 600 mg PO bid for 2 d *Children:* 10 mg/kg q12h for 2 d (max 600 mg/dose) *Infants < 1 mo:* 5 mg/kg q12h for 2 d	As above
	H. influenzae meningitis prophylaxis (off-label)		*Adults:* 600 mg PO once/d for 4 d *Children:* 20 mg/kg once daily for 4 d (10 mg/kg if infant <1 mo)	As above
	Staphylococcal infections as part of combination therapy		*Adults:* 600 mg once daily or 300 mg bid–tid	As above
Rifabutin (Mycobutin)	MAC treatment and prophylaxis, as part of combined drug therapy	Capsules: 150 mg	*Adults and adolescents:* 300 mg once daily *Infants and children:* 10–20 mg/kg once daily (maximum 300 mg/day)	May need to monitor platelet count and WBC. Rifabutin increases rate of metabolism of many drugs, including anti-HIV agents; monitor drug response and/or blood levels, if available. Also, rifabutin is affected by strong inhibitors of CYP 3A4, thus dosing of rifabutin may need to be adjusted based on specific drug interactions.

Table 24–28 ⚛ **Dosage Schedule: Selected Antimycobacterials—cont'd**

Drug	Indication	Dosage Form	Initial Dose	Comments
				Counsel patient to report allergic reaction, GI intolerance, or asthenia. May turn secretions reddish brown that can stain clothing and soft contact lenses. May be administered without regard to food. If unable to tolerate single dose, split into 2 equal doses with food. May need to adjust dose up or down for patient taking antiretrovirals.
	Tuberculosis treatment, as part of combined drug therapy		*Adults:* 300 mg daily, but may vary based on other medications	As above
Rifapentine (Priftin)	Inactive or latent tuberculosis	Tablets: 150 mg	*Adults:* 15 mg/kg once weekly with INH	Give only as directly observed therapy
	Tuberculosis treatment, as part of combined drug therapy		*Adults:* 600 mg twice weekly for the first 2 mo, then 600 mg weekly	As above
Streptomycin	Tuberculosis, as part of combined drug therapy	Injection: 400 mg/mL	*Adults:* 1 g once daily IM. Reduce to 1 g 2–3 times/wk as soon as clinically feasible *Children:* 20 mg/kg once daily IM, not to exceed 1 g/d *Elderly:* 500–750 mg once daily IM Duration of therapy may be 1–2 yr	Maximum adult daily dose 4 g daily. Maximum pediatric daily dose 1 g. Renal impairment requires reduced dosage. Monitor serum concentrations: peak concentrations >50 mcg/mL are associated with nephrotoxicity and should not be >20–25 mcg/mL in patients with pre-existing renal damage. Caloric stimulation tests may be required before, during, and after prolonged therapy to detect vestibular toxicity. Do audiograms and renal function tests periodically and frequent urinalysis to detect albumin, casts, cells, and decreased specific gravity. Educate patient to report signs of hypersensitivity (skin itching, rash, swelling), vestibular ototoxicity (clumsiness, dizziness, nausea, vomiting), auditory ototoxicity (hearing loss; fullness, ringing, buzzing in ears), peripheral neuritis (burning of face or mouth, numbness, tingling), and nephrotoxicity (altered frequency or amount of urination, thirst, anorexia, nausea and vomiting). Administer deep IM, alternating injection sites. Concentration of solution should not exceed 500 mg/mL. After reconstitution, solution retains potency for 2–28 d at room temperature and 14 d in refrigerator, depending on manufacturer. See package insert. Darkening of solution does not affect potency.

women receive prophylaxis. In a day-care center attended by unvaccinated children younger than 2 years, prophylaxis with rifampin 20 mg/kg up to 600 mg once daily for 4 days for all contacts and vaccination of all unvaccinated children should be considered. If all contacts are older than 2 years, prophylaxis is not indicated. If there have been two or more cases in the center within 60 days and unvaccinated children attend, prophylaxis is recommended for children and personnel.

Finally, rifampin has an off-label use in the treatment of leprosy and concurrently with other antistaphylococcal agents in the treatment of serious infections in hospitalized patients caused by *Staphylococcus,* including methicillin-resistant and multidrug-resistant strains.

Patient Education

Administration

Because of the long duration of therapy and complexity of the protocols in tuberculosis infections, instruction and support are essential. Multidrug therapy, essential to prevent development of resistance, presents serious challenges for adherence. Some protocols are given daily for 8 weeks (56 doses) or 5 days/week for 8 weeks (40 doses) in the initial phase and then given twice weekly for 18 weeks (36 doses) during the continuation phase. To maintain this complex two- to four-drug regimen requires commitment on the part of the patient and usually outside help. This is especially true for lower-socioeconomic populations and other high-risk groups that normally have limited contact with the health-care system. Directly observed therapy (DOT), in which each dose is observed by a health-care provider or other designated person, has proved very effective in promoting compliance and improving response to therapy. Lifestyle implications of tuberculosis include general health promotion strategies such as good nutrition, rest, and appropriate exercise.

Adverse Reactions

Adverse effects, especially GI upset, are relatively common in the first few weeks of initial phase therapy. However, first-line drugs, particularly rifampin, must not be discontinued because of minor adverse effects. Although taking the drug with food may delay or moderately decrease the absorption, the effects of food have little clinical significance. Patients who have epigastric distress or nausea with this drug should be told that they can take their whole drug protocol with meals or that the hour of dosing can be changed. Administration with food is preferable to splitting a dose or changing to a second-line drug.

Rifamycins may discolor urine, tears, saliva, and sweat. This may result in the staining of clothing, dentures, or contact lenses. Patients receiving ethambutol should be advised to contact their provider if they experience eye pain or visual changes.

Lifestyle Management

Lifestyle management related to HIV infection is discussed in Chapter 37 and in Chapter 45 related to tuberculosis. Dosages, monitoring, and patient education are summarized in Table 24-28.

ANTIVIRALS

Viral infections range from the annoying, but short-lived and self-limiting, "common cold" to the progressive and, to date, incurable HIV. Discussion in this section focuses on nucleoside analogues used to treat herpes virus infections. Chapter 37 discusses drugs to treat HIV. Drugs used to treat cytomegalovirus (CMV) retinitis and other CMV disease in HIV patients (e.g., foscarnet, ganciclovir, valganciclovir) are also discussed in Chapter 37.

Viruses are obligate intracellular agents that depend on use of the host cell's genetic material for replication. As a result, antiviral drugs must either block entry into the cells or be active inside host cells to be effective. Ideally, an antiviral medication would be selective to specific viral components or pathways; however, many antivirals are nonselective and so damage to host cells and virus may result concomitantly. To further complicate treatment, replication of the virus may peak at or before clinical symptoms appear in many viral infections, so optimal clinical efficacy depends on early recognition and treatment or prevention. Finally, many viruses depend on enzymes to reproduce and can quickly mutate in the presence of drug therapy.

Viral replication consists of several steps: (1) adsorption to and penetration into susceptible cells; (2) uncoating of viral nucleic acid; (3) synthesis of early, regulatory proteins; (4) synthesis of RNA or DNA; (5) synthesis of late, structural proteins; (6) assembly of viral particles; and (7) release from the cell. Antiviral drugs target these steps. Many of the currently available antiviral agents act on synthesis of purine and pyrimidine (step 4).

NUCLEOSIDE ANALOGUES

Pharmacodynamics

The nucleoside analogues are used mainly to treat herpes infections by interfering with DNA synthesis and inhibiting viral replication. Acyclovir (Zovirax) is an acyclic guanosine derivative that requires three phosphorylation steps for activation. It is first converted to the monophosphate derivative by the virus-specific thymidine kinase and then to the di- and triphosphate compounds by the host's cellular enzymes. Because it requires the viral kinase for the first step, it is selectively activated only in infected cells. The final step, acyclovir triphosphate, inhibits viral DNA synthesis.

Valacyclovir (Valtrex) is the L-valine ester of acyclovir. It is rapidly converted after oral administration to acyclovir and so its mechanism of action is that of acyclovir; however, serum levels are 3 to 5 times higher than those achieved with oral acyclovir.

Famciclovir (Famvir) is the diacetyl ester prodrug of 6-deoxy penciclovir, an acyclic guanosine analogue. It is rapidly metabolized to penciclovir in the intestinal mucosa and liver. Penciclovir has a mechanism of action and spectrum of activity similar to acyclovir. Activation is catalyzed by virus-specified thymidine kinase in infected cells, resulting in competitive inhibition of the viral DNA polymerase and inhibition of DNA synthesis. It has lower affinity for the viral DNA polymerase than acyclovir, but it achieves higher intracellular concentrations and has a more prolonged intracellular effect.

Another nucleoside analogue, ribavirin (Virazole), is active against a wide range of DNA and RNA viruses, including influenza A and B, parainfluenza, respiratory syncytial virus (RSV), paramyxoviruses, hepatitis C virus (HCV), and HIV-1. Oral ribavirin plays a key role when combined with interferon for the treatment of HCV; however, it has not proved beneficial for RSV or HIV-1 infections. It is given via a

SPAG-2 aerosol treatment for RSV, usually in the hospital. It is not discussed further in this chapter.

Spectrum of Activity

Acyclovir is active against herpes simplex virus (HSV) 1 and 2; varicella-zoster virus (VZV); and, to a lesser extent, Epstein-Barr virus (EBV), CMV, and herpes virus 6 (HSV-6), which is implicated as the cause of roseola and other febrile diseases in childhood. Valacyclovir is converted to acyclovir after oral administration and is active against the same viruses. Famciclovir is active against HSV-1 and HSV-2, VZV, EBV, and hepatitis B virus.

Resistance

Resistance to acyclovir can develop in HSV and VZV through alteration in either the viral thymidine kinase or viral DNA polymerase. Because most resistance is based on deficient thymidine kinase activity, cross-resistance occurs with acyclovir, valacyclovir, and famciclovir.

Pharmacokinetics

Absorption and Distribution

Absorption following oral administration varies by drug. Acyclovir is poorly absorbed orally (15% to 20%), although therapeutic levels are achieved at recommended doses. Topical formulations (acyclovir, docosanol, penciclovir) produce local concentrations that may exceed 10 mcg/mL in herpetic lesions, but systemic concentrations are undetectable. Valacyclovir is 54% bioavailable as acyclovir after oral administration. Famciclovir is absorbed in the intestine for conversion to its active form, penciclovir. Food slows absorption but does not affect the extent of absorption. Penciclovir is marketed as a topical preparation only.

Acyclovir, famciclovir, and valacyclovir are widely distributed. Areas of distribution of acyclovir include the brain, kidney, saliva, semen, herpetic lesions, and lung. CSF concentrations are 50% of plasma for acyclovir and valacyclovir. Acyclovir and penciclovir are less than 33% protein bound. Acyclovir crosses the placenta and is found in breast milk.

Metabolism and Excretion

Acyclovir is 90% eliminated in the urine as unchanged drug, primarily by glomerular filtration and tubular secretion. The liver metabolizes the remaining 10%. The kidneys also excrete the active metabolite of famciclovir (penciclovir). Because valacyclovir is rapidly converted to acyclovir, it shares the same excretion pattern. Dosage adjustments are required for each of these drugs in the presence of renal impairment because of prolonged half-lives.

Table 24-29 presents the pharmacokinetics of nucleoside analogues for herpes virus infections.

Pharmacotherapeutics

Precautions and Contraindications

Renal failure has been reported with all drugs in this group. Therefore, dose adjustment and cautious use is advised for patients with renal impairment. This caution is also important in older adults, who commonly have diminished renal function or have inadequate hydration. Other nephrotoxic agents should be avoided if possible. Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS) has been reported with acyclovir therapy.

Acyclovir, valacyclovir, and famciclovir are listed as Pregnancy Category B; however, little information is available for famciclovir. Acyclovir and valacyclovir are preferred in pregnancy because there is more data supporting the safety of acyclovir. Acyclovir is excreted in breast milk; however, the concentrations are low and considered to pose minimal risk to infants. Famciclovir has not been well studied in breastfeeding; therefore, caution or alternative therapy is advised.

Among these drugs, acyclovir is the safest for children. Oral formulations are approved for children older than 2 years of age. Famciclovir does not have established safety and efficacy for children younger than 18 years. The safety and efficacy of valacyclovir have not been established for children.

Adverse Drug Reactions

Adverse drug reactions vary by drug. Acyclovir has few reactions when given orally at recommended doses. Those reactions associated with short-term administration include headache, skin rash, nausea and vomiting, and diarrhea. Oral and intravenous acyclovir therapy has been associated with renal dysfunction. This typically occurs with high doses when the maximum solubility of free drug is exceeded, leading to

Table 24–29 ⬥ Pharmacokinetics: Nucleoside Analogues for Herpes Virus Infections

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Acyclovir	UA	1.5–2.5 h	4 h	9%–33%	15%–20%	3–4 h; 20 h in anuria	>90% in urine; rest metabolized by liver
Famciclovir	Rapid	1 h	8–12 h	20%	77%	2–3 h; prolonged in renal impairment	Mostly in urine
Valacyclovir	UA	1.5–2.5 h	8–24 h	13%–18%	54%	2.5–3h; 14 h in anuria	>90% in urine; rest metabolized by liver

UA = information unavailable.

crystalluria. But acute tubular necrosis has also been reported. Patients receiving IV acyclovir, other nephrotoxic drugs, and those with preexisting renal dysfunction or who are dehydrated are at particular risk of developing renal dysfunction or failure.

Neurologic effects such as ataxia, dizziness, confusion, encephalopathy, tremor, and seizures have been reported. Elderly patients and those with renal dysfunction are more likely to experience these effects. The most frequent adverse reactions associated with famciclovir are headache, dizziness, somnolence, and paresthesias.

Because it is converted to acyclovir, the adverse reactions for valacyclovir are the same as for acyclovir. Valacyclovir does have a higher incidence of adverse reactions when compared to oral acyclovir, including serious ones (TTP/HUS) in immunocompromised patients.

Drug Interactions

Drug interactions are minimal for acyclovir, famciclovir, and valacyclovir. Table 24-30 presents the few drug interactions that exist for nucleoside analogues.

Clinical Use and Dosing

The most important variable in selecting the dosage of nucleoside analogues is renal function. The dosing interval, dosage, or both are adjusted for patients with impaired renal function, depending on the dosage and degree of impairment. For example, the usual dose of valacyclovir for herpes zoster treatment in a patient with CCr greater than 50 mL/min is 1 g every 8 hours, whereas the dosage for a CCr less than 10 mL/min is 500 mg every 24 hours; for acyclovir the usual dose is 800 mg every 4 hours (5 times per day). If CCr is less than 10 mL/min, the dose is 200 mg every 12 hours. The prescriber should consult the package insert or a comprehensive reference for specific dosing guidelines.

The nucleoside analogues are recommended for the treatment of infections by the herpes simplex virus commonly seen in primary care, specifically genital herpes, herpes zoster (shingles), varicella (chickenpox), and gingivostomatitis in children. The nucleoside analogues do not cure herpes infections but may shorten duration, decrease severity, and reduce the incidence of sequelae of the infection.

Oral forms of acyclovir, valacyclovir, and famciclovir are all indicated for primary genital herpes; they increase the rate of healing but do not prevent recurrences. Although topical acyclovir is also approved for treatment of initial herpes genitalis infections, it is less effective than the oral nucleoside analogues and is not recommended.

The oral nucleoside analogues should be initiated as soon as possible after the onset of a recurrent episode. Patients are usually provided with a prescription that can be filled at the first sign of recurrence. Topical acyclovir has no benefit in recurrent disease in immunocompetent patients, although it has some value in suppression of mucocutaneous herpes in immunocompromised individuals.

Patients with frequent recurrences can be placed on suppression therapy, which decreases subclinical shedding between active episodes and the number of symptomatic recurrences. Suppressive therapy is costly, averaging annually between $300 for acyclovir 400 mg twice a day, $3,600 for 1 g/day and $2,100 for 500 mg/day for valacyclovir, and $3,700 for famciclovir 500 mg tablets. In untreated patients, the number of recurrences tends to decrease over time during the first 5 years of the disease. By 3 to 5 years after the initial episode, the number of recurrences may have declined to the point that episodic treatment of recurrences may be preferable. Therefore, the need for suppressive therapy should be reconsidered annually.

Oral acyclovir is indicated for the treatment of varicella in immunocompetent patients when started within 24 hours of the chickenpox rash. For immunocompromised patients, parenteral acyclovir should be used. The AAP does not recommend acyclovir for the treatment of uncomplicated chickenpox in healthy children. Acyclovir is recommended for healthy, nonpregnant patients 13 years and older; children older than 12 months with a chronic cutaneous or pulmonary disorder; and children receiving short, intermittent, or aerosolized courses of corticosteroids. If possible, the steroids should be discontinued after known exposure to varicella. The CDC recommends aggressive treatment of varicella in adults 20 years and older, in that the majority of deaths from chickenpox occur in this age group. Varicella-zoster immune globulin should be given within 96 hours of known exposure of a susceptible adult. If prophylaxis fails, early initiation of

Table 24–30 ⚏ Drug Interactions: Nucleoside Analogues

Drug	Interacting Drug	Possible Effect	Implications
Acyclovir, famciclovir	Probenecid	Increased serum levels and terminal half-life of acyclovir; decreased renal clearance	Avoid concurrent use
	Nephrotoxic drugs	Potential increased risk for renal toxicity	Monitor renal function closely
Famciclovir	Cimetidine	Penciclovir AUC and urinary recovery increased 18% and 12%, respectively	No clinical significance
	Theophylline	Penciclovir AUC increased 22% Renal clearance decreased 12%	No clinical significance
	Digoxin	C_{max} of digoxin increased 19% in healthy male volunteers	Probably of no clinical significance, but to be prudent, monitor digoxin levels closely

acyclovir within 24 hours of onset of varicella rash is urged. Susceptible adults at high risk (e.g., immunosuppressed, HIV, corticosteroid users) should be vaccinated. Varicella is the leading cause of vaccine-preventable deaths in the United States, so vaccination of children is recommended (see Chapter 19 for the latest immunization schedule or go to http://www.cdc.gov).

Therapy with nucleoside analogues should be initiated within 3 days of the outbreak of the rash in herpes zoster. Therapy is most effective if initiated within 48 hours of the outbreak of the rash. Drug therapy speeds healing and reduces the duration of postherpetic neuralgia.

Other recommended uses of oral acyclovir include prophylaxis of herpes simplex and herpes zoster in immunocompromised patients, Bell's palsy, and primary gingivostomatitis in children. Parenteral acyclovir is used to treat herpes encephalitis, perinatal herpes simplex of mother and neonate, herpes pneumonia, and herpes simiae from a monkey bite.

Table 24-31 presents the dosage schedule for nucleoside analogues for herpes virus infections.

Rational Drug Selection

Three of the nucleoside analogues used to treat herpes simplex infections have shown equal efficacy in the treatment of genital herpes; hence, the selection of the specific agent is based on cost and convenience. Acyclovir is available as a generic preparation and is generally less expensive than the other nucleoside analogues. However, it must be dosed 3 to 5 times daily, which may be disruptive and promote noncompliance. Famciclovir is dosed 2 to 4 times daily, and valacyclovir requires one to two doses daily, depending on the indication. However, both of the latter drugs are more expensive.

Because of long experience and more extensive research, acyclovir is approved for the most indications, including use by children. Many experts consider valacyclovir to be the drug of choice for treatment of herpes zoster because clinical

Table 24–31 ⊗ Dosage Schedule: Nucleoside Analogues for Herpes Virus Infections

Drug	Indication	Dosage Form	Initial Dose	Comments
Acyclovir (Zovirax)	Genital herpes, initial episode (mild to moderate)	Tablets: 400, 800 mg (G); 400, 800 mg (B) Capsules: 200 mg (G), 200 mg (B) Suspension: 200 mg/ 5 mL (G), 200 mg/ 5 mL (B)	*Adults:* 200 mg q4h while awake, 5 times/d for 10 d; accepted off-label dose: 400 mg PO 3 times/d for 10 d	Severe cases and infections in immuno-compromised patients require hospitalization and IV therapy. Acute or chronic renal impairment may require dosage adjustment, depending on CCr and dose. Suspension should be well shaken before measurement, using a calibrated device. Take with water. Suspension retains its potency for 24 mo from date of manufacture. Does not require reconstitution or refrigeration. May be taken without regard to meals. Cross-allergy to valacyclovir.
	Genital herpes, intermittent therapy for recurrent infections (<6 episodes/yr)		*Adults:* 200 mg q4h while awake, 5 times/d for 5 d; accepted off-label dose: 400 mg PO 3 times daily for 5 d or 500 mg bid for 5 d	As above
	Genital herpes, chronic suppressive therapy (≥6–10 episodes/yr)		*Adults:* 400 mg PO twice/d or 200 mg 3–5 times/d for up to 12 mo	As above
	Herpes zoster (shingles)		*Adults:* 800 mg PO q4h while awake, 5 times/d, for 7–10 d	As above
	Gingivostomatitis, primary, in children		*Children 2–12 yr and <40 kg:* 15 mg/kg 5 times/d for 7 d or 20 mg/kg qid for 5 d	
	Oral labial (fever blister) in normal host (off-label)		400 mg 5 times/d for 5 d	Duration of symptoms decreased by ½ d.
	Herpes simplex (Whitlow)		400 mg tid for 10 d	Risks and benefits to fetus and mother still unknown. Experts recommend treatment, especially during third trimester.

Continued

Table 24–31 ⊗ **Dosage Schedule: Nucleoside Analogues for Herpes Virus Infections—cont'd**

Drug	Indication	Dosage Form	Initial Dose	Comments
	Varicella during pregnancy		800 mg 5 times/d for 5 d	May add VZIG
	Varicella (chickenpox) Initiate at earliest sign of the infection (treatment of chickenpox in children 2–12 yr not recommended by American Academy of Pediatrics)		*Adolescents and adults:* 800 mg PO q4h for 5 d	As above
	Herpes simplex, mucocutaneous prophylaxis (off-label)		*Adults:* 400 mg PO q12h	As above
	Bell's palsy due to herpes simplex virus 1 or 2		*Adults:* 400 mg PO 5 times/d for 10 d	As above
Famciclovir (Famvir)	Genital herpes, initial episode (mild to moderate)	Tablets: 125, 250 mg (B), 500 mg (B)	*Adults:* (off-label) 250 mg PO 3 times/d for 7–10 d	Renal impairment may require decreased dosage. May be taken without regard to meals. Initiate as soon as possible after onset of signs or symptoms.
	Genital herpes, intermittent therapy for recurrent infections (<6 episodes/yr)		*Adults:* 125 mg twice/d for 5 d	
	Genital herpes, chronic suppressive therapy (≥6–10 episodes/yr)		*Adults:* 250 mg PO twice/d or 500 mg once/d for up to 1 yr	
	Oral labial (fever blisters) in normal host		500 mg bid for 7 d	Duration of symptoms decreased by 2 d
	Varicella (chickenpox) (off-label) Herpes zoster (shingles)		*Adolescents and young adults:* 500 mg tid for 5 d	
			750 mg daily for 7 d or 500 mg bid for 7 d or 250 mg tid for 7 d	Adjust dose for renal failure. If CCr 10–50 mL/min, change tid dose to bid and bid dose to q24h. No 750 mg dose. For CCr <10 mL/min, dose is 250 mg daily.
Valacyclovir (Valtrex)	Genital herpes, initial episode (mild to moderate)	Tablets: 500 mg (B), 1 g (B)	*Adults:* 1 g PO twice/d for 10 d	Renal impairment may require dosage adjustment. Hepatic impairment may slow rate, but not extent, of conversion to acyclovir, but dosage adjustment is not required for hepatic impairment. Not indicated for immunocompromised patients (bone marrow transplant, human immunodeficiency syndrome, renal transplantation) because of risk of thrombotic thrombocytopenic purpura/ hemolytic uremic syndrome. May be taken without regard to meals. Cross-allergy to acyclovir.

Table 24–31 ⊗ **Dosage Schedule: Nucleoside Analogues for Herpes Virus Infections—cont'd**

Drug	Indication	Dosage Form	Initial Dose	Comments
	Genital herpes, intermittent therapy for recurrent infections (<6–10 episodes/yr)		*Adults:* 500 mg PO twice/d for 3 d	
	Genital herpes, chronic suppressive therapy (≥6 episodes/yr)		*Adults:* 1 g PO once/d for up to 1 yr 500 mg PO daily with 1 g given instead if breakthrough lesions	
	Herpes zoster (shingles)		1 g PO 3 times/d for 7 d	
	Oral labial (fever blisters) in normal host		2 g q12h for 1 d	Duration of symptoms decreased by 1 d
	Varicella (chickenpox) (off-label)		*Adolescents and young adults:* 1 g tid for 5 d	

Topical applications are discussed in Chapters 23 and 32.

CCr = creatinine clearance; VZIG = varicella-zoster immune globulin; CMV = cytomegalovirus.

trials have indicated that it decreased the duration of postherpetic neuralgia in patients older than 50 years better than acyclovir.

Monitoring

The characteristic herpetic lesions of genital herpes, herpes zoster, and chickenpox should be evaluated for resolution or signs of secondary bacterial infection. Temperature and general condition also reflect resolution. BUN and serum creatinine may be assessed prior to therapy in those with risk factors for renal impairment and periodically during prolonged therapy to detect changes in renal function.

Patient Education

Administration

The nucleoside analogues can all be taken without regard to meals, in that food does not alter absorption. All forms should be taken with a full glass of water. It is important that the drug be initiated at the earliest sign of recurrence of genital herpes simplex, so the patient must be taught the symptoms of recurrence and how to self-initiate the medication. Early initiation of drug therapy also increases its efficacy for treatment of varicella and herpes zoster, so public education needs to emphasize the treatability of these infections. It is particularly important for adolescents or adults with chickenpox to seek treatment at the first sign of rash or in the prodromal period if they know they are susceptible and have been exposed.

Adverse Reactions

Although acute renal failure from precipitation of acyclovir in the tubules is most common with parenteral acyclovir, patients on oral agents have developed acute renal failure and should drink sufficient fluids to remain well hydrated during therapy. Signs of declining renal function that should be reported include abdominal pain, decreased frequency or amount of urination, thirst, anorexia, and nausea or vomiting. Other reportable signs and symptoms include encephalopathic changes (coma, confusion, hallucinations, seizures, tremor), blood dyscrasias (unusual tiredness, chills, fever, sore throat, black stools, unusual bleeding, pinpoint red spots on skin, bruising), and skin reactions like Stevens–Johnson syndrome (peeling, blistering, or loosening of skin; muscle cramps, pain, or weakness; red eyes; rash, itching, or hives).

Lifestyle Management

Keeping herpetic lesions clean and dry promotes healing. Wearing loose clothing that does not rub on the lesions decreases pain and enhances healing. Herpes genitalis may be sexually transmitted even if the partner is asymptomatic. Sexual activity should be avoided whenever either partner has symptoms. Oral or topical drug therapy does not prevent transmission of the virus. A male or female condom may decrease the risk of transmission, but spermicides and diaphragms have no effect on transmission. Women with a history of genital herpes are more likely to develop cervical cancer; annual or more frequent Pap tests are required. Those who develop postherpetic neuralgia following herpes zoster should be provided with appropriate pain management for this neuropathic pain syndrome.

ANTIVIRALS FOR INFLUENZA

Amantadine (Symmetrel) and rimantadine (Flumadine) are FDA approved for prevention and treatment of respiratory infections due to influenza A virus; however, the CDC no longer recommends their use due to high levels (up to 92%) of resistance to influenza A (Fiore et al, 2011). These agents will not be discussed further in this chapter. Information on amantadine and rimantidine is discussed in Chapter 15 with Parkinson's drugs.

Zanamivir (Relenza), oseltamivir phosphate (Tamiflu), and peramivir (Rapivab) are approved for treatment of acute illness in adults. Zanamivir has been approved for children older than 7 years and oseltamivir for children older than 2 weeks. Antivirals to treat influenza are the most effective in patients who have been symptomatic less than 48 hours. Oseltamivir and zanamivir are approved for prophylaxis of influenza in patients age 1 year or older and 5 years and older, respectively. Zanamivir should not be used in patients with underlying respiratory disease. Therapy is recommended for patients who are hospitalized, have severe disease, or are at risk of developing complications. The CDC updates recommendations for antivirals annually based on prevalent influenza strains and resistance patterns. The antiviral drugs do not substitute for vaccination.

Pharmacodynamics

Mechanism of Action

Zanamivir, oseltamivir, and peramivir are neuraminidase inhibitors and are active against influenza A and B. Neuraminidase is a viral enzyme responsible for cleaving viral attachment to the host cell surface allowing for viral circulation. Inhibition of this enzyme prevents release of the virus and halts propagation of infection. Vaccination does not appear to alter the activity of zanamivir, oseltamivir, or peramivir.

Resistance

Resistance to zanamivir and oseltamivir is associated with mutations that result in amino acid changes in the viral neuraminidase. Sporadic cases of oseltamivir resistance occurred during the 2009 H1N1 pandemic. Almost all cases were associated with a H257Y mutation that retained susceptibility to zanamivir. After the 2009 pandemic, the CDC concluded that there is no evidence of continued transmission of this resistant influenza A virus (Fiore et al, 2011). Peramivir was approved in December 2014 and there is no documented resistance as this book goes to press.

Pharmacokinetics

Absorption and Distribution

Oseltamivir is available as an oral tablet and is well absorbed after administration. Oseltamivir is a prodrug of the active

---

CLINICAL PEARL

CDC Influenza Antiviral Recommendations
The CDC tracks influenza worldwide to determine circulating and emerging strains. Weekly updates on flu activity and surveillance provide information on what strains are circulating in each state. The CDC also provides recommendations for the use of antivirals during influenza season, including updates as resistance patterns emerge. Providers can refer to "Information for Health Professionals," accessible at http://www.cdc.gov/flu, for the latest information.

---

compound oseltamivir carboxylate. Zanamivir is a dry powder available for oral inhalation with a provided inhalation device. Approximately 4% to 17% of the inhaled dose of zanamivir is systemically absorbed. Oseltamivir is poorly distributed into breast milk (LactMed, 2014); distribution of zanamivir into breast milk is unknown. Zanamivir is poorly absorbed orally, so it is unlikely to be absorbed by the breastfeeding infant in significant amounts. Protein binding of oseltamivir is around 42% and that of zanamivir is less than 10%. Peramivir is administered IV and is 30% bound to protein. Peramivir has not been studied in nursing mothers.

Metabolism and Excretion

Oseltamivir is almost completely converted to the active metabolite (greater than 90%). The active metabolite is excreted unchanged in the urine. Children 12 years and younger have higher clearance of oseltamivir and its metabolite, resulting in decreased drug exposure. Zanamivir is excreted as unchanged drug in the urine. Peramivir is not metabolized and is excreted unchanged via the kidneys.

Table 24-32 presents the pharmacokinetics of antivirals for influenza.

Pharmacotherapeutics

Precautions and Contraindications

Oseltamivir, peramivir, and zanamivir are listed as Pregnancy Category C. Although zanamivir crosses the placenta in animal studies, fetal blood concentrations were significantly lower than those of the mother. With no adequate, well-controlled studies in pregnant women, cautious use of all three agents is recommended. Oseltamivir is poorly excreted in breast milk and is not expected to cause adverse effects in breastfed infants. There is no information available regarding zanamivir use during breastfeeding. The inhaled medication is poorly absorbed orally, so it is assumed there would be little effect on the breastfed infant with maternal use. For zanamivir and oseltamivir, safety and efficacy have been established for children as described above. Safety and effectiveness of peramivir has not been established in children.

Adverse Drug Reactions

Bronchitis, cough, and shortness of breath are associated with use of zanamivir. These problems may be related to irritation from inhalation of the drug; however, reactions may be related to the underlying illness because the incidence of reactions was either equal or greater in the placebo-controlled groups. For oseltamivir, nausea and vomiting are the most common adverse effects and occurred more frequently than in placebo-controlled groups. Rare cases of severe skin reactions and neuropsychiatric events have been reported for all three medications.

Drug Interactions

No drug interactions are reported for oseltamivir, peramivir, and zanamivir. Although they have not been formally evaluated, these agents may impair immune response if coadministered

Table 24–32 🔲 **Pharmacokinetics: Antivirals for Influenza**

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Oseltamivir	Rapid	2.5–6 h	UA	UA	80%	6–10 h	Prodrug; active metabolite excreted unchanged in urine
Peramivir	Rapid	30 min	UA	30%	100%	20 h	Excreted unchanged in urine
Zanamivir	Rapid	1–2 h	UA	<10%	UA	2.5–5.1 h	Excreted unchanged in urine

UA = information unavailable.

with the live attenuated influenza vaccine (LAIV). LAIV should not be administered 2 weeks before or 48 hours after administration of either drug. The inactivated virus vaccine can be administered without regard to antiviral drug administration.

Clinical Use and Dosing

Oseltamivir and zanamivir are approved for the prophylaxis and treatment of influenza types A and B. Peramivir is approved for the treatment of acute influenza in patients age 18 years or older. The CDC does not recommend routine prophylaxis with neuraminidase inhibitors. Judicious use is advised to prevent the development of resistance pathogens. The only strongly recommended indication for prophylaxis is to control outbreaks among high-risk individuals in institutional settings (Fiore et al, 2011). In times of pandemic, the neuraminidase inhibitors may be recommended for prophylaxis, particularly when an unvaccinated high-risk patient is exposed to influenza. The individual is vaccinated immediately and started on neuraminidase inhibitors to allow the antibody response to the vaccine to achieve protective concentrations.

Treatment is recommended for patients identified with influenza who are hospitalized, have severe disease, or are at risk of developing complications. No dosage adjustment is recommended for zanamivir for patients with renal impairment, but because the active metabolite of oseltamivir is excreted renally, adjustment is recommended. For patients with CCr of 10 to 30 mL/min, the treatment dose should be reduced to once daily and the prophylactic dose to once every other day. Peramivir dosage is decreased in patients with decreased renal function.

The CDC maintains an updated Web site with information regarding recommendations for antivirals based on the circulating influenza strain (http://www.cdc.gov/flu). These recommendations are updated based on emerging resistance patterns; therefore, the provider is wise to refer to the recommendations multiple times during the influenza season.

Table 24-33 presents the dosage schedule for antivirals used for influenza.

Table 24–33 ⊗ **Dosage Schedule: Antivirals for Influenza**

Drug	Indications	Dosage Form	Initial Dose	Comments
Oseltamivir (Tamiflu)	Influenza A and B treatment and prophylaxis Chemoprophylaxis	Capsules: 75 mg (B) Powder for oral suspension: 12 mg/mL (reconstituted) (B)	*Adults:* 75 mg PO twice daily for 5 d; start within 48 h of onset of symptoms *Children:* (oral suspension dosing by body weight) ≤15 kg: 30 mg bid (2.5 mL) <15–23 kg: 45 mg bid (3.8 mL) >23–40 kg: 60 mg bid (5 mL) >40 kg: 75 mg bid (6.2 mL)	For prophylaxis after exposure: Adults 75 mg daily for 7 days Children: Treat for 7 days If child is 3 months or older and younger than 1 yr old 3 mg/kg/dose once daily If 1 yr or older, dose varies by child's weight: ≤15 kg or less: 30 mg once a day >15 to 23 kg: 45 mg once a day >23 to 40 kg: 60 mg once a day >40 kg: 75 mg once a day All unimmunized patients should receive inactivated influenza vaccine. Less nausea if taken with food.
Zanamivir (Relenza)	Influenza A or B treatment	Blisters of powder for inhalation: 5 mg	*Children ≥7 yr and adults:* 2 (5 mg) inhalations twice daily for 5 d; take 2 doses on day 1 if at least 2 h apart, and start within 48 h of initial onset of symptoms	Not FDA-approved for influenza prophylaxis, although studies have indicated efficacy. For prophylaxis after exposure, immunize with inactivated flu vaccine and administer two inhalations once/d for 4 wk.
Peramivir (Rabivab)	Influenza	200 mg in 20 mL	*Adults age ≥ 18 yrs:* 600 mg IV over 15 min × 1 *CrCl 30–49 mL/min:* 200 mg IV ×1 *CrCl 10–29 mL/min:* 100 mg IV × 1	Not approved for use in children <18 yrs of age

Rational Drug Selection

The benefit of influenza drugs is tempered by the need to initiate treatment within 48 hours of the onset of the illness. Although the presence of fever, cough, myalgia, and known influenza activity in the community provide the basis for clinical diagnosis, these symptoms are not definitive. Rapid testing for influenza should be conducted if available. These tests take no more than 20 minutes, cost between $15 and $20, and have acceptable sensitivity and specificity.

The selection of an anti-influenza agent depends on the adverse effect profile, cost, and convenience. The inhaled route of administration of zanamivir has the advantage of decreased systemic effects compared with oseltamivir, but the inhalation procedure may contribute to noncompliance. Peramivir is administered IV in a single dose and may be the drug of choice in patients unable to take oral or inhaled medications.

Monitoring

Baseline evaluation of renal function should be considered for older and debilitated patients who are taking oseltamivir or peramivir. For older and debilitated patients, monitoring should include breath sounds (for evidence of heart failure or development of pneumonia), heart sounds, and weight. Vital signs will also evidence resolution of the influenza and development of adverse effects or sequelae.

Patient Education

Administration

As with all antivirals, the importance of taking the full course of therapy and following the label directions should be stressed. Patients on zanamivir require instruction on the proper use of the diskhaler. Oseltamivir can be taken without regard to food.

Adverse Reactions

If asthmatics on zanamivir experience severe bronchospasm after using the diskhaler, an alternative treatment may be needed. Nausea and vomiting are common with use of oseltamivir.

Lifestyle Management

The single most important factor in influenza prevention is annual vaccination. It is now recommended that all people 6 months and older be vaccinated. The wholesale cost of a course of therapy with a neuraminidase inhibitor is approximately $45 to $67, exclusive of diagnostic testing, whereas the cost of annual vaccination is $12 to $25. Other components of prevention include good hand washing, disposing of contaminated tissues properly, and encouraging infected individuals to convalesce at home rather than in crowded schools and workplaces.

SYSTEMIC AZOLES AND OTHER ANTIFUNGALS

Fungi are eukaryotic cells with a nucleus and a rigid cell wall. Reproduction generally occurs via asexual sporulation. Fungi occur ubiquitously in soil, water, air, and on plants. While few are capable of causing disease in humans, the incidence of infection has increased dramatically in recent years due to increased use of immunosuppressive drugs and the rising incidence of HIV. *Candida albicans,* a member of the yeast family of fungi, is now the fourth most common organism found in blood cultures in the United States (Wisplinghoff et al, 2004).

Most fungi are completely resistant to conventional antibiotics, and new classes of drugs were created to treat them. There are four main classes of antifungal drugs. The first class, macrocyclic polyenes, includes amphotericin B (Ambisome, Abelecet, Amphotec). Because this drug is available only in IV formulations, it will not be discussed further in this chapter. The second main class, the azole group, includes two subgroups, the imidazoles and the triazoles. The imidazoles are used mainly for topical treatment and will not be discussed further in this chapter. The triazoles include fluconazole (Diflucan), itraconazole (Onmel, Sporanox), posaconazole (Noxafil), and voriconazole (Vfend). The third main class, allylamines, includes terbinafine (Lamisil). The fourth main class, nuclear acid synthesis inhibitors, includes flucytosine (Ancobon), the use of which is limited to treatment of cryptococcosis.

Griseofulvin is a miscellaneous antifungal. Other antifungals used mainly as topical preparations include butoconazole (Gynazole-1), ciclopirox (Loprox), clotrimazole (Gyne-Lotrimin, Lotrimin, Mycelex), econazole (Spectazole), ketoconazole (Nizoral), miconazole (Micatin, Monistat), naftifine (Naftin), nystatin (Nystop, Nyamyc), oxiconazole (Oxistat), terconazole (Terazol), tioconazole (Vagistat), and tolnaftate (Tinactin, Absorbine, Aftate). The topical use of antifungals to treat dermatological infections is discussed in Chapters 23 and 32, and their use in treating vaginal infections is discussed in Chapter 44. This section discusses the systemic use of antifungals via the oral route of administration. The drugs most commonly used in primary care settings to be discussed here include fluconazole, itraconazole, posaconazole, voriconazole, and terbinafine.

Pharmacodynamics

Fungal cell membranes are comprised of components similar to those found in human cells with the exception of the cholesterol ergosterol. This component serves as the target for most systemic antifungal agents. Azole antifungals reduce ergosterol production by inhibition of the fungal CYP450 enzyme 14-α-demethylase. Although mainly inhibiting fungal

On The Horizon **ISAVUCONAZOLE**

Isavaconazole is a novel, broad-spectrum azole intended to treat most yeasts and molds, including fluconazole-resistant *Candida* strains, *Aspergillus*, and *Zygomyces*. It is currently in phase III trials.

CYP450, some inhibition of human CYP450 occurs, resulting in potential drug interactions and adverse reactions. Fluconazole appears to have the least effect on human CYP450.

In general, the azoles are fungistatic at low drug concentrations and fungicidal at higher concentrations (Hawser, 1999). Terbinafine interferes with the synthesis of ergosterol at an earlier step than the azoles through inhibition of squalene epoxide. Cell death is thought to occur by accumulation of squalene and not due to the decreased availability of ergosterol.

Spectrum of Activity

The azoles have a broad spectrum of activity that includes *Candida* species, *Cryptococcus* species, the endemic mycoses (blastomycosis, coccidioidomycosis, histoplasmosis), and the dermatophytes. In addition, itraconazole, posaconazole, and voriconazole have reliable activity against *Aspergillus* species. The azoles are approved for a variety of clinical syndromes caused by various fungi. The use of itraconazole has been mainly supplanted by voriconazole because it has superior clinical efficacy. Use of itraconazole is now limited to treatment of histoplasmosis and blastomycosis. Although possessing activity against *Aspergillus* and *Candida* species, posaconazole is used almost exclusively for prophylaxis of bone marrow transplant patients and for infection refractory to other agents.

Terbinafine (Lamisil) has in vitro activity against yeasts and a wide range of dermatophyte, filamentous, and dimorphic fungi (Garcia-Effron et al, 2004). It is fungicidal against dermatophytes, such as *Trichophyton* species, *Microsporum* species, and *Epidermophyton floccosum*. It is fungistatic against *C. albicans*. Terbinafine is only approved for treatment of onychomycosis (fungal infection of the nails) but is used off-label for tinea capitis (ringworm of the scalp), tinea corporis (ringworm of the body), tinea pedis (ringworm of the feet—athlete's foot), and tinea cruris (ringworm of the groin—jock itch). Oral terbinafine is not effective in the treatment of pityriasis versicolor; the concentrations attained by oral terbinafine in the stratum corneum are not adequate to treat this infection.

Resistance

Resistance to azoles occurs through a variety of mechanisms. Although less common, the incidence of resistance is increasing as these drugs are used for prophylaxis as well as therapy. *C. kruseii* is intrinsically resistant to fluconazole, and alternative therapy should be used. *C. glabrata* is responsible for 21% of candidemia in the United States (Pfaller et al, 2001). The Clinical and Laboratory Standards Institute developed a new classification of "susceptible dose-dependent" for fluconazole against *C. glabrata*. Isolates in this category may still be treated effectively with fluconazole if higher doses are used. The concept of dose-dependent susceptibility is restricted to *C. glabrata* that has inducible or acquired resistance (Pfaller, Diekema, & Sheehan, 2006). Cross-resistance between fluconazole and voriconazole for *C. glabrata* has been shown to be significant and caution is advised if considering voriconazole for treatment (Panackal et al, 2006). Ten to fifteen percent of *C. glabrata* is resistant to fluconazole or voriconazole. In contrast, only 1% to 2% of *C. albicans* is resistant to fluconazole or voriconazole (Rodloff, Koch, & Schaumann, 2011).

