and rye fiber; polyphenols in tea; and calcium decrease absorption (Schrier, 2013). Medications that reduce acid secretion by the parietal cells (e.g., H_2 blockers and proton pump inhibitors) may produce IDA because acid is necessary for the uptake of iron in the GI tract. Sulfonamides can also decrease plasma iron levels by binding to plasma stores of iron. Bile-sequestering acids such as cholestyramine bind with iron and decrease absorption in the GI tract. Vitamin A mobilizes iron from its storage sites, so a deficiency in vitamin A limits the body's ability to use stored iron and may also lead to IDA.

IDA develops slowly in three overlapping stages. In stage 1, the body's iron stores are depleted and the patient has iron deficiency without anemia. Erythropoiesis proceeds normally with the Hgb content of RBCs remaining normal also. The patients usually have few, if any, symptoms and those who do have a vague expression of fatigue. Diagnosis is made by measuring serum ferritin, with a ferritin level of less than 30 ng/mL indicative of iron deficiency (Short & Domagalski, 2013). In stage 2, iron deficiency with mild anemia, iron transportation to bone marrow is diminished and iron-deficient erythropoiesis takes place. During this stage laboratory values begin to show changes. Patients have Hgb levels of 9 to 12 g/dL, serum ferritin of less than 20 ng/mL, and serum iron level of less than 60 mcg/dL and usually have no symptoms or vague symptoms of fatigue or headache. Those with lower Hgb levels may have more definitive symptoms, such as weakness and shortness of breath. Table 27-2 shows the laboratory values consistent with a variety of anemias. Stage 3, severe iron deficiency with severe anemia, begins when the small, hemoglobin-deficient cells enter the circulation in sufficient numbers and replace normal erythrocytes that have reached maturity and been removed from the circulation.

RBCs have a normal life expectancy of about 120 days. This stage is associated with IDA, depleted iron stores, and diminished Hgb production. Hgb levels are now 6 to 7 g/dL. Serum ferritin levels are very low at this point, less than 10 mg/mL and serum iron levels are less than 40 mcg/cL (Schrier, 2013). The earlobes, palms, and conjunctivae become pale. Nails become brittle, thin, coarsely ridged, and spoon-shaped as a result of impaired oxygen transport. The tongue becomes red, sore, and painful owing to atrophy of papillae. Dry, sore skin at the corners of the mouth and difficulty swallowing exacerbated by decreased salivation may also occur. Mental confusion, memory loss, and disorientation frequently are associated with anemia secondary to poor oxygen transport to cerebral tissue. This is especially problematic in the older adult population if they are wrongly perceived to be normal events related to aging (Rote & McCance, 2010). Severe IDA with Hgb levels below 7 g/dL may result in postural hypotension, dizziness, weakness, gastritis, irritability, numbness, and lethargy.

Folic Acid Deficiency Anemia (FOA)

Folate deficiency is rare in developed countries, but certain groups are at risk for deficiency, including alcoholics because alcohol interferes with folate absorption and metabolism, patients with malabsorptive disorders, and pregnant women (ODS, 2012). Folic acid deficiency anemia (FOA) decreases oxygen-carrying capacity because of a low Hgb concentration. Folic acid is necessary for the normal maturation and functioning of RBCs. Folic acid deficiency produces a macrocytic-normochromic anemia within 3 months of the start of an inadequate diet, because folate stores are rapidly depleted.

The primary biochemical function of folate coenzymes is the synthesis of purines and pyrimidines, the bases for DNA and RNA. These coenzymes also are involved in the synthesis of thymidylate, which is also a precursor of DNA. Symptoms of folic acid deficiency become apparent when the synthesis of thymidylate is critically impaired. Apoptosis of RBCs in the late stages of differentiation is thought to occur with this disorder. Because of its role in DNA and RNA synthesis, folate is a critical component of the diet of pregnant women and folate supplementation is recommended (ODS, 2012). Along with anemia, folate deficiency is associated with neural tube defects of the fetus and heart disease. It is also implicated in several cancers, especially colorectal cancers.

Folate is absorbed primarily in the upper small intestine independent of any facilitating factor. It is then circulated to the liver where it is stored. Folate deficiency is more common than vitamin B_{12} deficiency and often associated with alcoholics, chronic malnutrition, fad diets, and diets low in vegetables. Some drugs interfere with the cobalamin-folate–dependent pathway (e.g., methotrexate and fluorouracil). Dilantin, sulfamethoxazole/trimethoprim, and oral contraceptives compete with folate metabolism and storage in the liver.