Pharmacokinetics

The pharmacokinetics of the different azoles and of terbinafine vary significantly. Table 24-34 presents these pharmacokinetic differences.

Absorption and Distribution

Fluconazole is well absorbed after oral administration, with excellent bioavailability (greater than 90%). It is widely distributed with good penetration into CSF, the eye, and the peritoneum.

Itraconazole is available for oral administration as a solution and a capsule. The bioavailability of the capsule and solution are not equivalent. The absorption of the capsule is enhanced when it is taken with food, resulting in a bioavailability of 55%. When taken on an empty stomach, absorption of the solution is about 30% greater than that of the capsule (Barone et al, 1998). Patients taking antacids (H_2 blockers and proton pump inhibitors) should not take the

Table 24–34 ⊞ Pharmacokinetics: Systemic Antifungal Agents

Drug	Onset	Peak	Duration	Protein Binding	Bioavailability	Half-Life	Elimination
Fluconazole	Slow	1–2 h	24 h	11%–12%	>90%	30 h*	>80% unchanged in urine; 11% as metabolites in urine
Itraconazole	Rapid	1.5–5 h	12–24 h	99%	55%	21 h–64 h	40% in urine as inactive metabolites; 3%–18% in feces
Ketoconazole	Rapid	1–4 h	24 h	99%	75%	8 h	85%–90% in bile and feces; 10%–15% in urine
Posaconazole	Moderate	3–5 h	UA	98%	54%	35 h	71% in feces
Terbinafine	Slow	2 h	UA	>99%	70%–80%	11–17 h	80% in urine as metabolites; 20% in feces
Voriconazole	Rapid	1–2 h	UA	58%	96%	6 h	Hepatic

*Increased in renal impairment.

capsule because absorption is markedly decreased; absorption of the solution is not affected. Due to higher bioavailability, the solution should be used preferentially in all instances (Wheat et al, 2007). Tissue concentrations are higher than plasma concentrations. Itraconazole does not enter the CSF but does enter breast milk.

Posaconazole is only available for oral administration as a suspension and delayed-release tablet. Absorption is highly variable but has been shown to be enhanced when taken with a high-fat meal. In addition, absorption is decreased with concurrent use of acid-suppressing medications (H_2 blockers and proton pump inhibitors) and avoidance is highly recommended (Krishna, Moton, Ma, Medlock, & McLeod, 2009). Despite a long half-life, absorption is saturable and administration 4 times a day is recommended. Monitoring of serum drug levels is recommended after 4 to 7 days of therapy (Andres, Pascual, & Marchetti, 2009).

Voriconazole is available in IV, oral tablet, and oral suspension formulations. The tablet and suspension are equivalent in absorption and have excellent bioavailability (greather than 90%). Voriconazole penetrates well into tissues, including the CNS (Weiler et al, 2011). Similar to posaconazole, monitoring of serum drug levels is recommended after 4 to 7 days of therapy (Andres et al, 2009).

Terbinafine is well absorbed after oral administration, with bioavailability of 70% to 85%, and is not affected by the presence of food. It is lipophilic and extensively distributed. It concentrates in the stratum corneum, attaining concentrations 25 times that in plasma. It is also distributed via the sebum to hair follicles, skin, and nails. It is not known whether terbinafine crosses the placenta, but it does enter breast milk.

Metabolism and Excretion

Fluconazole is cleared primarily by renal excretion, with 80% appearing as unchanged drug in the urine and 11% as metabolites. All azoles are inhibitors of various CYP450. Fluconazole inhibits CYP3A4 and 2C9 but has the least inhibition of the azoles discussed in this chapter. Half-life is markedly affected by renal impairment, with an inverse relationship between the elimination half-life and CCr. Dosage adjustments are required for patients with impaired renal function.

Itraconazole is extensively metabolized by the liver into several active metabolites, and fecal excretion varies from 3% to 18% of the dose. Itraconazole and its metabolites are inhibitors of CYP3A4. About 40% of the dose is excreted in urine as metabolites.

Posaconazole undergoes metabolism by CYP450, with approximately 14% of the dose excreted as an inactive metabolite in the urine. The remainder is excreted as unchanged drug in the feces. Similar to other azoles, posaconazole is a strong inhibitor of CYP3A4.

Voriconazole is extensively metabolized by CYP450, and dose reduction is required in poor metabolizers of CYP2C19 (15% to 20% of those of Asian descent) (Scholz et al, 2009). This agent is also a strong inhibitor of CYP3A4. Excretion is almost entirely nonrenal.

Terbinafine undergoes extensive first-pass metabolism. Metabolism involves only a small fraction (less than 5%) of the hepatic CYP450 capacity, so the drug interactions that are common with the azoles do not affect terbinafine. Fifteen inactive metabolites have been identified. About 80% of the dose is excreted in the urine as metabolites, and 20% is eliminated in the feces. Both liver impairment and renal impairment require dosage reduction.

Table 24-34 depicts the pharmacokinetics of these selected systemic antifungals.

Pharmacotherapeutics

Precautions and Contraindications

All of the azoles and terbinafine have been associated with hepatotoxicity. Rare cases of hepatitis that are usually reversible with discontinuance of the drug have been reported. Transaminase elevations are common with the azoles and occur in 2% to 12% of patients. Monitoring of transaminases is recommended. The azoles and terbinafine are used cautiously for patients with hepatic impairment. For those patients with renal impairment undergoing extensive renal elimination, cautious use is required. With both hepatic and renal impairment, dosage adjustments may be required. The dose of fluconazole should be reduced by 50% when the CCr is less than 50 mL/min. Because of the burden on the liver, terbinafine should be used with caution by patients with alcoholism, either active or in remission.

Voriconazole is Pregnancy Category D; the other azoles are Pregnancy Category C. Itraconazole, posaconazole, and voriconazole have teratogenic effects in animals. There are no adequate, well-controlled studies in pregnant women. These drugs should be used during pregnancy only when the potential benefits to the mother clearly outweigh the risks to the fetus and there is no reasonable alternative drug. Terbinafine is Pregnancy Category B; animal studies show no effects on fertility or fetal toxicity, but adequate studies in humans have not been conducted.

Fluconazole, itraconazole, and terbinafine are excreted in breast milk; no data exist for posaconazole and voriconazole. After a single 500 mg dose of terbinafine, 0.2 to 0.7 mg of terbinafine was detected in breast milk. In spite of these low concentrations, it is prudent to avoid administration of antifungal drugs to nursing mothers.

The safety and efficacy of these drugs in children vary. The safety and efficacy of itraconazole have not been established for children. Children aged 3 to 16 years, however, have been treated with 100 mg/d for systemic fungal infections without report of serious adverse reactions. One study with the oral solution was conducted on 26 pediatric patients receiving doses of 5 mg/kg a day for 2 weeks. Fluconazole is safe and effective for infants and children. Experience with neonates is limited, but a dosage schedule exists. Although the safety and efficacy of terbinafine have not been established in children, it has been used in a small number of children aged 3 to 16 years and was well tolerated. Although voriconazole has not been formally studied

in children, its use is well established in those with hematological malignancies. Several pharmacokinetic studies of posaconazole have been conducted but use has not been standardized.

Adverse Drug Reactions

Azoles are relatively nontoxic, and the most common adverse reactions are relatively minor GI symptoms. Patients taking azoles have rarely developed exfoliative skin disorders. Patients who develop rashes should be carefully monitored and the drug discontinued if the lesion progresses. All of the azoles may cause QT prolongation. Itraconazole has been rarely associated with development of heart failure and should be used cautiously in patients with preexisting heart failure or ventricular dysfunction. Voriconazole causes visual disturbances in up to 19% of patients. These changes include photopsia (flashes of light), photophobia, and color changes. This usually occurs within 30 minutes of administration and lasts for about 30 minutes. These effects usually subside after several weeks of use. In addition to visual changes, patients may experience more serious neurological symptoms, including visual hallucinations, confusion, agitation, and myoclonus, which are usually associated with toxic drug levels.

The most common adverse reactions with terbinafine are also GI and include nausea, vomiting, and diarrhea. Reversible loss or change of taste has occurred after 5 to 8 weeks of therapy, requiring 2 to 6 months to recover after the drug was discontinued. Other adverse effects reported include hypersensitivity, hepatitis, blood dyscrasias, and Stevens–Johnson syndrome (Amichai & Grunwald, 1998).

Drug Interactions

Drug interactions are more common for the drugs with greater human CYP450 activity. All of these drugs are inhibitors of CYP3A4 and other CYP enzymes as well (see above). Additive hepatotoxicity is also possible with other hepatotoxic drugs.

Itraconazole has many drug interactions, including rifampin, histamine-2 blockers, and warfarin. Fluconazole has slightly fewer drug interactions but also interacts with rifampin and warfarin.

Additive hepatotoxicity may occur with concurrent administration of terbinafine, alcohol, or other hepatotoxins. Because terbinafine is hepatically metabolized by CYP450, drugs that induce or inhibit these enzymes may alter the clearance of terbinafine. Those interactions that have been documented for the azoles and terbinafine are listed in Table 24-35.

Table 24–35 ▦ Drug Interactions: Selected Systemic Antifungal Agents

Drug	Interacting Drug	Possible Effect	Implications
Fluconazole	Cimetidine	Reduced fluconazole AUC.	Separate doses.
	Hydrochlorothiazide	Significant increase in fluconazole AUC, possibly because of reduced renal clearance.	Avoid concurrent use.
	Rifampin	Increased phenytoin AUC.	Monitor serum phenytoin levels.
	Phenytoin	A single dose of fluconazole after chronic rifampin resulted in a decrease in AUC and a shorter half-life for fluconazole.	If both must be taken, monitor effectiveness of fluconazole and adjust dose if needed.
	Sulfonylureas	Significant increase in AUC of tolbutamide, glyburide, and glipizide. Several patients experienced hypoglycemic episodes, some requiring oral glucose treatment.	If both must be used, monitor blood glucose levels closely while azole is taken.
	Theophylline	Theophylline AUC and half-life increased and clearance decreased. Increased toxicity risk.	Monitor serum theophylline levels. Dosage adjustment may be needed.
	Warfarin	Fluconazole increases effects of warfarin, which results in an increase in PT/INR and risk of bleeding.	Monitor PT/INR closely while taking azole.
Itraconazole	Benzodiazepines	Elevated plasma concentrations of oral midazolam and triazolam. Prolonged sedative/hypnotic effects.	Select different benzodiazepine.
	Buspirone	May elevate buspirone levels, increasing the pharmacological and adverse effects.	Closely monitor clinical response to buspirone. Prudent to start with conservative dose and adjust dose of buspirone as needed.
	Calcium channel blockers	Edema with concurrent use of dihydropyridines.	Monitor cardiac status
	Phenytoin, phenobarbital, isoniazid, carbamazepine	Increased metabolism of itraconazole. Decreased metabolism of phenytoin.	Increased dosage of azole may be needed. Monitor phenytoin levels; dosage adjustments may be needed.
	Cyclosporine, tacrolimus, oral hypoglycemic agents, and warfarin	Itraconazole decreases metabolism of these drugs. Increased risk for toxicity, hypoglycemia, and anticoagulant effect.	Monitor cyclosporine levels. Monitor for indications of hypoglycemia. Monitor PT/INR.
	Digoxin	Increased digoxin levels.	Monitor digoxin levels closely.
	Antacids, H$_2$ blockers, and other drugs that increase gastric pH	Reduced plasma itraconazole levels.	Much less of a problem with oral solution than with capsules.
Ketoconazole	Antacids, H$_2$ blockers, proton pump inhibitors, and other	Inhibit ketoconazole absorption	Avoid concurrent use. Fluconazole absorption is not affected.
		Bioavailability and serum levels of either drug may be affected	Avoid concurrent use.

Continued

Table 24–35 ⊞ **Drug Interactions: Selected Systemic Antifungal Agents—cont'd**

Drug	Interacting Drug	Possible Effect	Implications
	drugs that increase gastric pH Rifampin, isoniazid Hepatotoxic drug Cyclosporine, corticosteroids, warfarin Theophylline	Additive hepatotoxicity Ketoconazole decreases metabolism of these drugs. Increased risk for toxicity, anticoagulant effect. Increased serum theophylline levels	Avoid concurrent use. Monitor serum levels. Monitor PT/INR more closely. Because the effect on cyclosporine levels is consistent and predictable, this combination has been used therapeutically to reduce cyclosporine dosage. Monitor theophylline levels. Dosage adjustment may be needed.
Posaconazole	Sirolimus	Increased sirolimus levels	Contraindicated
	Drugs that prolong QT interval	Enhanced prolongation of QT interval and increased risk of torsade de pointes	Contraindicated
	HMG-CoA Reductase Inhibitors primarily metabolized by CYP 3A4	Increased levels of HMG-CoA inhibitors, increased risk of rhabdomyolisis	Contraindicated
	Ergot alkaloids Efavirenz Phenytoin Rifabutin	Increased risk of ergotism Increased posaconazole levels	Contraindicated Avoid concomitant use
	Digoxin	Increased digoxin levels	Avoid concomitant use. Monitor digoxin levels.
	Efavirenz Phenytoin Rifabutin	Decreased posaconazole levels and increased serum concentrations potentially leading to increased adverse effects or toxicity of coadministered drug	Avoid concomitant use
	Atazanavir, ritonavir	Increased exposure to protease inhibitors, which may increase adverse effects	Use with extreme caution. Do not use high-dose ritonavir with posaconazole.
	Midazolam	Inhibition of midazolam metabolism, 5-fold increase in midazolam serum concentrations	Use a different benzodiazepine
Voriconazole	Carbamazepine Rifamycins St. John's wort	Increased voriconazole metabolism and clearance leading to subtherapeutic voriconazole levels and treatment failures	Contraindicated
	Efavirenz Phenytoin	Increased voriconazole metabolism and clearance leading to subtherapeutic voriconazole levels	Increase voriconazole dose. Monitor for efficacy. Monitor phenytoin levels.
	Medications that prolong QT interval	Enhanced prolongation of QT interval and increased risk of torsade de pointes	Avoid concurrent use
	Benzodiazepines extensively metabolized by CYP 3A4 Cyclosporine Fentanyl, methadone, oxycodone NSAIDS Oral contraceptives Tacrolimus	CYP 3A4 inhibition by voriconazole increases drug levels. Enhanced effects and risk of toxicity with affected drug.	Use with caution. Monitor for toxicity and adverse events. Dose adjustments recommended for cyclosporine and tacrolimus.
	Ergot alkaloids Rifabutin Sirolimus	Significant increases in serum concentrations of affected drugs	Contraindicated
Terbinafine	Alcohol, hepatotoxins Cimetidine Phenytoin, rifampin Caffeine Cyclosporine	Additive liver damage Decreased metabolism of terbinafine Increased metabolism of terbinafine Decreased metabolism of caffeine Increased clearance of cyclosporine, possibly leading to organ rejection	Avoid concurrent use or monitor hepatic function closely. Avoid concurrent use. Avoid concurrent use or monitor response to terbinafine. Prudent use of caffeinated beverages. Avoid concurrent use or monitor cyclosporine levels.

INR = international normalized ratio; PT = prothrombin time.

Clinical Use and Dosing

Because of its long half-life, fluconazole does not achieve steady state for 5 to 10 days with standard doses but can be achieved in 2 days with a loading dose (twice the usual dose) on the first day. Hence, most dosage regimens for fluconazole include a loading dose. Because it may undergo saturation metabolism at higher plasma concentrations, the initial dose of itraconazole is often doubled, resulting in a 3-fold increase in the plasma concentration. However, patients with hepatic or renal insufficiency may need reduced maintenance doses of fluconazole and terbinafine. For serious infections, voriconazole should be administered IV as a loading dose over the first day.

Oral antifungal drugs are used to treat superficial infections by yeasts (*Candida,* pityriasis versicolor) and dermatophytes (tinea infections) and to treat invasive systemic mycoses (e.g., paracoccidioidomycosis, blastomycosis, histoplasmosis, aspergillosis, candidiasis). Indications and dosages of the oral antifungal drugs are summarized in Table 24-36.

Rational Drug Selection

Antifungal drug selection is based on susceptibility, pharmacokinetics, and adverse effects. The spectrum of terbinafine includes dermatophytes, and it is recommended for treatment of onychomycosis and tinea infections. The spectrum of the azoles includes dermatophytic and superficial fungi, as well as invasive systemic fungi. Fluconazole has more reliable bioavailability than the other azoles and is generally recommended for the treatment of mild to moderate systemic fungal infections. Fluconazole also has fewer drug interactions than other azoles and has a single-dose regimen for some indications; it is preferred by many clinicians for these reasons. It is also the drug of choice for treating vaginal yeast infections in patients with diabetes. As discussed previously, itraconazole should be reserved for blastomycosis and histoplasmosis because alternative treatments for other indications are preferred. Fluconazole is available as a generic and is the most affordable azole.

Monitoring

Prompt recognition of liver injury is essential with oral antifungal drugs. AST, ALT, alkaline phosphatase, and bilirubin should be monitored prior to initiation of therapy, monthly for 3 to 4 months, and frequently thereafter during treatment. Because of the numerous drug interactions with azoles, it is important to monitor the drug response of concurrent medications. Therapeutic response should be evaluated at 6 to 8 weeks after initiation of drug therapy for tinea infections, 4 to 6 months for fingernail onychomycosis, and 8 to 9 months for toenail mycoses. Monitoring of serum drug levels for several azoles is recommended as stated above.

Patient Education

Administration

Itraconazole capsules should be taken with food to alleviate GI symptoms and promote absorption. Antacids should not be used in conjunction with the capsule. Itraconazole solution

Table 24–36 ✄ Dosage Schedule: Selected Systemic Antifungal Agents

Drug	Indication	Dosage Form	Initial and Maintenance Dose	Comments
Fluconazole (Diflucan)	Vaginal candidiasis	Tablet: 50, 100, 150, 200 mg Powder for oral suspension: 10 mg/mL, 40 mg/mL	*Adults:* 150 mg as single PO dose	Maximal daily pediatric dose 600 mg. Shake suspension well before measurement, using calibrated liquid-dosing device. Store suspension in refrigerator or at room temperature. Dispose of unused suspension 2 wk after reconstitution.
	Oropharyngeal candidiasis		*Adults:* 200 mg PO on first day, followed by 100 mg once daily for 2 wk *Children:* 6 mg/kg PO on first day, followed by 3 mg/kg once daily for at least 2 wk	May be taken without regard to meals
	Esophageal candidiasis		*Adults:* 200 mg PO on first day, followed by 100 mg once daily for 2 wk; doses up to 400 mg may be used based on patient response *Children:* 6 mg/kg PO on first day, followed by 3 mg/kg once daily for at least 3 wk and 2 wk beyond resolution of symptoms; doses up to 12 mg/kg/d have been used	Doses are reduced by 50% for CCr <30 mL/min. Older adults may have impaired renal function and require lower dose.

Continued

Table 24–36 ⊗ Dosage Schedule: Selected Systemic Antifungal Agents—cont'd

Drug	Indication	Dosage Form	Initial and Maintenance Dose	Comments
	Other *Candida* infections		*Adults:* 50–400 mg/d PO *Children:* 6–12 mg/kg/d PO have been used	
Itraconazole (Sporanox)	Onychomycosis	Capsule: 100 mg, Oral solution: 10 mg/mL	*Adults:* 200 mg PO once daily with meal for 12 consecutive wk	Safety and efficacy not established for children. A small number of children aged 3–16 yr with systemic infections have taken itraconazole capsules, 100 mg daily, without serious adverse effects. In life-threatening conditions, a loading dose of 200 mg 3 times/d (600 mg/d) is given for first 3 d. Continue treatment for minimum of 3 mo until clinical parameters indicate fungal infection has subsided. Take capsules with food or cola beverage for better absorption. Oral solution should be vigorously swished in mouth, 10 mL at a time, for several seconds and swallowed. Solution should be taken on an empty stomach. Dispense solution with calibrated liquid-measuring device.
	Onychomycosis, fingernail		*Adults:* 200 mg bid for 1 wk; repeat after 3 wk period without itraconazole	Doses are reduced by 50% for CCr <30 mL/min. Older adults may have impaired renal function and require lower dose.
	Onychomycosis, toenail		200 mg once daily for 12 consecutive wk	
	Aspergillosis		*Adults:* 200–400 mg PO once daily	
	Blastomycosis or histoplasmosis		*Adults:* 200 mg PO once daily with meal; if no improvement or progression, increase in 100 mg increments to 400 mg maximum daily dose. Give doses >200 mg daily in 2 divided doses.	
	Candidiasis, esophageal		*Adults:* For solution: 100 mg PO (swish and swallow) once daily for minimum of 3 wk (2 wk after resolution of symptoms); off-label: 100–200 mg capsules PO once daily after a meal for 14 d; dose for AIDS and neutropenic patients is 200 mg for 4 wk	
	Candidiasis, oropharyngeal		*Adults:* For solution: 200 mg PO (swish and swallow) once daily for 7–14 d; if refractory to fluconazole, use 100 mg twice/d for 2–4 wk; off-label: 100–200 mg capsules PO once daily after a meal for 14 d; dose for AIDS and neutropenic patients is 200 mg for 4 wk	

Table 24–36 ⊗ **Dosage Schedule: Selected Systemic Antifungal Agents—cont'd**

Drug	Indication	Dosage Form	Initial and Maintenance Dose	Comments
	Candidiasis, vulvo-vaginal (off-label)		*Adults:* 200 mg PO once daily for 3 d	
	Coccidioidomycosis (off-label)		*Adults:* 200 mg PO twice daily	
	Histoplasmosis suppression (off-label)		*Adults:* 200 mg PO twice daily	
	Paracoccidioidomycosis (off-label)		*Adults:* 100 mg PO once daily for 6 wk	
	Tinea corporis or cruris (off-label)		*Adults:* 100 mg PO once daily for 15 d	
	Tinea manus or pedis (off-label)		*Adults:* 100 mg PO once daily for 30 d	
Ketoconazole (Nizoral)	Candidiasis, vulvovaginal	Tablets: 200 mg	*Adults:* 200–400 mg PO once daily for 5 d *Children >2 yr:* 3.3–6.6 mg/kg/d as a single dose *Children <2 yr:* Dosage not established	Maximal adult daily dosage is 1 g. Therapy should be continued 1–2 wk in candidiasis (3–5 d in vaginal candidiasis); for 1–8 wk in dermatophytic infections and mycoses of hair and scalp; for 3 mo–1 yr for paracoccidioidomycosis; and for 6 mo in other systemic mycoses. Chronic mucocutaneous candidiasis following a remission usually requires indefinite maintenance treatment to prevent relapse. Take with food to promote absorption and decrease GI irritation. In patients with hypochlorhydria or achlorhydria, take with acid drink. May be dissolved in cola or seltzer water or taken with these fluids. Shake suspension well before measurement using a calibrated liquid-measuring device. Store at room temperature.
	Paronychia		*Adults:* 400 mg PO once daily *Children >2 yr:* 5–10 mg/kg PO once daily *Children <2 yr:* Dosage not established	
	Pityriasis versicolor		*Adults:* 200 mg PO once daily for 5–10 d	
	Fungal pneumonia or septicemia		*Adults:* 400 mg–1 g PO once daily *Children >2 yr:* 5–10 mg/kg PO once daily *Children <2 yr:* Dosage not established	
	All other antifungal indications		*Adults:* 200–400 mg PO once daily *Children >2 yr:* 3.3–6.6 mg/kg PO once daily *Children <2 yr:* Dosage not established	

Continued

Table 24–36 ⊗ Dosage Schedule: Selected Systemic Antifungal Agents—cont'd

Drug	Indication	Dosage Form	Initial and Maintenance Dose	Comments
	Candidiasis, esophageal		*Adults:* For solution: 100 mg PO (swish and swallow) once daily for minimum of 3 wk (2 wk after resolution of symptoms); off-label: 100–200 mg capsules PO once daily after a meal for 14 d; dose for AIDS and neutropenic patients is 200 mg for 4 wk	
Posaconazole (Noxafil)	Oropharyngeal candidiasis	Delayed-release tablet: 100 mg Oral suspension: 40 mg/mL	*Adults:* Loading dose: 100 mg bid for first day Maintenance dose: 100 mg daily for 13 d	Take during or immediately after a full meal. Other dosing regimens are recommended for prophylaxis of *Aspergillus* and *Candida* infections and for oropharyngeal candidiasis refractory to azole therapy.
Voriconazole (Vfend)	Invasive aspergillosis	Tablet: 50, 200 mg Powder for oral suspension: 40 mg/mL	*Adults:* Loading dose: 6 mg/kg IV every 12 h for first day Maintenance dose: 200 mg PO bid	If patient response is inadequate, may increase maintenance dose to 300 mg bid. Maintanence dose should be reduced by 50% in setting of hepatic impairment. When used with phenytoin or efavirenz, maintanence dose should be increased to 400 mg PO bid. Monitoring of serum voriconazole levels may be advised for severe infections or prolonged therapy.
	Candidemia or deep-tissue *Candida* infection		As above	
Terbinafine (Lamisil)	Onychomycosis, fingernail	Tablet: 250 mg	*Adults:* 250 mg PO once daily for 6 wk	May be taken without regard to meals. Patients with preexisting stable liver disease, impaired renal function (CCr <50 mL/min), or serum creatinine <3.4 mg/dL should receive 50% reduction in dosage. Safety and efficacy for children and children's dosage not established. Following dosages have been use in treatment of children age 3–16 yr: Children 12.5–18.5 kg: oral 62.5 mg once daily
	Onychomycosis, toenail		*Adults:* 250 mg PO once daily for 12 wk; extensive toenail infections may take longer	Children 18.5–25 kg: 125 mg once daily Children >25 kg: 250 mg once daily
	Tinea capitis (off-label)		*Adults:* 250 mg PO once daily for 4–6 wk	
	Tinea corporis or cruris (off-label)		*Adults:* 250 mg PO once daily for 2–4 wk	
	Tinea pedis (plantar or interdigital) (off-label)		*Adults:* 250 mg PO once daily for 2–6 wk	

CCr = creatinine clearance.

should be taken on an empty stomach; fluconazole, terbinafine, and voriconazole can be taken without regard to meals. Posaconazole should be taken with a high-fat meal. Because these drugs have many drug interactions, any time a new drug is added to the patient's treatment regimen, it should be reviewed for possible interactions.

Adverse Reactions

Because hepatotoxicity is common to all the oral antifungals, concurrent use of alcohol is discouraged. Patients should report signs of liver toxicity (unusual tiredness, anorexia, nausea and vomiting, jaundice, pale stools, dark urine), Stevens–Johnson syndrome (rash, blisters, loosening of skin, red joints), and leukopenia (sore throat or fever). Patients on terbinafine should know that loss of taste is a reversible adverse effect.

Lifestyle Management

Factors that have contributed to the rise of fungal infections are overuse of antibiotics, increased numbers of immunocompromised patients, and increased environmental exposure. Patients and providers should try to limit antibiotic use, which will decrease emergence of bacterial resistance and fungal superinfection.

ANTHELMINTICS

Infestation with parasitic worms is a major health problem throughout the world infecting billions and killing millions annually (WHO, 2010). In the United States, approximately 60 million people are estimated to harbor a helminthic parasite (VandeWaa, Henderson, White, & Nowatzke, 1998). The worms are divided into three groups: nematodes ([intestinal and tissue] roundworms), cestodes (flatworms and tapeworms), and trematodes (flukes) (McCarthy, Loukas, & Hotez, 2011). The only common helminthic infections in the United States are caused by intestinal nematodes: *Enterobius vermicularis* (pinworm), *Trichuris trichiura* (whipworm), *Ascaris lumbricoides* (roundworm), *Strongyloides stercoralis* (threadworm), and the hookworms *Ancylostoma duodenale* and *Necator americanus.* Only those drugs used to treat these infections are discussed in this chapter.

Pharmacodynamics

The benzimidazoles (mebendazole, thiabendazole [Mintezol], albendazole [Albenza]) bind to β-tubulin of the microtubule causing inhibition of polymerization and loss of function. In addition, these agents have a range of other possible inhibitory mechanisms including blocking glucose uptake.(Prichard, 1994). Thiabendazole is no longer available in the United States or Canada for human use and will not be discussed.

Pyrantel (Pinworm, Pin X, Parasitol, Pronto Plus, Vermocks) is a depolarizing neuromuscular blocking agent that creates spastic paralysis in the worm. It also inhibits cholinesterases (Robertson, Pennington, Evans, & Martin, 1994). Ivermectin (Stromectol) binds selectively to glutamate-gated chloride ion channels of the muscle and nerve resulting in hyperpolarization, paralysis, and eventual death of the parasite.

Drugs of choice for treating intestinal nematodes include mebendazole and pyrantel. Tissue nematodes are best treated with mebendazole, albendazole, or ivermectin.

Pharmacokinetics

Absorption and Distribution

Ivermectin is well absorbed with wide tissue distribution following oral administration. Albendazole, mebendazole, and pyrantel are very poorly absorbed with limited serum concentrations. The bioavailability of albendazole and ivermectin are significantly enhanced if coadministered with a fatty meal (2.5- to 5-fold increase). Absorbed albendazole is widely distributed in nearly all organs and body compartments. The distribution of mebendazole and pyrantel is not known.

Metabolism and Excretion

Albendazole is rapidly converted by the liver to the primary metabolite, albendazole sulfoxide, which is further converted to other metabolites. These metabolites undergo almost exclusive biliary elimination. Absorbed mebendazole is extensively metabolized by the liver. More than 95% is excreted in feces and the remainder by the kidney. Ivermectin is metabolized by CYP450. The parent drug and its metabolites are excreted almost exclusively in feces over an estimated 12 days. Pyrantel pamoate undergoes limited metabolism, and more than 50% is excreted as unchanged drug in the feces. Less than 7% is found in urine as parent drug and metabolites. Table 24-37 presents the pharmacokinetics of selected anthelmintics.

Pharmacotherapeutics

Precautions and Contraindications

Because the activity of these drugs is specific to the parasites, precautions and contraindications are minimal. Drugs extensively metabolized by the liver require cautious administration to patients with hepatic impairment. Drugs excreted extensively by the kidney may require careful monitoring of renal function. Albendazole and mebendazole have been linked to rare reports of bone marrow suppression.

Albendazole, mebendazole, ivermectin, and pyrantel pamoate are all designated as Pregnancy Category C. Albendazole and ivermectin have demonstrated teratogenic and embryotoxic effects in some animal studies. The WHO has determined that for albendazole, mebendazole, and pyrantel pamoate, the benefits of treatment outweigh the risks and allow administration to pregnant women in their second or third trimester (CDC, 2013d). For ivermectin, the WHO excludes pregnant patients from mass prevention campaigns (CDC, 2013c).

It is not known whether albendazole, mebendazole, or pyrantel pamoate is excreted in breast milk. Caution should

Table 24–37 ✥ Pharmacokinetics: Selected Anthelmintics

Drug	Onset	Peak	Protein Binding	Bioavailability	Half-Life	Elimination
Albendazole	UA	2–5 h	70%	UA	8–12 h	Mainly in urine; small amount in feces
Ivermectin	UA	4 h	UA	UA	16 h	Fecal elimination; <1% in urine
Mebendazole	UA	2–4 h	95%	2%–3%	2.5–5.5 h	>90% fecal elimination; 2% in urine
Pyrantel pamoate	UA	1–3 h	UA	UA	UA	50% unchanged drug in feces; <7% in urine
Thiabendazole	Rapid	1–2 h	UA	UA	1.2 h	5% in feces; 90% in urine

Duration of action of all of these drugs is unknown.

UA = information unavailable.

be exercised if used by a nursing mother. Ivermectin is known to be excreted in breast milk in low quantities equaling 0.98% of the weight-adjusted maternal dose (LactMed, 2014). Mebendazole and pyrantel pamoate are not recommended for children younger than age 2 years. Albendazole is not recommended for children younger than 6 years (although no adverse reactions have been found in studies of children as young as 1 year). In children weighing less than 15 kilograms, ivermectin is contraindicated.

Adverse Drug Reactions

The most common adverse reactions associated with use are nausea, vomiting, diarrhea, transient abdominal pain, fever, pruritus, and skin rash. Albendazole and mebendazole are associated with transient elevations of liver function tests and rarely hepatitis. Reversible bone marrow suppression has also occurred with both of these agents.

Some patients taking ivermectin for treatment of *Onchocerca volvulus* experience the Mazzotti reaction (fever, headache, dizziness, somnolence, weakness, rash, pruritus, diarrhea, joint pain and muscle spasms, hypotension, tachycardia, lymphadenitis, and peripheral edema). The reaction is due to the death of *Onchocerca volvulus* and is not related to ivermectin toxicity. Corticosteroids may be needed for several days to suppress the inflammatory response.

Drug Interactions

There are few drug–drug interactions with any of these drugs. Table 24-38 lists these interactions.

Clinical Use and Dosing

The five common intestinal helminthic infections in the United States are described here, with indication of the usual antimicrobial agents. Dosages of the anthelmintic drugs are summarized in Table 24-39.

Enterobius vermicularis (Pinworm)

The pinworm is named for the morphology of the posterior of the female. As many as 50 million people in the United States, primarily children, are infected with pinworm. The primary symptoms of pinworm, perianal itching and sleep disruption, are related to the fact that the female lays eggs nocturnally in the perianal area. Drugs used to treat pinworms include pyrantel pamoate, albendazole, and mebendazole.

Trichuris trichiura (Whipworm)

Some 80 million people worldwide and 2.2 million in the United States are infected with whipworm. People acquire whipworm by ingesting uncooked vegetables grown in soil contaminated by human feces. The infection is usually asymptomatic, although heavy infestations may produce anemia, bloody diarrhea, and growth retardation. Drugs used for whipworm infections include pyrantel pamoate, albendazole, and mebendazole.

Ascaris lumbricoides (Roundworm)

The roundworm is the most common helminthic parasite worldwide and affects 4 million people in the United States, primarily in the Southeast. Infection generally is derived from eating feces-contaminated raw vegetables. The parasite has a

Table 24–38 ✥ Drug Interactions: Selected Anthelmintics

Drug	Interacting Drug	Possible Effect	Implications
Albendazole	Dexamethasone	Steady-state trough of main metabolite 50% higher	Avoid coadministration
Mebendazole	Carbamazepine, phenytoin	May reduce plasma levels of mebendazole; possible decrease in therapeutic effects	Avoid concomitant use
	Cimetidine	Increased plasma concentrations of mebendazole	May be used therapeutically
Pyrantel pamoate	Theophylline	May increase serum levels of theophylline	Monitor theophylline levels
Thiabendazole	Xanthines	Thiabendazole may compete with these drugs for metabolism sites; may elevate serum levels of xanthine with increased toxicity risk	Monitor serum levels of xanthine closely

Table 24–39 ⊗ Dosage Schedule: Selected Anthelmintics

Drug	Indication	Dosage Form	Initial Dose	Comments
Albendazole (Albenza)	Ascariasis Enterobiasis Hookworm infections Trichuriasis Strongyloidiasis Giardiasis	Tablets: 200 mg	*Children >2 yr and adults:* 400 mg PO once daily for 3 d; may repeat in 3 wk *Children <2 yr:* 200 mg PO as single dose; may repeat in 3 wk *Children >2 yr and adults:* 400 mg PO once daily for 3 d; may repeat in 3 wk *Children <2 yr:* 200 mg PO once daily for 3 d; may repeat in 3 wk *Adults:* 400 mg PO daily for 5 d	Maximal daily dose for adults and adolescents <60 kg is 800 mg. Take with food containing fat. Swallow tablets whole with small amount of liquid. Shake suspension well before measurement with calibrated liquid-measuring device. Store at room temperature.
Ivermectin (Stromectol)	Strongyloidiasis Scabies in immuno-compromised patients	Tablets: 6 mg	*Children >15 kg and adults:* 200 mcg/kg as single dose *Adults:* 200 mcg/kg as a single dose	Take with full glass of water 1 h before breakfast. Repeat in 1 to 2 wk.
Mebendazole (Vermox)	Ascariasis Trichuriasis Hookworms Roundworms Enterobiasis	Chewable tablets: 100 mg	*Children >2 yr and adults:* 100 mg PO twice daily, morning and evening, for 3 d; may repeat in 2–3 wk if required *Adults:* 100 mg PO as single dose; may repeat in 2–3 wk if required	Take with high-fat meals. Tablets may be chewed, crushed, or swallowed whole.
	Pinworms		*Children and adults:* One single 100 mg chewable tablet; repeat in 2 wk	
Pyrantel pamoate (Pin-Rid, Pin-X,Reese's Pinworm, Antiminth)	Enterobiasis Ascariasis Trichuriasis Hookworms	Capsules: 180 mg (62.5 mg of pyrantel base) Liquid: 50 mg/mL	*Children and adults:* 11 mg/kg as single dose	Maximum daily dose 1 g. May be taken with milk, food, or juice at any time of day. Shake suspension well, and measure with calibrated liquid-measuring device. Store at room temperature.
Thiabendazole (Mintezol)	Strongyloidiasis, uncomplicated Strongyloidiasis, hyperinfection	Tablets: 500 mg Oral suspension: 50 mg/mL	*Children >13.6 kg and adults:* 25 mg/kg twice daily for 2 d *Children >13.6 kg and adults:* 25 mg/kg twice daily for 5–7 d; may be repeated if required	Maximum adult daily dose 3 g. Chew or crush tablets before swallowing. Take after meals. Shake suspension well before measurement with calibrated liquid-dosing device. Take after meals.

larval stage that migrates through the lungs, causing seasonal pneumonitis, but GI symptoms are more common. Massive infections can cause intestinal obstruction. The drug used for roundworm infections is mebendazole.

Ancylostoma duodenale or *Necator americanus* (Hookworm)

Hookworms comprise pathogens from two genera, *A. duodenale* and *N. americanus.* The larvae live in the soil and must penetrate the skin to enter the circulation, where they are carried to the lungs. Here they penetrate the alveoli, crawl up the pharynx, and are swallowed. They attach to

the intestinal wall and can cause anemia. A recent phenomenon is the use of hookworms to treat allergies and asthma. Although there is little evidence regarding the effectiveness of this treatment, patients can purchase hookworms via the Internet and self-medicate. Drugs used for hookworm infections include pyrantel pamoate, albendazole, and mebendazole.

Strongyloides stercoralis (Threadworm)

The larvae of the threadworm are found in warm, moist soil in the tropics and the southern United States. The larvae may penetrate the skin or be ingested. Pulmonary and

GI symptoms are common. The drug used for threadworm infections is ivermectin.

Scabies

Ivermectin may be prescribed off-label to selected patients with scabies (Currie & McCarthy, 2010). It is particularly effective in treating scabies in patients who are immunocompromised. The dose is 200 mcg/kg given as a single dose (Currie & McCarthy). Because ivermectin is not ovicidal, it should be repeated in 1 to 2 weeks.

Rational Drug Selection

The CDC Web site and guidelines should always be consulted prior to choosing and initiating drug therapy (CDC, 2013d, 2013e). Patient-specific factors such as pregnancy status and age should be carefully considered when choosing therapy. Albendazole and pyrantel pamoate are both available as a suspension. Pyrantel pamoate is also available over the counter, which may reduce inconvenience and promote adherence.

Monitoring

Evaluation of the efficacy of the anthelmintic drugs includes assessing the eradication of the helminth. For *E. vermicularis,* cellophane tape swabs of the perianal area should be obtained before starting and 1 week after drug therapy, especially in patients with persistent symptoms. The swab should be obtained every morning prior to defecation and bathing for at least 3 days to determine proof of cure.

For roundworms, hookworms, ascariasis, trichuriasis, and whipworms, stool samples are obtained before and 1 to 3 weeks after treatment to determine proof of cure. For strongyloidiasis, routine stool examinations and special examinations such as the Baermann technique may be required prior to treatment and repeated at intervals of 3 months, beginning at 6 weeks after treatment, to establish proof of cure.

Patients taking prolonged therapy with these agents should have periodic evaluation of hepatic function and CBCs. These tests should also be repeated whenever there is clinical evidence of hepatotoxicity or blood dyscrasias.

Patient Education

Administration

The available dosage forms are shown in Table 24-39. Albendazole should be swallowed whole with a small amount of water and a high-fat meal to decrease GI effects and increase absorption. Mebendazole is also taken with a high-fat meal, but it can be chewed or crushed. Ivermectin must be taken with a full glass of water on an empty stomach 1 hour before a meal. Pyrantel pamoate can be taken without regard to meals or time of the day.

Adverse Reactions

Women of childbearing capacity should take albendazole after a negative pregnancy test in the first 7 days following the onset of menses and should use a backup barrier method of contraception for 1 month after completing therapy. Albendazole should not be used in conjunction with cimetidine, which decreases clearance of albendazole. Patients who have recently taken albendazole should also report signs of neutropenia (sore throat, fever, unusual tiredness). Mebendazole should also be avoided during pregnancy.

Ivermectin can cause light-headedness, so hazardous activities should be avoided during therapy. Use may be associated with a skin rash or itching during treatment of strongyloidiasis because of the death of microfilariae in the skin. If serious, this syndrome may require short-term therapy with corticosteroids to suppress the inflammatory response.

Lifestyle Management

Patients with hookworm and whipworm infections may require iron replacement therapy. Eradication of pinworm infections usually requires simultaneous treatment of all household contacts; a vigorous hygiene program of cleaning bed linens, nightwear, and underwear; and good hand-washing habits. Contrary to popular belief, treatment of helminthic infections does not require special diets or purging with laxatives before or after the antimicrobial drug.

METRONIDAZOLE, NITAZOXANIDE, AND TINIDAZOLE

Metronidazole (Flagyl) is effective at managing bacterial as well as parasitic infections and is therefore discussed separately from the other antibiotics classes. It is available in oral, intravenous, and topical preparations. Topical applications are discussed in Chapters 23 and 32 for skin conditions and in Chapter 44 for vaginal disorders. Nitazoxanide (Alinia) is used in the treatment of diarrhea caused by *G. lamblia* and *C. parvum*. Tinidazole (Tindamax) is approved for treatment of amebiasis, bacterial vaginosis, giardiasis, and trichomoniasis. Both nitazoxanide and tinidazole are available only for oral administration.

Pharmacodynamics

Metronidazole is a nitroimidazole that disrupts DNA and protein synthesis. Upon entry into the microorganism, the nitro group of metronidazole is reduced, creating a highly reactive molecule that binds nonspecifically and deactivates DNA and other proteins. Aerobic cells lack sufficient reduction potential to produce the reactive molecule, rendering it ineffective in treatment of these organisms (Lofmark, Edlund, & Nord, 2010). Metronidazole is bactericidal against anaerobic bacteria and its efficacy is best correlated to the AUC to MIC ratio (Sprandel et al, 2006). It has reliable activity against gram-positive, and gram-negative anaerobes including *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, *Bacteroides fragilis*, and *Fusobacterium* species. It also has activity against *H. pylori, Entamoeba histolytica, T. vaginalis, Gardnerella vaginalis*, and *G. lamblia*.

Nitazoxanide interferes with the pyruvate ferredoxin oxidoreductase (PFOR) enzyme-dependent electron transfer reaction, which is essential to anaerobic energy metabolism in the protozoa. It is active against the sporozoites and oocysts of *C. parvum* and trophozoites of *G. lamblia.*

Tinidazole is an antibacterial and antiprotozoal agent with mechanism of action similar to metronidazole. Like metronidazole, it undergoes intracellular nitro group reduction and is thought to subsequently deactivate DNA and other proteins. While the mechanism is not completely understood, tinidazole has activity against *Bacteroides* species, *Gardnerella vaginalis, Prevotella* species, *G. lamblia,* and *Entamoeba histolytica.*

Pharmacokinetics
Absorption and Distribution
Oral metronidazole is readily absorbed and widely distributed into most tissue and fluids, including CSF, breast milk, alveolar, bone, liver abscesses, vaginal secretions, seminal fluid, as well as crossing the placenta. Serum levels are proportional to the administered dose and are similar for oral and intravenous routes. Following administration, nitazoxanide is rapidly metabolized to two active metabolites, tizoxanide and tizoxanide glucuronide. Administration with food is recommended as the AUC and C_{max} are both decreased when taken without food. An oral suspension of nitazoxanide is available and has roughly 70% of the bioavailability of the oral tablet. The active metabolites of nitazoxanide are poorly distributed, with 99% of tizoxanide bound to plasma proteins. Tinidazole is rapidly and completely absorbed after oral administration. Administration with food does not appreciably alter absorption. It is widely distributed to virtually all tissues, crosses the blood–brain barrier and the placental barrier, and is secreted in breast milk.

Metabolism and Excretion
Metronidazole is metabolized into several degradation products with the majority (60% to 80%) being renally eliminated. Tizoxanide and tizoxanide glucuronide are mainly excreted in the feces (about two-thirds) with a small portion excreted renally (about one-third). Tinidazole undergoes extensive metabolism by CYP3A4. It is excreted by the liver and can also be recovered in the urine as unchanged drug. Table 24-40 presents the pharmacokinetics of these three drugs.

Pharmacotherapeutics
Precautions and Contraindications
Cautious use is recommended with metronidazole for patients with a history of blood dyscrasias. Seizures have occurred as an adverse reaction, and patients with a history of seizure disorder or neurological problems should use this drug with caution. Severe hepatic dysfunction may decrease plasma clearance, and metronidazole should be used cautiously with these patients. Tinidazole is also a nitroimidazole and has the same precautions and contraindications.

The pharmacokinetics of nitazoxanide in patients with compromised renal or hepatic function has not been studied. It must be administered with caution to patients with hepatic and biliary disease and to patients with renal disease or a combination of the two.

Metronidazole is listed as Pregnancy Category B. Several studies have shown the development of cleft palate when the fetus is exposed during the first trimester, but these studies have not been confirmed. Metronidazole is contraindicated for treatment of trichomoniasis during the first trimester. It has been used to treat trichomoniasis in the second and third trimesters of pregnancy, but not as a single-dose regimen. Although this drug has been used for more than 20 years with no increase in congenital abnormalities, stillbirths, or low birth weight reported, as with any drug given during pregnancy, prudence suggests that it be used only when clearly indicated.

Nitazoxanide is also listed as Pregnancy Category B. Animal studies have shown no evidence of impaired fertility or harm to the fetus. However, there are no adequate, well-controlled studies in humans. It should be used only when clearly indicated and when there is no other reasonable drug.

Tinidazole is Pregnancy Category C. It has not been studied in pregnant patients but is known to cross the placental barrier. It should not be given to pregnant patients in the first trimester. Given the long history of use of metronidazole,

Table 24–40 ⊞ Pharmacokinetics: Metronidazole, Nitazoxanide, and Tinidazole

Drug	Onset (h)	Peak (h)	Duration (h)	Protein Binding	Bioavailability	Half-Life	Elimination
Metronidazole	Rapid	1–3 h	8	<20%	100%	7.5 h	20% unchanged in urine; 6%–15% in feces
Nitazoxanide	UA	1–4; 2–8 h*	12	99%	Tablet: 100%; oral suspension: 70%	UA	As metabolites

*The first number is for the tizoxanide metabolite; the second number is for the tizoxanide glucuronide metabolite.

it is a better drug choice for treatment of *G. lamblia* in pregnancy.

A nursing mother who needs metronidazole or tinidazole should interrupt nursing for 24 hours and use a single-dose regimen if clinically appropriate. Safety and efficacy in young children have not been established. It is not known if nitazoxanide is excreted in breast milk, and the choice to use it for a lactating mother should be made with extreme caution.

The safety and efficacy of metronidazole in children have been established only for treatment of amebiasis, although there are also drug dosages published for trichomoniasis and giardiasis. Elimination relates inversely to age. A single tablet of nitazoxanide contains more drug than is allowed for pediatric patients 11 years or younger; only oral suspension should be used for children aged 1 to 11 years. It should not be used for children younger than 1 year. Nitazoxanide is approved for treatment of *G. lamblia* and *C. parvum* in children. Tinidazole is approved for treatment of intestinal amebiasis and giardia in children 3 years of age or older.

Adverse Drug Reactions

Anorexia, nausea, abdominal pain, dizziness, and headache commonly occur with metronidazole. Dry mouth and a metallic taste may also develop. Although irritating, these adverse reactions are mild and transient. Infrequent adverse reactions include diarrhea, glossitis, rashes, leukopenia, seizures, aseptic meningitis, and peripheral neuropathy. Taking the drug with meals lessens the GI irritation. GI irritation with abdominal pain, nausea, and diarrhea are the main adverse reactions for nitazoxanide. Adverse effects associated with tinidazole are similar to those for metronidazole.

Drug Interactions

Drug interactions with all three drugs are few. As metronidazole undergoes metabolism by CYP450, known inhibitors (such as cimetidine) and inducers (such as phenytoin, phenobarbital) affect drug concentration. As metronidazole potentiates the anticoagulant effects of warfarin; the prothrombin time/international normalized ratio (PT/INR) should be carefully monitored. A disulfiram-like reaction may occur with alcohol ingestion, and patients are warned not to consume alcohol while taking this drug and for 48 hours after completing it.

Metronidazole may increase serum levels of lithium and close monitoring is recommended. Drug interactions are similar for tinidazole. Nitazoxanide is heavily bound to plasma proteins and may interact with other drugs that are also heavily protein bound (competition for binding sites), especially those with narrow therapeutic ranges (e.g., warfarin).

Clinical Use and Dosing

Metronidazole and tinidazole have antiparasitic and antibacterial properties. They are used against the common protozoal infections by *T. vaginalis, G. lamblia,* and *E. histolytica.* Metronidazole is also used to treat less common parasites, such as the protozoon *Balantidium coli* (with an oral dose of 750 mg 3 times daily for 5 days), as an alternative to tetracycline, and to treat the helminth *Dracunculus medinensis,* or guinea worm (with an oral dose of 250 mg 3 times daily for 10 days). Antibacterial uses of metronidazole include treatment of anaerobic bacterial infections, bacterial vaginosis, CDI, and eradication of *H. pylori* in gastritis and peptic ulcer disease. Many of the anaerobic bacterial infections treated with metronidazole are serious, even life-threatening, with treatment initiated in the hospital. Dosages of metronidazole for these diverse conditions are summarized in Table 24-41. In severe hepatic or renal disease, the dosage of metronidazole may need to be decreased; increased dosages might be required for successful therapy of patients taking inducers of hepatic CYP450, such as phenobarbital and phenytoin. Nitazoxanide is used for diarrhea casued by *G. lamblia* or *C. parvum.* Tinidazole is indicated for the treatment of trichomoniasis caused by *T. vaginalis*, giardiasis, bacterial vaginosis, intestinal amebiasis, and amebic liver abscess.

Trichomonas vaginitis

Trichomonas vaginal infection often occurs during or shortly after menses and is characterized by copious foamy discharge with a pH greater than 5, positive "whiff test," punctate hemorrhages of vaginal mucosa, and vaginal irritation. Although it is generally sexually transmitted, the organism can live for weeks on wet towels and toilet seats, so fomite transfer is theoretically possible. In the male, the infection may cause urethral discharge, but it is usually mild, if present at all. Both partners should be treated and a condom used during intercourse for a week to prevent reinfection. One-day treatment with metronidazole is 2 g as a single dose; 7-day treatment is 500 mg twice a day for 7 days (CDC, 2010e). If the infection occurs in the first trimester of pregnancy, deferral of treatment is recommended. Experts disagree over whether the long or short treatment is preferable during pregnant and nonpregnant states. Single-dose therapy promotes compliance, especially if administered under supervision.

Tinidazole is also used for this indication. The dose is 2 g as a single dose with food (CDC, 2010e). Both partners should be treated. This drug is Pregnancy Category C, so metronidazole is the preferred drug in those circumstances.

Giardiasis

The life cycle of the protozoon *G. lamblia* involves two stages: a cyst and a trophozoite. The cyst form can live in cold water for months and is ingested by the human hosts. It can also be transmitted during sexual activity. The trophozoite—or actively metabolizing, motile form—lives in the upper two-thirds of the small intestine and can be so numerous that it can mechanically interfere with digestion. *Giardia* infections may be asymptomatic or cause disease ranging from self-limiting diarrhea to a severe chronic syndrome with malnutrition.

In the United States, metronidazole, 250 mg 3 times a day for 5 days in adults and 15 mg/kg every 8 hours for 5 to 10 days in children, is used to treat giardiasis, although it is not approved for this indication. Asymptomatic cyst passers

Table 24–41 ⊗ Dosage Schedule: Metronidazole, Nitazoxanide, and Tinidazole

Drug	Indication	Dosage Form	Initial Dose	Comments
Metronidazole (Flagyl, Metric 21, Protostat)	Anaerobic bacterial infection	Tablets: 250 mg (G) 250 mg (F) 250 mg (P) 500 mg (G) 500 mg (F) 500 mg (P) Tablet, extended release: 750 mg (G), 750 (F) Capsules: 375 mg (F)	*Adults* 500 mg PO q8h *Children:* 7.5 mg/kg PO q6h *or* 10 mg/kg q8h	Maximum adult daily dosage is 4 g. Maximum daily dose in children is 2000 mg. Reduction in dosage may be required for patients with severe hepatic or renal impairment. May be taken with meals or a snack to decrease GI irritation. Avoid alcoholic beverages during therapy and for 48 h after completing it. Sexual partners of patients with *T. vaginalis* should be treated even if asymptomatic. Abstain from sexual contact or use condom for 7 d after therapy begins.
	C. difficile infection (CDI)		*Adults:* 500 mg PO 3 times daily *or* 250 mg PO 4 times daily for 10–14 d *Children:* 30 mg/kg/day divided qid for 7–14 days. Max 2000 mg/day	
	Bacterial vaginosis associated with *T. vaginalis* (off-label)		*Adults* 500 mg PO twice daily for 7 d	
	Giardiasis (*Giardia lamblia*) (off-label)		*Adults* 250 mg PO 3 times daily for 5–7 d *Children:* 5 mg/kg/dose PO 3 times daily for 5–7 d	
	Amebiasis (*E. histolytica*) dysentery		*Adults* 750 mg PO 3 times daily for 5–10 d *Children:* 35–50 mg/kg/24 h PO in 3 divided doses for 7–10 d *or* 11.6–16.7 mg/kg/dose PO 3 times daily for 7–10 d	
	Amebiasis (*E. histolytica*) liver abscess		*Adults:* 500–750 mg PO 3 times daily for 5–10 d *Children:* 35–50 mg/kg/24 h PO in 3 divided doses for 10 d *or* 11.6–16.7 mg/kg/dose PO 3 times daily for 10 d	
	Balantidiasis (off-label) (*Balantidium coli*)		*Adults:* 500–750 mg PO 3 times/d for 5–10 d *Children:* 11.6–16.7 mg/kg/dose 3 times daily for 10 d	
	Gastritis or peptic ulcer, *H. pylori*–associated		*Adults:* In combination with other antibiotic therapy : 500 mg PO 2–3 times daily for 7–14 d	
	Trichomoniasis (*T. vaginalis*)		*Adults:* 2 g PO as a single dose or 2 divided doses in 1 d; alternative: 250 mg PO 3 times/d for 7 d *Children:* 5 mg/kg/dose PO 3 times daily for 7 d	

Continued

Table 24–41 ⊗ **Dosage Schedule: Metronidazole, Nitazoxanide, and Tinidazole—cont'd**

Drug	Indication	Dosage Form	Initial Dose	Comments
	Anthelmintic		*Adults*: 250 mg PO 3 times daily for 10 d *Children*: 8.3 mg/kg/dose PO, up to a maximum of 250 mg, 3 times/d for 10 d	
Nitazoxanide	*G. lamblia*	Tablets: 500 mg (B) Powder for oral suspension: 100 mg/5 mL	*Children 1–3 yr*: 5 mL oral suspension* q12h *4–11 yr*: 10 mL oral suspension q12h *≥ 12 yr*: 1 tablet (500 mg) q12h or 25 mL oral suspension q12h	Take with food. Duration of therapy is 3 d.
	C. parvum		*Children 1–3 yr*: 5 mL oral suspension q12h *4–11 yr*: 10 mL oral suspension q12h	
Tinidazole	Intestinal amebiasis	Tablets: 250, 500 mg	*Adults* 2 g/d *Children ≥3 yr*: 50 mg/kg/d	Duration of therapy is 3 d.
	Giardiasis		*Adults*: 2 g *Children ≥3 yr*: 50 mg/kg	Single dose.
	Trichomoniasis		*Adults*: 2 g	Single dose.
				Partner should also be treated.

*Oral suspension is 100 mg/5 mL.

should also be treated. The nitazoxanide dose in adults is 500 mg twice daily for 3 days. Nitazoxanide is FDA approved for treatment of *G. lamblia* in children older than 1 year and will also treat intestinal parasites. Dosing of nitazoxanide for children age 1 to 3 years is 100 mg twice a day for 3 days, 200 mg twice a day in children age 4 to 11 years and children age 12 years or older prescribed the adult dose. Nitazoxanide is available in an oral suspension to make administration easier and more accurate in very young children. Tinidazole dosing to treat giardiasis in adults is a single 2 g dose with food and 50 mg/kg (up to 2 g) in children older than 3 years. Doses are provided in Table 24-41.

Amebiasis

Several species of *Entamoeba* infect humans, but *E. histolytica* is the only species known to cause disease. Like many protozoa, *Entamoeba* has two life stages: the cyst and the trophozoite. Infection of the human usually involves ingestion of cysts from fecally contaminated food, water, or hands. Transmission of cysts and trophozoites can also occur with fecal exposure during sexual contact. In the intestine, cysts undergo excystation into the trophozoite form and multiply. In many cases, the cysts remain in the intestinal lumen (noninvasive infection), resulting in asymptomatic carriers and cyst passers. In some patients, the cysts invade the intestinal lumen (invasive intestinal disease), resulting

in diarrhea or dysentery. Trophozoites also can travel through the bloodstream to form abscesses in the liver, brain, or lung (extraintestinal disease) that are manifested by local signs such as hepatomegaly or cholestasis. Drugs administered for presumptive treatment (broad-spectrum antibiotics, kaolin, bismuth, soapsuds enema, barium) can suppress shedding of amoebas into the stool and delay diagnosis. For invasive intestinal amebiasis in adults, metronidazole 750 mg orally 3 times daily for 10 days may be used (35 to 50 mg/kg/24 hours divided into three doses in children). Metronidazole can be used to treat the extraintestinal form of the disease IV or orally.

Metronidazole is so well absorbed that it is not effective against the noninvasive infection, and it may be necessary to add a luminal amoebicide like paromomycin (Humatin), 500 mg orally 3 times daily for 7 days. Paromomycin is an unabsorbable aminoglycoside similar to neomycin. If the intestinal mucosa is not intact, as in concomitant inflammatory bowel disease, paromomycin can be absorbed and cause ototoxicity and nephrotoxicity.

Tinidazole may also be prescribed for invasive intestinal amebiasis or amoebic liver abcess. The adult dose of tinidazole for invasive intestinal amebiasis or liver abcess is 2 g daily with food for 3 days. The pediatric dose of tinidazole for invasive intestinal amoebiasis or liver abcess is 50 mg/kg/day daily for 3 days. The advantage of tinidazole is the once-daily dosing.

Bacterial Vaginosis

Bacterial vaginosis develops when the bacterial flora are altered, with loss of the normally predominant lactobacilli and overgrowth of strict and facultative aerobic species such as *Bacteroides, Peptococcus, Mobiluncus, Gardnerella, Streptococcus,* and *Mycoplasma.* The infection manifests with foul-odored, clear, copious vaginal discharge with a pH greater than 4.5, positive "whiff test," and few WBCs. Untreated bacterial vaginosis has been associated with pelvic inflammatory disease, cervicitis, abnormal Pap smear cytology, preterm labor, and low birth weight. During pregnancy, symptomatic women are screened and treated if they are at high risk for preterm delivery. Treatment of low-risk and symptomatic women during pregnancy is controversial. Metronidazole, 500 mg orally twice daily for 7 days, or metronidazole intravaginal gel, 1 full applicator twice daily for 5 days, is the drug of first choice for bacterial vaginosis (CDC, 2010e). Dosing in pregnant women is 500 mg twice a day for 7 days or 250 mg 3 times a day for 7 days (CDC, 2010e).

The recommended dose of tinidazole in nonpregnant females with bacterial vaginosis is a 2 g oral dose once daily for 2 days taken with food or a 1 g oral dose once daily for 5 days taken with food. Use of tinidazole in pregnant women has not been studied. It is not necessary to treat sexual partners of women with bacterial vaginosis unless balanitis is present. Doses are provided in Table 24-41.

Cryptosporidium parvum

Nitazoxanide is the only drug in this group approved for treatment of the diarrhea caused by *C. parvum* in children 11 years old or younger. Its safety and efficacy have not been established for older children or adults, but doses are provided in the literature for these age groups. Its action appears to be caused by interference with the PFOR enzyme-dependent electron transfer reaction essential for anaerobic energy metabolism in the organism. This protein sequence is similar to the one used by *G. lamblia.* Dosing for each age group is found in Table 24-41.

Rational Drug Selection

For most of the infections for which metronidazole is used, it is the drug of choice because it is clearly more efficacious than the alternatives. Metronidazole is on many retail $4 lists, so cost is not an issue. Issues in drug selection for these conditions are the lack of effective alternatives for use in the first trimester of pregnancy, comparative efficacy of the long- and short-term oral dosing regimen, and the choice between topical and oral forms for vaginal infections.

For *G. lamblia,* nitazoxanide and tinidazole have FDA approval for this indication in children; metronidazole use is off-label. Only nitazoxanide has approval for treatment of *C. parvum* infections.

Monitoring

For most of the conditions treated with metronidazole, resolution of symptoms indicates effective treatment and further evaluation is not required. For giardiasis treated with any of these drugs, symptoms may persist for weeks or months after the organism is eradicated because of the lactose intolerance brought on by the infection (Gardner & Hill, 2001). If symptoms persist, three stool samples should be collected and cultured several days apart about 3 to 4 weeks after completion of treatment.

Patient Education

Administration

Although oral metronidazole and tinidazole can be taken without regard to meals, they should be taken with food or snacks to decrease GI irritation. Nitazoxanide should be taken with food and the oral suspension should be shaken well before administration. If vaginal or topical preparations of metronidazole are used, the patient should be provided with instruction and the opportunity to manipulate a model applicator in the office. Use of the extended-release form of metronidazole that can be administered once daily should be considered if nonadherence is an issue, although the vaginal gel and delayed-release oral form are considerably more expensive than other oral forms.

Adverse Reactions

Chewing sugarless gum or sucking on ice or candy can help to overcome the dry mouth and metallic taste that metronidazole can cause. Alcoholic beverages should be avoided during therapy with metronidazole or tinidazole and for 48 hours after the last dose because disulfiram-like reactions occur in about 40% of patients who consume alcohol. Because metronidazole can cause dizziness or light-headedness, hazardous activities should be avoided until the patient's response to the medication is established. Headache is a common adverse effect of metronidazole that can be treated with acetaminophen or an NSAID.

Metronidazole causes a harmless darkening of urine. Female patients should be counseled about the symptoms of vaginal candidiasis superinfection, which can complicate therapy and could be mistaken for recurrence of the original infection. The patient and family members should know to report CNS symptoms (ataxia, mood and mental changes, clumsiness, ataxia, seizures), peripheral neuropathy (numbness, tingling, pain, or weakness in hands or feet), and leukopenia (sore throat or fever).

Lifestyle Management

Many of the infections treated with metronidazole and tinidazole are sexually transmitted. Male or female condom usage may decrease transmittal of some, but not all, infections. Patients should be advised of the route of transmission and practices that promote transmittal of the infection. Concurrent treatment and refraining from sexual activity until the treatment is complete may be necessary to resolve the infections. Foreign travel and wilderness travel are other sources of exposure to *Giardia* and amoebas that should be considered in the history for diagnosing these conditions.

DRUGS USED IN TREATING INFLAMMATORY PROCESSES

Teri Moser Woo

Inflammation is a common symptom of many diseases, including arthritis, with an estimated 52.5 million adults reporting they have some form of arthritis, rheumatoid arthritis, gout, lupus, or fibromyalgia according to the 2010–2012 National Health Interview Survey (Centers for Disease Control and Prevention [CDC], 2013). This chapter discusses the medication used to treat inflammation—specifically inflammation associated with gout—and the nonspecific anti-inflammatory drugs. The anti-inflammatory actions of the corticosteroids are reviewed as well as the nonsteroidal anti-inflammatory drugs (NSAIDs) and the salicylates.

ANTIGOUT AND URICOSURIC AGENTS

Gout was the first form of arthritis to be recognized as crystal induced. Gout affects 8.3 million Americans (4%); the prevalence has increased over the past 20 years with the increased incidence of obesity and hypertension (Zhu, Pandya, & Choi, 2011). The peak incidence occurs in patients 70 to 79 years old, and it is much more common in men than in women (Lawrence et al, 2008). Gout in women occurs exclusively postmenopause and is associated with hypertension, renal insufficiency, and exposure to diuretics.

The gout syndrome is caused by an alteration in purine metabolism, the end product of which is uric acid. This alteration results in hyperuricemia and in the deposition of urate crystals in various tissues. The four phases of gout are asymptomatic hyperuricemia, acute gouty arthritis, intercritical gout, and chronic tophaceous gout. Patients with asymptomatic hyperuricemia do not require treatment, but efforts are made to lower their urate levels by encouraging them to make changes in diet and lifestyle. Acute gout is characterized by the sudden onset of pain, erythema, limited range of motion, and swelling in the involved joint, with approximately 50% of cases involving the first metatarsal join of the great toe, but other joints can be involved (CDC, 2011).

The key elements in treatment of the latter three phases of this disorder are management of the acute pain and use of antigout and uricosuric agents. The drugs used to manage the pain are most often NSAIDs and corticosteroids, which are discussed later in the chapter. The three antigout drugs, allopurinol (Zyloprim), colchicine, and febuxostat (Uloric), and the two uricosuric agents, probenecid (Benemid) and sulfinpyrazone (Anturane), are the focus of this section.

Pharmacodynamics

Antigout Drugs

Antigout drugs act to reduce the inflammatory process or to prevent the synthesis of uric acid. Allopurinol and febuxostat inhibit xanthine oxidase, the enzyme responsible for the conversion of hypoxanthine and xanthine to uric acid. Allopurinol has a metabolite (alloxanthine) that is also an inhibitor of xanthine oxidase. Allopurinol acts directly on purine metabolism, reducing the production of uric acid, without disrupting the biosynthesis of vital purines. Allopurinol and febuxostat are the only drugs that act directly on the pathophysiological cause of gout.

Administration of allopurinol generally leads to a fall in both serum and urinary uric acid in 2 to 3 days. The magnitude of this decrease is dose-dependent. A week or more of treatment may be necessary before the full effects of the drug can be seen.

Febuxostat is used to treat hyperuricemia in patients with gout. The goal is to have a serum uric acid level of less than 6 mg/ dL. It may take 2 weeks or more to see the effect of febuxostat.

Unlike allopurinol, colchicine does not affect purine metabolism. It binds to microtubular proteins to interfere with the function of the mitotic spindles and inhibit the migration of granulocytes to the inflamed area. It reduces lactic acid production by granulocytes, which decreases deposition of uric acid, and it interferes with kinin formation and reduces phagocytosis. Taken together, these actions decrease the inflammatory response to the deposited urate crystals.

Although it relieves pain in acute attacks, colchicine is not an analgesic. It is also not uricosuric and does not prevent gout from progressing to chronic gouty arthritis. Its prophylactic, suppressive effect helps reduce the incidence of acute attacks and relieves the patient's occasional residual pain and mild discomfort.

Uricosuric Drugs

Uricosuric drugs, unlike antigout drugs, increase the rate of uric acid secretion. Both probenecid and sulfinpyrazone inhibit renal tubular reabsorption of urate and thus increase the renal excretion of uric acid and decrease serum uric acid levels. Effective uricosuria reduces the miscible urate pool, retards urate deposition, and promotes reabsorption of urate deposits. Sulfinpyrazone also competitively inhibits platelet prostaglandin synthesis, which prevents platelet aggregation and gives the drug an antithrombotic effect. Both drugs lack anti-inflammatory activity. They are most useful for patients with reduced urinary excretion of uric acid. They are not intended for treatment of acute attacks.

Pharmacokinetics

Absorption and Distribution

All gout drugs are well absorbed after oral administration (Table 25-1). Febuxostat absorption is decreased with a high-fat meal, but there is not a clinically significant change in serum uric acid concentration, so it may be taken without regard to food. Allopurinol is widely distributed to tissues. Colchicine concentrates mainly in white blood cells. Probenecid crosses the placenta without producing adverse effects in the fetus or infant. Sulfinpyrazone also crosses the placenta but may be hazardous to the fetus. Both probenecid and sulfinpyrazone are highly protein bound and tend to displace other drugs that have a high affinity for the same binding sites.

Metabolism and Excretion

The liver metabolizes all five drugs used in gout treatment. All have active metabolites. Both biliary and renal routes excrete allopurinol, colchicines, and febuxostat. However, colchicine is not effective in the presence of renal failure. The other two drugs are excreted primarily in urine, and the dose of probenecid may need to be reduced in the presence of renal impairment.

Pharmacotherapeutics

Precautions and Contraindications

Allopurinol (Zyloprim), colchicines, probenecid (Benemid), and sulfinpyrazone (Anturane) are associated with poor urate clearance in the presence of renal impairment. They should be used cautiously, and renal function tests should be performed regularly to determine appropriate dosage of the drug. Data are insufficient regarding the use of febuxostat in patients with renal impairment.

Allopurinol and colchicine are associated with hepatotoxicity. They are not recommended for patients with severe hepatic dysfunction. If patients taking these drugs develop anorexia, weight loss, or pruritus, evaluation of liver function should be part of the diagnostic work-up. For milder hepatic disorders, close monitoring of liver function is required.

Colchicine, probenecid, and sulfinpyrazone are all used cautiously in the presence of peptic ulcer disease or spastic colon. Gastrointestinal (GI) adverse reactions from these drugs are likely to make these disorders worse. Because probenecid and sulfinpyrazone are sulfa-based drugs, patients with known or suspected sulfa allergies should not use them.

Febuxostat, a xanthine oxidase inhibitor, is contraindicated in patients being treated with drugs requiring xanthine oxidase for metabolism (azathioprine, mercaptopurine, or theophylline) because of increased risk for toxicity.

Table 25–1 Pharmacokinetics: Antigout and Uricosuric Agents

Drug	Onset	Peak (in plasma)	Duration	Protein Binding	Half-Life	Elimination
Allopurinol	2–3 d*	1.5 h allopurinol 4.5 h oxipurinol	1–2 wk*	NA	1–2 h allopurinol 15 h oxypurinol	20% in feces; remainder in urine
Colchicine	12 h†	0.5–2 h	UK	50%	60 min in plasma <60 h in leukocytes	10%–20% in urine; remainder in bile and feces
Febuxostat	NA	1–1.5 h	UK	99.2%	5–8 h	Urine; 49% as metabolites, feces; 45% as metabolites
Probenecid	30 min*	2–4 h	8 h	85%–95%	5–8 h dose-dependent	In urine; primarily as metabolite
Sulfinpyrazone	NA	4 h	UK	98%–99%	4 h	50% in urine: 90% of this as unchanged drug; 10% as metabolite

UK = unknown.
  *Hypouricemic action.
  †Anti-inflammatory action.

There is a risk of gout flare-up when febuxostat is started. Patients should be concurrently treated with an NSAID or colchicine for up to 6 months.

Pregnancy categories vary by drug. Allopurinol is Pregnancy Category C, but there are no adequate, well-controlled studies in pregnant women. Use only when benefits clearly outweigh potential risks to the fetus. Colchicine is Pregnancy Category C when given orally, D when given parenterally. This drug can cause fetal harm when administered to pregnant women and should be used only when benefits clearly outweigh risks to the fetus and other drugs are not effective. Probenecid is Pregnancy Category B. It crosses the placenta, but it has been used during pregnancy without producing harmful effects in the fetus. Sulfinpyrazone is Pregnancy Category D, but there are no adequate, well-controlled studies in pregnant women. Its use should be avoided in pregnancy unless no other drug is effective and reduction in urate levels is essential. Febuxostat is Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. Febuxostat should only be used if the benefits outweigh the risks.

Allopurinol has been found in breast milk. It is not known whether the other three drugs are excreted in breast milk. Exercise caution when prescribing these drugs for nursing women. Febuxostat is excreted in the milk of rats; it is unknown whether it is excreted in human milk.

These drugs are generally not indicated for use in children, except in hyperuricemia associated with the treatment of malignancy, and this disorder would likely be followed by a specialist. Dosage schedules are published for children only for the indication discussed and for the use of probenecid for retarding penicillin or cephalosporin excretion in selected infections.

Adverse Drug Reactions

Urates tend to crystallize out in acid urine. Fluid intake of more than 3,000 mL/d, along with sufficient sodium bicarbonate (3–7.5 g/d) or potassium citrate (7.5 g/d), maintains alkaline urine. Continue alkalization until the serum uric acid level returns to normal limits and the tophaceous deposits disappear.

Colchicine, probenecid, and sulfinpyrazone are associated with adverse reactions affecting the GI tract. Symptoms include nausea, vomiting, diarrhea, and abdominal pain. These symptoms are particularly troublesome for patients with a history of peptic ulcer disease or active peptic ulcer disease.

Probenecid and sulfinpyrazone are sulfa-based drugs. They have been associated with hypersensitivity reactions related to this base. Severe, anaphylactic reactions are rare and usually occur within several hours after administration of the first dose of a restart regimen, following prior use of the drug. The appearance of a hypersensitivity reaction requires immediate discontinuance of the drug.

Allopurinol is associated with a maculopapular skin rash that sometimes is scaly or exfoliative. The incidence of this adverse reaction is increased in the presence of renal disorders. Because skin reactions may be severe and sometimes fatal, the drug should be discontinued at the first sign of rash. The most severe reactions include fever, chills, arthralgia, cholestatic jaundice, eosinophilia, mild leukocytosis, or leukopenia.

Patients on standard therapy with colchicine who have elevated plasma levels because of renal function have developed myopathy and neuropathy that result in weakness. This problem is often unrecognized and misdiagnosed as polymyositis

or uremic neuropathy. Proximal weakness and elevated serum creatinine kinase are generally present. The condition resolves 3 to 4 weeks after drug withdrawal. Colchicine also induces reversible malabsorption of vitamin B $_{12}$, perhaps because it alters the function of the ileal mucosa.

There is a risk of liver function abnormalities in patients taking febuxostat (6.6% in patients taking 40 mg/d and 4.6% taking 80 mg/d). A small number of patients (1.1%) experience nausea and arthralgia when taking 40 mg/d of febuxostat.

Drug Interactions

Colchicine has very few drug interactions. Probenecid, allo-purinol, and sulfinpyrazone have many drug interactions.

Probenecid inhibits the tubular secretion of most penicillins and cephalosporins and increases plasma levels by any route these antibiotics are given. Sulfinpyrazone reduces renal tubular secretion of organic anions (e.g., antimicrobials and sulfonamides) and displaces other anions bound extensively to plasma proteins (e.g., tolbutamide, warfarin).

Salicylates have a mutually antagonistic effect with both of these drugs. Because these drugs, with the exception of colchicine, have many drug interactions, checking drug interactions before prescribing them is important. Febuxostat should not be administered with drugs that are metabolized by xanthine oxidase, including theophylline, mercaptopurine, and azathioprine, because toxicity may occur. Table 25-2 lists the drug interactions.

Table 25–2 ▦ Drug Interactions: Antigout and Uricosuric Agents

Drug	Interacting Drug	Possible Effect	Implications
Allopurinol	Angiotensin-converting enzyme inhibitors	Higher risk of hypersensitivity reaction	Avoid concurrent use
	Aluminum salts	Decreased effects of allopurinol	Separate administration
	Ampicillin	Rate of ampicillin-induced rash much higher	Warn patients
	Anticoagulants	Anticoagulant effect of some drugs enhanced; not warfarin	Use warfarin for anticoagulation; conflicting data
	Cyclophosphamide	Myelosuppressive effects enhanced; increased risk for bleeding	If must be used together, monitor for bleeding risk
	Theophylline	Theophylline clearance decreased with large doses of allopurinol; increased toxicity risk	Select different respiratory drug
	Thiazide diuretics	Increased incidence of hypersensitivity reactions	Avoid concurrent use or monitor for hypersensitivity
	Thiopurines	Clinically significant increases in pharma-cological and toxic effect of thiopurines	Avoid concurrent use
	Uricosuric agents	Uricosuric agents that increase excretion of urate also likely to increase excre-tion of oxypurinol and lower degree of inhibition of xanthine oxidase; avoid concurrent use	Dosage adjustments may be needed if uricosuric added to treatment regimen
Colchicine	NSAIDs	Additive adverse GI effects	Avoid concurrent use; monitor for GI bleeding
Febuxostat	Drugs that are metabolized by xanthine oxidase: theophylline, mercapto-purine, azathioprine	Febuxostat may cause increased plasma levels	Concurrent use is contraindicated
Probenecid	Acyclovir	Decreased acyclovir renal clearance and increased bioavailability	Associated with IV use of drug; avoid this route
	Allopurinol	Increased blood levels for allopurinol	Beneficial effect; may be used therapeutically
	Barbiturates	Increased blood levels	Monitor central nervous system (CNS) effects
	Benzodiazepines (BDZs)	More rapid and prolonged BDZ effect	Monitor BDZ effects
	Clofibrate	Accumulation of clofibric acid; higher steady-state serum concentrations	Select different antilipidemic
	Dapsone	Possible accumulation of dapsone and its metabolites	Monitor for adverse effects or avoid concurrent use
	Dyphylline	Increased half-life, decreased clearance	May be used therapeutically to extend dyphylline dosing interval
	Methotrexate	Increased plasma level; therapeutic ef-fects and toxicity increased	Avoid concurrent use
	NSAIDs	Increased plasma levels and toxicity	Avoid concurrent use
	Pantothenic acid	Renal transport inhibited; plasma levels increased	No specific action required
	Penicillamine	Effects of penicillamine attenuated	Avoid concurrent use
	Penicillins, cephalosporins	Inhibits tubular secretion of most	Monitor for adverse effects
	Salicylates		
	Sulfonamides		
	Sulfonylureas		
	Zidovudine		

Table 25–2 ▦ Drug Interactions: Antigout and Uricosuric Agents—cont'd

Drug	Interacting Drug	Possible Effect	Implications
		penicillins and cephalosporins; usually increases plasma levels by any route these antibiotics are given Mutually antagonistic Renal transport inhibited; plasma levels increase Half-life of sulfonylurea increased Increased zidovudine bioavailability; cutaneous eruptions accompanied by malaise, myalgia, or fever have occurred	Avoid concurrent use Select different antimicrobial Monitor blood glucose closely Avoid concurrent use
Sulfinpyrazone	Acetaminophen Anticoagulants, oral Niacin Salicylates Theophylline Tolbutamide Verapamil	Risk of hepatotoxicity may be increased Anticoagulant activity of warfarin enhanced: increased bleeding risk Reduced uricosuric activity of sulfinpyrazone Mutually antagonistic Increased theophylline clearance and decreased plasma levels Decreased clearance and increased half-life of tolbutamide; hypoglycemia may result Increased clearance; decreased bioavailability	Conflicting data Use probenecid if warfarin must be used Avoid concurrent use Avoid concurrent use Avoid concurrent use or adjust dosage based on serum levels Glyburide not affected; change hypoglycemic drug Select different calcium channel blocker

Clinical Use and Dosing

Gout

Colchicine given orally is the time-honored drug for treatment of acute gouty attacks, but its efficacy is limited by the adverse reactions that commonly occur with doses adequate to manage the symptoms. In addition, dosages must be adjusted for patients with impaired renal or hepatic function, and it must be administered with caution to older adults. When colchicine is given, the usual regimen is an initial dose of 1.2 mg at the first sign of flare, followed by 0.6 mg 1 hour later (maximum 1.8 mg over 1 h).

Historically, a non-FDA approved schedule of dosing is to administer 0.6 to 1.2 mg every 1 to 2 hours until relief is obtained or until adverse reactions (usually diarrhea, nausea, and vomiting) develop, with 4 to 8 mg total administered. A randomized, double-blind, placebo-controlled, parallel-group, dose-comparison trial of a low dose (1.8 mg total over 1 h) and a high dose (4.8 mg total over 6 h) of colchicine found that low-dose colchicine had a better treatment response at 24 hours than did the high dose (37.8% versus 32.7%), with fewer adverse effects such as diarrhea (Terkeltaub, Furst, Bennett, Crockett, & Davis, 2010). The low-dose colchicine group had adverse effects similar to placebo. Therefore, the historic treatment regimen of high-dose colchicine is not recommended by this author. Articular pain and swelling usually abate within 12 hours and are usually gone in 24 to 48 hours.

Preventive therapy for patients who have fewer than one acute attack per year is 0.6 mg/d of colchicine for 3 or 4 days a week. For patients who have more than one acute attack per year, the dose is 0.6 mg every day. Serious cases may require 1.2 to 1.8 mg/d.

Allopurinol, the drug of choice for patients with a history of urinary calculi, renal insufficiency, chronic tophaceous gout, or high levels of serum urate, is given in doses of 200 to 300 mg/d for mild gout and 400 to 600 mg/d for moderately severe tophaceous gout. The minimum effective dose is 100 to 200 mg/d, and the maximum dose is 800 mg/d. Doses greater than 300 mg/d must be divided. Dosage adjustments for patients with renal insufficiency are based on creatinine clearance (CCr) values. These adjustments are listed in Table 25-3.

Febuxostat is indicated for the chronic management of hyperuricemia in patients with gout. The starting dose of febuxostat is 40 mg per day, once daily. If serum uric acid is not lowered to below 6 mg/dL after 2 weeks, then the dose is increased to 80 mg/d, once daily. Febuxostat is taken without regard to food or meals and no dosage adjustment is needed for renal or hepatic impairment. Periodic uric acid levels are drawn, the first at 2 weeks of therapy. Liver function should be tested at 2 months and 4 months after starting therapy. It is recommended that NSAIDs or colchicine be administered prophylactically for the first 6 months of febuxostat therapy to prevent acute gout flare.

Inhibitors of uric acid synthesis are more toxic, especially in older adults, and should be reserved for patients who "overproduce" urate (e.g., those who excrete more than 800 mg in 24 h). Probenecid is the uricosuric agent of choice because of its well-established safety and its relatively long duration of action. Therapy should not be initiated until the acute attack has completely resolved, because rapid decrease in serum urate levels has been shown to exacerbate a gouty attack.

Doses of probenecid are 250 mg (1/2 tablet) twice daily for 1 week and then 500 mg twice daily. Doses may be increased

Table 25–3 ⊗ Dosage Schedule: Antigout and Uricosuric Agents

Drug	Indication	Dosage Form	Initial Dose	Maintenance Dose
Allopurinol (Zyloprim)	Management of gout Hyperuricemia associated with treatment of malignancy Recurrent calcium oxalate stones	Tablets: 100 mg Tablets: 300 mg	*Adults:* Mild disease: 200–300 mg/d Moderately severe, topha-ceous: 400–600 mg/d *Adults:* 600–800 mg/d for 2–3 d with a high fluid intake *Children 6–10 yr:* 300 mg/d (100 mg tid) *Children <6 yr:* 150 mg/d (50 mg tid) *Adults:* 200–300 mg/d in single or divided doses	Minimum effective dose is 100–200 mg/d; maximum dose is 800 mg/d Doses >300 mg/d must be divided Dosage adjustments for renal insufficiency in adults: CCr 60 mL/min: 200 mg/d CCr 40 mL/min: 150 mg/d CCr 20 mL/min: 100 mg/d CCr 10 mL/min: 100 mg every other day CCr <10 mL/min: 100 mg 3 times/wk After 48 h titrate dose in all age groups according to serum uric acid levels Another recommended regimen for children: 1 mg/kg/d in 4 divided doses given q6h; maxi-mum dose 600 mg/d Dosage adjusted up or down based on control of hyper-uricemia according to 24 h urinary urate determinations
Colchicine	Acute gouty attacks Management of gout	Tablets: 0.5, 0.6 mg	*Adults:* 1.2 mg followed by 0.6–1.2 mg every 1–2 h up to 16 doses	Total needed during acute attack is usually 4–8 mg Wait 3 days before starting another course Adults with <1 acute attack/yr: 0.6 mg/d for 3–4 d/wk Adults with >1 acute attack/yr: 0.6 mg/d Serious cases: 1.2–1.8 mg/d
Febuxostat (Uloric)	Management of hyper-uricemia in patients with gout	Tablets: 40, 80 mg	*Adults:* Start at 40 mg once daily. If uric acid levels not <6 mg/dL after 2 wk, in-crease dose to 80 mg once a day.	40 or 80 mg/d NSAIDs or colchicine is needed in the first 6 mo of therapy to prevent acute gout attack.
Probenecid (Benemid)	Management of gout*	Tablets: 0.5 mg	*Adults:* 0.25 g bid for 1 wk	0.5 g bid; if no acute attack in >6 mo, reduce dose by 0.5 g/d every 6 mo
Sulfinpyrazone (Anturane)	Management of gout	Tablets: 100 mg Capsules: 200 mg	*Adults:* 200–400 mg/d in 2 divided doses	400 mg/d in 2 divided doses; doses as low as 200 mg/d and as high as 800 mg/d have been used

CCr = creatinine clearance.

*Probenecid is not effective for management of gout in the presence of chronic renal failure with CCr <30 mL/min.

by 500 mg/mo to a maximum of 2 to 3 g/d. Gastric intoler-ance may indicate overdose, and decreasing the dosage may ease it. The dosage that maintains normal serum uric acid levels is continued for maintenance. When the patient has had no acute attacks for 6 months, the dose is decreased by

500 mg every 6 months. Do not reduce the maintenance dose to the point at which serum uric acid levels begin to rise.

In the presence of renal impairment, a once-daily dose of 1 g probenecid may be used. The daily dose may be increased

in 500 mg increments every 4 weeks (usually to less than 2 mg/d) if symptoms are not controlled or the 24-hour urate excretion is less than 700 mg. Probenecid is not effective in chronic renal failure if the glomerular filtration rate is 30 mL/min or less. Patients must maintain hydration and adequate sodium bicarbonate (2 to 7.5 g daily) or potassium citrate (7.5 mg daily) to maintain an alkaline urine while on probenecid to prevent formation of uric acid crystals. Alkalization of the urine is recommended until the uric acid level is in the normal range.

Sulfinpyrazone is a potent uricosuric agent, but it must be given several times daily, is more likely than the other drugs to cause gastric adverse reactions, and can cause platelet dysfunction. For these reasons, it is prescribed only when probenecid and allopurinol are not tolerated. Initial dosage is 200 to 400 mg daily in two divided doses. Taking the drug with meals or milk reduces its adverse GI reactions. The dose is gradually increased to a maintenance dose of 400 mg daily in two divided doses. Doses can be as low as 200 mg/d or as high as 800 mg/d to control blood urate levels. Therapy is continued even in the presence of acute exacerbations. This drug can be used concomitantly with colchicine. Patients previously controlled on probenecid may be transferred to sulfinpyrazone at the full maintenance dose.

For all of these drugs, the goal of treatment is a urate level less than 6 mg/dL. Doses are titrated upward until that goal is reached.

Hyperuricemia Associated With Malignancies

Allopurinol is approved for use in hyperuricemia associated with malignancies. Doses of 600 to 800 mg daily for 2 or 3 days, with a high fluid intake, have proved effective. Dosage is similar to the dose given for gout.