Patients with folic acid deficiency commonly complain of glossitis, stomatitis, nausea and anorexia, and diarrhea. A systolic ejection murmur may be heard. A positive Romberg's sign and increased or decreased deep tendon reflexes (DTRs) may also occur along with mild confusion, depression, apathy, and intellectual loss. Peripheral neuropathies will be present only if vitamin B_{12} is also deficient.

Pernicious Anemia (PA)

Pernicious anemia (PA) also has a low Hgb concentration. Vitamin B_{12} is necessary for maturation and DNA synthesis in RBCs, and when the cause of vitamin B_{12} deficiency is autoimmune and linked to heredity, it is PA. PA is also associated with other autoimmune conditions, particularly those that affect the endocrine, such as Hashimoto's thyroiditis, type 1 diabetes mellitus, Addison's disease, and Graves' disease. PA produces a macrocytic-normochromic anemia that develops slowly, often over years, and it is frequently severe before it is diagnosed. In the absence of genetic mutations, vitamin B_{12} deficiency is practically nonexistent because there are rich dietary sources in animal proteins. However, other patients are prone to consume too little vitamin B_{12}—vegetarians, particularly vegans, those with Crohn's disease, in which a section of the small intestine may be destroyed or others with resection of the bowel such as gastric bypass surgery, and pregnant women who are strict vegetarians (ODS, 2011).

Gastric parietal cells secrete intrinsic factor, which binds to dietary vitamin B$_{12}$ during digestion and absorption of nutrients. Adequate intrinsic factor, along with hydrochloric acid, is needed to permit this vitamin to be absorbed. Patients with PA have a genetic absence of intrinsic factor. Other causes include gastrectomy and gastric atrophy of parietal cells associated with type A chronic gastritis.

Vague early symptoms of PA (e.g., infections; mood swings; and GI, cardiac, or kidney problems) are often ignored. The classic symptoms of anemia are not seen until Hgb approaches 7 to 8 g/dL. Neurological symptoms are the result of nerve demyelination, and the patient may experience loss of position and vibratory sense, ataxia, and spasticity. Concomitant symptoms include a beefy red tongue secondary to glossitis, and peripheral neuropathy; the latter is often used to clinically differentiate between FDA and PA. The liver may be enlarged, especially in older adults, indicating right-sided heart failure.

Anemia of Chronic Disease (ACD)

ACD is also associated with low Hgb, but it is caused by destruction of RBCs by a hyperactive reticuloendothelial system, decreased production of RBCs by hypoactive bone marrow, or altered iron metabolism, with defective transfer of iron from stores to the plasma. Overall, ACD appears to be produced by the activation of the cellular immune system. Specific cytokines that have been implicated in ACD include tumor necrosis factor alpha, interferon delta, interleukin-1 beta, and interleukin-6. Microvascular eruptions occur in the GI tract in response to the inflammatory mediators. This results in occult blood escaping into the intestines. Chronic use of NSAIDs, such as aspirin or ibuprofen, must also be considered as the source of occult bleeding. ACD produces a normocytic-normochromic anemia in 75% of cases but is microcytic in 25% of cases. It develops slowly and is often mild or asymptomatic.

Anemias that resemble ACD include anemias secondary to malignancy, chronic renal disease, HIV infection, and heart failure (Schrier & Camaschella, 2013). Anemia in patients with malignancy may be multifactorial in origin due to red blood cell losses, increased red cell destruction, or decreased red cell production (Drews, 2013). Patients with chronic kidney disease develop normochromic, normocytic anemia due to decreased erythropoietin production (Rosenberg, 2013). Medications used to treat HIV may cause anemia, including zidovudine (AZT) and may suppress erythropoiesis leading to anemia. Patients with heart failure may have anemia due to inflammation, dilutional anemia, iron deficiency anemia, or anemia caused by medications such as angiotension-converting enzyme inhibitors (Colucci, 2013).

Sickle Cell Anemia (SCD)

The National Heart, Lung, and Blood Institute (NHLBI, 2004) recommends universal screening for SCD. More than 98% of children born in the United States are screened for sickle cell anemia (SCA) as part of the routine newborn screening for preventable diseases (CDC, Division of Laboratory Services, 2013b).

Patients with SCA have a normal amount of Hgb (normocytic-normochromic), but their RBCs contain an abnormal type of Hgb, hemoglobin S (HbS). SCD is actually a group of autosomal recessive genetic disorders characterized by the predominance of this Hgb. These disorders include SCA, a homozygous form that is the most severe; sickle cell thalassemia syndromes and sickle cell HbC disease are heterozygous forms in which the child also inherits another type of abnormal Hgb from one parent. Sickle cell trait, in which the child inherits HbS from one parent and normal hemoglobin (HbA) from the other parent, is a heterozygous carrier state. It does not cause abnormalities in the blood count, and it does not produce vaso-occlusive symptoms under physiological conditions.