Children age 6 to 10 with hyperuricemia secondary to malignancy are given 10 mg/kg/d in two to three divided doses. Younger children are generally given 150 mg/d in three divided doses. Another suggested dosing regimen is 300 mg/d in two to three divided doses in children aged 6 to 10 years.

Recurrent Calcium Oxalate Calculi

Allopurinol 200 to 300 mg/d in single or divided doses is given to prevent recurrent calcium oxalate renal stones. Patients also benefit from dietary modifications such as increases in oral fluids and dietary fiber and reductions in animal protein, sodium, refined sugars, oxalate-rich food, and excessive calcium intake.

Off-Label Uses

Colchicine also has several off-label uses. These purposes and the recommended doses are the following:

1. Hepatic cirrhosis: 1 mg/d for 5 days each week.
2. Primary biliary cirrhosis: 0.6 mg twice daily.
3. Refractory idiopathic thrombocytopenic purpura: 1.2 to 1.8 mg/d for 2 weeks or more.
4. Skin manifestations of scleroderma: 1 mg/d.

5. Familial Mediterranean fever: 1.2 to 2.4 mg/d in one to two divided doses. Increase or decrease dose in 0.3 mg increments, to a maximum of 2.4 mg/d.

Rational Drug Selection

Specific disease processes, for which each of these drugs is most appropriate, have already been mentioned. In general, allopurinol or febuxostat is best for patients who overproduce uric acid; probenecid is best for patients who undersecrete uric acid and have adequate renal function; sulfinpyrazone is best for patients who undersecrete uric acid when on a regular diet and those who need antiplatelet activity. Additional considerations in choosing the appropriate drug are shown in Table 25-3. Table 25-3 also presents available dosage forms of gout medications.

Renal Insufficiency

Because allopurinol blocks urate production, it is especially useful for patients with a history of urinary calculi, with renal insufficiency, or with excessive basal urinary uric acid excretion (750 to 800 mg/24 h). Serious adverse reactions occur in fewer than 2% of patients, typically within the first 2 months of therapy. Patients should be kept under close surveillance during this period. Toxicity seems more likely when allopurinol is given concomitantly with thiazide diuretics.

Peptic Ulcer Disease

IV colchicine rapidly provides a therapeutic plasma level and does not cause GI adverse reactions. It is useful for patients who cannot take the drug orally, have peptic ulcer disease, or have contraindications to NSAIDs. Diluted in 20 mL of normal saline and given over 10 minutes, 2 mg usually provides relief within 6 to 8 hours. Care must be used to prevent extravasation because colchicine may cause tissue necrosis.

High Levels of Serum Urate Associated With Secondary Gout

Allopurinol is the drug of choice because it is the only drug in this group that blocks urate production.

Monitoring

All patients receiving these drugs require monitoring of the serum uric acid level. A baseline assessment is done at initiation of therapy. Uric acid levels should be normal after 1 to 3 weeks of therapy, and serum levels should be drawn again then and periodically throughout therapy or in the presence of exacerbations. The upper limit of normal for men and postmenopausal women is 7 mg/dL; for premenopausal women, it is 6 mg/dL.

For allopurinol, liver and renal function must be assessed prior to initiation of therapy and periodically during the first few months of therapy, particularly for patients with preexisting liver disease. Perform blood urea nitrogen (BUN), serum creatinine, and CCr tests, and reassess dosages based on the results.

Probenecid and sulfinpyrazone both have blood dyscrasias (anemia, hemolytic anemia) as adverse reactions. Patients taking these drugs should have periodic complete blood counts (CBCs).

Patients whose urine is being alkalinized to prevent crystallization of urates in the urine should have their acid–base balance monitored.

Patient Education

Administration

Each drug should be taken exactly as prescribed. A dose that is missed should be taken as soon as the patient remembers but without doubling doses. For allopurinol, if the dosing schedule is once daily, it should not be taken until the next day. If the dosing schedule is more than once a day, the next dose should be up to 300 mg. None of these drugs should be discontinued without first consulting the health-care provider. Uric acid levels rise when the drug is stopped.

In the event of an acute attack during maintenance therapy, allopurinol, febuxostat, probenecid, and sulfinpyrazone should be continued while colchicine is added to the regimen to treat the acute attack. Dosage adjustments of the maintenance drugs may be necessary. Allopurinol can be crushed and given with fluid or mixed with food for patients who have difficulty in swallowing.

Patients should avoid taking aspirin or salicylates while taking probenecid or sulfinpyrazone. These drugs are mutually antagonistic.

Adverse Reactions

The main adverse reaction for all these drugs is GI distress. Taking these drugs with food or milk may minimize gastric irritation.

Probenecid and sulfinpyrazone are sulfa-based drugs that have been associated with hypersensitivity reactions related to this base. Patients should be asked about sulfa allergies and taught the indications of a hypersensitivity reaction and the importance of reporting it. A hypersensitivity reaction requires immediate discontinuance of the drug. Other symptoms to report with these drugs include sore throat, fatigue, yellowing of the skin or eyes, and unusual bleeding or bruising. These drugs have been associated with blood dyscrasias and hepatotoxicity.

Allopurinol has been associated with a maculopapular rash that sometimes is scaly or exfoliative. Because this skin reaction can be severe or even fatal, patients should report the first indication of a rash to their health-care provider, who should evaluate this rash and consider discontinuance of the drug.

Drowsiness and dizziness have occasionally affected patients who are taking allopurinol. Caution patients to avoid driving or other activities requiring alertness until their response to the drug is known.

Patients taking standard doses of colchicine have developed proximal muscle weakness related to myopathy and neuropathy. Patients should be warned to report these symptoms to their health-care provider. Stopping the drug usually reverses the symptoms within 3 to 4 weeks.

Lifestyle Management

To reduce available urates, an alkaline diet may be prescribed that includes reductions in sodium, refined sugars, oxalate-rich foods (e.g., liver, kidney, anchovies, sardines, herring, mussels, bacon, codfish, scallops, trout, haddock, veal, venison, turkey), and excessive calcium intake, as well as increases in oral fluids and dietary fiber. Fluid intake in excess of 3,000 mL/day also reduces the risk for renal calculi. Because large amounts of alcohol increase uric acid concentrations and may decrease the effectiveness of medications, alcohol should be avoided or consumed in very small amounts.

CORTICOSTEROIDS

Cortisol, the endogenous glucocorticoid in the body, is produced and secreted on the basis of feedback mechanisms of the hypothalamus-pituitary-adrenal (HPA) axis. The adrenal cortex synthesizes and secretes the steroid hormones that include mineralocorticoids and glucocorticoids and, to a lesser extent, androgens. Figure 25-1 depicts this feedback system. Exogenously administered adrenal cortex hormones (corticosteroids) affect this feedback mechanism.

Corticosteroids have a major role in the management of a variety of disease processes. In primary or secondary adrenal cortex insufficiency, they are used for replacement therapy. In rheumatic disorders, they may be short-term adjunctive therapy for acute episodes or exacerbation. These drugs are also used to treat collagen disease, dermatological conditions, asthma, allergic rhinitis, neoplastic disorders, inflammatory bowel disease, and idiopathic thrombocytopenia purpura. The role of inhaled corticosteroids in the management of respiratory disorders is covered in Chapter 17. Topical corticosteroids used to manage dermatological conditions are covered in Chapter 23. This chapter focuses on the use of systemic corticosteroids to manage inflammatory conditions in primary care situations.

Pharmacodynamics

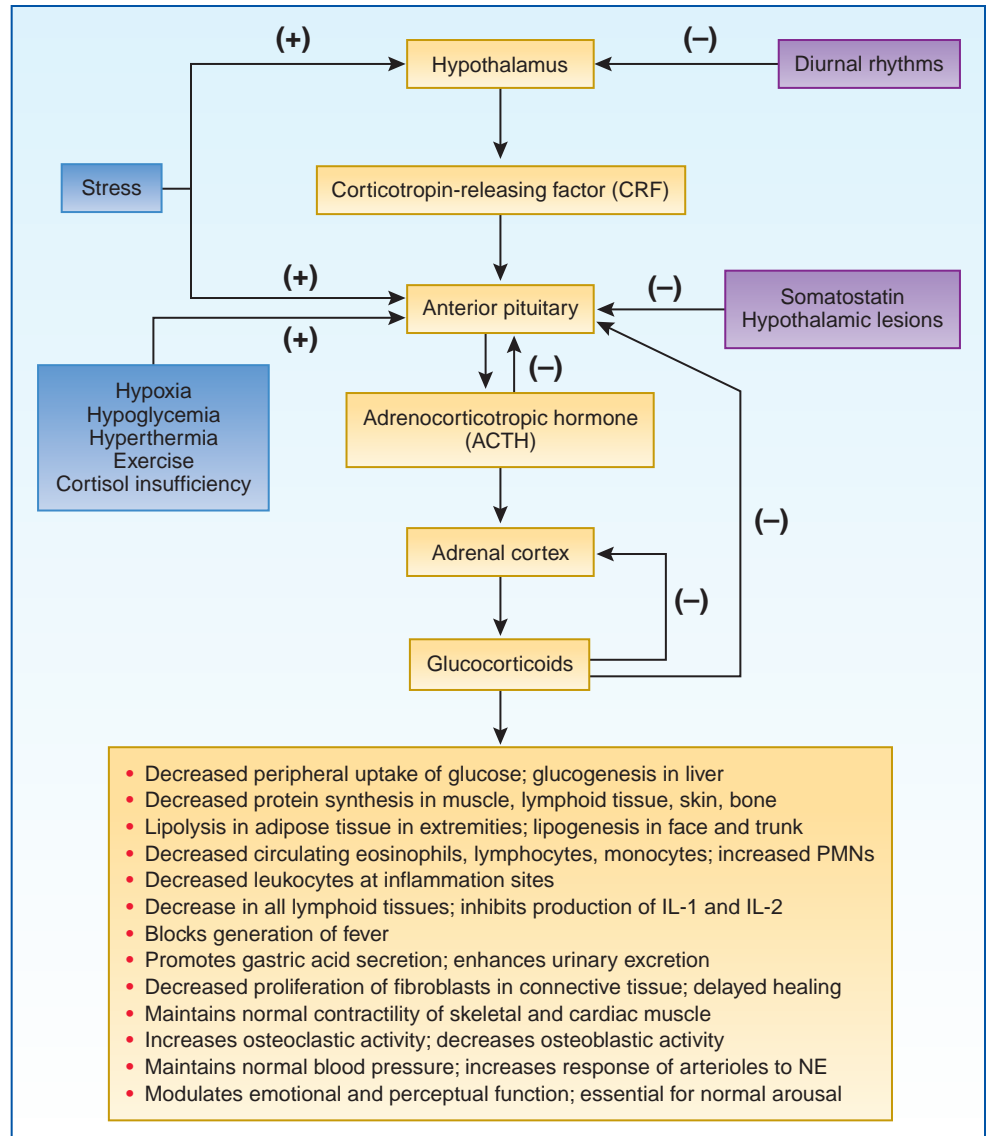
Glucocorticoids have metabolic, anti-inflammatory, and growth-suppressing effects. Cortisol is the "wake-up" hormone, and altered levels result in changes in levels of awareness and sleep patterns. Central nervous system (CNS) effects also result in labile emotional states, and high levels of cortisol are associated with decreased recent memory recall. Glucocorticoids increase blood glucose concentration by stimulating gluconeogenesis in the liver and by decreasing uptake of glucose into muscle, lymphatic, and adipose cells. In extrahepatic tissues, they stimulate protein catabolism and inhibit amino acid uptake and protein synthesis. Decreased proliferation of fibroblasts in connective tissue in concert with the poor protein synthesis leads to poor wound healing (McCance & Huether, 2010).


Figure 25–1. Hypothalamus-pituitary-adrenal axis and feedback control of cortisol.

Glucocorticoids inhibit the immune and inflammatory systems by their actions at several sites: depressing proliferation of T lymphocytes, including those that produce the antiviral protein interferon; decreasing natural killer cell activity; reversing macrophage activity; and suppressing the synthesis, secretion, and actions of chemical mediators involved in inflammatory and immune responses. These chemical mediators include interleukins, prostaglandins, leukotrienes, bradykinin, serotonin, and histamine.

Glucocorticoids also increase circulating erythrocytes; increase appetite; promote fat deposits in the face and cervical areas, while promoting lipolysis in the extremities; increase uric acid excretion; and decrease serum calcium levels, possibly by inhibiting GI absorption of calcium and phosphate (American College of Rheumatology, 2001 update). They also promote gastric acid secretion. In the urinary tract, glucocorticoids enhance urinary excretion. Their feedback activity on the HPA axis suppresses secretion and

synthesis of adrenocorticotropic hormone (ACTH) and suppresses prostaglandin E production of insulin-like growth hormone secretion so that somatic growth is inhibited. Skeletal wasting also occurs and is most rapid during the first 6 months of therapy. This osteoporotic process is a result of stimulation of osteoclastic activity and inhibition of osteoblastic activity. An additional factor in bone loss is the effect of glucocorticoids on sex hormones, which results in decreased circulating levels of anabolic hormones. Bone mineral density (BMD) rapidly declines beginning within the first 3 months of glucocorticoid therapy and peaks at 6 months, with continued BMD loss with ongoing therapy (Grossman et al, 2010). Finally, they potentiate the effects of catecholamines, thyroid hormone, and growth hormone on adipose tissue. Figure 25-1 depicts the control of cortisol secretion.

Mineralocorticoids (predominantly aldosterone) are also secreted by the adrenal cortex under the control of the renin-angiotensin-aldosterone system. The main role of aldosterone

is to retain sodium and water and excrete potassium. Naturally occurring adrenocorticosteroids have both cortisol and aldosterone properties in varying amounts. This difference in percentage of hormone may be a factor in the choice of corticosteroid. Hydrocortisone and cortisone are naturally occurring glucocorticoids with predominant cortisol activity and are used as replacement therapy in adrenocortical deficiency states and may be used as anti-inflammatory drugs. Prednisone, prednisolone, and fludrocortisone are synthetic steroids with mixed cortisol and aldosterone activity but are used mainly for their cortisol effects. Triamcinolone, dexamethasone, methylprednisolone, and betamethasone are also synthetic compounds that have almost no aldosterone activity and are used for their potent anti-inflammatory activity.

Pharmacokinetics

Absorption and Distribution

Corticosteroids are all well absorbed from the upper jejunum (Table 25-4). Those with IM formulations are well absorbed from IM sites. Injections of suspensions and esters produce greatly altered onset and duration times. Absorption is rapid for esters (sodium phosphates and sodium succinate) and relatively slow for other derivatives (acetates, acetonides, and tebutates). Absorption from local sites (e.g., intra-articular or intrasynovial) is slower than from IM sites. Because onset, peak, and duration of action vary, these drugs are classified into short-, intermediate-, and long-acting forms.

Corticosteroids are reversibly bound to corticosteroid-binding proteins. They have significantly altered pharmacological effects on patients with altered protein-binding capacities. Pregnancy, for example, is a hyperproteinemic state in which the total plasma level of steroid would be elevated. All these drugs are widely distributed, cross the placenta, and enter breast milk.

Metabolism and Excretion

The liver metabolizes hydrocortisone (Cortef), and this is the rate-limiting step in its clearance. The metabolism and excretion of other corticosteroids generally parallel those of hydrocortisone. Induction of hepatic enzymes increases the

Table 25–4 Pharmacokinetics: Selected Corticosteroids

Drug	Onset (hours)	Peak (hours)	Duration (days)	Protein Binding	Half-Life	RAP	RMP	Elimination
Cortisone* PO	Rapid	2	1.25–1.5	Very high	30 min P 8–12 h B	0.8	2	1% unchanged in urine
Cortisone* IM	Slow	20–48	1.25–1.5	Very high	—	0.8	2	1% unchanged in urine

*Short-acting.
†Intermediate-acting.
‡Long-acting.

metabolic clearance of all corticosteroids. The liver converts cortisone (Cortone) to hydrocortisone, and prednisone (Deltasone) is converted to prednisolone (Delta-Cortef, Prelone). These metabolites are then clinically active and metabolized by the liver for clearance. Approximately 1% of the daily dose of the drug is excreted unchanged in urine. Renal clearance is increased when plasma levels are increased.

Table 25-4 depicts the pharmacokinetics of selected corticosteroids, including their relative anti-inflammatory and mineralocorticoid activity.

Pharmacotherapeutics

Precautions and Contraindications

The wide range of contraindications and warnings about cautious use associated with corticosteroids is a factor of their numerous actions. They are contraindicated in the presence of active, untreated infections because they may mask the indications of infection, and new infections may appear during their use. A patient may also have decreased resistance, and the host defense mechanisms may be unable to prevent dissemination of the infection. Corticosteroids may exacerbate systemic fungal infections; therefore, corticosteroids are contraindicated in patients with these infections. Cortico - steroids may activate latent amebiasis or tuberculosis. Although their use has been advocated for the treatment of chronic active hepatitis, they may be harmful in hepatitis positive for hepatitis B surface antigen.

For many disorders, these drugs should be used cautiously. Average and large doses of drugs with high relative mineralocorticoid potency (e.g., cortisone and hydrocortisone) can cause elevated blood pressure, salt and water retention, and increased excretion of potassium. These effects can be especially problematic for patients with hypertension and cardiovascular disorders (e.g., heart failure [HF]). Sodium restriction and potassium supplementation may be necessary. Edema can occur in the presence of renal disease with a fixed or decreased glomerular filtration rate (GFR). These drugs should be used with caution in renal insufficiency, acute glomerulonephritis, or chronic nephritis.

All corticosteroids increase calcium excretion, which creates problems for postmenopausal women and others at risk for osteoporosis (patients with a lower body mass index or parental history of hip fracture, smokers, or those who consume more than three alcoholic drinks per day) (Grossman et al, 2010).

Patients with diabetes mellitus may have difficulty maintaining glycemic control because corticosteroids alter the liver's glucose regulation. The relationship between peptic ulceration and corticosteroid therapy is unclear, with no difference seen in endoscopic peptic ulcers compared to placebo in patients treated with prednisone 60 mg daily for 3 months (Hsiang et al, 2010). Patients with ulcerative colitis or peptic ulcer disease or with concomitant use of gastric irritants (e.g., NSAIDs) and stress have an increased probability of GI bleeding and perforation.

Some of these products contain tartrazine or sodium bisulfite, both of which can cause severe allergic reactions. Patients with these allergies should notify their health-care provider, and the label of the drug should be reviewed carefully for these ingredients.

Corticosteroids cross the placenta (prednisone has the least transport), and most are Pregnancy Category C. In animal studies, large doses resulted in cleft palate, stillborn fetuses, and decreased fetal size. Chronic ingestion during the first trimester in humans has shown a 1% incidence of cleft palate. In considering use of these drugs during pregnancy or in women with childbearing potential, the benefits must be carefully weighed against the potential risks to the fetus. Infants of mothers who have taken these drugs should be observed for signs of hypoaldosteronism.

Corticosteroids appear in breast milk and could retard the nursing infant's growth, interfere with endogenous cortico - steroid production, or cause other unwanted effects. Several studies suggest that the amount excreted in breast milk is negligible with prednisone or prednisolone doses of 20 mg or less per day and methylprednisolone (Medrol) doses of 8 mg or less per day. For mothers who want to nurse, waiting 3 to 4 hours after taking the drug and using one of these drugs within these doses may be tried (LactMed, 2013).

When given corticosteroids, children may experience altered growth and development, and they require monitoring of height and weight if they must be on prolonged therapy. Some of these products contain benzyl alcohol, which has been associated with a fatal "gasping syndrome" in infants.

Older adults often have chronic disorders that are worsened by corticosteroids. Consider the risk/benefit factors of steroid use. Lower doses and careful monitoring of blood pressure, blood glucose, and electrolytes at least every 6 months are appropriate.

Adverse Drug Reactions

Adverse reactions can be discussed by the body system that is affected.

Muscle and Skin

Common skin changes reported with systemic cortico - steroids include atrophy and thinning of the skin, alopecia, acneiform eruptions, poor healing, purpura, striae, hirsutism, and desquamation. Myopathy is also seen, with marked muscle wasting. No relationship between dose or duration of therapy and these adverse reactions is apparent. Alteration in body fat is also noted, particularly in patients who take corticosteroids for more than 60 days, with the most common changes being truncal obesity, buffalo hump, and moon faces.

Skeletal Tissues

Osteoporosis develops in 11% to 20% of patients treated with glucocorticosteroids for more than 1 year, with decreased BMD found within the first 3 months of therapy (Grossman et al, 2010). Skeletal fractures, mainly of the spine, ribs, and pelvis, may occur secondary to the reduced bone density. Glucocorticoid therapy at doses of 7.5 mg/d or greater of

prednisone for 6 or more months results in a rapid loss of trabecular bone in the spine, hip, and forearm. BMD should be measured in all individuals who are likely to be on this therapy long-term (American College of Rheumatology, 2001 update; Grossman et al, 2010). The American College of Rheumatology guidelines recommend treating patients on long-term (3 months or greater) glucocorticoid therapy with the bisphosphonates alendronate (Fosamax) or risedronate (Actonel) based on a risk-assessment algorithm (Grossman et al, 2010).

Ocular Tissues

Prolonged use of corticosteriods may produce subcapsular cataracts, glaucoma with possible damage to the optic nerve, and increased risk for secondary ocular infections due to fungi or viruses.

Gastrointestinal System

Corticosteroids have been implicated in the induction of peptic ulcer disease. Patients who appear to be at risk are those being treated for nephrotic syndrome or hepatic disease; are taking a total dose of prednisone exceeding 1 g; or have a history of ulcer disease, concomitant use of a known gastric irritant, or stress. Combining corticosteroids and NSAIDs or aspirin increases the risk of peptic ulcer disease. Prophylaxis with proton pump inhibitors (PPIs) or H_2 blockers is suggested for patients with two or more of these risk factors (Feldman & Das, 2010; Saag & Furst, 2010). Patients also taking NSAIDs may require misoprostol (Cytotec); misoprostol's use is described in Chapter 34.

Cardiovascular System

Hypertension is a common adverse reaction. This and other cardiovascular problems (e.g., fluid and electrolyte disturbances) are discussed in the Precautions and Contraindications section.

Central Nervous System

Delirium, agitation, insomnia, mood swings, and severe depression characterize steroid psychosis. The onset of symptoms is usually within 15 to 30 days. Predisposing factors include doses above 40 mg of prednisone or its equivalent dose in another drug, female gender, and a family history of psychiatric disorder. The incidence is correlated with dose. If the steroid cannot be stopped, psychotropic drugs are effective in relieving the symptoms.

Endocrine System

Prolonged therapy with corticosteroids may lead to adrenal suppression. The degree of suppression depends on dosage, relative glucocorticoid (anti-inflammatory) potency, biological half-life, and duration of therapy. As a general rule, suppression occurs with doses above the physiological range that are given for more than 1 month. It can be minimized by using intermediate-acting agents on an alternate-day dosing schedule. Abrupt withdrawal after adrenal suppression has occurred may result in a withdrawal syndrome, with symptoms similar to those seen in adrenal insufficiency. To minimize this adverse reaction, the dose

of corticosteroids used for prolonged therapy should be tapered. Recovery from HPA suppression can take up to 12 months.

The effect on glucose metabolism and regulation is discussed in the Precautions and Contraindications section. Amenorrhea, postmenopausal bleeding, and other menstrual irregularities have also been seen.

Drug Interactions

Additive hypokalemia may occur with drugs that also produce this adverse reaction. This hypokalemia increases the risk for toxicity in digoxin. Several drugs stimulate the metabolism of corticosteroids, and oral contraceptives decrease their metabolism. NSAIDs and alcohol increase the risk for GI adverse reactions. Other drug interactions are in Table 25-5.

Clinical Use and Dosing

Adrenocortical Insufficiency

In primary adrenocortical insufficiency, glucocorticoid and mineralocorticoid properties are lost; however, in secondary adrenocortical insufficiency, mineralocorticoid function is preserved. In the United States, primary adrenocortical insufficiency is an uncommon disorder. Widespread corticosteroid use has made secondary adrenocortical insufficiency due to steroid withdrawal much more common. Approximately 6 million persons are considered to have undiagnosed adrenocortical insufficiency only during times of physiological stress. The key to treatment of primary or secondary disease is replacement of the missing hormones. The drugs of choice are hydrocortisone, cortisone, and prednisone because each has both glucocorticoid and mineralocorticoid effects and requires no additional mineralocorticoid.

Initial doses for hydrocortisone are 50 mg every 8 hours for 48 hours for adults; then the dose is tapered to 30 to 50 mg/d in divided doses. In children, the dose is 2.5 to 10 mg/kg/d for children under age 12, in three to four divided doses, and then the dose is tapered to the maintenance dose over 14 days. Children over 12 years are dosed as adults. For cortisone, the initial adult dose is 25 to 300 mg/d in two divided doses, and the pediatric dose is 0.25 to 0.35 mg/kg/d IM in two divided doses. Once again, the drug is tapered over 14 days to the maintenance dose. Prednisone is started at 5 to 60 mg/d in two divided doses for adults and 1 to 2 mg/kg/d in a once- or twice-daily dose for children. This drug is tapered in the same way (Klauer, 2009).

For maintenance replacement of cortisol, under normal circumstances patients are given 15 to 20 mg of cortisol or its equivalent daily. Dosage schedules vary, but the simplest and least expensive in adults is cortisone 25 mg daily. Hydrocortisone 20 mg or prednisone 5 to 20 mg may also be used on the same schedule. To approach diurnal rhythms, the dose is given in the morning before 9 a.m. Equivalent doses of another corticosteroid may be used but have no specific advantage. In addition, other corticosteroids have less relative

Table 25–5 ▦ **Drug Interactions: Selected Corticosteroids**

Drug	Interacting Drug	Possible Effect	Implications
Betamethasone, cortisone	Insulin, oral hypoglycemics	Decreased effectiveness, resulting in altered glycemic control	Monitor blood glucose levels more closely if drugs must be given concurrently
Hydrocortisone	Cholestyramine	Hydrocortisone area under the curve (AUC) decreased	Separate dose by 4 h and give hydro-cortisone first
	Insulin, oral hypoglycemics	Decreased effectiveness, resulting in altered glycemic control	Monitor blood glucose levels more closely if drugs must be given concurrently
Dexamethasone	Ephedrine	Decreased half-life and increased clearance of dexamethasone	Avoid concurrent administration
	Insulin, oral hypoglycemics	Decreased effectiveness, resulting in altered glycemic control	Monitor blood glucose levels more closely if drugs must be given concurrently
Prednisone	NSAIDs, other GI irritants	Increased risk for GI bleed	Avoid concurrent use
	Insulin, oral hypoglycemics	Decreased effectiveness, resulting in altered glycemic control	Monitor blood glucose levels more closely if drugs must be given concurrently
Methylprednisolone	Macrolide antimicrobials (e.g., erythromycin, clarithromycin)	Significant decrease in methylpred-nisolone clearance	Has been used therapeutically to decrease methylprednisolone dose
	Insulin, oral hypoglycemics	Decreased effectiveness, resulting in altered glycemic control	Monitor blood glucose levels more closely if drugs must be given concurrently
All corticosteroids	Barbiturates	Decrease the pharmacological effects of the corticosteroid	Avoid concurrent use
	Oral contraceptives		May require dosage adjustment
	Estrogens	Corticosteroid half-life and concentra-tion increased; clearance decreased	May require dosage adjustment
	Hydantoins, rifampin		May require dosage adjustment
	Ketoconazole	Corticosteroid clearance decreased	Select different imidazole
	Digoxin	Corticosteroid clearance increased; reduced therapeutic effects	Avoid coadministration
	Isoniazid	Corticosteroid clearance decreased; AUC increased	If must be used together, dosage adjustments may be needed; monitor therapy closely
	Potassium-depleting agents (e.g., thiazide and loop diuretics, mezlocillin, piperacillin, ticarcillin)	May increase risk of digitalis toxicity Isoniazid serum concentrations decreased	Avoid concurrent use; monitor serum potassium levels
	Salicylates	Additive hypokalemia	Avoid concurrent use
	Somatrem	Reduced serum salicylate levels; decreased therapeutic effectiveness Inhibits growth-promoting effect of somatrem	Consult with endocrinologist for best action

mineralocorticoid potency, and an additional drug to provide mineralocorticoid activity might be required if they are used.

The response to any of these drugs is highly variable. Doses are highly individualized, and much higher doses given in divided doses may be needed. Specific doses and ranges for each of the corticosteroids for this indication, for both adults and children, are provided in Table 25-6.

Inflammation

Any of the corticosteroids may be used to reduce or prevent inflammation. Because the need for mineralocorticoid activity is low to absent in this indication, drugs with more anti-inflammatory activity—methylprednisolone, prednisone, and triamcinolone (Aristocort)—are appropriate. Betamethasone also has only anti-inflammatory activity, but it is 4 to 5 times more potent than the other drugs, which increases the risk for adverse reactions. Dexamethasone is used most often in

acute care to relieve the inflammation that causes intracranial pressure after closed head injury or cranial surgery. Doses are shown in Table 25-6.

Immunosuppression

Although all corticosteroids have immunosuppressive capa-bility, the most commonly used is prednisone. It has a short half-life, low cost, negligible mineralocorticoid activity, and is available in 5 and 20 mg tablets that make dosage changes simple for the patient to manage. Post-transplant immuno-suppression is often a combination of immunosuppressants and high-dose corticosteroids. Patients are often on high-dose corticosteroids for 6 to 12 months then tapered off slowly. Prednisolone, the active hepatic metabolite of pred-nisone, is useful in the presence of hepatic dysfunction. Other drugs in this class may also be used for this indication, and their dosing schedule is presented in Table 25-6.

Table 25–6 ⊗ **Dosage Schedule: Selected Corticosteroids**

Drug	Indication	Dosage Form	Dose	Notes
Betamethasone (Celestone)	Inflammation, immunosuppression	Oral solution: 0.6 mg/5 mL Suspension for injection: betamethasone sodium phosphate 3 mg/mL and beta-methasone acetate 3 mg/mL = 6 mg/mL Tablet: 25 mg	*Adults:* 0.6–7.2 mg/d PO as single or divided doses *Children:* 62.5–250 mcg/kg/d PO in 3 divided doses	Long-acting. Suppresses HPA at doses >0.6 mg/d.
Cortisone (generic only)	Adrenocortical insufficiency Inflammation, immunosuppression	Tablet: 25 mg	*Adults:* Initial dose 25–300 mg Maintenance dose is 10–37 mg/d in single or divided dose *Children:* Initial dose 25–300 mg orally or 0.25–0.35 mg/kg/d IM in 2 divided doses Maintenance dose is 0.56 mg/kg/d *Adults:* 25–300 mg/d PO in single or divided doses *Children:* 2.5–10 mg/kg/d PO as single or divided doses	Has mineralocorticoid activity but may need additional drug; short-acting; suppresses HPA at doses >20 mg/d. Taper initial dose to maintenance dose over 14 d. Has mineralocorticoid activity but may need additional drug; short-acting; suppresses HPA at doses >20 mg/d.
Dexamethasone (Decadron)	Adrenocortical insufficiency Inflammation, im-munosuppression	Oral solution concen-trate: 1 mg/mL Syrup: 0.5 mg/5 mL Tablets: 0.5 mg 0.75 mg 1 mg 1.5 mg 2 mg 4 mg 6 mg	*Children:* 23.3 mcg/kg/d PO in 3 divided doses *Adults:* 0.5–9 mg/d PO in single or divided doses *Children:* 83.3–333.3 mcg/kg/d PO in 3–4 divided doses	Not commonly used for this indication in adults; required addition of mineralocorticoid. Long-acting. Suppresses HPA at doses >0.75 mg/d.
Hydrocortisone (Cortef, Solu-Cortef)	Adrenocortical insufficiency Inflammation, immunosuppression Inflammatory bowel disease	Tablet: 5, 10, 20 mg Injection: 100, 250, 500, 1,000 mg	*Adults:* Initial dose 50 mg q8h for 48 h Maintenance dose 20–240 mg/d in single or divided doses *Adults:* 20–240 mg/d PO in 1–4 divided doses *Children:* 2–8 mg/kg/d in single or divided doses *Adults:* 100 mg nightly in retention enema for 21 d or until remission	Has mineralocorticoid activity; short-acting; suppresses HPA at doses >20 mg/d. Taper initial dose to maintenance dose over 14 d. Has mineralocorticoid activity; short-acting; suppresses HPA at doses >20 mg/d. Has mineralocorticoid activity; short-acting; suppresses HPA at doses >20 mg/d.
Methylprednisolone (Medrol) (Depo-Medrol)	Inflammation, immunosuppression Multiple sclerosis	Tablets: 2 mg 4 mg 8 mg 16 mg 32 mg Solution for injection: 20, 40, 80 mg/mL	*Adults:* 4–48 mg/d PO in single or divided doses initially; up to 240 mg/d for maintenance *Children:* 0.117–1.67 mg/kg/d PO in 3–4 divided doses *Adults:* 160 mg/d for 7 d; then 64 every other day for 1 mo	Intermediate-acting; suppresses HPA at doses of 4 mg/d Intermediate-acting; suppresses HPA at doses of 4 mg/d
Prednisolone (Prelone, Orapred, Millipred)	Adrenocortical insufficiency Inflammation, immunosuppression	Tablets: 5 mg Syrup: 5 mg/5 mL, 15 mg/5 mL	*Adults:* Initial dose and main-tenance dose 5–60 mg *Children:* 1–2 mg/kg/d initial and maintenance doses	Intermediate-acting; suppresses HPA at doses >5 mg/d. Taper over 14 d.

Table 25–6 ⊗ **Dosage Schedule: Selected Corticosteroids—cont'd**

Drug	Indication	Dosage Form	Dose	Notes
	Multiple sclerosis		*Adults:* 5–60 mg/d PO in single or divided doses *Children:* 0.5–2 mg/kg/d PO in 3–4 divided doses *Adults:* 200 mg/d for 7 d; then 80 mg every other day for 1 mo	Intermediate-acting; suppresses HPA at doses >5 mg/d. Intermediate-acting; suppresses HPA at doses >5 mg/d.
Prednisone (Prednicolone)	Adrenocortical insufficiency Inflammation, immunosuppression Nephrotic syndrome	Tablets: 1, 2.5, 5 mg, 10 , 20, 50 mg Intensol syrup: 5 mg/mL Solution: 5 mg/5 mL	*Adults:* 5–60 mg/d PO in single or divided doses *Adults:* 5–60 mg/d PO in single or divided doses *Children:* 0.14–2 mg/kg/d PO in 4 divided doses *Children:* Initial dosing 2 mg/kg/day in 1–3 divided doses (maximum 80 mg/d) until urine is protein-free. Maintenance dose 2 mg/kg/dose administered every other day. Taper and discontinue after 4–6 weeks.	Minimal mineralocorticoid activity; intermediate-acting; suppresses HPA at doses >5 mg. Taper over 14 d. Minimal mineralocorticoid activity; intermediate-acting; suppresses HPA at doses >5 mg. Minimal mineralocorticoid activity; intermediate-acting; suppresses HPA at doses >5 mg.
Triamcinolone (Kenalog)	Adrenocortical insufficiency Rheumatic disorders Systemic lupus erythematosus Other inflammatory diseases or for immunosuppression	Suspension for injection: 10 mg/mL, 40 mg/mL	*Adults:* 4–12 mg/d PO in single or divided doses *Children:* 117 mcg/kg/d in single or divided doses *Adults:* 8–12 mg/d PO *Adults:* 20–32 mg/d PO *Adults:* 4–48 mg/d PO in single or divided doses *Children:* 0.416–1.7 mg/kg/d PO in single or divided doses	No mineralocorticoid activity; requires addition of mineralocorticoid drug. Intermediate-acting; suppresses HPA at doses >4 mg/d. No mineralocorticoid activity; requires addition of mineralocorticoid drug. Intermediate-acting; suppresses HPA at doses >4 mg/d. No mineralocorticoid activity; requires addition of mineralocorticoid drug. Intermediate-acting; suppresses HPA at doses >4 mg/d. No mineralocorticoid activity; requires addition of mineralocorticoid drug. Intermediate-acting; suppresses HPA at doses >4 mg/d. No mineralocorticoid activity; requires addition of mineralocorticoid drug. Intermediate-acting; suppresses HPA at doses >4 mg/d.

HPA = hypothalamus-pituitary-adrenal axis.
   For parenteral doses, see other sources.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a system inflammatory disorder, and treatment to reduce inflammation is appropriate. First-line therapy includes disease-modifying antirheumatic drugs (DMARDs) and biological agents, including anti-TNF (adalimumab, etanercept, infliximab, certolizumab pegol, golimumab) and non-TNF agents (abatacept, rituximab, tocilizumab) (Singh et al, 2012). Oral glucocorticoids are prescribed for moderate to severe RA to gain initial control of inflammation while awaiting response to DMARDs.

The initial dose is 5 to 2 mg per day of prednisone depending on the severity of symptoms (Schur & Cohen, 2014). Glucocorticoids should be tapered and discontinued as soon as possible.

The following principles are used when dosing corticosteroids (McCance & Huether, 2010).

1. The maximum activity of the adrenal cortex in producing cortisol is between 2 and 8 a.m. To best match this natural body rhythm, daily doses are best taken in the morning before 9 a.m.

2. The initial dose depends on the specific disease being treated. Maintain or adjust the dose until an acceptable response is achieved. Establish a time frame within which to expect this response. If such a response does not occur within that time frame, discontinue the corticosteroid and consult or refer the patient for other therapy.

3. After an acceptable response is achieved, determine the maintenance dose by decreasing the dosage in small amounts at intervals until the lowest dosage that maintains an adequate clinical response is reached. The lowest possible dose is always best, especially with long-term therapy, to avoid or reduce adverse reactions. In the presence of increased stress (e.g., trauma, surgery, or infection), a temporarily increased dosage may be needed.

4. If, after long-term therapy or because of spontaneous remission, the drug is to be stopped, withdraw it gradually to prevent an adrenal insufficiency crisis. Tapering is generally not necessary after short-term therapy (e.g., up to 3 weeks) because adrenal suppression has not occurred.

5. Most conditions that require chronic corticosteroid therapy can be well controlled on alternate-day therapy, although the therapy must usually be started with daily dosing. For alternate-day dosing, twice the daily dose is given every other morning before 9 a.m. It works best if the patient is taking an intermediate-acting drug but may be used with short-acting drugs as well. The purpose of this schedule is to provide the patient on long-term therapy the benefits of the drug while minimizing the HPA-axis suppression, withdrawal symptoms, and, for children, growth retardation. Long-acting agents may still produce HPA suppression, even with alternate-day dosing. The regimen is only for patients on long-term therapy who can be trusted to follow this schedule without needing the prompting of daily therapy. In the advent of a flare-up in the disease process, a return to daily dosing may be necessary, at least until the flare-up clears.

6. Unlike a tapering schedule, alternate-day scheduling retains the same total steroid dose. Switching is carried out by gradually increasing the dose on the first day and then decreasing it on the second day until a double dose is taken every other day with no drug on the in-between days. A rough guideline for switching is to make changes in increments of 10 mg of prednisone (or its equivalent) when the daily dose is more than 40 mg, and in 5 mg increments when the daily dosage is 20 to 40 mg. Below 20 mg, the change is made in increments of 2.5 mg. The interval between changes varies from 1 day to several weeks and is empirically based on the clinical response.

7. The schedule for tapering and withdrawing is different. The goal is to reduce the drug to physiological levels or to eliminate the drug altogether. For doses above 40 mg, the dose is reduced by 10 mg of prednisone (or its equivalent) every 1 to 3 weeks. Doses below 40 mg require reductions of 5 mg every 1 to 3 weeks. Once the physiological dose is reached (5 to 7.5 mg/d), the patient can be switched to 1 mg tablets so that dosage reductions can be continued. Weekly or biweekly reductions can then be done 1 mg at a time.

Rational Drug Selection

Length of Therapeutic Activity

Corticosteroids are classified according to their therapeutic effects into short-, intermediate-, and long-acting forms. Short-acting agents are less likely to produce HPA suppression, especially when taken only in the morning and in low doses on an alternate-day schedule. Long-acting agents are preferred if the effects of high doses must be sustained (e.g., increased intracranial pressure or organ transplant rejection).

Relative Potency

Mineralocorticoid activity is desirable in adrenocortical insufficiency but not if the primary goal of therapy is anti-inflammatory or immunosuppressive. Drugs with higher relative mineralocorticoid potency (RMP) are selected for adrenal insufficiency. Drugs high in relative anti-inflammatory potency (RAP) are selected when the goal is to reduce inflammation or suppress the immune system.

Monitoring

Monitoring is based on the common adverse reactions associated with the use of corticosteroids: weight gain, edema, hypertension, and indications of excessive potassium loss and negative nitrogen balance associated with protein catabolism. BMD testing is also appropriate for patients on long-term therapy in which osteoporosis is a significant risk. Carefully monitor the growth and development of children on prolonged therapy.

Laboratory monitoring begins with an initial assessment of serum electrolytes, glucose, and CBC. For patients on long-term therapy or high doses, annual monitoring of these parameters, as well as guaiac testing of stools and serum lipid analysis, is appropriate. For patients at risk for or with indications of GI adverse reactions, upper GI x-rays are desirable.

Systemic corticosteroids may produce subcapsular cataracts in as many as 30% of patients, and patients who have or are at risk for increased intraocular pressure (IOP) may experience increases in IOP while on these drugs. A slit-lamp examination is recommended every 6 to 12 months for patients on long-term corticosteroid therapy.

Patient Education

Administration

Instruct the patient to take the drug exactly as prescribed. Missed doses should be taken as soon as the patient remembers, unless it is almost time for the next dose. Doses should not be doubled. If the patient is being switched from daily

to alternate-day therapy or is on a tapering or withdrawal protocol, make the changes as simple as possible and provide written instructions.

Corticosteroids should not be discontinued or the dosage changed without first consulting the health-care provider. Adrenal insufficiency (anorexia, nausea, weakness, fatigue, dyspnea, hypotension, and hypoglycemia) may result when the drug is stopped suddenly. If these signs appear, then the health-care provider should be notified immediately. Adrenal insufficiency can be life-threatening.

Adverse Reactions

Corticosteroids cause immunosuppression and may mask symptoms of infection. Instruct the patient to avoid people with known contagious illnesses and to report possible infections immediately. Patients should avoid vaccinations unless they first consult their health-care provider.

Review the probable adverse reactions with the patient. Patients should immediately report severe abdominal pain or tarry stools to their health-care provider. They should also report unusual swelling, weight gain, tiredness, bone pain, nonhealing sores, visual disturbances, and behavioral or mood changes.

Discuss possible changes in body image, and explore coping mechanisms for them.

Advise patients to wear medical identification that describes their disease process and drug regimen in the event of a medical emergency that prevents patients from relating their medical history. They should also inform any health-care professional who provides care that they are taking corticosteroids.

Lifestyle Management

A diet high in protein, potassium, and calcium and low in sodium and carbohydrates can counteract some of the adverse reactions associated with corticosteroids. Multivitamins with minerals, calcium, and vitamin D are appropriate. Caloric management to prevent obesity should also be implemented. Alcohol should be avoided during therapy. Osteoporosis risk can be reduced not only with calcium intake but also with regular exercise. Because stress can be a source of HPA stimulation, stress management techniques are used.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)

Inflammation, pain, and fever are common manifestations of many diseases. NSAIDs offer the advantage of having activity in all three areas, which allows a less complex and less costly regimen. They also reduce the need for opioid analgesics, which are associated with chemical dependency and addiction. These advantages have resulted in NSAIDs becoming the most widely used prescription and over-the-counter (OTC) drugs in use today.

Aspirin and other salicylates that are members of this class are discussed in the next section. Acetaminophen (Tylenol), although not an anti-inflammatory drug by chemistry, is often used to treat pain and fever and so is included in this section.

Pharmacodynamics

The inflammatory response is the same, regardless of the injury. Destruction of cell membranes results in release of chemical mediators, including histamine, prostaglandins, leukotrienes, cytokines, oxygen radicals, and enzymes. The cascade of events is depicted in Figure 25-2. Two major enzymes, lipo-oxygenase and cyclo-oxygenase, are required to produce these mediators. Although the exact mode of action of NSAIDs is not known, the major mechanism is thought to be inhibition of cyclo-oxygenase activity and prostaglandin synthesis. Inhibition of lipo-oxygenase, leukotriene synthesis, lysosomal enzyme release, neutrophil aggregation, and various cell membrane functions may also occur. These agents may also suppress rheumatoid factor.

Two cyclo-oxygenase isoenzymes have been identified: COX-1 and COX-2. COX-1 is expressed systemically and synthesized continuously so that it is present all the time in all tissues and cells, especially platelets; endothelial cells; the GI tract; and renal microvasculature, glomeruli, and collecting ducts. It has roles in homeostatic maintenance, such as platelet aggregation, the regulation of blood flow to the kidney and stomach, and the regulation of gastric acid secretion and production of protective mucus, especially in the stomach. Inhibition of these activities by NSAIDs accounts for their adverse reactions, especially on the renal and GI tracts.

COX-2 is an "inducible" enzyme that is synthesized mainly in response to pain and inflammation. However, there is some synthesis in the kidney, brain, bone, female reproductive system, and GI tract. Nonspecific NSAIDs inhibit both COX-1 and COX-2. Most NSAIDs (e.g., aspirin, ketoprofen [Actron, Orudis], flurbiprofen (Ansaid), indomethacin [Indocin], piroxicam [Feldene], sulindac [Clinoril]) are mainly selective for COX-1. Some (e.g., ibuprofen [Advil, Motrin], naproxen [Aleve, Naprosyn], diclofenac [Cambia, Cataflam, Voltaren]) are slightly selective for COX-1, and others (e.g., etodolac [Lodine], nabumetone [Relafen], meloxicam [Mobic]) are slightly selective for COX-2.

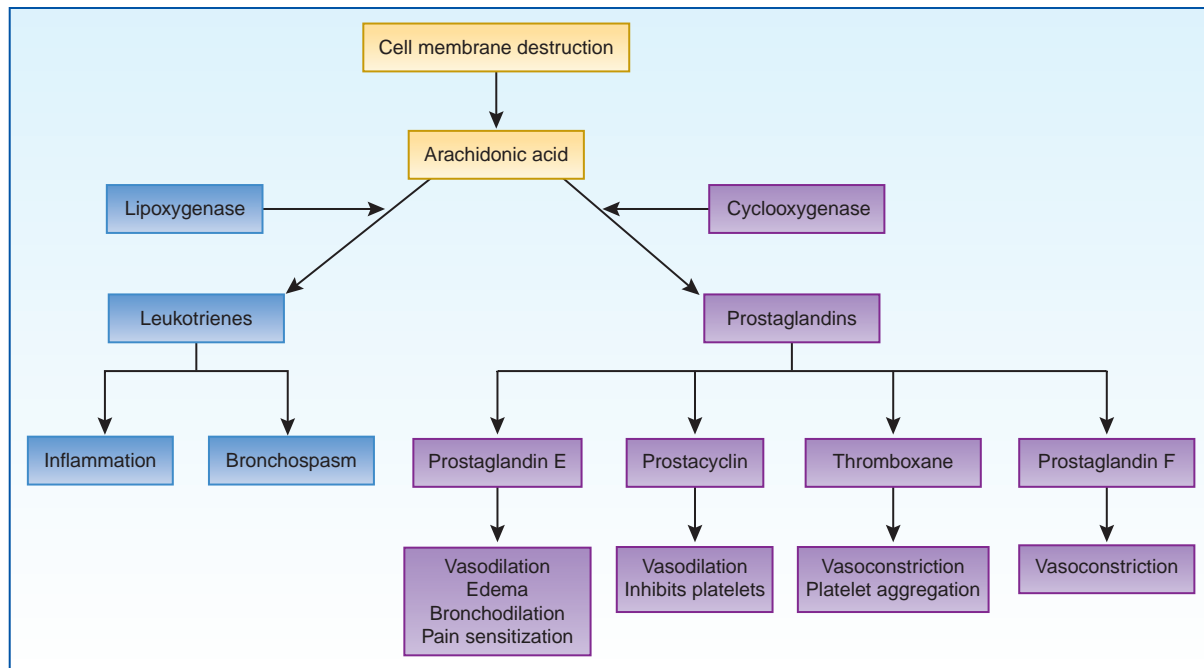
Three COX-2 selective drugs (e.g., celecoxib [Celebrex], rofecoxib [Vioxx], valdecoxib [Bextra]) have been developed that appear not to inhibit COX-1. These drugs were used for patients who had higher risks for GI bleeding. However, in 2004, research indicated that the overall risk for GI bleeding was not sufficient to compensate for the increased risk for cardiovascular events that occurred with these drugs. In September 2004, rofecoxib was voluntarily removed from the market. In April 2005, the U.S. Food and Drug Administration (FDA) requested that valdecoxib be removed from the market. At that time, a Black-Box Warning was placed on all NSAIDs and on celecoxib related to this risk. All OTC NSAIDs also had their labeling revised to


Figure 25–2. Sequence of events in inflammatory response. The sequence of events is the same, regardless of the source of injury.

include more specific information about potential GI and cardiovascular risks. In 2005, the FDA requested that sponsors of all NSAIDs and celecoxib, both prescription and OTC, add to the labeling a boxed warning about cardiovascular risk events and the well-described, serious, potentially life-threatening GI bleeding associated with their use. In addition, a Medication Guide must now be provided with each prescription.

The NSAIDs are primarily used for their anti-inflammatory activity, but they are effective analgesics useful for the relief of mild to moderate pain. They also have antipyretic properties. Because the mechanism of antiplatelet activity is reversible binding to thromboxane, antiplatelet activity exists only while the NSAID is in the blood. For this reason, NSAIDs are not used for antiplatelet therapy.

Acetaminophen is an analgesic and antipyretic with limited anti-inflammatory activity. Although its mechanism of action is not known, it is thought to act by inhibiting central and peripheral prostaglandin synthesis. The central inhibition is almost as potent as that of aspirin, but its peripheral action is minimal. It reduces fever by direct actions on the hypothalamic heat-regulating centers, which increase dissipation of body heat via vasodilation and sweating. It has the advantages of minimal GI irritation and of not affecting bleeding times, uric acid levels, or respiration.

Pharmacokinetics
Absorption and Distribution
After oral administration, NSAIDs are rapidly and almost completely absorbed (Table 25-7). Naproxen sodium

(Naprosyn) is more rapidly absorbed than naproxen and is used when rapid analgesia is desired. Diclofenac potassium (Cataflam) is formulated to release the drug in the stomach, whereas the sodium formulation (Voltaren) is released in the higher pH environment of the duodenum. In general, food delays absorption of all NSAIDs but does not affect the total amount absorbed. Administration with food reduces GI adverse reactions. Ketorolac (Toradol) is the only drug in the class with an IM route of absorption.

All NSAIDs are more than 90% protein bound. They are widely distributed in tissues, cross the placenta, and enter breast milk in low concentrations.

Acetaminophen is also rapidly and almost completely absorbed after oral administration. Rectal absorption is variable. Serum protein binding is low at therapeutic concentrations but varies from 20% to 50% with toxic concentrations. It is relatively uniformly distributed in body tissues, crosses the placenta, and enters breast milk.

Metabolism and Excretion
The NSAIDs are all metabolized by the liver and excreted by the kidneys, primarily as metabolites. Sulindac and nabumetone are inactive prodrugs converted by the liver to active metabolites.

Acetaminophen is extensively metabolized by the liver and excreted by the kidneys, primarily as inactive metabolites. When it is taken regularly or in large doses, the stores of one hepatic conjugate (glutathione) become depleted, and hepatic necrosis may occur. Half-life is prolonged in neonates, and severe hepatic dysfunction is related to its dependence on a liver function for metabolism.

Table 25–7 ✚ Pharmacokinetics: Selected NSAIDs and Acetaminophen

Drug	Onset Anal/AntiR	Peak Anal/AntiR	Duration Anal/AntiR	Protein Binding	Bioavailability	Half-Life	Elimination
Propionic Acid Group							
Ibuprofen	0.5 h/7 d	1–2 h/1–2 wk	4–6 h/UK	90%–99%	>80%	1.8–2.5 h	45%–79% in urine

Table 25–7 ❖ **Pharmacokinetics: Selected NSAIDs and Acetaminophen—cont'd**

Drug	Onset Anal/ AntiR	Peak Anal/ AntiR	Duration Anal/ AntiR	Protein Binding	Bioavailability	Half-Life	Elimination
COX-2 Inhibitor							
Celecoxib	UK	3 h	12–24 h	97.5%	UK	11 h	27% in urine; 57% in feces
Acetaminophen	PO: 0.5–1 h	1–3 h	3–8 h	20%–50%		1–4 h	90–100% in urine (metabolites)
	Rect: 0.5– 1 h	1–3 h	3–4 h				

Anal. = analgesic action; AntiR = antirheumatic action; NA = no action; not used for this indication; UK = unknown.

*Prolonged in older adults and impaired renal function.

Table 25-7 provides pharmacokinetic information on NSAIDs, including the one remaining COX-2 inhibitor, celecoxib, and acetaminophen.

Pharmacotherapeutics

Precautions and Contraindications

The only relative contraindications are for ketorolac, mefenamic acid (Ponstel), flurbiprofen, and nabumetone in the presence of preexisting renal impairment. Because NSAID metabolites are excreted primarily by the kidneys, all others should be used with caution in the presence of renal function impairment. Renal function should be assessed prior to initiation of therapy and during therapy.

The liver extensively metabolizes NSAIDs. Naproxen may exhibit an increase in unbound fraction and reduced clearance of free drug in cirrhotic patients. A reduced dose may be necessary. The area under the curve (AUC) of sulindac may be increased in patients with cirrhosis because of alterations in sulfide formation and metabolism. In patients treated with a single 15 mg dose of meloxicam, there was no marked difference in plasma concentrations in patients with mild to moderate hepatic impairment compared with healthy subjects. Protein binding was also not affected in these patients. Because the effects of hepatic disease on other NSAIDs are not known, they should be used cautiously in patients with hepatic impairment.

The liver also extensively metabolizes acetaminophen. High doses or long-term use and chronic alcoholism have been associated with hepatotoxicity. Avoid high doses or long-term use. For patients with chronic alcoholism, no safe dose has been determined. It should not be used for these patients.

GI adverse reactions are the most common reasons for cautious use. Serious GI bleeding, ulceration, and perforation can occur at any time without warning symptoms. Studies have not identified any subset of patients not at risk for these problems. A history of serious GI events, alcoholism, and smoking are the only specific factors associated with increased risk. Based on these data, active or chronic inflammation or ulceration of the GI tract relatively contraindicates use of all NSAIDs, especially indomethacin and sulindac. Other NSAIDs are sometimes used concurrently with a cytoprotective agent such as sucralfate (Carafate) or misoprostol (Cytotec). Diclofenac is produced in a combination with misoprostol under the brand name Arthrotec. Cytoprotective agents are discussed in Chapter 20. Wherever possible, however, these patients should be treated with nonulcerogenic drugs.

Indomethacin may aggravate depression or other psychiatric disturbances. A different NSAID should be chosen in this situation.

Age appears to increase the risk for adverse reactions to NSAIDs. The risk for serious ulcer disease is greater in adults over age 65. This risk appears to be dose-dependent, and reduced dosages may be necessary. Ketorolac is cleared more slowly in older adults. Nabumetone shows no difference in overall efficacy and safety between older adults and younger patients.

The NSAIDs are Pregnancy Category C (etodolac [Lodine], flurbiprofen, ibuprofen, indomethacin, ketoprofen ketorolac, mefenamic acid, nabumetone, naproxen, oxaprozin [Daypro]), piroxicam [Feldene], sulindac). Diclofenac is Pregnancy Category C before 30 weeks' gestation and Pregnancy Category D after 30 weeks' gestation. There are no adequate and well-controlled studies in pregnant women, so use during pregnancy must be carefully weighed in terms of risks and benefits. Agents that inhibit prostaglandin synthesis may cause closure of the ductus arteriosus and other untoward effects in the fetus. Use in the first trimester is less troublesome; NSAIDs should be avoided during the last trimester.

Acetaminophen is Pregnancy Category B. Although it crosses the placenta, it has been routinely used during all stages of pregnancy. At therapeutic doses, it appears safe for short-term use.

Most NSAIDs are excreted in breast milk. At doses of 400 mg bid and 400 mg every 6 hours, ibuprofen is not detected in breast milk; naproxen was detected at 1.9% of maternal concentration, and 0.18% of the maternal dose of ketorolac was detected (LactMed, 2014). Of the NSAIDS, ibuprofen is the safest during breastfeeding. Naproxen should be avoided due to its long duration of action and potential for harm to the neonate.

Acetaminophen is excreted in breast milk in low concentrations, with reported milk:plasma ratios of 0.91 to 1.42 at 1 and 12 hours, respectively. No adverse effects on nursing infants have been reported.

Mefenamic acid and meclofenamate are not recommended for children under age 14 years. Children under age 14 should not take indomethacin except in circumstances that clearly warrant the risk. Closely monitor the liver function of children between ages 2 and 14 who take it. Cases of hepatotoxicity, including fatalities, have been reported in children with juvenile rheumatoid arthritis. Indomethacin is not approved for children younger than 14, although it is used in neonates to close a patent ductus arteriosis. Flurbiprofen, diclofenac, and ketoprofen are not approved for use in children. Other NSAIDs may be used to treat children, and pediatric doses are published for these drugs. Acetaminophen is safe for infants and children.

Adverse Drug Reactions

The most common adverse reactions with NSAIDs are GI disturbances, in particular nausea, vomiting, constipation, and diarrhea. Taking the drug with food can reduce these reactions. GI bleeding and ulceration were discussed in the Precautions and Contraindications section and in the Pharmacodynamics section.

Acute renal insufficiency has occurred in patients with pre-existing renal disease or compromised renal perfusion. Patients at greatest risk are older adults, premature infants, those taking diuretics, and those with heart failure, systemic lupus erythematosus, or chronic glomerulonephritis. Stopping the drug usually brings recovery. Interstitial nephritis has occurred with increasing frequency in patients who take NSAIDs, and it may be due to altered prostaglandin metabolism.

Hematological effects are less common but can be related to the actions of the drugs. NSAIDs inhibit platelet aggregation and may increase bleeding time. Decreased hemoglobin and hematocrit levels have occurred rarely. Patients with initial values below 10 g/dL who are to receive long-term therapy should have these values regularly monitored.

Fluid retention and peripheral edema are not severe but can be problematic for patients with compromised cardiovascular function. Patients with severe heart failure may have significant deterioration in hemodynamic function, presumably related to the inhibition of prostaglandin-dependent compensatory mechanisms.

Cholestatic hepatitis, jaundice, and abnormal liver function tests have occurred rarely. Pancreatitis has developed in patients who take sulindac.

Adverse reactions associated with acetaminophen are few; however, those that do exist are significant. Acute hepatic necrosis occurs with doses of 10 to 15 g. Doses above 25 g are usually fatal. Children appear less susceptible to toxicity than adults because they have less capacity for glucuronidation, the metabolic pathway for acetaminophen. Acute poisoning is manifested by nausea, vomiting, drowsiness, confusion, liver tenderness, and renal failure, which occur within the first 24 hours and may persist for more than 1 week. Acute renal failure may also occur.

Acetaminophen Poisoning

Acetaminophen is a common cause of poisoning, either intentional or accidental, due to the lay public's underestimating the toxicity of the drug. A single dose of 150 mg/kg of acetaminophen in children or 7.5 g to 10 g in adults may be toxic. Drugs that induce CYP2E1 enzymes (carbamazepine, phenobarbitol, phenytoin, isoniazid, and rifampin) or alcohol ingestion may cause hepatotoxicity when combined with acetaminophen. The course of acetaminophen poisoning is divided into four stages:

1. 0.5 to 24 hours: Nausea, vomiting, diaphoresis, pallor, and anorexia. Some patients may be asymptomatic initially.
2. 24 to 72 hours: Clinically improved; aspartate transaminase (AST), alanine transaminase (ALT), bilirubin, and prothrombin levels begin to rise.
3. 72 to 96 hours: Peak hepatotoxicity; jaundice, confusion, AST of 10,000 not unusual.
4. 4 to 14 days: Death or recovery. Patients who survive enter a recovery phase.

Acute acetaminophen poisoning should be referred to a poison control center hospital. If this is not possible, the following treatment regimen may be followed. If the acute ingestion is more than 150 mg/kg or the dose cannot be determined, obtain a serum acetaminophen assay 4 hours after ingestion. If the level is more than 300 mg/mL, hepatic damage has occurred in 90% of patients. Minimum hepatic damage results from a level below 120 mg/mL. Treatment is by gastric lavage in all cases, preferably within 4 hours of ingestion. Oral *N*-acetylcysteine is a specific antidote for acetaminophen toxicity. Contact a poison control center for correct dosing of the antidote.

The FDA asked manufactures to reduce the amount of acetaminophen in combination products to 325 mg in each tablet or capsule. In 2014, the FDA issued a statement to prescribers recommending discontinuing prescribing and dispensing of combination acetaminophen prescription products (FDA, 2014).

Anemia, neutropenia, pancytopenia, and thrombocytopenia also occur but are not severe. The skin eruptions and urticarial skin reactions that may develop are also transient and not severe.

Drug Interactions

Both NSAIDs and acetaminophen have many drug interactions. NSAIDs decrease the effectiveness of antihypertensive drugs because of their tendency to cause fluid retention and increased extracellular fluid volume. Coadministration with anticoagulants may prolong prothrombin time because both drugs affect platelet aggregation. Drugs that have adverse reactions associated with increased risk for GI bleeding or ulceration have an even higher risk if taken with NSAIDs. Drugs that require glucuronidation for metabolism may affect the metabolism of acetaminophen by competing for metabolic sites. These and other interactions are listed in Table 25-8.

Table 25–8 ▦ **Drug Interactions: Selected NSAIDs and Acetaminophen**

Drug	Interacting Drug	Possible Effect	Implications
Acetaminophen	Alcohol	Increased risk for hepatotoxicity	Avoid alcohol intake
	Anticholinergics	Delayed onset of action of acetaminophen; ultimate pharmacological effects not altered	No action required
	Beta-adrenergic blockers	Propranolol inhibits the enzyme systems responsible for glucuronidation and oxidation of acetaminophen, resulting in increased pharmacological effects	Select different beta adrenergic blocker
	Contraceptives, oral Probenecid Loop diuretics Zidovudine	Increased glucuronidation, resulting in increased plasma clearance and decreased half-life of acetaminophen Increases the therapeutic effectiveness of acetaminophen Decreased effectiveness of diuretic because acetaminophen may decrease renal prostaglandin excretion and decrease plasma renin activity Decreased pharmacological effects of zidovudine related to enhanced nonhepatic or renal clearance of zidovudine	Select NSAID for treatment if long-term therapy; not a problem with single dose Used therapeutically Avoid concurrent use Avoid concurrent use; select NSAID for long-term use
All NSAIDs	Anticoagulants Beta adrenergic blockers Hydantoins Lithium Loop diuretics Probenecid Salicylates	May prolong prothrombin time (PT) Antihypertensive effect impaired; sulindac and naproxen do not affect atenolol Serum levels of phenytoin increased, resulting in increased pharmacological and toxic effects of phenytoin Serum lithium levels increased; sulindac has no effect or decreases levels Decreased effects of loop diuretics Probenecid may increase concentrations and toxicity risk of NSAIDs Decreased plasma concentrations of NSAIDs	Avoid coadministration; monitor PT and patients closely; instruct patients to watch for indications of bleeding Select appropriate drug match If they must be used together, monitor serum levels and adjust dose accordingly Avoid concurrent use or select sulindac; monitor serum levels Avoid concurrent use for long-term therapy or select different diuretic Avoid concurrent use Avoid concurrent use; offers no therapeutic advantage and significantly increases incidence of GI adverse reactions
Indomethacin	Digoxin Phenylpropanolamine Dipyridamole	May decrease digoxin serum levels; ibuprofen has similar effect Increased blood pressure Additive fluid retention	Select different NSAID Avoid coadministration Select different NSAID
Indomethacin, naproxen	Thiazide diuretics	Decreased antihypertensive and diuretic action; sulindac may enhance effects	Avoid concurrent use; select sulindac if enhanced effect is desired

Clinical Use and Dosing

Rheumatoid Arthritis

The ultimate goals in managing RA are to prevent and control joint damage, prevent loss of function, and decrease pain. NSAIDs, glucocorticoid joint injection, and/or low-dose prednisone may be used for control of symptoms (Grossman et al, 2010). The initial drug treatment involves the use of salicylates, NSAIDs, or celecoxib to reduce joint pain and swelling and to improve joint function. They have analgesic and anti-inflammatory properties but do not alter the course of the disease or prevent joint destruction, so

they should not be used as the sole treatment for RA. Most patients are started on DMARDS, and NSAIDS are used as adjunct treatment.

Although most NSAIDs have been used for this indication, no one NSAID has demonstrated a clear advantage for the treatment of RA. Ketorolac and mefenamic acid do not have a labeled indication for treatment of RA. Choice is determined by adverse reactions, cost, duration of action, and patient preference. For women of childbearing age, Pregnancy Category may affect choice. Nabumetone, piroxicam, and oxaprozin have longer durations of action than the other drugs commonly used.

Ibuprofen is the least expensive and is available OTC. Diclofenac comes in a combination with a cytoprotective agent (misoprostol) to reduce the risk for GI bleeding and ulceration, but this combination is quite expensive. Doses of the drugs with this indication are presented in Table 25-9.

Osteoarthritis

OA is the most common form of arthritis in the United States. Patients have joint pain that typically worsens with weight-bearing and activity and improves with rest as well

Table 25–9 ⊗ Dosage Schedule: Selected NSAIDs and Acetaminophen

Drug	Indication	Dosage Forms	Dosage Schedule	Comments
Acetaminophen (Tylenol)	Mild to moderate pain and/or fever Osteoarthritis	Tablets: 325 mg, 500 mg, 500 mg extra-strength Chewable tablets: 80 mg, 160 mg Caplets: 325 mg 650 mg extended-relief Gelcaps: 500 mg extra-strength Elixir: 160 mg/5 mL Liquid: 500 mg/15 mL Infant drops: 100 mg/mL Tablets: 325 mg, 500 mg, 650 mg Chewable tablets: 80, 160 mg Orally disintegrating tablets: 80, 160 mg Liquid: 160 mg/5 mL Suppository: 120, 300, 325, 650 mg	ORAL DOSES *Adults and children >14 yr:* 325–650 mg every 4–6 h *or* 1 g tid *Children* 10 to 15 mg/kg/dose every 4 h SUPPOSITORIES *Adults and children >12 yr:* 650 mg every 4–6 h *Children 3–11 mo:* 80 mg up to every 6 h *Children 1–3 yr:* 80 mg up to every 4 h *Children 3–6 yr:* 120–125 mg every 4–6 h *Children 6–12 yr:* 325 mg every 4–6 h *Adults:* Up to 1 g qid	Not to exceed 3 g/d For all ages of children, doses not to exceed 5 doses in 24 h Max dose 650 mg/dose Not to exceed 4 g/d Not to exceed 720 mg/d Not to exceed 2.6 g/d Not to exceed 4 g/d
Celecoxib (Celebrex)	Osteoarthritis, juvenile idiopathic arthritis, rheumatoid arthritis	Capsules: 100, 200, 400 mg	*Children (JIA):* ≥10 kg to <25 kg = 50 mg bid; ≥25 kg: 100 mg bid *Adults:* Acute pain: 400 mg initially followed by 200 mg bid OA: 200 mg/d RA: 100 to 200 mg bid	
Etodolac (Lodine)	Osteoarthritis, rheumatoid arthritis Analgesia	Capsules: 200 and 300 mg Tablets: 400 and 500 mg	*Adults:* 800–1,200 mg/d in divided doses, followed by dosage adjustments within the range of 600–1,200 mg/d in divided doses *Adults:* 200–400 mg every 6–8 h as needed	Not to exceed 1,200 mg/d; for patients ≤60 kg, do not exceed 20 mg/kg Not to exceed 1,200 mg/d; for patients ≤60 kg, do not exceed 20 mg/kg
Diclofenac (Voltaren) (Cataflam)	Rheumatoid arthritis Osteoarthritis Ankylosing spondylitis Analgesia, primary dysmenorrhea	Tablets: 25, 50, 75 mg Extended-release: 100 mg	*Adults:* 100–200 mg/d in divided doses (50 mg tid–qid or 75 mg bid) Chronic therapy with extended-release tablets: 100 mg/d *Adults:* 100–200 mg/d in divided doses (50 mg bid–tid or 75 mg bid) Chronic therapy with extended-release tablets: 100 mg/d *Adults:* 100–125 mg/d delayed-release tablets (25 mg qid with an extra dose at bedtime if needed) *Adults:* 50 mg tid; some patients may need 100 mg tid initially, followed by 50 mg tid	Doses above 225 mg/d not recommended Doses above 200 mg/d are not recommended Doses above 125 mg not recommended After first day, maximum dose 200 mg; doses generally should not exceed 150 mg

Continued

Table 25–9 ⚕ **Dosage Schedule: Selected NSAIDs and Acetaminophen—cont'd**

Drug	Indication	Dosage Forms	Dosage Schedule	Comments
Fenoprofen	Rheumatoid arthritis, osteoarthritis Mild-to-moderate pain	Capsules: 200 mg Tablets: 600 mg	*Adults:* 300–600 mg 3–4 times a day *Adults:* 200 mg q4–6 hr	Not approved for use in children <18 years. Not recommended in patients with advanced renal disease
Flurbiprofen	Rheumatoid arthritis, osteoarthritis		*Adults:* 200–300 mg/ day in two, three, or four divided doses. Maximum of 100 mg in a single dose	Not approved for use in children <18 years.
Ibuprofen (Advil, Motrin)	Rheumatoid arthritis, osteoarthritis Juvenile arthritis Acute gouty arthritis Mild to moderate pain Muscle sprain, strain (anti-inflammatory, analgesic) Primary dysmenorrhea Fever reduction OTC use for pain and/or fever	Tablets: 100, 200, 300, 500, 600, 800 mg Junior-strength tablets: 100 mg Chewable tablets: 50, 100 mg Gelcaps: 200 mg Suspension: 100 mg/5 mL Oral drops: 40 mg/mL, 50 mg/.25 mL IV solution: 10 mg/mL, 400 mg/4 mL	*Adults*: 1.2–3.2 g/d (300 mg qid or 400, 600, or 800 mg tid–qid) *Children:* 30–70 mg/kg/d in 3–4 divided doses; 20 mg/kg/d may be adequate in milder disease *Adults:* 800 mg qid; taper to eliminate as soon as pain is relieved *Adults:* 400 mg every 4–6 h as needed *Adults:* 600 mg qid or 800 mg tid for 5 d *Children:* 20–40 mg/kg/d in divided doses *Children >12 yr and adults:* 400 mg every 4 h as needed *Adults:* 200–400 mg every 4–6 h *Children 6 mo–12 yr:* 5 mg/kg for temperature <39.1°C (102.5°F) or 10 mg/kg for higher temperatures; may be repeated every 4–6 h *Adults:* 200 mg every 4–6 h while symptoms persist; if response is not adequate, may use 400 mg *Children ≥6 mo:* 5 mg–10 mg every 6–8 hr	Not to exceed 3.2 g/d; higher doses usually needed for rheumatoid arthritis Not to exceed 3.2 g/d Not to exceed 1,200 mg/d Not to exceed 3,600 mg/d Not to exceed 50 mg/kg/d Not to exceed 1,200 mg/d Not to exceed 1,200 mg/d Not to exceed 40 mg/kg/d Not to exceed 1,200 mg/d; do not take for >10 d for pain or >3 d for fever Do not administer to children <6 mo
Indomethacin (Indocin)	Moderate to severe rheumatoid arthritis, ankylosing spondylitis, and osteoarthritis Acute gouty arthritis Acute painful shoulder (bursitis or tendinitis) Acute gouty arthritis	Tablets: 200 mg, 400 mg, 600 mg, 800 mg Suspension: 100 mg/5 mL	*Children >14 yr and adults:* 25 mg bid–tid initially; increase dose by 25–50 mg at weekly intervals until satisfactory response Sustained release: 75 mg can be taken daily as alternative to 25 mg tid or bid as alternative to 50 mg tid *Adults:* 25 to 50 mg qid; taper to eliminate as soon as pain is relieved *Children >14 yr and adults:* 75–100 mg/d in 3–4 divided doses for 7–14 d *Adults:* 50 mg tid; taper to eliminate drug as soon as pain is relieved	Not to exceed 200 mg/d; for patients with persistent night pain or morning stiffness; give larger portion of dose at bedtime (up to 100 mg) Not to exceed 200 mg/d Do not use sustained-release form
Ketoprofen (Orudis)	Rheumatoid arthritis, osteoarthritis Acute gouty arthritis Mild to moderate pain, primary dysmenorrhea	Tablets: 12.5 mg Capsules: 25, 50 mg, 75 mg Extended-release: 100, 150, 200 mg	*Adults:* 75 mg tid *or* 50 mg qid initially Maintenance dose is 150–300 mg/d in 3–4 divided doses	Reduce dose by 1/2–1/3 for older adults and those with renal impairment; not to exceed 300 mg/d Not to exceed 300 mg/d

Table 25–9 ✤ **Dosage Schedule: Selected NSAIDs and Acetaminophen—cont'd**

Drug	Indication	Dosage Forms	Dosage Schedule	Comments
	OTC use for pain		Extended-release: 200 mg once daily *Adults:* 75 mg qid; taper to eliminate as soon as pain is relieved *Adults:* 25–50 mg every 6–8 h as needed *Children >16 yr and adults:* 12.5 mg with full glass of liquid every 4–6 h; if pain or fever persists after 1 h, follow with 12.5 mg	Doses >50 mg have not increased efficacy; not to exceed 300 mg/d Not to exceed 25 mg in a 4–6 h period or 75 mg/24 h
Ketorolac (Torodal)	Acute, moderately severe pain	Tablets: 10 mg Injection: 15 mg/mL, 30 mg/mL	*Adults <65 yr:* 60 mg IM single dose or 30 mg every 6 h (not to exceed 120 mg/d); then 20 mg PO initially, followed by 10 mg every 4–6 h as needed (not to exceed 40 mg/d) *Adults >65 yr or <50 kg or with renal impairment:* 30 mg IM single dose or 15 mg every 6 h (not to exceed 60 mg/d); then 10 mg PO every 4–6 h as needed (not to exceed 40 mg/d)	Not intended for >5 d combined IM and PO, or for minor or chronic pain; oral therapy is intended only as continuation from IM therapy
Meclofenamate	Rheumatoid arthritis, osteoarthritis Mild to moderate pain Excessive menstrual bleeding, dysmenorrhea	Capsules: 50, 100 mg	*Adults:* 200–400 mg/d in 3–4 equally divided doses *Children >14 yr and adults:* 50–100 mg every 4–6 h *Children >14 yr and adults:* 100 mg tid for up to 6 d, starting with first day of menstrual flow	Not to exceed 400 mg/d Not to exceed 400 mg/d Not to exceed 400 mg/d
Mefenamic acid (Ponstel)	Acute pain Primary dysmenorrhea	Capsules: 250 mg	*Children >14 yr and adults:* 500 mg, then 250 mg every 6 h as needed *Children >14 yr and adults:* 500 mg, then 250 mg every 6 h as needed starting at onset of bleeding or symptoms	Not to exceed 1 wk Should not be necessary for more than 2–3 d
Meloxicam (Mobic) Nabumetone (Relafen)	Rheumatoid arthritis, osteoarthritis Juvenile arthritis Rheumatoid arthritis, osteoarthritis	Tablet: 7.5, 15 mg Suspension: 7.5 mg/15 mL Tablets: 500, 750 mg	*Children >2 yr with JIA:* 0.125 mg/kg once daily; maximum 7.5 mg/daily *Adults:* 7.5 mg daily *Adults:* 1,000 mg daily; may increase to 1,500–2,000 mg/d	Not to exceed 2,000 mg/d
Naproxen (Aleve) Naproxen Sodium	Rheumatoid arthritis, osteoarthritis, ankylosing spondylitis Juvenile arthritis Acute gouty arthritis Acute gout Mild to moderate pain, dysmenorrhea, acute tendinitis or bursitis	Tablets: 250, 375, 500 mg Enteric-coated: 375, 500 mg Tablets, delayed-release: 375 mg and 500 mg Suspension: 125 mg/5 mL Tablets: 275, 550 mg	*Adults:* 250–500 mg bid; may increase to 1.5 g/d for limited periods Delayed-release: 375–500 mg bid Controlled-release: 750–1,000 mg once daily Naproxen sodium: 275–550 mg bid; may increase to 1.65 mg for limited periods	Morning and evening doses do not need to be equal; more than twice-daily dosing does not improve efficacy Not to exceed 1 g/d Not to exceed 1.25 g/d

Table 25–9 ⊗ **Dosage Schedule: Selected NSAIDs and Acetaminophen—cont'd**

Drug	Indication	Dosage Forms	Dosage Schedule	Comments
			Children: 10 mg/kg/d in 2 divided doses. Suspension: 13 kg child = 2.5 mL bid; 25 kg child = 5 mL; 38 kg child = 7.5 mL *Adults:* 500 mg bid; taper to eliminate as soon as pain is relieved Controlled-release: Same Naproxen sodium: Same *Adults:* 750 mg, then 250 mg every 8 h until attack subsides Controlled release: 1,000–1,500 mg once daily on first day, then 1,000 mg once daily until the attack subsides Naproxen sodium: 825 mg, then 275 mg every 8 h until attack subsides *Adults:* 500 mg, then 250 mg every 6–8 h as needed Controlled-release: 1,000 mg once daily; 1,500 mg/d may be used for limited period	
	OTC use for pain		Naproxen sodium: 550 mg, then 275 mg every 6–8 h as needed *Children:* Naproxen suspension, 5 mg/kg/d in 2 divided doses *Adults:* 200 mg with full glass of liquid every 8–12 h while symptoms persist; dose of 400 mg initially, then 200 mg doses, may be necessary *Adults >65 yr:* Do not take >200 mg every 12 h *Children:* Do not give to children <12 yr, except under advice/supervision of HCP	Not to exceed 1.375 g/d Not to exceed 600 mg/d
Oxaprozin (Daypro)	Rheumatoid arthritis, osteoarthritis	Caplets: 600 mg Tablet: 600 mg	*Adults:* 1,200 mg once daily; patients with low body weight or milder disease may use 600 mg once daily	Not to exceed 1,800 mg/d or 26 mg/kg, whichever is lower; doses >1,200 mg/d should be divided
Piroxicam (Feldenea)	Rheumatoid arthritis, osteoarthritis Dysmenorrhea	Capsules: 10, 20 mg	*Adults:* 20 mg once daily; may divide dose *Adults >65 yr:* 10 mg once daily initially *Adults:* 40 mg first day, then 20 mg/d	
Sulindac (Clinoril)	Rheumatoid arthritis, osteoarthritis, ankylosing spondylitis Acute gout, painful shoulder (tendinitis, bursitis)	Tablets: 150, 200 mg	*Adults:* 150 mg bid *Adults:* 200 mg bid	Therapy usually not longer than 7 d

HCP = health-care provider; OTC = over the counter.

as experience stiffness and swelling of the involved joint after periods of inactivity. Although there is no known cure for OA, treatment can help to maintain or improve joint mobility and limit functional impairment. With OA, nonpharmacological modalities are as important as drug therapy. They include weight loss; aerobic, range-of-motion, and muscle-strengthening exercises; appropriate footwear; and assistive devices for ambulation and activities of daily living when necessary. Drug therapy includes acetaminophen, NSAIDs, and COX-2 inhibitors. Topical agents such as capsaicin (hand OA only) and trolamine salicylate may also be used (Hochberg et al, 2012).

The patient's pain, disability, and comorbidities provide the guidelines for management of OA. Initially, acetaminophen in doses 650 mg 4 times a day or 1 g 3 times a day (maximum 3 g/24 h) are given to manage joint pain. If this drug fails to control pain, NSAIDs are prescribed (Hochberg et al, 2012). Patients who do not have a good response to full-dose acetaminophen should be trialed on systemic NSAIDS or intra-articular corticosteroid injections (Hochberg et al). The American College of Rheumatology recommends use of topical rather than oral NSAIDS in patients age 75 years or older (Hochberg et al, 2012). Although NSAIDs have both analgesic and anti-inflammatory actions, they do not alter the course of the disease or prevent joint destruction. All NSAIDs except ketorolac and mefenamic acid have an indication for treatment of OA. Doses are presented in Table 25-9. As in RA, the choice of NSAID to be used is determined by adverse reactions, cost, duration of action, and patient preference. For patients who experience adverse GI effects, adjunctive administration of proton pump inhibitors or cytoprotective agents (misoprostol) may be needed. Both of these drug classes are discussed in Chapter 20.

The use of both glucosamine (1,500 mg daily) and chondroitin (1,200 mg daily) for joint pain due to knee OA is a common practice among patients who are self-prescribing for OA. The evidence on the use of glucosamine and chondroitin does not consistently show improvement in pain; therefore, the American College of Rheumatology clinical guidelines do not recommend either for knee arthritis (2012). Because these two agents are available OTC and encouraged in many health food establishments, providers should ask the patient about their use and effectiveness for that patient.

Gout

Indomethacin, naproxen, and sulindac list acute gout as an indication. Ibuprofen and ketoprofen have also been used. Table 25-9 provides dosage schedules for these five drugs.

Mild to Moderate Pain

Almost every individual at some time experiences an episode of mild to moderate pain. Regardless of the source of the pain, nonopioid analgesia is the primary choice for management, especially if inflammation accompanies or is the cause of the pain. Although any NSAID may be used for this indication, several have been routinely used and proved effective.

Ibuprofen is the most commonly used because it is inexpensive, available OTC, and short-acting so that acute pain can be managed without long-term effects and adverse reactions. For women of childbearing age, it is Pregnancy Category C, and for nursing women it is not detected in breast milk. Naproxen sodium is used as an analgesic because it reaches its peak more rapidly and is longer-acting. Other drugs used for this indication include ketoprofen, ketorolac, meclofenamate, and mefenamic acid. When an injectable NSAID is needed, only ketorolac has such a formulation. Ibuprofen (Caldolor) and acetaminophen (Ofirmev) are available in IV form.

As with other indications, there is no clear difference in efficacy. Taking the drug around the clock, rather than as necessary, is most effective. Choice is based on adverse reactions, cost, duration of action, and patient preference. Health-care providers often choose one short-acting drug (ibuprofen, diclofenac, ketoprofen, ketorolac, meclofenamate), an intermediate-acting one (naproxen), and a long-acting drug (ketoprofen ER) and use the same drugs repeatedly. Because different patients seem to respond better to different NSAIDs, if one drug does not produce the desired effect, another one can be tried.

Acetaminophen is useful in treating mild to moderate pain that is not accompanied by or caused by inflammation. It is not intended for pain management for more than 5 days in children or 10 days in adults because of the increased risk for hepatic adverse reactions. For adults, a dose of 325 to 650 mg every 4 to 6 hours usually suffices. Children's doses are based on weight: 10 to 15 mg/kg per dose every 4 to 6 hours. After age 14 years, the adult dose is used. These doses are shown in Table 25-9.

Primary Dysmenorrhea

Ibuprofen, diclofenac potassium, ketoprofen, meclo-fenamate, mefenamic acid, and naproxen are the drugs used for dysmenorrhea. The best response occurs if NSAIDS are starting with the onset of menses symptoms. Doses are shown in Table 25-9.

Tendinitis and Bursitis

Indomethacin SR, naproxen, and sulindac are used for tendinitis and bursitis. Naproxen and sulindac both are intermediate-acting and provide longer duration of action than indomethacin, even in its sustained-release form. They also have fewer drug interactions. Naproxen is less likely to produce GI adverse reactions. These same three drugs are used to manage the pain in gout because it is associated with inflammation. Treatment choices are determined on the same basis.

Fever

Ibuprofen is the NSAID of choice for fever in children over age 6 months and adults. Doses are published for both adults and children. Acetaminophen may also be used for this purpose, but not for longer than 3 days. Acetaminophen is used for children younger than age 6 months and patients who do not tolerate ibuprofen (blood coagulation disorders; upper GI disease). Patients should be well hydrated if using ibuprofen for fever to decrease renal toxicity.

Rational Drug Selection

There is no clear difference in efficacy between NSAIDs, although there may be individual differences in response. The rationale for choices is provided in the Clinical Use and Dosing section. Acetaminophen is used for fever and for mild to moderate pain not associated with inflammation.

Monitoring

Monitoring is required only for long-term therapy. Because NSAIDS may produce acute renal insufficiency, assess renal function (serum creatinine) before initiation of therapy and annually throughout long-term therapy. A CBC prior to initiation of therapy and annually thereafter is appropriate because of the risk for GI bleeding. Any other monitoring is related to the disease being treated.

Patient Education

Administration

Take the drug exactly as prescribed (Table 25-12). A missed dose should be taken as soon as the patient remembers unless it is almost time for the next dose. For drugs taken more than once daily, ideally the missed dose should be taken within 1 to 2 hours of the time it was scheduled. Doses should not be doubled. Taking higher doses than those prescribed does not increase efficacy and may increase adverse reactions.

For some NSAIDs, there is a prescribed length of time beyond which the drug may not be taken. Patients should be informed of this time limitation. Taking the drug with food or a full glass of fluid and remaining in an upright position for 15 to 30 minutes may reduce GI discomfort and adverse reactions. Remind patients to avoid aspirin, alcohol, or other GI irritants while taking these drugs. Patients should be aware of products that may contain acetaminophen, including cough and cold products and combination opioid products, to avoid accidental overdose of acetaminophen.

Adverse Reactions

Advise patients about probable adverse reactions and what they should do if reactions occur. The most common adverse reaction is GI bleeding. They should contact their healthcare provider if they experience coffee-ground emesis or black, tarry stools. The provider should also be notified of skin rash, itching, visual disturbances, weight gain, edema, or persistent headache. With meclofenamate and mefenamic acid, if rash, diarrhea, or other digestive problems occur, patients should discontinue the drug and contact their healthcare provider.

These drugs may cause drowsiness. Patients should avoid activities requiring mental alertness until their response to the drug is known.

Lifestyle Management

Lifestyle modifications are only those related to the disease being treated.

ASPIRIN AND NONACETYLATED SALICYLATES

Aspirin is the prototype drug for this class, which makes it one of the most used drug classes for the treatment and prevention of a wide variety of disorders. Although salicylates are prescribed for conditions similar to those that the NSAIDs are used for, in addition to the analgesic, anti-inflammatory, and antipyretic properties common to the NSAIDs, the salicylates also possess antiplatelet properties to varying degrees. This latter property accounts for some of their adverse reactions but also for the increased breadth of their use beyond those for which NSAIDs are prescribed. The ability of aspirin to reduce platelet aggregation has given it a role in managing rheumatic fever, transient ischemic attacks (TIAs), coronary artery disease, and deep vein thrombosis. The antiplatelet role of aspirin is discussed in Chapter 18. Its nonspecific anti-inflammatory effect is invaluable in reducing cardiac workload for patients with severe carditis and heart failure. Aspirin has been shown to reduce the incidence of myocardial infarction (MI) and the incidence of death in all patients with unstable angina. These roles are discussed in Chapters 28, 33, 36, and 40. Salicylates are also used topically as keratolytic agents and counterirritants. This role is discussed in Chapters 23 and 32.

Pharmacodynamics

All salicylates have analgesic, anti-inflammatory, antipyretic, and antiplatelet actions. The pharmacological effects are qualitatively similar. Salicylates lower body temperature through their effect on the hypothalamic thermostat and vasodilation of peripheral vessels, thus enhancing dissipation of heat. The anti-inflammatory and analgesic activities are mediated through inhibition of prostaglandin synthesis in the same manner as NSAIDs. However, aspirin more potently inhibits prostaglandin synthesis and has greater anti-inflammatory activity than the NSAIDs. The acetyl group of the aspirin molecule is thought to be responsible for these differences. Aspirin acetylates the cyclo-oxygenase enzyme in the prostaglandin biosynthesis pathway; therefore, it may be theoretically classified as a COX inhibitor.

Aspirin also irreversibly inhibits platelet aggregation. Single analgesic-level doses prolong bleeding time. Acetylation of platelet cyclo-oxygenase prevents synthesis of thromboxane A, which is a potent vasoconstrictor and inducer of platelet aggregation for the life of the platelet (7 to 10 d). This drug has shown success as an antiplatelet agent for patients with thromboembolic disease. For this indication, low doses appear to be more effective than higher ones. Further discussion is found in Chapter 18.

The nonacetylated salicylates (salsalate [Disalcid], choline magnesium trisalicylate [Trilisate], and choline salicylate [Arthropan]) and diflunisal (Dolobid) are salicylic acid derivatives not metabolized to salicylic acid, are not as potent as aspirin, and do not possess the same degree of antiplatelet activity.

Pharmacokinetics

Absorption and Distribution

Salicylates are rapidly and completely absorbed after oral administration (Table 25-10). Bioavailability depends on the dosage form, gastric emptying time, gastric pH, presence of antacids or buffering agents, and particle size. The bioavailability of enteric-coated products may be erratic. The presence of food in the gut slows absorption, and absorption from rectal suppositories is also slower, resulting in lower salicylate levels.

Aspirin is partially hydrolyzed to salicylic acid during absorption and is distributed to all body tissues and fluids, including fetal tissue, breast milk, and the CNS. The highest concentrations are in plasma, the liver, the renal cortex, the heart, and lung tissues.

Protein binding of salicylates is concentration-dependent. At low concentrations (100 mcg/mL), 90% is bound; at higher concentrations (400 mg/mL), only 76% is bound.

Diflunisal is also rapidly and completely absorbed after oral administration. It crosses the placenta and enters breast milk. The first dose tends to have slower onset of pain relief than other drugs but achieves comparable peak effects. More than 99% is bound to plasma proteins.

Metabolism and Excretion

Salicylic acid is eliminated by renal excretion of salicylic acid and by oxidation and conjugation of metabolites by the liver. The amount excreted depends on urine pH. As urine pH increases from 5 to 8, renal clearance of free ionized salicylate increases from 2% to 3% to more than 80%. Alteration of urine pH is used in the treatment of salicylate poisoning to increase excretion.

Aspirin has a half-life of 15 to 20 minutes. Salicylic acid's half-life is 2 to 3 hours at low doses; at higher doses, it ranges from 6 to 12 hours. Plasma levels increase disproportionately as salicylate doses increase.

Diflunisal has a long half-life and nonlinear pharmacokinetics so that time to steady state is 3 to 4 days with 125 mg twice daily and 7 to 9 days with 500 mg twice daily. A loading dose shortens the time to steady state. Because 90% of each dose is eliminated by the kidneys, the half-life increases with renal impairment.

Pharmacotherapeutics

Precautions and Contraindications

Taking salicylates, especially aspirin, by children or adolescents with influenza or chickenpox has been associated with the development of Reye syndrome, a rare but life-threatening condition characterized by vomiting, lethargy, and eventually delirium and coma. The mortality rate is 20% to 30%, and permanent neurological deficits has been reported in survivors. Children or adolescents with influenza or chickenpox should not take salicylates.

Aspirin should be avoided for 1 week before any surgery because of the increased risk for post-operative bleeding due to its antiplatelet effects. For similar reasons, salicylates in general are contraindicated for patients with active peptic ulcer disease or other GI bleeding–related disorders or a history of such disorders. Salsalate and choline salicylate may cause less GI irritation and bleeding than aspirin. The antiplatelet effects contraindicate salicylate use for patients who are taking anticoagulants or who have anemia or a history of blood coagulation defects.

Salicylates should be used cautiously for patients with hepatic impairment. Reversible hepatic encephalopathy has occurred after even therapeutic doses for RA. Cautious use is also required for patients with renal insufficiency because salicylates may cause a transient decrease in renal function and aggravate chronic kidney diseases. Magnesium salicylates are contraindicated in the presence of renal insufficiency because the kidney cannot eliminate the magnesium, and hypermagnesemia results.

Salicylates affect uric acid accumulation. In low doses (less than 2 g/d), they decrease urate excretion and raise serum uric acid levels. At high doses (3 to 5 g/d), they have a uricosuric effect; however, they are rarely tolerated at this high a dose. They should be used with caution in the presence of gout.

Table 25–10 ✛ Pharmacokinetics: Salicylates

Drug	Onset	Peak	Duration	Protein Binding	Half-Life	Elimination
Acetylsalicylic acid	15–20 min	1–3 h	3–6 h	90%–91%; 25%–76%*	15–20 min; 2–3 h; 15–30 h*	In urine and by liver*
Choline salicylate	5–30 min	1–3 h	3–6 h	90%–91%; 25%–76%*	15–20 min; 2–3 h; 15–30 h*	In urine and by liver*
Choline magnesium salicylate	5–30 min	1–3 h	3–6 h	90%–91%; 25%–76%*	15–20 min; 2–3 h; 15–30 h*	In urine and by liver*
Salsalate	5–30 min	1–3 h	3–6 h	90%–91%; 25%–76%*	15–20 min; 2–3 h; 15–30 h*	In urine and by liver*
Diflunisal	1 h	2–3 h	8–12 h	8–12 h		90% in urine; <5% in feces

*See discussion in text.

Aspirin is Pregnancy Category D; salsalate and magnesium salicylate are Pregnancy Category C. Ingestion during pregnancy may produce anemia in the mother and increase the risk for postpartum hemorrhage. Inhibition of prostaglandin synthesis may cause constriction of the ductus arteriosus and other possible untoward effects in the fetus. Avoid use in pregnancy, especially during the third trimester. Diflunisal is Pregnancy Category C. Although its safety during pregnancy has not been established, it should not be used, especially during the last trimester.

After aspirin ingestion salicylate is excreted in breast milk in low concentrations. Adverse effects on nursing infants have not been reported when low-dose aspirin is used (75 to 162 mg/day) as an antiplatelet (LactMed, 2014). High-dose aspirin should be avoided while breastfeeding. Diflunisal is excreted in breast milk in concentrations of 2% to 7% of the maternal plasma. Because of potential adverse effects, discontinuing either diflunisal or using a shorter-acting drug such as aspirin is recommended.

The safety and efficacy of magnesium salicylate and salsalate have not been established in children. Aspirin should not be used in children with acute febrile illness. Children with dehydration appear more at risk for salicylate toxicity.

Adverse Drug Reactions

The most common adverse reaction to salicylates is GI irritation and bleeding. Although fecal blood loss is lower with enteric-coated products, these drugs have erratic absorption and still must be used cautiously by patients with GI disorders. The amount of blood lost from GI bleeding secondary to salicylate use is usually clinically insignificant, but with prolonged use it can result in iron deficiency anemia. Patients who have developed peptic ulcers while taking salicylates have healed these ulcers with the use of proton pump inhibitors, H_2 blockers, and antacids, despite continued salicylate use. Only 20% to 25% of patients on chronic aspirin therapy for RA develop mucosal injury.

Hypersensitivity reactions have occurred with salicylates. Hypersensitivity to salicylates or NSAIDs contraindicates aspirin use and requires extremely cautious use of the other salicylates. Cross-sensitivity exists between aspirin and NSAIDs and between aspirin and tartrazine dye. This cross-sensitivity does not appear to occur with choline salicylate. Aspirin sensitivity is more prevalent in patients with asthma, nasal polyps, or chronic urticaria.

Salicylates are ototoxic at increased blood levels. They should be discontinued if dizziness, tinnitus, or impaired hearing develops. Temporary hearing loss disappears gradually when the drug is stopped.

Toxicity

The acute lethal dose of salicylates in adults is 10 to 30 g, and in children it is 3 g. Chronic salicylate toxicity can occur when more than 100 mg/kg is ingested daily for 2 or more days. Signs of salicylate poisoning appear at serum levels of 30 to 60 mg/dL. Respiratory alkalosis is seen initially. Hyperpnea and tachypnea occur as a result of increased CO_2 production and a direct stimulatory effect of the salicylate on the respiratory center in the brain. Other symptoms include nausea, vomiting, hypokalemia, tinnitus, disorientation, irritability, seizures, dehydration, hyperthermia, thrombocytopenia, and other hematological disorders.

Treatment for salicylate toxicity includes induction of emesis or gastric lavage to remove any unabsorbed drug from the stomach. Activated charcoal diminishes salicylate absorption if it is given within 2 hours of ingestion. Salicylate levels and acid–base, fluid, and electrolyte balances are carefully monitored. The rest of therapy is supportive. Forced alkaline diuresis by administering sodium bicarbonate increases salicylate excretion. Hemodialysis is reserved for those patients with severe poisoning.

Drug Interactions

Aspirin may potentiate the anticoagulant action of heparin, warfarin, or thrombolytic agents (Table 25-11). It may increase the risk for bleeding with cefamandole, cefoperazone, cefotetan, valproic acid, or plicamycin.

All salicylates may enhance the activity of penicillins, phenytoin, methotrexate, valproic acid, sulfonylureas, and sulfonamides. They may antagonize the beneficial effects of probenecid or sulfinpyrazone and blunt the therapeutic response to diuretics, antihypertensives, and some NSAIDs. Glucocorticoids decrease serum salicylate levels.

There is an increased risk for GI bleeding when aspirin is taken with any other drug with any other GI irritant, such as ethanol. The risk for ototoxicity is increased when it is taken with any other drug that causes ototoxicity (e.g., aminoglycosides, loop diuretics).

Some foods contain salicylate. Foods and spices high in salicylate include curry, paprika, licorice, Benedictine liqueur, prunes, raisins, tea, and gherkins. Foods that acidify the urine may increase serum salicylate levels, and those that alkalinize the urine may have the opposite effect.

Clinical Use and Dosing

Fever

Aspirin is the salicylate of choice for reduction of fever in adults. It is contraindicated for use with pregnant patients, however. To be used with children, the cause of the fever must first be determined. It is contraindicated in children and adolescents if the cause of the fever is influenza or chickenpox. Although not clearly stated in the literature, this warning may extend to other viral URIs. Many providers do not use it as an antipyretic for any children because there are other drugs that do not carry the concern about Reye syndrome. Acetaminophen or ibuprofen is probably better for fever management in children. Adults' and children's doses of aspirin are shown in Table 25-12.

Diflunisal is not recommended as an antipyretic. In single doses, it reduces fever in some patients but not in a clinically significant amount.

Table 25–11 ▦ Drug Interactions: Salicylates

Drug	Interacting Drug	Possible Effect	Implications
Acetylsalicylic acid	Angiotensin-converting enzyme inhibitors, beta adrenergic blockers	Decreased antihypertensive effect because of prostaglandin inhibition	Consider discontinuing salicylate or selecting different antihypertensive
	Heparin, warfarin	Prolonged bleeding time, impaired platelet function	Avoid concurrent use
	Nitroglycerin	Unexpected hypotensive effects	Reduce nitroglycerin dose
	NSAIDs	Aspirin may decrease serum concentrations	Avoid concomitant use; no therapeutic advantage and may increase risk for GI bleed
All salicylates	Alcohol, cefamandole, cefoperazone, cefotetan, valproic acid, plicamycin	Increased risk for GI bleeding	Avoid alcohol while taking salicylates; select different antimicrobial or avoid use of salicylate
	Loop diuretics, aminoglycosides, bumetanide, ethacrynic acid	May increase risk for ototoxicity	Avoid concurrent use or monitor for tinnitus, hearing loss
	Probenecid, sulfinpyrazone	Salicylates antagonize uricosuric effects	Avoid concurrent use
	Spironolactone	Salicylates inhibit diuretic effects	Avoid concurrent use
	Sulfonylureas	Salicylates in doses >2 g/d have hypoglycemic effect; potentiate glucose-lowering effect	Select different drug combination
	Penicillins, phenytoin, methotrexate, valproic acid, sulfonamide	May enhance effects of these drugs	Monitor for potential dosage adjustments
	Foods that acidify urine*	Decreases renal excretion and increases serum levels of salicylates	May increase risk for toxicity
	Foods that alkalinize urine*	Increases renal excretion and decreases serum levels of salicylates	May be used therapeutically to treat overdose
Diflunisal	Acetaminophen	Concurrent administration may result in 50% increase in acetaminophen levels	Increased risk for hepatotoxicity; avoid concurrent use
	Heparin, warfarin	Competitively displaces warfarin from protein-binding sites; increased risk for bleeding	Avoid concurrent use; monitor PT/INR closely
	Hydrochlorothiazide (HCTZ)	Significantly decreased HCTZ plasma levels	Avoid concurrent use
	Aspirin, NSAIDs, colchicine, glucocorticoids, alcohol	Additive risk for GI bleeding	Avoid concurrent use
	Lithium	May increase serum lithium levels	Select different salicylate
	Probenecid	Increased risk of diflunisal toxicity	Avoid concurrent use or monitor closely for indications of toxicity
	Antacids	Concurrent administration decreases absorption of diflunisal	Separate administration by at least 1 h
	Indomethacin	Decreased renal clearance and significantly increased indomethacin serum levels	Avoid concurrent use
	Sulindac	Increased renal clearance and significantly decreased sulindac serum levels	Avoid concurrent use

INR = international normalized ratio; PT = prothrombin time.

*Foods that alkalinize urine: all fruits except cranberries, prunes, plums; all vegetables; milk. Foods that acidify urine: cheeses, cranberries, eggs, fish, grains, meats, plums, poultry, and prunes.

Mild to Moderate Pain

Pain associated with inflammation is especially well managed with salicylates or NSAIDs. Aspirin, choline salicylate, choline magnesium salicylate, and diflunisal are all approved for this indication. Aspirin is the gold standard against which others are judged. It is inexpensive, available OTC, the most potent analgesic in the class, and short-acting, so acute pain can be managed without long-term effects and adverse reactions. It has limitations, however. It is Pregnancy Category D, especially in the third trimester and contraindicated in children with influenza or chickenpox.

Diflunisal offers the advantage of analgesia comparable with that of aspirin, with longer-lasting responses. Like the other drugs in this group, it can be used for this indication, but all four are more often used to treat arthritic conditions.

Rheumatoid Arthritis

Salicylates or NSAIDs can be used as adjunctive treatment for RA. Serum levels can easily be measured to determine adherence and therapeutic efficacy, and it is the least expensive salicylate. Nonacetylated salicylates are less potent anti-inflammatory agents, but they have fewer adverse reactions

Table 25–12 ⚕ Dosage Schedule: Salicylates

Drug	Indication	Dosage Forms	Dose	Comments
Acetylsalicylic acid (aspirin) (Bayer Aspirin)	Fever, pain, headache, dysmenorrhea Rheumatoid arthritis, osteoarthritis Juvenile rheumatoid arthritis Acute rheumatic fever Transient ischemic attack Myocardial infarction prophylaxis	Tablets: 325 mg Chewable tablets: 81 mg Enteric-coated tablets: 325 mg Timed-release tablets: 650 mg Caplets: 325 mg, 500 mg Tablets: 325 mg, 500 mg Enteric-coated tablets: 325 mg, 650 mg, 975 mg Suppository: 120, 200, 300, 600 mg	*Adults:* 325–650 mg every 4 h; with extra-strength may use 500 mg every 3 h *or* 1 g every 6 h; not to exceed 4 g/d *Children 2–11 yr:* 65 mg/kg/d in 4–6 divided doses* *Adults:* 3.2–6 g/d in divided doses *Children <25 kg:* 60–110 mg/kg/d in divided doses (every 6–8 h); start with 60 mg/kg/d and increase by 20 mg/kg/d after 5–7 d, then increase by 10 mg/kg/d after another 5–7 d *Children >25 kg:* 50–60 mg/kg/d with a similar dosing increase schedule *Adults:* 5–8 g/d initially in 3–4 divided doses; increase dose to reach serum salicylate level of 15–30 mg/mL; not to exceed 8 g/d *Children:* 100 mg/kg/d for 2 wk, then decrease to 75 mg/kg/d for 4–6 wk; not to exceed 130 mg/kg/d *Adults:* 50–325 mg/d *Adults:* 81–160 mg/d	*Use cautiously in children Toxicity risk increased at this dose Maintain a serum salicylate level of 15–30 mg/mL for anti-inflammatory effects Aspirin combined with extended-release dipyridamole is recommended over aspirin alone
Choline magnesium salicylate (Trilisate)	Fever, pain, rheumatoid arthritis	Tablets: 500, 750 mg 1 g Liquid: 500 mg/ 5 mL	*Adults:* 2–3 g/d in divided doses or 150 mg bid *Children >37 kg:* 2.2 g/d in 2 divided doses* *Children <37 kg:* 50 mg/d in 2 divided doses*	Has fewer adverse reactions than aspirin
Salsalate (Disalsid)	Rheumatic conditions	Capsules: 500 mg Tablets: 500 mg, 750 mg	*Adults:* 1,500 mg bid *or* 750 mg qid; not to exceed 4 g/d	
Diflunisal (Dolobid)	Mild to moderate pain Osteoarthritis	Tablets: 250, 500 mg	*Adults:* 1 g initially, followed by 500 mg every 8–12 h *Adults:* 500 mg–1 g/d in two divided doses; not to exceed 1.5 g/d	Half this dose initially and following may be effective

*Dosing schedules are published for analgesia and fever reduction. Use cautiously. Not recommended for children with influenza or chickenpox because of risk for Reye syndrome.

than aspirin. The main disadvantages of aspirin are the high incidence of GI intolerance (take with food or use enteric-coated tablets), the inconvenience of taking four or five doses daily, and the relatively long interval (4 to 7 d) before a full anti-inflammatory effect is reached. A therapy trial of 3 to 4 g/d for 4 to 6 days is recommended, because 70% to 80% of patients who will respond will do so within this time frame. Older adults are predictably less tolerant to the adverse GI reactions, and their trial dose should be 2 to 3 g/d. If the response is inadequate and adherence has been good, a salicylate level should be drawn before changing drugs. If the drug level is within therapeutic parameters (20 to 25 mg/dL in adults; 15 to 20 mg/dL in older adults) without adequate response, or if the drug is not tolerated, another drug should be tried. If the salicylate level is too low but the patient has been adherent and tolerates the aspirin, the dose should be increased by 325 to 650 mg/d until the desired anti-inflammatory level of the drug is reached.

The margin is narrow between a good therapeutic level and toxicity in treating patients with RA because the dose is higher than that used for fever or analgesia. The earliest manifestation of toxicity is tinnitus or mild deafness. Aspirin should be stopped immediately if these symptoms occur. Once they abate, it may be restarted at a lower dose, or an

NSAID may be chosen. Toxicity is discussed in the Adverse Reactions section.

For patients whose main reason for discontinuing aspirin is GI intolerance, salsalate is a good alternative. It can be given in twice-daily dosing and has a much lower incidence of GI bleeding. Choline salicylate and choline magnesium salicylate can also be used and may be given in 2 to 4 times daily dosing.

Osteoarthritis

Patients with OA may present occasionally with acute or subacute painful episodes in which the underlying problem is inflammation. No drugs have proven efficacy in altering the course of OA, but both salicylates and NSAIDs are used successfully to treat the pain associated with these exacerbations. Aspirin is an effective analgesic and anti-inflammatory that is usually well tolerated in divided doses of 1.2 to 2.4 g/d. NSAIDs tend to have more adverse reactions with no better pain relief when given at anti-inflammatory doses over the course of more than a few days. Acetaminophen is helpful for analgesia but has no anti-inflammatory effects.

The nonacetylated salicylates are also effective and have fewer GI adverse reactions than aspirin. Diflunisal has the advantage of twice-daily dosing but may take up to 2 weeks to achieve full anti-inflammatory effects. Although it is more expensive than aspirin, the cost may approach that of many of the NSAIDs. Discussion of NSAIDs is in the section preceding this one.

Juvenile Rheumatoid Arthritis

Juvenile RA is an autoimmune disease that occurs in four different forms, all of which are characterized by joint inflammation. Pediatric specialists generally follow children with the disorder and determine their treatment protocol. Salicylates and NSAIDs are commonly part of this protocol.

Aspirin is prescribed in daily doses of 60 to 110 mg/kg for children. NSAIDs are prescribed if the child does not respond to or cannot tolerate aspirin therapy.

Nonacetylated salicylates are not indicated for treatment of juvenile forms of RA.

Acute Rheumatic Fever

Acute rheumatic fever is usually a sequela of group A beta-hemolytic streptococcal infection. Rheumatic fever incidence is 0.1 to 0.2 cases per 100,000 persons in Canada, the United States, and western Europe (Madden & Kelly, 2009). There is a higher incidence (10 to 20 cases/100,000) of rheumatic fever in emerging economies, indigenous peoples, and tropical regions (Madden & Kelly). Acute rheumatic fever is treated with antimicrobials, but the inflammatory manifestations are treated with aspirin. Although this disorder is more common in children, it can also occur in adults. Dosage schedules for both are presented in Table 25-12.

Myocardial Infarction Prophylaxis

The American College of Chest Physicians (ACCP) Guidelines for Primary and Secondary Prevention of Cardiovascular Disease recommend low-dose aspirin (75 to 100 mg/d) in patients age 50 years or older for primary prevention of cardiovascular disease (Vandvick et al, 2012). The ACCP guidelines recommend low-dose aspirin (75 to 100 mg daily) or clopidogrel in patients with established coronary artery disease, patients with coronary stenosis greater than 50%, and those with evidence of cardiac ischemia. Aspirin (75 to 10 mg/d) is combined with ticagrelor or clopidogrel for the first year after coronary stent placement (Vandvick et al, 2012).

Transient Ischemic Attacks

The American Heart Association/American Stroke Association recommends the use of aspirin for the prevention of stroke in patients with stroke and transient ischemic attack (Kernan et al, 2014). Aspirin (50 to 325 mg/d) monotherapy or a combination of aspirin and extended-release dipyridamole are accepted therapy options for stroke prevention (Kernan et al, 2012). Clopidogrel and its dosing for this indication are discussed in Chapter 18. Dosing schedules for aspirin for each indication are presented in Table 25-12.

Rational Drug Selection

Rational drug selection is based largely on indication, cost, and convenience of therapy. All of these are discussed in the Clinical Use and Dosing section.

Monitoring

A random salicylate level should be drawn 7 to 10 days after initiation of chronic therapy. Periodic salicylate levels should be drawn during long-term management to check maintenance of therapeutic levels and monitor for toxic manifestations.

Because all of these drugs are eliminated by the kidneys and dosage adjustments may be required based on renal function, serum creatinine levels should be assessed before therapy is begun and annually throughout long-term therapy. Urinary pH should also be monitored regularly. Sudden acidification of urine can more than double the plasma salicylate level, resulting in toxicity.

Salicylates interfere with homeostasis. A CBC should be drawn prior to initiating therapy and at least annually throughout long-term therapy. A CBC should also be drawn and fecal occult blood studies should be done as well if there is any indication of GI bleeding.

Hepatic function should be monitored prior to antirheumatic therapy and if hepatotoxicity symptoms occur. These problems are more likely in patients with rheumatic fever, juvenile RA, or preexisting hepatic diseases, especially children.

Ophthalmic effects have been reported in patients taking diflunisal. Ophthalmic studies are appropriate for patients who develop eye complaints during therapy.

Patient Education

Administration

Instruct the patient to take salicylates exactly as prescribed. Taking with food or a full glass of water and remaining in an upright position for 15 to 30 minutes after administration can reduce GI irritation. Food slows absorption but does not alter the total amount absorbed.

Remind patients not to crush or chew enteric-coated tablets or take antacids within 1 hour of enteric-coated tablets. Chewable tablets may be chewed, dissolved in liquid, or swallowed whole. Tablets with a vinegar-like odor (acetic acid) should be discarded.

Instruct patients not to increase the dose beyond that prescribed. Increased doses increase the risk for salicylate poisoning. For patients taking aspirin for MI or TIA prophylaxis, increasing the dose has not proved to provide additional benefits but does increase the risk for adverse reactions.

Adverse Reactions

The most common adverse reactions are ototoxicity and GI irritation and bleeding. Advise patients to report tinnitus; unusual bleeding from the gums; bruising; black, tarry stools; or fever lasting longer than 3 days. Patients who are taking salicylates should not use alcohol or other substances that increase GI irritation.

Reye syndrome practically disappeared after the Centers for Disease Control and Prevention (CDC) started warning against giving aspirin to children or adolescents with influenza, influenza-like syndromes, or chickenpox (varicella) because of a possible association with Reye syndrome, a "public health triumph" (Monto, 1999). Parents should be informed of the risk of Reye syndrome and educated regarding not giving aspirin to a child with a viral illness.

Lifestyle Management

Rest, heat, exercise, and other lifestyle modifications are part of the management of arthritic conditions. The modifications are as important as the pharmacological management and should be stressed.

DRUGS USED IN TREATING EYE AND EAR DISORDERS

Teri Moser Woo

This chapter discusses the medications used to treat eye and ear disorders, including the common anti-infective agents for conjunctivitis, the medications used for allergic conjunctivitis, and common anti-inflammatory agents used for ocular inflammation. Although primary care providers may not prescribe some of the glaucoma medications, many drugs interact with these ophthalmic medications and therefore a basic understanding of these agents is necessary and included. Eye lubricants and vasoconstrictors are discussed here. The use of fluorescein, a diagnostic agent commonly used in primary care, is also addressed in this chapter. The ear medications discussed here include the anti-infectives, analgesics, and ceruminolytics.

DRUGS USED IN TREATING EYE DISORDERS

OPHTHALMIC ANTI-INFECTIVES

Common eye infections that are treated by primary care providers include bacterial conjunctivitis, viral conjunctivitis, blepharitis, and hordeolum. An estimated 4 million cases of bacterial conjunctivitis occur in the United States annually (Smith & Waycaster, 2009). In children, 54% to 73% of cases of conjunctivitis are bacterial, with the most common pathogens being *H. influenzae* (29%) and *S. pneumoniae* (20%) (Buznach, Dagan, & Greenberg, 2005). The commonly used antibacterial agents for conjunctivitis are sulfacetamide sodium

(Bleph-10), bacitracin, erythromycin (Ilotycin), tobramycin (Tobrex), gentamicin (Garamycin, Genoptic), azithromycin (AzaSite) and the fluoroquinolones besifloxacin (Besivance), ciprofloxacin (Ciloxan), gatifloxacin (Zymar, Zymaxid), levofloxacin (Iquix), moxifloxacin (Moxeza, Vigamox), norfloxacin (Chibroxin, Noroxin), and ofloxacin (Ocuflox). The combination drugs Polytrim (polymyxin b/trimethoprim) and Polysporin (polymyxin b/bacitracin) Ophthalmic may also be used and are discussed here. Chloramphenicol (Chloroptic) is rarely used in primary care because of its adverse effects. More serious infectious eye disorders such as herpes simplex virus (HSV) infection, keratitis, and corneal ulcers are treated by ophthalmologists and, therefore, are not covered at great length in this chapter, although the antiviral agents that may be used to treat viral eye infections are briefly discussed.

Pharmacodynamics

Ophthalmic antibiotics may be bacteriostatic or bactericidal. Bacitracin is bacteriostatic and inhibits the incorporation of amino acids and nucleotides into the cell. It is active against many gram-positive (staphylococci, streptococci, clostridia, corynebacteria, and anaerobic cocci) and gram-negative (gonococci, meningococci, and fusobacteria) organisms.

Erythromycin is a bacteriostatic macrolide antibiotic that is active against a wide range of organisms. It binds to the 50S ribosomal subunit, inhibiting bacterial protein synthesis. The gram-positive organisms that are susceptible to

erythromycin include *Staphylococcus aureus, Streptococcus pyogenes, S. pneumoniae,* the *Streptococcus viridans* group, and *Corynebacterium diphtheriae.* Erythromycin has limited gram-negative coverage. It is also active against *Chlamydia trachomatis.*

Sulfacetamide is a synthetic sulfonamide that inhibits bacterial dihydrofolate synthetase. It is active against the following susceptible organisms: streptococci, staphylococci, *Escherichia coli, Klebsiella pneumoniae, Pseudomonas pyocyanea, Neisseria gonorrhoeae,* and *C. trachomatis.*

Tobramycin is a broad-spectrum aminoglycoside. The exact mechanism by which it is bactericidal is unknown. It is active against staphylococci, streptococci, *Corynebacterium* species, *K. pneumoniae, Moraxella* species, *Proteus* species, beta-hemolytic streptococci, and *Haemophilus influenzae.* Tobramycin ophthalmic is not active against *N. gonorrhoeae* or *C. trachomatis.*

Gentamicin is a broad-spectrum antibiotic that is active against a wide range of gram-positive and gram-negative organisms. It is unclear how gentamicin causes cell death. It is active against staphylococci, *S. pneumoniae,* beta-hemolytic streptococci, *E. coli, H. influenzae, N. gonorrhoeae,* and *Enterobacter* species.

Azithromycin (AzaSite) is a macrolide antibiotic active against both gram-positive and gram-negative organisms. The manufacturer's premarketing studies indicated that azithromycin drops eradicated 88% of gram-positive bacteria and 92% of gram-negative bacteria in randomized controlled trials (RCT), including 93% of *H. influenzae,* a common pathogen in pediatric conjunctivitis (Inspire Pharmaceuticals, 2008).

The fluoroquinolones besifloxacin, ciprofloxacin, garifloxacin, levofloxacin, moxifloxacin, norfloxacin, and ofloxacin are bactericidal via inhibition of DNA gyrase. It is unclear how inhibition of DNA gyrase leads to cell death. The fluoroquinolones are active against staphylococci, *S. pneumoniae, H. influenzae, K. pneumoniae, Proteus* species, *Enterobacter* species, and *Pseudomonas aeruginosa.*

Polytrim is an ophthalmic antibacterial preparation that combines polymyxin B and trimethoprim. Polymyxin B binds to cell membranes with high affinity, specifically the phospholipids in the cell wall. This causes increased cellular permeability. Polymyxin B is generally active against gram-negative bacteria (*E. coli, P. aeruginosa, H. influenzae*). Trimethoprim inhibits bacterial dihydrofolate reductase. Trimethoprim has both gram-positive and gram-negative activity. Trimethoprim is active against *S. aureus, S. pneumoniae,* and *S. pyogenes.*

Polysporin Ophthalmic contains polymyxin B and bacitracin. This combination provides activity against gram-positive and gram-negative bacterial organisms, as discussed previously.

Antiviral ophthalmic agents that may be prescribed by an ophthalmologist are gancyclovir (Zirgan), vidarabine (Vira-A), and trifluridine (Viroptic). Gancyclovir inhibits replication by herpes simplex viruses by inhibiting the synthesis of viral DNA. Vidarabine inhibits viral DNA replication, although the exact mechanism of action is not known. Vidarabine has antiviral activity against HSV types 1 and 2, varicella-zoster virus, cytomegalovirus, vaccinia, and hepatitis B. The exact mechanism of action of trifluridine is not known, although it is thought to interfere with DNA synthesis. Trifluridine is active against HSV-1 and HSV-2, adenovirus, and vaccinia virus.

Pharmacokinetics

Ophthalmic antibiotic and antiviral preparations generally penetrate only the ocular fluid and tissues. Systemic absorption is minimal, although there may be enough absorption for sensitization to occur, specifically with sulfacetamide. There is no information regarding the metabolism and excretion of ophthalmic anti-infectives.

Pharmacotherapeutics

Precautions and Contraindications

Hypersensitivity to any component of the preparation is a contraindication to its use. There may be cross-sensitivity between the individual aminoglycosides (tobramycin and gentamicin). The same is found with the fluoroquinolones.

The vehicles used in ophthalmic ointments may retard corneal healing after ocular trauma or ocular surgery. Improvements in ophthalmic ointment vehicles have changed this situation for the better, but manufacturers still warn that many preparations may retard corneal healing.

Purulent exudates that contain para-aminobenzoic acid may inactivate sulfacetamide antibacterial activity.

Antibacterial agents are not effective against fungal infection, viral infection, or all types of bacterial infection. If the patient is not responding to therapy, reevaluation, including appropriate cultures, is indicated.

Erythromycin, azithromycin, and tobramycin ophthalmic preparations are Pregnancy Category B. Gentamicin, ciprofloxacin, gatifloxacin, levofloxacin, moxifloxin, norfloxacin, ofloxacin, polymyxin B, and sulfacetamide are Pregnancy Category C. The antiviral ophthalmic agents gancyclovir, vidarabine, and trifluridine are all Pregnancy Category C. Safety for use during pregnancy has not been determined.

The use of the sulfacetamides and the fluoroquinolones should be avoided during lactation because they are harmful to the infant and breast milk excretion is unknown.

Erythromycin and tobramycin are safe and effective in children. The safety of the fluoroquinolones (besifloxacin, ciprofloxacin, gatifloxacin, moxifloxacin [Vigamox], levofloxacin, norfloxacin, ofloxacin, and besifloxacin) and azithromycin in children under age 1 has not been established. Moxifloxacin (Moxeza) is approved for children 4 months of age and older. Sulfacetamide and polymyxin B/bacitracin should not be prescribed to infants younger than 2 months.

Adverse Drug Reactions

All of the ophthalmic anti-infective preparations may cause local irritation, which is usually transient. Irritation may include burning, itching, and inflammation. Superinfection may occur with prolonged or repeated use of ophthalmic anti-infectives.

Bacitracin may cause blurred vision, which usually lasts only a few minutes.

Sulfacetamide ophthalmic preparations may cause a hypersensitivity reaction in patients who have previously

exhibited sensitivity to sulfonamides. Stevens–Johnson syndrome is a rare adverse reaction that has been reported with sulfacetamide ophthalmic ointment use. Fever, bone marrow depression, and lupus erythematosus may rarely occur with sulfonamides, including topical preparations. There may be intense burning and stinging, especially with the 30% sulfacetamide sodium solution (Sulamyd 30%).

Aminoglycosides may cause localized ocular toxicity and hypersensitivity.

The fluoroquinolones may cause a white crystalline precipitate to form in the superficial portion of the cornea. This was observed in about 17% of the patients on ciprofloxacin. Lid margin crusting, crystals, scales, and the sensation of a foreign body in the eye are also reported with ophthalmic fluoroquinolones. Patients also report a bitter or bad taste in the mouth, specifically with ciprofloxacin solution. Fluoroquinolones may also cause photophobia, tearing, nausea, decreased vision, conjunctival hyperemia, and corneal staining.

The ophthalmic antiviral preparations may cause burning and irritation on instillation into the eye. Gancyclovir may cause blurred vision, punctate keratitis, and conjunctival hyperemia. Vidarabine may also cause photophobia, pruritus, erythema, ocular pain, and, less commonly, increased lacrimation. Patients who are using ophthalmic vidarabine may develop superficial punctate keratitis after exposure to ultraviolet (UV) light, and they should wear sunglasses to protect their eyes when exposed to bright light. Trifluridine has adverse reactions similar to those of vidarabine, with the addition of reported increases in intraocular pressure (IOP).

Drug Interactions

There are no drug interactions reported for ophthalmic preparations of bacitracin, gentamicin, tobramycin, polymyxin B, azithromycin, and erythromycin.

Sulfacetamide is incompatible with silver-containing preparations and should not be used in conjunction with ophthalmic products containing silver salts, including silver nitrate. Concomitant use of ophthalmic sulfacetamide with zinc sulfate causes a precipitate to form. Ester-type local anesthetics including benzocaine, chloroprocaine, cocaine, procaine, propoxycaine, and tetracaine should not be used concurrently with sulfacetamide because they can antagonize the therapeutic actions of the sulfonamide.

The fluoroquinolones (besifloxicin, ciprofloxacin, gatifloxacin, moxifloxacin, levofloxacin, norfloxacin, and ofloxacin) may increase theophylline levels and potentiate oral anticoagulants if significant systemic absorption occurs. These interactions are theoretical with ophthalmic use of fluoroquinolones, in that little is known regarding the amount of medication that is systemically absorbed and whether enough is absorbed to cause a drug interaction.

Table 26-1 presents drug interactions with ophthalmic anti-infectives.

Table 26–1 ▦ Drug Interactions: Ophthalmic Anti-Infectives

Drug	Interacting Drug	Possible Effect	Implications
Sulfacetamide sodium	Silver preparations	Incompatibility	Do not use concurrently
Erythromycin	None reported		
Tobramycin	None reported		
Gentamicin	None reported		
Gatifloxacin	Theophylline, caffeine, oval anticoagulants	May raise serum levels	Monitor PT/INR levels
Levofloxacin	Theophylline, caffeine, oval anticoagulants	May raise level of these drugs	Monitor INR/PT levels
Moxifloxacin	None reported		
Norfloxacin	Warfarin, theophylline, cyclosporine	May raise levels of these systemic drugs	Monitor theophylline level and PT/PTT times
Ciprofloxacin	Warfarin, theophylline, cyclosporine	May raise levels of these systemic drugs; may increase renal toxicity from cyclosporine	Monitor theophylline level
Ofloxacin	Warfarin, theophylline, caffeine, cyclosporine	May raise levels of these systemic drugs; may increase renal toxicity from cyclosporine	Monitor PT/INR levels closely
Polymyxin B–trimethoprim	None reported		
Polymyxin B-bacitracin ophthalmic	None reported		

PT = prothrombin time; PTT = partial thromboplastin time; INR = international normalized ratio.

Clinical Use and Dosing

Conjunctivitis

The common organisms that are associated with bacterial conjunctivitis vary with the age of the patient. Newborns should be evaluated for ophthalmia neonatorum. Preschool children most commonly have bacterial conjunctivitis, with viral etiology (adenovirus) more likely in schoolchildren. *N. gonorrhoeae* conjunctivitis should be excluded in sexually active adolescents and adults. Adults may have viral or bacterial conjunctivitis. Chlamydia is seen in the neonate and sexually active teen and adult. Table 26-2 presents the clinical and laboratory features of conjunctivitis.

Ophthalmia Neonatorum

Any infant younger than 1 month who presents with conjunctivitis should have Gram's stain, antigen detection tests, and cultures of the eye discharge to rule out gonococcal, chlamydial, or HSV origin. Chlamydia is the most common cause of neonatal conjunctivitis (American Academy of Pediatrics [AAP], 2012a). Gonococcal conjunctivitis is the most serious cause of ophthalmia neonatorum owing to concerns about the bacteria causing blindness (AAP, 2012a). In the newborn, gonococcal conjunctivitis requires intramuscular (IM) ceftriaxone (50 mg/kg, maximum 125 mg) given once (AAP, 2012b). If there are extraocular manifestations, a 7-day course of IM or IV ceftriaxone is warranted. Ceftriaxone is not given to neonates with hyperbilirubinemia; cefotaxime (50 to 100 mg/kg/d divided bid for 7 d) is an alternative used in neonates with hyperbilirubinemia (AAP, 2012b). To prevent ophthalmia neonatorum, the Centers for Disease Control and Prevention (CDC) and the U.S. Preventive Services Task Force recommend prophylactic administration of antibiotic eye medication within 1 hour of delivery (CDC, 2010; US Preventive Services Task Force, 2011). The recommended antibiotic is erythromycin ointment 0.5% (0.25 to 0.5 inch ribbon in each eye).

Chlamydial conjunctivitis in the newborn requires treatment with systemic erythromycin (30–50 mg/kg/d) for 2 to 3 weeks; topical treatment is ineffective (AAP, 2012c). A short course of azithromycin 20 mg/kg per day for 3 days may also be effective (AAP, 2012c). Chlamydial conjunctivitis is not prevented by prophylactic use of erythromycin at birth; therefore, any mucopurulent eye discharge in the first few weeks of life should be evaluated for chlamydia.

Bacterial Conjunctivitis

Children between ages 3 months and 8 years are most likely to have staphylococcal, streptococcal, or *Haemophilus* conjunctivitis. Nontypable *H. influenzae* is seen more in warmer climates between May and October. *S. pneumoniae* is seen in colder climates and during the winter. *S. aureus* shows no geographic or seasonal pattern. In studies of children with acute bacterial conjunctivitis, *H. influenzae* is the most common organism isolated in children younger than 7 years (Buznach et al, 2005; Hautala, Hautala, & Koskela, 2008). *S. aureus* and *Pseudomonas aeruginosa* are the most common pathogens in the elderly (older than age 70) (Hautala et al, 2008).

Although bacterial conjunctivitis is considered a self-limited disease (unless caused by gonorrhea), patients who receive topical antibiotic therapy have faster clinical improvement. When conjunctivitis prevents the patient from going to school or work, antibiotics can speed the recovery. Most schools require treatment for the child to return to school.

Uncomplicated conjunctivitis may be treated with sulfacetamide 10% ophthalmic solution or ointment, erythromycin ointment, trimethoprim/polymyxin B (Polytrim), or bacitracin/polymyxin B (Polysporin). Sulfacetamide gives no

Table 26–2 Clinical and Laboratory Features of Conjunctivitis

Type	Common Patient Group	Common Pathogens	Clinical Features
Ophthalmia neonatorum	Infants <1 mo	*Neisseria gonorrhoeae, Chlamydia*	Erythema, purulent exudate, chemosis
Bacterial conjunctivitis	Most common in children between 3 mo and 8 yr; can happen at any age	*H. influenzae* *S. aureus* *S. pneumonia*	Erythema, purulent discharge, itching, burning, matted eyelashes
Conjunctivitis-otitis syndrome	Predominantly in children <6 yr	*H. influenzae* (~82% of patients)	Bacterial conjunctivitis accompanied by otitis media
Gonococcal conjunctivitis	Newborns, sexually promiscuous teens, and adults	*N. gonorrhoeae*	Eye is markedly inflamed, with copious discharge and swollen lids
Blepharitis	Any age group	May be infected with *S. aureus*	Chronic or acute inflammation of the eyelash follicles
Hordeolum	Any age group	*S. aureus*	Tender, swollen red furuncle along eyelid margin
Viral conjunctivitis	Any age group, most common in children	Adenovirus Herpes simplex virus	Redness, chemosis, photophobia

coverage against *H. influenzae* and stings with application, a consideration in choosing an antibiotic. Gram's stain or culture can further guide the choice of antibiotic. Other choices for uncomplicated bacterial conjunctivitis include tobramycin, gentamicin, azithromycin, or any of the fluoroquinolones. See Table 26–3 for dosing information.

Bacterial conjunctivitis caused by dacryostenosis is most commonly *S. pneumonia* (35%) or *H. influenzae* (20%) and may be treated with erythromycin ophthalmic ointment, tobramycin ophthalmic, or the fluoroquinolones (moxifloxacin, ciprofloxacin, ofloxacin, norfloxacin) (Paysse, Coats, & Cassidy, 2014).

Table 26–3 ⊗ **Dosage Schedule: Ophthalmic Anti-Infectives**

Drug	Indication	Dosage Form	Dose	Comments
Sulfacetamide sodium Bleph 10 Sodium Sulamyd	Conjunctivitis Trachoma	10% solution 10% ointment	Solution: 1–2 drops q2–3h during the day, less often at night Trachoma: 2 drops q2h with systemic therapy Ointment: Small amount tid-qid and qhs	Not recommended for infants <2 mo
Erythromycin Ilotycin	Conjunctivitis and flare-ups of chronic blepharitis Prophylaxis of ophthalmia neonatorum	Ointment: 5 mg/g	Ointment: 0.25 to 0.5 in. ribbon 2–3 times/d Ointment: 0.5 in. ribbon of ointment in each conjunctival sac no later than 1 h after birth	Safe in infants Use a new tube in each infant
Azithromycin Azasite	Bacterial conjunctivitis	Solution: 1%	*Age ≥1 yr*: 1 drop in affected eye(s) bid (8–12 h apart) for 2 d and then once daily for the next 5 d	Not recommended for children <age 1 yr
Gentamicin Garamycin Genoptic	Conjunctivitis	Solution: 3 mg/mL Ointment: 3 mg/g	Severe infections: 2 drops q1h or 0.5 in. ointment q3–4h; may prolong interval as infection improves Mild/moderate infections: 0.5 drop q4h or 0.5 in. of ointment bid–tid	May be used in children
Tobramycin Tobrex	Susceptible infections of conjunctiva and cornea	Solution: 0.3% Ointment: 3 mg/g	Severe infections: 2 drops q1h or 0.5 in. ointment q3–4h; may prolong interval as infection improves Mild to moderate infections: 1–2 drops q4h or 0.5 in. of ointment bid–tid	Safe and effective in children >1 mo
Besifloxacin Besivance	Bacterial conjunctivitis	Suspension: 0.6%	One drop TID × 7 days	Not recommended for children <1 yr of age
Ciprofloxacin Ciloxan	Susceptible infections of conjunctiva and corneal ulcer	Solution: 3 mg/mL	Solution: Corneal ulcer: day 1, 2 drops q15min, then 2 drops q30min; day 2, 2 drops q1h; days 3–14, 2 drops q4h; treat for 14 d or until corneal epithelialization occurs Conjunctivitis: 1–2 drops q2h while awake × 2 d; then 1–2 drops q4h while awake for next 5 d Ointment: For conjunctivitis: 0.5 in. tid × 2 d, then bid × 5 d	Solution not recommended for children <1 yr Ointment not recommended for children <2 yr
Gatifloxacin Zymar	Bacterial conjunctivitis	0.3% solution	*Adults and children ≥1 yr*: 1 drop q2h while awake (max 8 times/day) on days 1 and 2; then 1 drop q4h while awake for next 5 d	Not recommended for children <1 yr

Continued

Table 26–3 ✖ **Dosage Schedule: Ophthalmic Anti-Infectives—cont'd**

Drug	Indication	Dosage Form	Dose	Comments
Levofloxacin Quixin Iquix	Bacterial conjunctivitis	0.5% solution 1.5% solution	*Adults and children ≥1 yr:* 1–2 drops in affected eye q2h while awake on days 1 and 2; then 1–2 drops q4h while awake, up to 4 doses/d on days 3–7	Not recommended for children <1 yr
Moxifloxacin Vigamox Moxeza	Bacterial conjunctivitis	0.5% solution	*Adults and Children ≥1 yr:* 1 drop in affected eye tid for 7 d	Not recommended for children <1 yr
Norfloxacin Chibroxin	Susceptible infections of conjunctiva and cornea	Solution: 3 mg/mL	1–2 drops qid for up to 7 d; may administer q2h while awake on day 1	Not recommended for children <1 yr
Ofloxacin Ocuflox	Susceptible infections of conjunctiva and corneal ulcer	Solution: 3 mg/mL	Corneal ulcer: days 1 and 2, 1–2 drops q20min while awake and 4 and 6 h after re-tiring; days 3–9, 1–2 drops q1h while awake; thereafter, 1–2 drops qid Conjunctivitis: 1–2 drops q2–4h while awake × 2 d, then 1–2 drops qid while awake for next 5 d	Not recommended for children <1 yr
Polymyxin-trimethoprim Polytrim Ophthalmic	Susceptible infections of conjunctiva and cornea	Solution: polymyxin B 10,000 U/g, trimethoprim 1 g/mL	1 drop q3h for 7–10 d, up to 6 doses/d	Not recommended for infants <2 mo Contraindicated in oph-thalmia neonatorum
Polymyxin B–bacitra-cinophthalmic Polysporin Ophthalmic	Susceptible infections of conjunctiva and cornea	Ointment: polymyxin B 10,000 U/g, baci-tracin 500 U/g	Ointment: Apply 0.5 in. ribbon q3–4 h	May be used safely in children
Trifluridine Viroptic	Herpes simplex Type 1 and 2 keratoconjunctivitis	Solution: 1%	1 drop every 2 h while awake (max 9 drops a day). After reepithelialization, 1 drop q4h for 7 d.	Do not exceed recom-mended dose. Not recommended for children <6 yr

Conjunctivitis-Otitis Syndrome

The syndrome of conjunctivitis accompanied by otitis media predominantly occurs in children younger than age 6 years. *H. influenzae* is the causative organism in the majority (82%) of patients with conjunctivitis-otitis syndrome (Buznach et al, 2005). Treatment is systemic antibiotics that are effective against *H. influenzae.* Amoxicillin-clavulanate (Augmentin) with amoxicillin dosed at 80 to 90 mg/kg/d is the first-line drug of choice. If systemic antibiotics are prescribed, topical ophthalmic treatment is usually not needed. See Chapter 46 for management of otitis media.

Gonococcal Conjunctivitis

Purulent bacterial conjunctivitis usually responds to topical antibiotic therapy. An exception is hyperpurulent gonococcal conjunctivitis, which is usually found in the newborn and in sexually promiscuous teenagers and adults. The eye discharge should be gram stained and cultured to confirm the diagnosis. Treatment consists of parenteral antibiotics (ceftriaxone 1 g IM in a single dose [CDC, 2010]) and sterile saline irrigations to clear the exudate. Use of a beta-lactamase–resistant cephalosporin such as ceftriaxone is warranted due to high levels of resistance to other antibiotics. Because untreated gonococcal infection can penetrate the intact eye, treatment should begin as soon as the diagnosis is suspected.

Blepharitis

Blepharitis is an acute or chronic inflammation of the eyelash follicles and meibomian glands of the eyelids. Treatment con-sists of warm compresses for 5 to 10 minutes at a time 2 to 4 times a day; scrubbing the eyelashes with gentle, no-tears shampoo; and applying erythromycin ophthalmic ointment (0.25-in. ribbon to each eye twice a day) until the symptoms clear and then for an additional 7 days. Ointment is preferred in the treatment of blepharitis due to the increased contact with the ocular tissue. Azithromycin 1% ophthalmic solution for 4 weeks may also be used (Shtein, 2014). The patient should not wear contact lenses during treatment, and the contacts should be sterilized before reinserting. Eye makeup should be discarded to prevent reinfection (Shtein, 2014).

Hordeolum

Hordeolum, commonly called a *sty,* is an infection of the sebaceous gland of the eyelash or eyelid. The causative organism is *S. aureus.* Treatment consists of warm, moist compresses 4 times a day for 15 minutes each time. Antibiotic eyedrops (sulfacetamide 10% or Polytrim drops) or ointment (erythromycin 0.5%) should be applied 4 times a day until the symptoms subside and then for an additional 2 to 3 days. The hordeolum usually spontaneously ruptures; if it does not, the patient should be referred to an ophthalmologist. Multiple or recurrent hordeolum may require systemic antibiotic treatment with dicloxacillin or other antibiotic that treats staph.

Viral Conjunctivitis

Viral conjunctivitis is usually caused by an adenovirus, HSV, or herpes zoster. Simple viral conjunctivitis caused by adenovirus is treated with sulfacetamide 10% solution or ointment 4 times a day or a broad-spectrum antibiotic, such as tobramycin, to prevent secondary bacterial infection. The course of the conjunctivitis runs 12 to 15 days. Herpes keratitis is a potentially serious consequence of infection with HSV. If herpes keratitis is suspected, a referral to an ophthalmologist for diagnosis and treatment is indicated. Commonly used antiviral agents are gancyclovir, trifluridine, and vidarabine. Table 26-3 presents the dosage schedule of ophthalmic anti-infectives.

Rational Drug Selection

Efficacy

A determination of the suspected organism guides the choice of an ophthalmic antibiotic. If *H. influenzae* is high on the list of suspected organisms, then sulfacetamide should not be the first choice for treatment because it has poor coverage for *H. influenzae.* A combination product such as Polysporin or Polytrim provides good coverage for the common organisms that cause bacterial conjunctivitis. In infants, erythromycin is usually the drug of choice because of its good coverage, and ointment is more easily administered than drops.

Cost

The least expensive ophthalmic is generally generic erythromycin, bacitracin, or sulfacetamide 10%. Azithromycin and the fluoroquinolones are more expensive, up to 10 times the cost of erythromycin.

Monitoring

There is no laboratory monitoring necessary with ophthalmic anti-infectives.

Lifestyle Management

The most important nonpharmacological measure is for the patient and family members to wash their hands thoroughly whenever the infected eyes are touched and before instilling medication. Hand washing will decrease spread of the infection to other contacts.

The patient with an eye infection should not share hand towels with the rest of the family. The patient with an eye

---

CLINICAL PEARL

Proper Instillation of Eyedrops

- Wash hands before administering eyedrops.
- Tilt head back or lie on back.
- Gently pull down lower eyelid to form a "pocket" to place the drop of medication into.
- Squeeze the medication onto the eye without touching eye with the dropper.
- Close eye. Do not rub. Try not to blink.
- To prevent cross-contamination, do not use medication labeled for another patient.
- Wait at least 5 minutes between administrations if administering more than one eye medication.

Proper Instillation of Eye Ointment

- Wash hands prior to administering eye medications.
- Warm the ointment by holding it in the hand for 1 to 2 minutes.
- With first use of a new tube, squeeze out and discard the first 0.25 in. of medication.
- Angle head back or lie on back.
- Gently pull down lower eyelid to form a "pocket" to place the drop of medication into.
- Squeeze 0.25 to 0.5 in. of medication onto the eye without touching eye with tip of tube.
- Close eye for 1 to 2 minutes. Do not rub.
- Wipe excess medication from around the eye with a tissue.
- To prevent cross-contamination, do not use medication labeled for another patient.
- Wait at least 10 minutes between administrations if administering more than one eye medication.
- Temporary blurred vision is typical after administration of ophthalmic ointment.

---

infection should use a separate towel or paper towels to prevent the spread of infection to family members.

Eye makeup needs to be thrown away after an eye infection because mascara and other makeup can harbor bacteria or viruses, and the patient can become re-infected.

Crusty, purulent discharge can be irritating and may be distressing to children whose eyes become "glued shut" with the dried discharge. Purulent discharge can be removed with cotton balls moistened with warm water. The cotton ball is wiped gently from the interior canthus to the external canthus to remove discharge. A clean cotton ball should be used for each wipe and for each eye. If a washcloth is used, patients or parents should be instructed to use a clean area of the cloth for each swipe of the eye and to use a clean washcloth every time.

Patient Education

Administration

Administration of ophthalmic medications can be challenging for patients. The patient should be instructed in the importance of keeping the tip of the dropper or tube from

touching the eye, fingertips, or any other surface to prevent contamination. Hands should be washed before and after instillation of eye medications. Eye medications should not be shared.

Ophthalmic ointment should be transferred from the tube onto a moistened cotton swab, then rolled into each conjunctival sac. Use one swab for each eye to prevent contamination.

Eyedrops are self-administered by holding the bottle of solution in the dominant hand and using the pointer finger of the other hand to gently pull down the lower eyelid to form a "pocket" for the solution to be dropped into. The patient can use this method for both eyes.

For children who may resist the "bull's-eye" method of instilling eyedrops, one of three methods may be used. School-age children can assist with the instillation by pulling down their own lower eyelid, while the parent or care provider instills the eyedrop into the pocket formed. If this method doesn't work, a child may lie down on his or her back and close the eyes, keeping the head still. A drop of the antibiotic or antiviral is placed on the inner canthus. After the eyedrops are placed on the internal canthus, the child should slowly open his or her eyes without moving the head. The eyedrops instill into the eyes. Younger children require immobilization to instill eyedrops or ophthalmic ointment. This can be accomplished by two people, one to hold the child and the other to administer the medication.

Adverse Reactions

The patient should be instructed that there might be transient burning or stinging with most of the ophthalmic anti-infective agents. If burning is severe or prolonged, the patient should contact the provider. Other adverse effects should be discussed with the patient, with instructions to report any unusual symptoms.

ANTIGLAUCOMA AGENTS

Glaucoma is a group of disorders in which IOP damages the optic nerve. In the United States, glaucoma affects 2.2 million people and is the leading cause of blindness in the world

---

CLINICAL PEARL

Tips for Administering Eye Medications to a Child
If only one adult is available to administer eyedrops, then the adult can sit on the floor with the child between his or her legs, with the child's legs in the same direction as the adult's. The child's head can be immobilized between the adult's thighs and the arms held firmly down under the adult's thighs. This leaves the adult's hands free to instill the medication. The child may kick, but this will not affect the administration of the medication. Although this method may sound drastic, trying to administer eye medication to a squirming toddler or preschooler can be almost impossible, and with this method, the eyedrops can be effectively administered in less than 1 minute.

(Glaucoma Research Foundation, 2013). Glaucoma can affect a patient of any age; 1 in 10,000 newborns is diagnosed with congenital glaucoma and 8% of adults over age 70 years are diagnosed with glaucoma (Glaucoma Research Foundation, 2013). Blindness from glaucoma is 6 to 8 times more common among African Americans than Caucasians. The patient may have open-angle glaucoma, in which a block at the level of the trabecular meshwork impairs aqueous humor reabsorption, or the patient may have angle-closure glaucoma, which develops when the normal path of the aqueous flow is interrupted in an eye with a shallow anterior chamber. Current medical therapies are aimed at decreasing the production of aqueous humor at the ciliary body and at increasing the outflow of this fluid from the angle structures. Glaucoma or the suspicion of glaucoma requires evaluation and treatment by an ophthalmologist. Primary care providers need to be aware of the medications that are prescribed, the drug interactions that may occur, and the adverse effects of the prescribed medications.

Pharmacodynamics

The antiglaucoma agents can be roughly divided into the following categories: beta blockers, adrenergic agonists, miotics, carbonic anhydrase (CA) inhibitors, sympathomimetics, and the prostaglandin agonist latanoprost (Xalatan).

Beta Blockers

Beta-adrenergic antagonists, also known as beta blockers, reduce IOP by interference with the production of aqueous humor induced by cyclic adenosine monophosphate (cAMP) through the ciliary processes in the eye, although the exact mechanism of action is not known. IOP is reduced in patients with either elevated or normal IOP. Visual acuity, pupil size, and accommodation do not appear to be affected by ophthalmic beta blockers.

Miotics, Cholinesterase Inhibitors

Cholinesterase inhibitors are indirect-acting agents that inhibit the cholinesterase enzyme. Topical application to the eye causes intense miosis and muscle contraction. The IOP is reduced by a decreased resistance to aqueous outflow. The cholinesterase inhibitors are divided into reversible and irreversible agents. The reversible agents physostigmine and demecarium combine with cholinesterase, and as the resulting union is hydrolyzed, the cholinesterase regenerates over a number of hours. Echothiophate iodide (Phospholine) is considered an irreversible agent that binds to cholinesterase in a covalent bond that does not hydrolyze. Cholinesterase must be synthesized or drawn from other parts of the body in order for ophthalmic action to return to normal.

Miotics, Direct-Acting

The direct-acting miotics are parasympathomimetic (cholinergic) drugs with muscarinic effects. When applied topically, these drugs produce pupillary constriction, stimulate the

ciliary muscles, and increase aqueous humor outflow. They also reduce outflow resistance by contraction of the iris sphincter. IOP is decreased with the increase in outflow.

Carbonic Anhydrase Inhibitors

CA inhibitors decrease aqueous humor secretion by slowing the formation of bicarbonate ions. This reduces sodium and fluid transport, leading to decreased aqueous humor production and subsequent decreased IOP.

Sympathomimetics

Sympathomimetics applied topically cause vasoconstriction, papillary dilation, and reduction of IOP. It is believed that sympathomimetics reduce IOP by reducing the production of aqueous humor and by increasing aqueous humor outflow.

Alpha-Adrenergic Agonists

Alpha-adrenergic agonists reduce IOP by reducing the production of aqueous humor and by increasing uveoscleral outflow.

Prostaglandin Agonists

Latanoprost is a selective agonist of a prostaglandin receptor known as the FP receptor. Latanoprost increases the outflow of aqueous humor by acting on this receptor, which leads to decreased IOP. Bimatoprost (Lumigan) is a prostamide, a synthetic prostaglandin. It lowers IOP by increasing aqueous humor outflow. Unoprostone (Rescula) and Travoprost (Travatan) are synthetic prostaglandin $F_{2\alpha}$ analogues whose exact mechanism of action is unknown, although they are thought to reduce IOP by decreasing uveoscleral outflow. Bimatoprost is also marketed as Latisse for treatment of eyelash hypotrichosis. Patients should experience thicker and darker eyelashes after 2 months of treatment.

Pharmacokinetics

Little is known about the specific pharmacokinetic parameters of the beta blockers. The duration of action is noted in Table 26-4. What is known is determined by clinical observation of pharmacodynamic responses. The amount of absorption is unknown, but systemic absorption is known to occur because both cardiac and pulmonary signs of beta blocker activity can occur. Beta blockers are metabolized in the liver and excreted in the urine and feces.

The pharmacokinetics of cholinesterase inhibitors and the direct-acting miotics are not known. The duration of action is noted in Table 26–4.

Following topical administration into the eye, brinzolamide (Azopt) is absorbed systemically, although plasma concentrations remain low and generally below the level of detection. It is widely distributed, including into the breast milk in animal studies. It may cross the placenta. Brinzolamide is metabolized to *N*-desthyl brinzolamide and excreted primarily in the urine.

Dorzolamide (Trusopt), when applied topically to the eye, has some systemic absorption, although no free drug is

Table 26–4 ■ Pharmacokinetics: Antiglaucoma Agents

Drug	Duration
Beta Blockers	
Betaxolol, carteolol	12 h
Levobunolol, metipranolol, timolol	12–24 h
Miotics	
Carbachol	6–8 h
Pilocarpine	4–8 h
Echothiophate	Days/weeks
Carbonic Anhydrase Inhibitors	
Acetazolamide	8–12 h
Brinzolamide	NA
Dorzolamide	About 8 h
Methazolamide	10–18 h
Sympathomimetics	
Epinephrine, dipivefrin	12 h
Alpha-Adrenergic Agonists	
Apraclonidine	7–12 h
Brimonidine	12 h
Prostaglandin Analogues	
Latanoprost	24 h
Bimatoprost	1.5 h
Unoprostone	<1 h
Travoprost	<1 h

NA = information not available.

measured in the plasma. Dorzolamide is excreted primarily unchanged in the urine.

Methazolamide (Neptazane) is an oral CA inhibitor. It is well absorbed from the gastrointestinal (GI) tract. Methazolamide is distributed throughout the body, including the plasma, cerebrospinal fluid, aqueous humor of the eye, red blood cells, bile, and extracellular fluid. Its exact metabolism is not described. Excretion is primarily renal, with 25% of the drug excreted unchanged in the urine.

The pharmacokinetics of the sympathomimetics is not known.

Following ophthalmic administration of brimonidine (Alphagan), peak serum levels occur in 1 to 4 hours. Brimonidine is extensively metabolized in the liver and eliminated in the urine.

Latanoprost is absorbed through the cornea, where it is hydrolyzed to become biologically active. Plasma levels of latanoprost can be measured. Distribution is unknown. It is not known whether latanoprost crosses the placenta, although in animal studies adverse fetal effects were found. It is not known whether latanoprost is excreted in breast

milk. Latanoprost is metabolized via fatty-acid beta oxidation in the liver. The metabolites are excreted primarily in the urine (88%).

Bimatoprost is absorbed and reaches a steady state in the plasma, with 12% remaining unbound in human plasma. It is metabolized by oxidation and is excreted in the urine (67%) and feces (25%). Travoprost is rapidly absorbed from the cornea and peaks in the plasma within 30 minutes. Travoprost is hydrolyzed by esterases in the cornea into free acid. Elimination of travoprost is rapid and within an hour of administration levels are unmeasurable. Unoprostone is rapidly absorbed from the cornea and hydrolyzed into unoprostone-free acid, which is eliminated rapidly in the urine.

Table 26-4 presents the pharmacokinetics of antiglaucoma agents.

Pharmacotherapeutics
Precautions and Contraindications

Although primary care providers do not prescribe ophthalmic antiglaucoma agents, the medications are absorbed and systemic levels reached in great enough amounts to cause complications of chronic conditions. Coordination of care with the ophthalmologist will ensure the optimal care for the patient's glaucoma and other medical problems.

The beta blocker ophthalmic medications are contraindicated in patients with asthma, a history of asthma, chronic obstructive pulmonary disease (COPD), or other pulmonary disease. There may be bronchospasm associated with the use of topical beta blockers, which may prove fatal to patients with respiratory disease.

Beta Blockers

Beta blockers suppress conduction through the atrioventricular (AV) node; therefore, topical beta blockers are contraindicated in patients with bradycardia or advanced AV block. Beta blockers should not be used in patients with compromised ventricular dysfunction, patients in cardiogenic shock, or patients with systolic congestive heart failure. Discontinue topical beta blockers at the first sign of cardiac failure. Beta blockers are contraindicated for patients with hypotension (standing blood pressure [SBP] less than 100 mm Hg).

Beta blockers should be used with caution in patients with poorly controlled diabetes mellitus because beta blockers can prolong or enhance hypoglycemia by interfering with glycogenolysis. Beta blockers may also mask the signs and symptoms of acute hypoglycemia. Because they may mask the clinical signs of hypothyroidism, beta blockers should be used with caution in patients with hyperthyroidism.

Patients using beta blockers during surgery should be monitored closely for signs of cardiac failure. Severe, protracted hypotension and difficulty in restarting the heart have been reported. Beta blockers may need to be withdrawn before surgery, with the last dose 2 days prior to surgery. Beta blockers are also contraindicated in patients with Raynaud's disease or peripheral vascular or cerebrovascular disease because decreased cardiac output can exacerbate symptoms.

Ophthalmic beta blockers are Pregnancy Category C. Fetal anomalies and fetotoxicity have been observed in animal studies. Most of the ophthalmic beta blockers are excreted in breast milk and are contraindicated in breastfeeding. Ophthalmic beta blocker agents are used in children, but they must be monitored closely.

Miotics

The miotics are contraindicated when active inflammation of the eye is present. They are also contraindicated when constriction is not wanted, for example, in iritis, uveitis, and some forms of secondary glaucoma.

The miotics are Pregnancy Category C, with demecarium (Humorsol) given the classification of Pregnancy Category X. Use with caution in lactating women. Use with extreme caution in children.

Carbonic Anhydrase Inhibitors

Dorzolamide and brinzolamide contain sulfonamide and are absorbed in amounts great enough to cause hypersensitivity reactions in patients with sulfonamide sensitivity. Dorzolamide and brinzolamide are Pregnancy Category C. They are contraindicated in lactation, and their safety for use in children is not known.

Methazolamide is contraindicated in patients with hyponatremia, hypokalemia, renal disease, liver disease, suprarenal gland failure, hyperchloremic acidosis, adrenocortical insufficiency, and severe pulmonary obstruction. It is Pregnancy Category C and not recommended for use in children.

Sympathomimetics

Apraclonidine (Iopidine) is contraindicated in patients with clonidine hypersensitivity. Dipivefrin (AKPro, Propine) is contraindicated in patients with narrow-angle glaucoma and aphakic patients. Apraclonidine is Pregnancy Category C, and dipivefrin is Pregnancy Category B. They are not recommended for use by nursing mothers or by children.

Alpha-Adrenergic Agonists

Brimonidine is contraindicated in patients taking monoamine oxidase inhibitors (MAOIs). Brimonidine should be used with caution in patients with cardiac, renal, or liver disease. It should not be instilled with contact lenses in place, and the patient should wait 15 minutes after instilling brimonidine before replacing contacts. Brimonidine is Pregnancy Category B. It should be avoided in children and lactating women.

Prostaglandin Agonists

Latanoprost should not be administered while the patient is wearing contact lenses. It should be used with caution in patients with intraocular inflammation (iritis) and aphakic patients. It is Pregnancy Category C, and it is not recommended for use during lactation or by children. Bimatoprost is Pregnancy Category C. If brimatoprost (Latisse) is being prescribed for hypotrichosis, it may lower IOP in patients with normal IOP, but the magnitude of change is not clinically significant.

Adverse Drug Reactions

All of the antiglaucoma medications may cause transient discomfort or tearing. Blurred vision, photophobia, and hyperemia may also occur. Allergic conjunctivitis may occur with any of the topical ophthalmic medications.

Headaches and dizziness may occur with the use of beta blockers. Patients may exhibit systemic beta blocker effects with the use of ophthalmic preparations. Symptoms include bradycardia, hypotension, bronchospasm, and, rarely, AV block.

Miotics may cause corneal clouding, ciliary spasm, headache, induced myopia, and retinal detachment. Patients may have systemic anticholinergic effects if excessive absorption occurs. These symptoms include headache, hypertension, salivation, sweating, nausea, and vomiting. Iris cysts may be seen with cholinesterase inhibitors.

Many patients (about 25%) report dysgeusia, or bitter taste in the mouth, after ocular administration of CA inhibitors. Superficial punctate keratitis is reported in 10% to 15% of patients using ophthalmic preparations.

Systemic CA inhibitors (methazolamide) may cause melena and GI upset, such as anorexia, nausea, and vomiting. Glycosuria and urinary frequency have been reported. Weakness, malaise, fatigue, bone marrow depression, thrombocytopenia, leukopenia, and hemolytic anemia have been reported with use of methazolamide. Renal calculi and nephrotoxicity have also been reported. Fever is a rare adverse effect of methazolamide.

The local effects of the sympathomimetics include conjunctival or corneal pigmentation. Systemic effects of topical sympathomimetic use include headache, hypertension, tachycardia, and cardiac arrhythmias (with excessive absorption).

The local effects of alpha agonists that occur in 10% to 30% of patients include the sensation of a foreign body in the eye and ocular pain. Systemic adverse effects include dry mouth, drowsiness, and headache. Corneal staining may occur.

The local adverse effects reported in 5% to 15% of patients using prostaglandin agonists include foreign body sensations, keratopathy, and iridal discoloration. The iridal discoloration may be gradual (many months) and is caused by an increase in the amount of brown pigmentation in the iris because of an increased number of melanosomes in melanocytes. The color change may be permanent. Bimatoprost (Latisse) may cause permanent brown iris pigmentation and hair growth outside the treatment area and must be applied only to the upper eyelid, using the sterile applicator supplied, and not allowed to drip down onto the cheek or other skin area.

Drug Interactions

Beta Blockers

The use of ophthalmic beta blockers with systemic beta blockers may cause additive beta blockade effects. Coadministration of ophthalmic timolol has caused bradycardia and asystole.

Miotics

Carbachol and pilocarpine solution have no reported drug interactions. Pilocarpine ocular sustained-release inserts (Ocusert Pilo) potentiate the absorption of epinephrine. Echothiophate may potentiate the effects of succinylcholine, leading to respiratory and possibly cardiovascular collapse. Echothiophate may have additive effects when used with systemic anticholinesterases used in the treatment of myasthenia gravis. There is additive toxicity (increased parasympathomimetic effects) if organic pesticides or carbamate is absorbed by someone using ophthalmic echothiophate.

Carbonic Anhydrase Inhibitors

Concurrent use of CA inhibitors (topical brinzolamide, dorzolamide, and systemic methazolamide) and high-dose salicylates may lead to metabolic acidosis and salicylate toxicity, which allow greater penetration of salicylate into the central nervous system (CNS). This interaction is theoretical with the topical CA inhibitors. CA inhibitors may inhibit excretion of basic drugs and promote excretion of acidic drugs. The concurrent use of oral and topical CA inhibitors is not recommended.

Sympathomimetics

There are no known drug interactions with ophthalmic dipivefrin. Apraclonidine may interact with cardiovascular drugs. Apraclonidine should not be used by patients who are using MAOIs because concurrent use may cause a hypertensive crisis.

Alpha-Adrenergic Agonists

The alpha-adrenergic agonists are contraindicated with the use of MAOIs. There may be additive CNS depression if topical alpha-adrenergic agonists are used concurrently with CNS depressants. Tricyclic antidepressants can affect the metabolism and uptake of circulating amines. Medications that may cause bradycardia (beta blockers, antihypertensives, and cardiac glycosides) may have additive depression of pulse and blood pressure if used concurrently with alpha-adrenergic agonists.

Prostaglandin Agonists

The only reported drug interaction noted with latanoprost is thimerosal, which can cause precipitation if administered concurrently. Advise the patient to wait at least 5 minutes between administration of two ophthalmic medications if one contains thimerosol.

Table 26-5 presents drug interactions with antiglaucoma agents.

Clinical Use and Dosing

Glaucoma

Antiglaucoma medications are prescribed by ophthalmologists. Dosage is determined by the clinical condition of the patient.

Rational Drug Selection

The ophthalmologist determines what medication should be used, based on the patient's glaucoma type and underlying medical conditions.

Table 26–5 ⠿ Drug Interactions: Antiglaucoma Agents

Drug	Interacting Drug	Possible Effect	Implications
Beta Blockers			
Betaxolol, carteolol, metipranolol	Oral beta blockers	Additive effects, excessive hypotension, increased reduction of IOP	Use with caution
	Antihypertensive agents	Additive antihypertensive effects	Monitor BP
	Antiarrhythmics (diltiazem, verapamil, amiodarone, digoxin)	Additive effects; may cause significant effects on AV node conduction; may cause complete heart block	Use with caution, monitor closely
	Beta agonist bronchodilators (albuterol, metaproterenol [Alupent], salmeterol)	Beta blocker may antagonize the effects of beta agonists	Use with caution; avoid concurrent use if possible
Levobunolol	Oral beta blockers	Additive effects, excessive hypotension, increased reduction of IOP	Use with caution
	Cimetidine	Interferes with hepatic metabolism of levobunolol, potentially increasing its effects	Avoid concurrent use
	Sympathomimetics, including inhaled beta agonists	Antagonism of desired therapeutic effects	Avoid concurrent use
Timolol	Oral beta blockers	Additive effects, excessive hypotension, increased reduction of IOP	Use with caution
	Antihypertensive agents	Additive antihypertensive effects	Monitor BP
	Antiarrhythmics (diltiazem, verapamil, amiodarone, digoxin)	Additive effects; may cause significant effects on AV node conduction; may cause complete heart block	Use with caution; monitor closely
	Verapamil	Coadministration of ophthalmic timolol has caused bradycardia and asystole	Do not use concurrently
	Beta-agonist bronchodilators (albuterol, metaproterenol [Alupent], salmeterol)	Timolol may antagonize the effects of beta agonists	Use with caution; avoid concurrent use if possible
	Quinidine	Quinidine can potentiate timolol-induced bradycardia	Use with caution; monitor closely
Miotics			
Carbachol, pilocarpine	No significant interactions		
Echothiophate	Succinylcholine (anesthetic)	May potentiate succinylcholine, leading to possible respiratory and cardiovascular collapse	Do not use concurrently; consider stopping echothiophate before surgery
	Systemic anticholinesterases	Additive effects	Coadminister cautiously
	Carbamate or organophosphate insecticides and pesticides	Increased parasympathomimetic effects	Warn patients who are gardeners or workers who may be exposed to these chemicals to protect themselves with masks, frequent washing of skin, and clothing changes
Carbonic Anhydrase Inhibitors			
Acetazolamide Brinzolamide	Barbiturates, aspirin, lithium	Excretion decreased	May lead to decreased effectiveness of interacting drugs
	Amphetamines, quinidine, procainamide, tricyclic antidepressants	Excretion decreased	May result in toxicity to interacting drugs
	No known drug interactions		
Dorzolamide	Oral CA inhibitors	Potential additive effects	Concurrent use not recommended
Methazolamide	Diflunisal	Significant decrease in IOP	Avoid concurrent use
	Salicylates	Accumulation of methazolamide, resulting in CNS depression and metabolic acidosis	Avoid concurrent use
	Topiramate	Increased risk of renal stone formation	Avoid concurrent use
	Basic pH drugs	Inhibited renal excretion of basic drugs	

Table 26–5 ▦ Drug Interactions: Antiglaucoma Agents—cont'd

Drug	Interacting Drug	Possible Effect	Implications
	Acidic pH drugs	Promotes excretion of acidic drugs	Monitor potassium
	Corticosteroids, potassium-depleting diuretics	Hypokalemia	Monitor potassium
Sympathomimetics			
Epinephrine	Anesthetics (cyclopropane, halogenated hydrocarbons)	May cause cardiac arrhythmias	Discontinue epinephrine prior to surgery
Dipivefrin	No significant interactions		
Alpha-Adrenergic Agonists Apraclonidine	Cardiovascular agents: antihypertensives, cardiac glycosides, beta blockers MAOIs	Apraclonidine may reduce pulse and BP	If using concurrently, monitor pulse and BP frequently Concurrent use contraindicated
Brimonidine	CNS depressants: alcohol, barbiturates, opiates, sedatives, or anesthetics Beta blockers, antihypertensives Tricyclic antidepressants MAOIs	Additive CNS depression Brimonidine may reduce pulse pressure and BP Tricyclic antidepressants can lower circulating amines	Use with caution Use with caution; monitor cardiac status Monitor IOP closely if necessary to administer concurrently Use contraindicated
Prostaglandin Analogues Latanoprost	Thimerosal	Precipitation of latanoprost occurs when used concurrently	Administer at least 5 to 10 min apart
Bimatoprost	No significant interactions		Allow 5 min between application of other topical ophthalmic agents
Unoprostone	No significant interactions		Allow 5 min between application of other topical ophthalmic agents
Travoprost	No significant interactions		Allow 5 min between application of other topical ophthalmic agents

IOP = intraocular pressure; BP = blood pressure; AV = atrioventricular; CA = carbonic anhydrase; CNS = central nervous system; MAOIs = monoamine oxidase inhibitors.

Monitoring

The patient who is prescribed antiglaucoma medications may require monitoring of blood pressure and cardiovascular status. IOP is measured and monitored by the ophthalmologist. No laboratory monitoring is necessary.

Patient Education

Administration

The patient should be instructed to administer the medication exactly as the ophthalmologist has prescribed (Table 26-6). Abruptly stopping the medication can increase adverse effects.

Adverse Reactions

The patient should have been instructed by the ophthalmologist regarding the adverse effects of the medication. Reinforcement may be necessary. If the patient is experiencing adverse effects

from the medication, the primary care provider can facilitate a referral back to the ophthalmologist.

OCULAR ANTIALLERGIC AND ANTI-INFLAMMATORY AGENTS

There are several ocular antiallergic and anti-inflammatory drugs. The antiallergic medications include the mast cell stabilizers lodoxamide (Alomide), nedocromil (Alocril) and cromolyn sodium (Crolom). Levocabastine (Livostin), antazoline (Vasocon-A, Antazoline-V), azelastine (Optivar), bepotastine (Bepreve), epinastine (Elestat), emedastine (Emadine), ketotifen (Zaditor), olopatadine (Patanol, Pataday), pheniramine (Naphcon-A), and emedastine (Emadine) are antihistamines. The NSAIDs are flurbiprofen (Ocufen), suprofen (Profenal), diclofenac (Voltaren ophthalmic

Table 26–6 ❈ Available Dosage Forms: Antiglaucoma Agents

Drug	Dosage Form	How Supplied
Beta Blockers		
BETAXOLOL		
Betoptic*	Solution: 5.6 mg/mL	In 2.5, 5, 10, 15 mL
Betoptic S*	Suspension: 2.8 mg/mL	In 2.5, 5, 10, 15 mL
CARTEOLOL		
Ocupress	1% solution	In 5 or 10 mL dropper bottles
Generic	1% solution	In 5, 10, 15 mL bottles
LEVOBUNOLOL		
Betagan	0.25% solution	In 5 or 10mL bottles
AKBeta, Generic	0.5% solution	In 2, 5. 10, or 15 mL bottles
	0.25% solution	In 5 or 10 mL bottles
	0.5% solution	In 5, 10, or 15 mL bottles
METIPRANOLOL		
OptiPranolol	0.3% solution	In 5 or 10 mL dropper bottle
TIMOLOL		
Timoptic	0.25%, 0.5% solution	In 2.5,5,10, or 15 mL bottles
Timoptic-XE	0.25%, 0.5% gel	In 2.5 or 5 mL bottles
Betimol	0.25%, 0.5% solution	In 5, 10, or 15 mL bottles
Generic	0.25%, 0.5% solution	In 5, 10, or 15 mL bottles
		In 5, 10, or 15 mL bottles
COMBINATION PRODUCTS		
β blocker timolol and Carbonic anhydrase inhibitor dorzolamide Cosopt	Solution: Timolol 0.5% and dorzolamide 2%	10 mL
Miotics		
CARBACHOL		
Isopto Carbachol	0.75% solution, 1.5% solution	In 15 or 30 mL dropper bottles
Carboptic	2.25% solution	In 15 mL bottles
	3% solution	In 15 or 30 mL dropper bottles
	3% solution	In 15 mL bottle
PILOCARPINE		
Isopto Carpine	Solution: 0.25%, 0.5%, 1%, 2%, 3%, 4%, 5%, 6%, 10%	In 15 or 30 mL dropper bottles
Pilocar		In 15 or 30 mL dropper bottles
Pilopine HS	Solution: 0.5%, 1%, 2%, 3%, 4%, 6%	In 3.5 g
Generic	Gel: 4%	In 15 or 30 mL dropper bottles
	Solution: 0.5%, 1%, 2%, 4%, 6%, 8%	
ECHOTHIOPHATE		
Phospholine iodide	Powder for solution: 0.03%, 0.06%, 0.125%, 0.25%	In 5 mL diluent
Carbonic Anhydrase Inhibitors		
ACETAZOLAMIDE		
Diamox	Tablets: 125 mg, 250 mg	In 100s
BRINZOLAMIDE		
Azopt*	1% suspension	In 10, 15 mL
DORZOLAMIDE		
Trusopt*	2% solution	In 5, 10 mL
METHAZOLAMIDE		
Neptazane	Tablets: 25 mg, 50 mg	In 100s
Generic	Tablets: 25 mg, 50 mg	In 100s

*Contains benzalkonium chloride, which cannot be administered with soft contact lenses in place.
†Contains sulfites.

solution), nepafenac (Nevanac), and ketorolac (Acular). Corticosteroid ophthalmic agents are used as anti-inflammatories, although they are rarely used in primary care because of the serious adverse effects. Anti-inflammatory agents are found in single formula or in combination with antibiotics.

Pharmacodynamics
Ophthalmic Antiallergic Agents
The mast cell stabilizers limit hypersensitivity reactions by inhibiting the degranulation of sensitized mast cells that occur after exposure to specific antigens. They also inhibit the release of histamine and SRS-A (slow-reacting substance of anaphylaxis). They have no intrinsic antihistamine activity.

Ocular antihistamines are selective for the H_1 histamine receptor. They block the H_1 histamine receptors and inhibit histamine-stimulated vascular permeability in the conjunctiva. This relieves ocular pruritus associated with allergic conjunctivitis.

Ocular Anti-Inflammatory Agents
The ocular NSAIDs have analgesic, antipyretic, and anti-inflammatory activity. The ophthalmic NSAIDs reduce prostaglandin E_2 in aqueous humor by inhibition of prostaglandin biosynthesis. The mechanism is thought to be by means of the inhibition of cyclo-oxygenase enzyme, which is essential to the synthesis of prostaglandins.

Topical steroids exert an anti-inflammatory action. The exact mechanism of action for ocular corticosteroids is not known. They are thought to act by the induction of phospholipase A_2 inhibitory proteins. These proteins control the mediators of inflammation, such as prostaglandins and leukotrienes. Corticosteroids can increase IOP; the mechanism is not clear.

Pharmacokinetics
Limited systemic absorption occurs with the use of ophthalmic anti-inflammatory and antiallergic agents. The metabolism and excretion of ophthalmic antiallergic and anti-inflammatory agents are unknown.

Pharmacotherapeutics
Precautions and Contraindications
Hypersensitivity to any component of the product is a contraindication for any of the ophthalmic medications. Use caution with patients with known sensitivity to acetylsalicylic acid when prescribing NSAIDs because cross-sensitivity may occur.

Ophthalmic Antiallergic Agents

Patients should not wear soft contact lenses while inserting any ophthalmic product that contains benzalkonium chloride (cromolyn sodium, lodoxamide, ketotifen, emedastine, levocabastine). Wear can be resumed within a few hours of discontinuing cromolyn, levocabastine, lodoxamide, and nepanfenac. Patients who are using ketotifen and emedastine may wear their soft contacts if they wait at least 10 minutes after instilling the eyedrops to insert their contacts.

Emedastine, cromolyn sodium, and lodoxamide are Pregnancy Category B. Antazoline, ketotifen, levocabastine, and nepafenac are Pregnancy Category C, although no studies have been done on pregnant women. Safe use in lactation has not been established, although such minimal amounts are absorbed that use during lactation is probably safe.

Lodoxamide is safe in children as young as age 2. Cromolyn sodium ophthalmic can be prescribed to children older than age 4. The safety of emedastine and ketotifen in children younger than age 3 has not been established. Nepanfenac is not recommended for children younger than 10 years of age.

Ocular Anti-Inflammatory Agents

Referral to an ophthalmologist is warranted for patients who appear to need corticosteroid therapy. They require slit-lamp examination to rule out herpes keratitis prior to initiating therapy.

Corticosteroid eye medications should not be administered to patients with acute, untreated purulent bacterial, viral, or fungal ocular infection. Prescribing ophthalmic corticosteroids to a patient with herpes keratitis can lead to serious complications, including blindness. This may also occur with ocular NSAIDs; therefore, a referral is indicated before treatment.

The ocular NSAIDs are Pregnancy Category C, and the ocular corticosteroids are also Pregnancy Category C. Safety in children has not been established.

Adverse Drug Reactions

All ophthalmic antiallergic and anti-inflammatory medications may cause transient discomfort or tearing. Blurred vision, photophobia, and hyperemia may also develop. Allergic conjunctivitis may occur with any of the topical ophthalmic medications.

Other adverse reactions reported (1% to 5%) with the use of the mast cell stabilizer lodoxamide include dry eye, foreign body sensation, ocular itching and pruritus, and crystalline deposits. Cromolyn sodium may also cause itchy eyes, eye dryness and puffiness, and stys.

The most frequent adverse reaction reported with the use of ocular H_1 histamine blockers is headache. Conjunctival injection and rhinitis are reported in 10% to 25% of patients treated. The adverse reactions that occur in fewer than 5% of patients include asthenia, blurred vision, corneal staining, dysgeusia, hyperemia, keratitis, pruritus, rhinitis, and sinusitis.

Naphazoline may precipitate narrow-angle glaucoma. It may also cause mydriasis, increased IOP, and allergic dermatitis. Systemic adrenergic or antihistamine effects may occur with excessive use.

The ocular NSAIDs may cause minor ocular irritation on instillation (less than 40% incidence). The other reported adverse reactions noted in 1% to 10% of patients using ocular NSAIDs include superficial ocular infection, superficial keratitis, ocular inflammation, corneal edema, and iritis. Reactions reported less frequently include corneal infiltrates, corneal ulcer, keratitis, and mydriasis.

The severe adverse reactions that can occur with the use of ocular corticosteroids include glaucoma (elevated IOP) with optic nerve damage, field defects and loss of visual acuity, cataract formation, secondary infection of the eye, exacerbation of existing infections, and perforation of the globe. Systemic side effects may develop with extensive use.

Drug Interactions

There are no drug interactions noted with any of the ocular antiallergic medications. Ocular NSAIDs may potentiate oral anticoagulants; the patient should be monitored for prolonged bleeding times if the drugs are used concurrently. Ophthalmic steroids have no known drug interactions.

Clinical Use and Dosing

Allergic or Vernal Conjunctivitis

Allergic conjunctivitis can occur in response to a variety of allergens; vernal conjunctivitis refers to conjunctivitis that occurs primarily in the spring, usually because of an allergen. The mast cell stabilizers (lodoxamide, cromolyn sodium) may be used to treat vernal conjunctivitis and may be used safely for up to 3 months.

The ophthalmic H_1 blocker ketotifen can be prescribed for allergic conjunctivitis and ocular pruritus. The dose used in adults and children over age 3 is 1 drop in the affected eye every 8 to 12 hours. The dosage for levocabastine, another prescription ophthalmic H_1 blocker, is 1 drop in the affected eye 4 times a day.

The over-the-counter (OTC) products available to treat allergic conjunctivitis combine a decongestant with an antihistamine. Products that combine antazoline and naphazoline (Vasocon-A) or naphazoline and pheniramine (Opcon-A, Naphcon-A) are used for temporary relief of the minor eye symptoms of itching and redness caused by pollen and other allergens such as animal hair. Patients may self-prescribe these products; therefore, the primary care provider needs to monitor the patient for proper use and the adverse effects associated with the use of these medications.

Ocular Inflammation

Consultation with an ophthalmologist is indicated in the treatment of ocular inflammation. The patient requires a slit-lamp examination to rule out herpes keratitis or other infectious disease before beginning therapy with ocular anti-inflammatory agents. The dosing of these agents may be found in Table 26-7.

Table 26–7 ⊗ **Dosage Schedule: Selected Ocular Antiallergic and Anti-Inflammatory Agents**

Drug	Indication	Dosage Form	Dose	Notes
Mast Cell Stabilizers				
Cromolyn sodium Crolom* Opticrom*	Allergic or vernal conjunctivitis	4% solution	*Adults and children ≥4 yr:* 1–2 drops each eye 4–6 times daily	Safety in children <4 yr is not known Advise the patient not to wear soft contact lenses while using ophthalmic cromolyn sodium
Lodoxamide Alomide	Vernal conjunctivitis, keratoconjunctivitis, vernal keratitis	0.1% solution	*Adults and Children >2 yr:* 1–2 drops qid for up to 3 mo	Not recommended in children <2 yr
Pemirolast (Alamast)	Allergic conjunctivitis	0.1% solution	*Children ≥3 yr:* 1–2 drops each eye qid	Not recommended in children <3 yr
Nedocromil (Alocril)	Allergic conjunctivitis	2% solution	*Children ≥3 yr:* Instill 1–2 drops in each eye bid at regular intervals	Continue treatment throughout period of exposure (e.g., until pollen season is over) Not recommended in children <3 yr
Antihistamines				
Antazoline-naphazoline Vasocon-A*	Allergic conjunctivitis	Solution: antazoline 0.5%, naphazoline 0.027%	*Adults:* 1–3 drops into eyes q3–4h	OTC; use for temporary relief of allergic conjunctivitis symptoms
Azelastine (Optivar)	Allergic conjunctivitis	0.05% solution	*Adults and children ≥3 yr:* Instill 1 drop each eye bid	Not recommended in children <3 yr
Epinastine (Elestat)	Allergic conjunctivitis	0.05% solution	*Adults and children ≥3 yr:* Instill 1 drop each eye bid	Not recommended in children <3 yr
Emedastine Emadine*	Allergic conjunctivitis	0.025% solution	*Adults and children ≥3 yr:* 1 drop qid	Not recommended in children <3 yr Soft contact wearers may reinsert lens 10 min after administration of emedastine
Zaditor* (OTC)	Temporary prevention of ocular itching due to allergic conjunctivitis	0.05% suspension	*Adults and children ≥3 yr:* 1–2 drops q8–12h	Not recommended in children <3 yr Soft contact wearers may reinsert lens 10 min after administration of ketotifen
Levocabastine Livostin	Seasonal allergic conjunctivitis	0.05% suspension	*Adults and children ≥12 yr:* 1 drop into affected eye qid for up to 2 wk	Not recommended for use in children
Pheniramine-naphazoline Naphcon-A* (OTC) Naphazoline Plus,*	Allergic conjunctivitis	Solution: 0.3% pheniramine, 0.025% naphazoline	*Adults:* Instill 1–2 drops q3–4h	OTC; use for temporary relief of allergic conjunctivitis symptoms
Olopatadine Patanol*	Temporary prevention of ocular itching due to allergic conjunctivitis	0.1% solution	*Adults and children ≥3 yr:* 1–2 drops bid, at least 6–8 h interval	Not recommended in children <3 yr Soft contact wearers may reinsert lens 10 min after administration of olopatadine

Continued

Table 26–7 ⊗ Dosage Schedule: Selected Ocular Antiallergic and Anti-Inflammatory Agents—cont'd

Drug	Indication	Dosage Form	Dose	Notes
NSAIDs				
Diclofenac Voltaren	Post-op inflammation after cataract surgery	0.1% solution	After surgery, instill 1 drop into affected eye qid for 2 wk, beginning 24 h after surgery	Prescribed by ophthalmologists
Flurbiprofen Ocufen	Post-op inflammation after cataract surgery	0.03%	On day of surgery, instill 1 drop into eye every 30 min, beginning 2 h prior to surgery	Prescribed by ophthalmologists
Ketorolac Acular* Acular PF	Seasonal allergic conjunctivitis	0.5% solution 0.5% solution, preservative free	*Adults and children ≥12 yr:* 1 drop in affected eye(s) qid	Patients wearing hydrogel soft contact lenses may experience ocular irritation when using concurrently Advise patients not to wear contacts while using this drug
Nepafenac Nevanac	Post-op pain and inflammation following cataract surgery	0.3% solution	*Adults ≥10 yr:* 1 drop in affected eye tid beginning the day before surgery	Prescribed by ophthalmologists
Suprofen Profenal†	Post-op inflammation after cataract surgery	1% solution	On day of surgery, instill 2 drops into eye at 3, 2, and 1 h prior to surgery; after surgery, instill 2 drops into affected eye q4h for 1 d	Prescribed by ophthalmologists

*Contains benzalkonium chloride, which cannot be administered with soft contact lenses in place.

　†Contains thimerosal.

Rational Drug Selection

Safety

The ophthalmic mast cell stabilizers are quite safe to use, even in children and in pregnant patients. The ocular antihistamines are safe and can be used in children as young as 2 years (lodoxamide). The ophthalmic H_1 blockers are safe for use in adults, with ketotifen safe for use in children as young as 3 years.

　The ocular NSAIDs are safe for treating a clear case of vernal conjunctivitis. If the diagnosis is unclear, an ophthalmological consult is indicated before prescribing to clarify the diagnosis and rule out herpes keratitis.

　The ophthalmic corticosteroid preparations have serious adverse effects. They should be prescribed only by an ophthalmologist.

Monitoring

The primary care provider needs to monitor the patient for effectiveness of therapy. There is no specific laboratory monitoring necessary with these medications. IOP should be periodically monitored by a trained eye professional if using medications that may increase IOP, ocular corticosteroids, and naphazoline.

Patient Education

Administration

The patient should be instructed to use the medication exactly as prescribed. Overuse or underuse can adversely affect the outcome of the clinical condition. Advise the patient to avoid touching the dropper to the eye or other surface, which may contaminate the medication. To prevent cross-contamination, neither prescription nor OTC products should be shared with another person.

Adverse Reactions

Alert the patient to the adverse reaction of transient stinging and burning that may occur with the use of ocular medications. If the burning or stinging is intense or prolonged or if there is any other adverse reaction, the patient should contact the primary care provider.

OCULAR LUBRICANTS

Ocular lubricants offer tear-like lubrication for the relief of dry eyes and eye irritation. Ocular lubricants are also referred to as *artificial tears.* An artificial tear insert consisting of hydroxypropyl cellulose (Lacrisert), which may be prescribed

by an ophthalmologist or optometrist, is not discussed in this chapter. The immunomodulator/anti-inflammatory cyclosporine (Restasis) is used to treat dry eye and is prescribed by an ophthalmologist.

Pharmacodynamics

Ocular lubricants contain a balanced solution of salts to maintain ocular tonicity, buffers to adjust pH, viscosity to prolong eye contact time, and preservatives.

Pharmacokinetics

Ocular lubricants are not absorbed in measurable amounts.

Pharmacotherapeutics

Precautions and Contraindications

There are no true contraindications to the use of ocular lubricants. Products that contain benzalkonium chloride (Teargen, Akwa Tears, Puralube Tears, Comfort Tears, Dry Eyes, HypoTears, Ultra Tears, Isopto Plain, Isopto Tears, Just Tears, LubriTears, Moisture Drops, Murine, Nature's Tears, Nu-Tears, Nu-Tears II, Tearisol, OcuCoat, Tears Naturale, Tears Renewed) should not be used with soft contacts.

Adverse Drug Reactions

The ocular lubricants may cause mild stinging and temporary blurred vision.

Drug Interactions

There are no significant drug interactions with the ocular lubricants.

Clinical Use and Dosing

Dry Eye Syndrome

Ocular lubricants or artificial tears are used as needed to provide relief of dry eyes and ocular irritation. They can also be used as lubricants for artificial eyes. The patient should be instructed to instill 1 or 2 drops into the eye(s) 3 to 4 times a day or as needed. Table 26-8 presents the dosing schedule.

Table 26–8 ✿ Dosage Schedule: Miscellaneous Ophthalmic Products

Drug	Indication	Dosage Forms	Dose	Comments
Ocular Lubricants				
Artificial tears Bion Tears Duratears Naturale Hypotears Lacri-Lube Muro 128	Ocular irritation, xerophthalmia	Preservative-free solution: dextran, hydroxypropyl methylcellulose Ointment: lanolin, mineral oil Solution: polyvinyl alcohol Preservative-free ointment: light mineral oil, white petrolatum Ointment: petrolatum, mineral oil Solution: sodium chloride	*Adults and children:* Instill 1–2 drops into affected eye(s) 3–4 times/d as needed	
Ophthalmic Vasoconstrictors				
Naphazoline Bausch & Lomb Allergy Drops Bausch & Lomb Maximum Strength Allergy Drops Clear Eyes Comfort Eye Drops	Relief of eye redness	0.012% solution 0.03% solution 0.012% solution 0.03% solution 0.012% solution 0.1% solution 0.1% solution 0.02% solution	Instill 1–2 drops qid as needed	Treatment should not continue for longer than 3 to 4 d without the supervision of an ophthalmologist
Oxymetazoline OcuClear Visine LR	Relief of eye redness	0.025% solution	*Adults and children:* 1–2 drops in affected eye(s) bid-qid but no more frequently than every 6 h	OTC
Tetrahydrozoline Visine Murine Plus	Relief of eye redness	0.05% solution	*Adults:* Instill 1–2 drops into the affected eye(s) up to 4 times/d	OTC

Continued

Table 26–8 ⊗ Dosage Schedule: Miscellaneous Ophthalmic Products—cont'd

Drug	Indication	Dosage Forms	Dose	Comments
Ophthalmic Diagnostic Products				
Fluorescein	Detection of corneal abrasion or defect	2% solution Strips: 0.6, 1, 9 mg	2% solution: Instill 1–2 drops into the eye; use Wood's lamp to detect staining of defect. Strips: Moisten strip with sterile water and place at fornix in the lower cul-de-sac; the patient should close lid tightly and blink several times; use Wood's lamp to detect defect	After examination, excess stain can be removed with sterile saline solution. Soft contact lenses can be reinserted 1 h after the eyes are flushed with saline to remove fluorescein

Monitoring

There is no laboratory monitoring needed with the use of artificial tears.

Patient Education

Administration

Advise the patient to avoid touching the dropper to the eye or another surface, which may contaminate the medication.

Adverse Reactions

Advise the patient that transient mild stinging and blurred vision may occur. The patient should contact the primary care provider if headache, eye pain, vision changes, prolonged redness, or discharge occurs.

OPHTHALMIC VASOCONSTRICTORS

Ophthalmic vasoconstrictors are used in primary care to provide temporary relief of redness of the eye due to minor eye irritants. There are ophthalmic vasoconstrictors that are used by eye-care specialists to dilate the pupil (hydroxyamphetamine Hbr, 2.5% and 10% phenylephrine); they are not covered in this chapter.

Pharmacodynamics

The ophthalmic vasoconstrictors are sympathomimetic agents that act by constricting the conjunctival blood vessels. The products used for eye redness are generally weak sympathomimetic solutions.

Pharmacokinetics

Information regarding the pharmacokinetics of the ophthalmic vasoconstrictors is not available, other than duration of action. The duration of action of naphazoline is 3 to 4 hours. Oxymetazoline's duration of action is 4 to 6 hours, and tetrahydrozoline's duration of action is 1 to 4 hours.

Pharmacotherapeutics

Precautions and Contraindications

The ophthalmic vasoconstrictors are contraindicated if the patient is sensitive to any of the components of the product. They are also contraindicated in any patient who has narrow-angle glaucoma.

The ophthalmic vasoconstrictors are Pregnancy Category C; the safety of their use in pregnancy has not been established.

Adverse Drug Reactions

The patient may experience transient stinging or burning on instillation. Blurring of vision may occur and is temporary, passing within minutes. Patients may experience mydriasis. Increased lacrimation, irritation, and discomfort may occur. The most serious adverse reaction that may occur is increased IOP.

Rebound congestion or redness can develop with frequent or extended use of ophthalmic vasoconstrictors.

Drug Interactions

There are no significant drug interactions with the use of oxymetazoline or tetrahydrozoline.

Tricyclic antidepressants and maprotiline (Ludiomil) may potentiate the pressor effects of naphazoline. If MAOIs are used with ophthalmic sympathomimetics, exaggerated adrenergic effects may result. Do not use MAOIs within 21 days of the ophthalmic sympathomimetics.

Systemic adverse effects may more easily occur if ophthalmic sympathomimetics are used with beta blockers.

Clinical Use and Dosing

Relief of Eye Redness

Ophthalmic vasoconstrictors that are used for temporary relief of eye redness due to irritation or allergic conjunctivitis include tetrahydrozoline, oxymetazoline, naphazoline, and phenylephrine. The usual adult dose is 1 or 2 drops instilled in the eyes 4 times a day. Use in children is not recommended.

Rational Drug Selection

Tetrahydrozoline, oxymetazoline, naphazoline (0.012%, 0.02%, 0.03%), and phenylephrine 0.12% are available OTC. Naphazoline 0.1% is available only by prescription. Phenyl-ephrine 2.5% and 10% are used only for pupil dilation and are instilled by eye-care specialists.

Monitoring

There is no laboratory monitoring necessary with the use of ophthalmic vasoconstrictors.

Patient Education

Administration

Advise the patient to avoid touching the dropper to the eye or another surface, which may contaminate the medication. The patient should avoid prolonged or excessive use of ocular vasoconstrictors because rebound congestion or redness may occur.

Adverse Reactions

Advise the patient that transient mild stinging and blurred vision may occur.

OPHTHALMIC DIAGNOSTIC PRODUCTS

The ophthalmic diagnostic that is used in primary care is topical fluorescein sodium. It is used to detect corneal epithelial defects or abrasions. The injectable form of fluorescein is used by ophthalmologists as a diagnostic aid in ophthalmic angiography. Only the topical form is discussed in this chapter.

Pharmacodynamics

Fluorescein is a yellow, water-soluble dibasic acid xanthine dye. It produces an intense fluorescent green color in alkaline (pH 0.5) solution. Fluorescein detects defects in the corneal epithelium. A corneal abrasion or corneal epithelial defect will uptake the dye and appear bright green under ultraviolet light (Wood's lamp). Fluorescein does not stain the intact cornea.

Pharmacokinetics

When used for the detection of corneal abrasion, topical fluorescein is not absorbed.

Pharmacotherapeutics

Precautions and Contraindications

Hypersensitivity to fluorescein is a contraindication to its use.

Do not use fluorescein with soft contact lenses, which become stained. Lenses can be reinserted after the eyes are flushed with sterile saline and the patient waits an hour.

Fluorescein is Pregnancy Category C, although there are no reports of fetal complications or anomalies.

Adverse Drug Reactions

There are no adverse drug reactions reported with topical fluorescein use, other than staining of soft contact lenses.

Drug Interactions

There are no drug interactions with the use of topical fluorescein.

Clinical Use and Dosing

Detection of Corneal Epithelial Defects

If a corneal abrasion or foreign body is suspected, the provider instills 1 or 2 drops of fluorescein 2% solution into the eye. After a few seconds, epithelial defects will stain. The use of a Wood's lamp enhances detection of defects. Fluorescein strips may be used. The strip is moistened with sterile water and placed at the fornix in the lower cul-de-sac close to the punctum. The patient should close the lid tightly over the strip until the desired amount of staining occurs. Have the patient blink several times to distribute the stain. After examination, excess stain can be removed with sterile saline solution. An anesthetic eyedrop can be administered before instilling the fluorescein if the patient is experiencing discomfort from the initial injury.

Monitoring

There is no specific laboratory monitoring necessary with the use of topical fluorescein.

Patient Education

Administration

Advise the patient that the staining of the cornea is temporary and will resolve within a few hours. The patient should not be wearing soft contact lenses during the examination. Advise the patient to wait at least 1 hour before reinserting the contact lenses.

DRUGS USED IN TREATING EAR DISORDERS

OTIC ANTI-INFECTIVES

Otitis externa (OE) is an acute, painful inflammatory condition of the external auditory canal. Commonly known as *swimmer's ear,* OE affects people of all ages, and it is the most common cause of visits for ear pain. It can easily be treated by a primary care provider, yet it can have serious, even life-threatening, complications, especially in diabetic or immuno-compromised patients.

OE occurs when there is a breakdown in several protective mechanisms. The normally acidic environment creates a hostile climate for bacterial growth. Cerumen is bacteriostatic and provides a protective layer that protects the epithelium against hyperhydration (Goguen, 2014). Factors that alter these defenses and contribute to OE include an abrasion in the ear canal, water in the ear canal, and maceration of the skin from heat and moisture. With OE, the acidic environment in the ear canal is changed to neutral or basic, usually

by retained moisture. Itching and a sense of fullness develop from damage to the epithelium caused by hyperhydration. Organisms invade wet intact skin as well as damaged epithelium. Devices (hearing aids, ear phones) that occlude the ear canal can predispose one to external otitis (Goguen, 2014).

Pharmacodynamics

The medications used in the treatment of OE include combination products (Cortisporin, Pediotic, Ciprodex, Cipro HC) that contain a corticosteroid (hydrocortisone) and antibiotic(s) (neomycin, polymyxin B, ciprofloxacin); antibiotic alone (gentamycin, ofloxacin); and acid or alcohol drops (Otic Domeboro, Burow's Otic, VoSol, VoSol HC).

Hydrocortisone reduces the inflammation caused by OE. The exact mechanism of action for topical corticosteroids is not known. They are thought to act by the induction of phospholipase A_2 inhibitory proteins. These proteins control the mediators of inflammation, such as prostaglandins and leukotrienes.

Neomycin is active against *S. aureus* and *Proteus* and *Enterobacter* species. Polymyxin B is generally active against gram-negative bacteria (*P. aeruginosa, E. coli, H. influenzae*). Gentamicin is a broad-spectrum aminoglycoside that is active against *P. aeruginosa,* staphylococci, *S. pneumoniae,* beta-hemolytic streptococci, and *Enterobacter* species. The fluoroquinolones (ciprofloxacin, ofloxacin) are active against staphylococci, *S. pneumoniae, Proteus* and *Enterobacter* species, and *P. aeruginosa.*

Acid and alcohol solutions such as Otic Domeboro and Burow's Otic contain 2% acetic acid in aluminum acetate solution. Another acid solution, VoSol Otic, contains 2% acetic acid solution and 3% propylene glycol. These solutions reduce inflammation and are antibacterial and antifungal.

Pharmacokinetics

Information regarding the pharmacokinetics of otic preparations is not available.

Pharmacotherapeutics

Precautions and Contraindications

Hypersensitivity to any component of the product is a contraindication to its use.

Ciprofloxacin is contraindicated if the tympanic membrane (TM) is perforated. Cortisporin otic solution is contraindicated if the TM is perforated. Cortisporin otic suspension may be used.

Prolonged use of topical antibiotics may lead to superinfection and overgrowth of nonsusceptible organisms and fungi.

Adverse Drug Reactions

Local reactions, such as contact dermatitis, may occur with any of the otic preparations. Superinfection may develop with prolonged use. Ofloxacin otic may cause taste alteration. Dizziness, vertigo, and paresthesias have also been reported with otic ofloxacin use. Ototoxicity may occur with prolonged use of Pediotic and Cortisporin otic solution.

Drug Interactions

There are no known drug interactions for the topical otic preparations.

Clinical Use and Dosing

Acute Otitis Externa (Swimmer's Ear)

On presentation of OE, the canal is swollen and full of discharge. The organisms found in OE (swimmer's ear) are usually gram-negative rods, *P. aeruginosa, Enterobacter* species, and *Proteus mirabilis. Pseudomonas* is the most common organism found in OE. Mycotic OE is less common, usually caused by *Aspergillus, Trichophyton,* or *Candida.* Occasionally, a furunculosis (small abscess) of the external canal may be caused by *S. aureus* or *S. pyogenes,* carried there by dirty fingers.

Once it has been determined that the TM is intact, the canal can be gently cleaned with warm saline or 3% hydrogen peroxide. If the TM cannot be visualized, irrigation should not be performed.

Topical medication is the treatment of choice. A steroid/antibiotic drop that combines hydrocortisone with neomycin and polymyxin B (Cortisporin Otic, Pediotic), colistin (Coly-Mycin S Otic), a hydrocortisone/ciprofloxacin (Ciloxan HC) suspension is instilled in the affected ear 4 times a day. The usual dose is 4 drops, and treatment should continue for 7 to 10 days. Gentamicin and ofloxacin provide good coverage for the common organisms, but the combination products decrease inflammation faster. Gentamycin, acetic acid, and Cortisporin Otic cannot be used if the TM is perforated.

A topical acid or alcohol solution (Otic Domeboro, Burow's Otic, VoSol) can be instilled into the ear 4 times a day if the TM is intact. A 1:1 mixture of vinegar and rubbing alcohol is just as effective, but it can be painful to administer. If excessive inflammation is present, a combination of acid with hydrocortisone (VoSol HC) may be effective.

If the canal is too swollen to allow the drops to be instilled, a wick of 0.25 in. gauze or cotton may be inserted into the swollen external canal for 24 to 36 hours. The medication can be dropped onto the wick. To evaluate progress, the patient will need to be reexamined 48 hours after the wick has been placed.

Chronic Otitis Externa

Chronic OE can be inflammatory or infectious. Psoriasis, eczema, or seborrhea can cause inflammatory chronic OE. Chronic infectious OE may be caused by infected sinus tracts, cysts, or fungi.

The treatment for inflammatory chronic OE is determined by the severity of presentation. If the patient is complaining of chronic itching, accompanied by dry skin elsewhere on the body, the treatment consists of placing 2 or 3 drops of baby oil or mineral oil in the canal daily. If the patient has psoriasis in the external canal, it can be treated with steroid cream or lotion (see Chap. 32). Seborrhea can cause a scaly inflammation in the external auditory canal and behind the ears, usually accompanied by seborrhea of the forehead, eyelids, and

face. Treatment is the use of selenium sulfide shampoo and topical corticosteroids (see Chap. 23, "Drugs Affecting the Integumentary System").

If the ear canal is greatly inflamed, treatment includes cleansing the external canal of debris and using a steroid otic solution (Decadron) 2 or 3 times a day until the swelling decreases. If needed to relieve the inflammation, a wick can be placed and Otic Domeboro or Burow's Otic dropped onto the wick for 24 to 48 hours.

Malignant Otitis Externa

Malignant OE is a rare but potentially lethal infection caused by *P. aeruginosa.* Malignant OE occurs mainly in older patients with diabetes (90%). It develops when OE extends and invades the surrounding tissues, causing osteomyelitis of the base of the skull and purulent meningitis, accompanied by multiple cranial nerve palsies. Standard treatment includes parenteral antibiotics with an aminoglycoside and carbenicillin for 4 to 6 weeks, plus surgical debridement.

Prevention of Swimmer's Ear

Most cases of acute OE (swimmer's ear) can be prevented by instilling isopropyl ear drops (Swim-Ear, EarSol) or 1 or 2 drops of rubbing alcohol into the ear canal to dry the ear after swimming. A combination of 1:1 isopropyl alcohol and white vinegar may also be used. The commercial preparations have the advantage of less stinging with application if the skin is slightly macerated.

Table 26-9 presents the dosage schedule of drugs used in treating ear disorders.

Table 26–9 ✂ Dosage Schedule: Drugs Used in Treating Ear Disorders

Drug	Indication	Dosage Forms	Dose	Comments
Otic Anti-Infectives				
Gentamicin Garamycin	Otitis externa	Solution: 3 mg/mL	Use ophthalmic drops: 4 drops in affected ear qid for 7–10 d	Broad-spectrum coverage
Ofloxacin Floxin Otic	Otitis externa Chronic suppurative otitis media with perforated tympanic membrane Otitis media in children with tympanostomy tubes	0.3% solution	*Children 6 mo–12 yr:* 5 drops in affected ear once daily for 10 d *Children ≥12 yr:* 10 drops in affected ear once daily for 10 d	To prevent dizziness, warm bottle in hand for 1–2 min prior to administering Not recommended for use in children <6 mo
Otic Anti-Infective-Steroid Combination				
Ciprofloxacin-hydrocortisone (Cipro HC Otic)	Acute otitis externa	Suspension: Ciprofloxacin 2 mg/mL hydrocortisone 10 mg/mL	*Children ≥1 yr:* 3 drops in affected ear bid for 7 d	To minimize dizziness warm suspension by holding bottle in hand for 1–2 min before use Not recommended in children <1 yr Contraindicated if tympanic membrane ruptured
Ciprofloxacin-dexamethasone (Ciprodex)	Acute otitis media in pediatric patients with tympanostomy tubes Acute otitis externa	Suspension: ciprofloxacin 0.3% dexamethasone 0.1%	*Children ≥6 mo:* 4 drops in affected ear bid for 7 d	Not recommended in children <6 mo
Hydrocortisone-neomycin-polymyxin B Cortisporin Otic Pediotic	Otitis externa Chronic suppurative otitis media with perforated tympanic membrane	Suspension: hydrocortisone 1%, neomycin 5 mg/mL, polymyxin B 10,000 U/mL Solution: hydrocortisone 1%, neomycin 5 mg/mL, polymyxin B 10,000 U/mL	*Children:* 3 drops of suspension in affected ear 3–4 times/d *Adults:* 4 drops of suspension in affected ear 3–4 times/d	Contraindicated if TM perforated
Hydrocortisone-neomycin-colistin Coly-Mycin S Otic	Otitis externa	Suspension: hydrocortisone 1%, neomycin 5 mg/mL, colistin 3 mg/mL	4 drops of suspension in affected ear 3–4 times/d	Contraindicated if TM perforated

Continued

Table 26–9 ⚮ **Dosage Schedule: Drugs Used in Treating Ear Disorders—cont'd**

Drug	Indication	Dosage Forms	Dose	Comments
Acid–Alcohol Solutions				
Acetic acid-aluminum acetate Otic Domeboro, Burow's Otic	Otitis externa	Solution	Clean ear canal; instill 4 drops 3–4 times/d for 7–10 d If canal swollen: Insert wick saturated with solution; instill 4–6 drops q2–3h; keep moist for 24 h	Contraindicated if TM perforated
Acetic acid-propylene glycol VoSol Otic	Otitis externa	Solution	Clean ear canal; instill 5 drops 3–4 times/d for 7–10 d If canal swollen: Insert wick saturated with solution; instill 4–6 drops q2–3h; after 24 h, remove wick and instill 5 drops qid	Contraindicated if TM perforated Not recommended in children ≤3 yr
Acetic acid-propylene glycol-hydrocortisone VoSol HC Otic	Otitis externa	Solution	Clean ear canal, and instill 5 drops 3–4 times daily for 7–10 d May use cotton wick for first 24 h	Contraindicated if TM perforated Not recommended in children ≤3 yr
Isopropyl alcohol-glycerine Swim-Ear	Drying solution for ear canal	Liquid: 95% isopropyl alcohol, 5% anhydrous glycerin	Instill 4–6 drops in each ear after swimming or bathing	
Isopropyl alcohol-propylene glycol EarSol	Drying solution for ear canal	Drops: 44% isopropyl alcohol, propylene glycol	Instill 6–8 drops in each ear after swimming or bathing bid	
Otic Analgesics				
Benzocaine-antipyrine-glycerin Auralgan	Analgesia in acute otitis media Adjunct in cerumen removal	Solution	Otitis media: Fill affected canal and insert cotton plug; may repeat every 1–2 h if needed Cerumen removal: Fill ear canal tid for 2–3 d	Contraindicated if TM perforated
Benzocaine-antipyrine-propylene glycol Tympagesic	Analgesia in acute otitis media	Solution	Fill ear canal and insert cotton plug; repeat q2–4h as needed	Contraindicated if TM perforated
Ceruminolytics				
Carbamide peroxide Debrox Murine Ear Auro Ear Drops	Cerumen removal	6.5% drops	Instill 5–10 drops in ear canal, keep drops in for several minutes, and repeat bid for up to 4 d	Contraindicated if TM perforated Not recommended in young children
Triethanolamine Cerumenex Drops	Cerumen removal	10% drops	Fill ear canal, insert cotton plug, allow to remain for 15–30 min, and flush ear	Contraindicated if TM perforated

TM = tympanic membrane

Monitoring

There is no laboratory monitoring necessary with these medications. The patient with a severely inflamed external canal requiring a wick should be reassessed 48 hours after treatment is begun and at the end of treatment to determine clinical cure. Patients with chronic OE need cleansing of the canal and reassessment every 2 to 3 weeks and may require alterations in topical medications, depending on clinical status.

Patient Education

Administration

Advise the patient to hold the bottle of medication in the hand for a few minutes to warm the medication before

instilling. The patient should lie on her or his side with the affected ear up, instill the drops, and keep the ear up for 2 minutes or insert a soft cotton plug to prevent the medication from draining out.

Adverse Reactions

Advise patients to notify their primary care provider if adverse effects occur.

OTIC ANALGESICS

Topical anesthetics are used in the ear to treat pain associated with otitis media. The local anesthetics antipyrine and benzocaine (Americaine, Dolotic, Auralgan, Auroto) are used to provide pain relief until systemic antibiotics can take effect. Analgesic eardrops are instilled into the affected ear 3 to 4 times daily or up to once every 1 to 2 hours as needed for pain. The tympanic membrane should be examined to ensure it is intact before prescribing topical anesthetic agents.

CERUMINOLYTICS

Some patients have an excessive accumulation of cerumen, which can lead to conductive hearing loss, impaction, and an environment for OE to develop. Patients who use cotton-tipped applicators (Q-Tips) to try to remove the cerumen actually push the cerumen farther into the canal. The cerumen often forms a hard plug that is painful to remove. Treatment includes instillation of mineral oil, which softens the wax, or the use of carbamide peroxide (Debrox, Dent's Ear Wax, Murine Ear Wax Removal), which softens and emulsifies the wax. Dosage of carbamide peroxide is to instill 1 to 5 drops (depending on the size of the ear canal) twice daily for up to 4 days. Once the cerumen is softened, the ear canal can be irrigated with *warm* water or saline. If the canal is excoriated, application of antibiotic or steroid eardrops for 7 to 10 days will prevent the development of OE.

PHARMACOTHERAPEUTICS WITH MULTIPLE DRUGS

ANEMIA

Teri Moser Woo • Kristen Osborn

Anemias are extremely common in primary care practice; there are 5.5 million ambulatory care visits annually that list anemia as the primary diagnosis (Schappert & Rechtsteiner, 2008). The World Health Organization (WHO) estimates that 2 billion people worldwide have anemia (2013). Anemia is a sign of disease rather than a disease itself. Iron deficiency anemia (IDA) is the most common type of anemia, with a prevalence of 14% in children age 1 to 2 years and 9% in women age 12 to 49 years (Centers for Disease Control and Prevention [CDC], 2013a). Anemia of chronic disease (ACD) develops secondary to a chronic disease, cancer, or long-term infection and is the second most common form of anemia, The third major form of anemia is sickle cell disease (SCD), which affects 90,000 to 100,000 Americans, mainly of African ancestry, with SCD occurring in approximately 1 in every 500 African American births (CDC, 2011). Other forms of anemia discussed in this chapter are folic acid deficiency and pernicious anemia.

Diagnosis and treatment of the various forms of anemia entail interpretation of blood studies and peripheral smears to correctly diagnose the type of anemia. Normal blood count values are found in Table 27-1. Treatment consists of lifestyle modifications in the form of diet and energy conservation and prescription of drugs specific to each disorder. This chapter reviews the relevant pathophysiology of the common anemias seen in primary care, as well as management or comanagement of the disorder.

PATHOPHYSIOLOGY COMMON TO ALL ANEMIAS

The underlying pathophysiology in all types of anemia is a decrease in the oxygen-carrying capacity of the blood. Figure 27-1 depicts the progression and manifestations of anemia. The reasons for this decrease vary by type of anemia. Anemias are classified by erythrocyte size and hemoglobin (Hgb) content. Size is referred to by the terms *microcytic* (small), *macrocytic* (large), and *normocytic.* Hgb content is referred to by the terms *hypochromic* (low Hgb) or *normochromic.*

Regardless of the disease process, the decreased oxygen transport to tissues carries the same results. Decreased mitochondrial oxygenation at the cellular level leads to decreased ATP production and reliance on the glycolytic process, resulting in poor energy generation and the formation of lactic acid, which affects the body's acid–base balance. It also affects the functioning of the body's largest energy consumer, the sodium-potassium-ATPase pump. As this pump works less efficiently, fluid and electrolyte shifts occur. Activation of the renin-angiotensin-aldosterone system augments the fluid shifts, with resultant sodium and water retention.

A reduction in the number of circulating red blood cells (RBCs) affects the consistency and volume of blood. Less viscous blood flows faster and more turbulently and may cause ventricular dysfunction, cardiac dilation, and heart valve insufficiency. Increased venous return to the heart stimulates the heart to pump harder and faster, resulting in tachycardia

Table 27–1   Normal Blood Values by Age and Gender

Age/Gender	Hemoglobin (g/100 mL)	Hematocrit	RBC Count (million/mm³)	Mean Corpuscle Volume (mcg³) Concentration (pg/cell)	Mean Corpuscle Hemoglobin Concentration (pg/cell)	RBC Distribution Width
Infants 3 mo	9.5–14.5 Mean 12	32%–41%	2.7–4.9	78	30–33	
Infants 6 mo to children 6 yr	10.5–14	32–41%	3.7–5.3	77–81	31–34	
Children 9–12 yr	12–15	34%–43%	4.0–5.2	83–86	31–34	
Adolescents 12–14 yr Male Female	12–16 11.5–15	35%–45% 34%–44%	4.5–5.3 4.1–5.1	78–88 78–90	31–34	
Adolescents 15–17 yr Male Female	12.3–16.6 11.7–15.3	37%–48% 34%–44%	4.5–5.3 4.1–5.1	Adult levels Adult levels	31–34	
Adults 18+ yr Male Female	13.2–17.3 11.7–15.5	40%–54% 35%–47%	Both genders: 4.2–5.4 3.6–5.0	Both genders: Microcytic = <87 Normocytic = 87–103 Macrocytic = >103	Hypochromic = <32 Normochromic = 32–36 Hyperchromic = >36	Both genders: 11.5%–14.5% CU

CU = conventional units.

and the risk of heart failure. To better oxygenate the reduced number of RBCs, the respiratory rate and depth increase. If the anemia is severe enough to overcome the usual compensatory mechanisms, the patient experiences shortness of breath, a rapid pounding pulse, dizziness, and fatigue, even at rest. Laboratory values with anemias are found in Table 27-2.

Iron Deficiency Anemia (IDA)

The World Health Organization (WHO) considers iron deficiency the most common and widespread nutritional disorder in the world (2013). Iron deficiency anemia (IDA) decreases oxygen-carrying capacity because of a low hemoglobin concentration that is due to reduced RBC production (lack of adequate iron intake, poor absorption of iron by the body, or lead poisoning) or acute or chronic blood loss. This produces a microcytic-hypochromic anemia that develops slowly after the normal stores of iron have been depleted in the body and particularly the bone marrow.

IDA may be caused by increased demand for iron during pregnancy, periods of growth in children, or blood loss from menstruation. IDA affects 9% of women of childbearing age, related largely to iron loss secondary to blood loss from menstruation (CDC, 2013a). Premenopausal women who are athletes may experience iron deficiency or iron deficiency anemia at a higher rate than nonathletes (McClung, Marchitelli, Friedl, & Young, 2006; McClung, 2013). About 50% of pregnant women worldwide have IDA based in part on the use of

iron by the fetus (WHO, 2013). An estimated 14% of children 1 to 2 years of age in the United States and 40% of preschool children worldwide are anemic. IDA also affects about 4% of males (Rote & McCance, 2010). IDA associated with increased demand can be easily managed by the use of vitamins that contain additional iron or iron supplements (Office of Dietary Supplements [ODS], 2010).

Pathological iron loss occurs most often from gastrointestinal (GI) bleeding. Gastric and duodenal ulcers, diverticula, hemorrhoids, and ulcerative colitis are common sources of this bleeding. GI bleeding is such a common cause of IDA that it is recommended all men and postmenopausal women with IDA and all premenopausal women whose IDA cannot be explained by heavy menses should be evaluated for occult GI bleed (Bull-Henry & Al-Kawas, 2013). Less common causes of IDA include malabsorption syndromes, achlorhydria, steatorrhea, and unrelenting diarrhea (Montoya, Wink, & Sole, 2002). Individuals with renal failure, especially those being treated with dialysis, are at high risk for developing IDA because their kidneys do not secrete sufficient erythropoietin. Erythropoietin and iron can both be lost in dialysis. The National Kidney Foundation (2006) has a clinical practice guideline specifically addressing this issue. Lead exposure can also lead to IDA because high blood lead levels impair iron uptake and prevent Hgb formation.

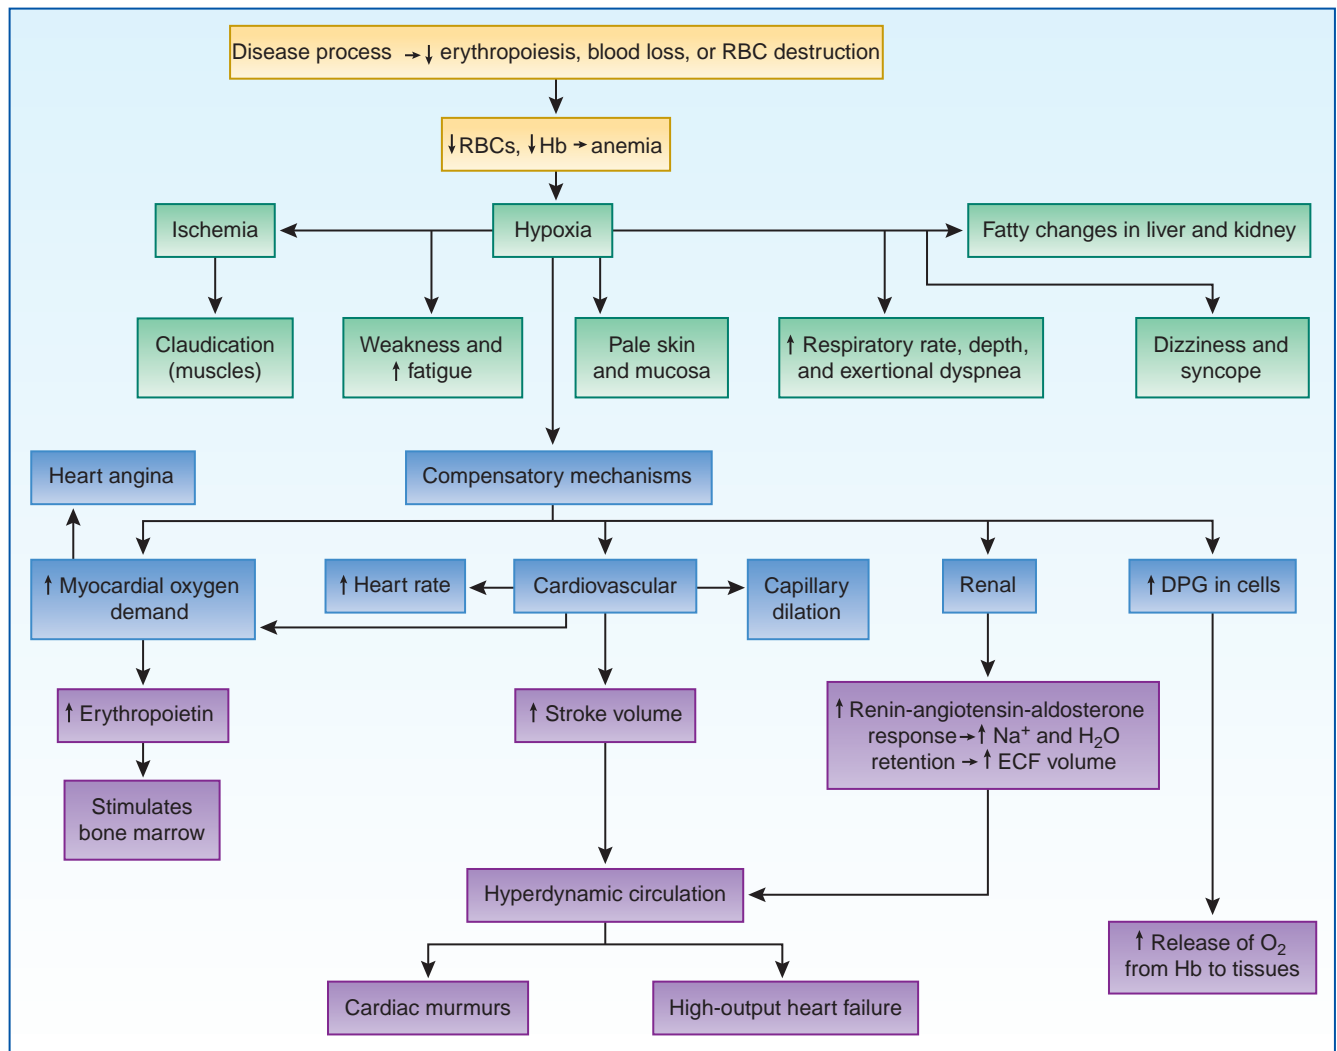
Iron absorption can be affected by food intake and medications. Foods containing ascorbic acid (vitamin C) can increase iron absorption, whereas phytate found in bran, oats,


Figure 27–1. Progression and manifestations of anemia.

Table 27–2 Laboratory Findings in Selected Anemias

Test	Iron Deficiency Anemia	Folic Acid Deficiency Anemia	Pernicious Anemia	Anemia of Chronic Disease	Sickle Cell Anemia
Hemoglobin	Low	Low	Low	Low	Low (5–11 g/dL)
Hematocrit	Low	Low	Low	Low	Low (about 20%)
Reticulocyte count	Normal	Low	Low	Normal	Low (5%–20%)
Plasma iron	Low	High	High	Normal or low	Normal
Total iron-binding capacity	High	Normal	Normal	Normal or low	Normal
Ferritin	Low	High	High	Normal	Normal
Transferrin	Low	Slightly high	Slightly high	Slightly high	Normal
Mean corpuscular volume (MCV)	Low	High	High	Normal to low	Normal to low*
Serum B_{12}	Normal	Normal	Low	Normal	Normal
Folate	Normal	Low	Normal	Normal	Normal

*MCV will be low if a combination of sickle cell disease (SCD) and beta thalassemia are present, and normal if only SCD is present.