These disorders are found in people of African, Mediterranean, Indian, and Middle Eastern heritage. In the United States, SCD occurs more commonly in African Americans, with a reported incidence ranging from 1 in 400 to 1 in 500 live births. Sickle cell HbC disease is less common (1 in 800 births), and sickle cell thalassemia is the least common (1 in 1,700 births). Sickle cell trait occurs in 7% to 13% of African Americans, but the incidence among East Africans may be as high as 45%. This trait may provide some protection against lethal forms of malaria that are endemic in the areas that provide the gene pool of African Americans, but it provides no genetic advantage to persons living in the United States.

Sickle cell Hgb is produced by a recessive allele of the gene encoding the beta chain of the protein hemoglobin. A single amino acid, glutamic acid, is replaced by valine at the sixth position of the chain, producing HbS. There are two cardinal pathophysiological features of SCD: chronic hemolytic anemia and vaso-occlusion, which results in ischemic tissue injury. Low oxygen tensions in the blood from ischemia or decreased partial pressures of oxygen in the air cause HgbS to crystallize, which distorts the RBCs into a sickle shape and makes them fragile and easily destroyed. The degree of deoxygenation required to produce sickling varies with the percentage of HbS in the cells. Sickle trait cells will sickle at oxygen tensions of about 15 mm Hg, whereas those with SCD will sickle at about 40 mm Hg.

Sickling is rarely permanent, and most sickled RBCs regain a normal shape when reoxygenated and rehydrated. Some irreversible sickling occurs based on damage to the plasma membrane of the RBC. Hemolytic anemia may be related to repeated cycles of sickling and unsickling. Tissue injury is usually produced by hypoxia secondary to the obstruction of blood vessels by sickled erythrocytes. The sickled cells are unable to squeeze through the smaller blood vessels, and tissues supplied by these blood vessels undergo ischemia. The organs at greatest risk for damage are those with venous sinuses in which blood flow is low and oxygen tension and pH are low (spleen and bone marrow) and those

with a limited terminal arterial blood supply (eye and head of the femur and humerus). The kidney is also at risk, especially as the patient ages.

Specific discussion of the complications associated with SCD and SCA are presented in the *Management of Sickle Cell Disease* (NHLBI, 2004). Additional information may also be found on several organizations' Web sites, including the American Sickle Cell Anemia Association (http://www.ascaa .org/); National Heart Lung and Blood Institute Sickle Cell Anemia (http:// http://www.nhlbi.nih.gov/health/health-topics/topics/sca/); and the Sickle Cell Anemia Center (scinfo .org), a program sponsored by a partnership among Emory University School of Medicine, Grady Health System, Morehouse School of Medicine, and others that offers extensive information on SCA for patients, families, and health-care providers. An expert panel is updating the NHLBI SCA guidelines, to be published in 2014.

GOALS OF TREATMENT

The ultimate goal of treatment for all types of anemia is to provide adequate oxygen transport to body tissues. For patients with IDA, FDA, and PA, this may be seen in a return to normal in the number and character of RBCs and to normal Hgb values. ACD is normocytic and normochromic, so the goal is a return to the normal number of RBCs and to normal Hgb values. Table 27-1 shows the normal blood indices for each age and sex grouping. The goal of treatment for SCA is prevention of the morbidity and mortality associated with this disease and reduction in the percentage of HgbS in the blood.

RATIONAL DRUG SELECTION

Iron Deficiency Anemia (IDA)

Risk Stratification and Screening

Growth, development, and gender factors play important roles in risk stratification. The fetus stores iron during the last trimester, providing the infant with stores that usually last about 6 months. Maternal conditions during pregnancy, including anemia, hypertension, or diabetes, can lead to low fetal iron stores (Baker, Greer, & the Committee on Nutrition, 2010). Preterm infants may have only 3 months of iron stores, and they grow at a more rapid rate, compounding the problem of poor iron stores.

The diet is the major source of iron. Human milk contains 0.35 mg/L of iron (Baker et al, 2010). The iron in breast milk is well absorbed (50% absorbed), as opposed to the iron in cow's milk, which is 10% absorbed. Breastfeeding reduces the risk for IDA in infants by providing a minimum of 0.27 mg/d of iron that term infants younger than age 6 months need (Baker et al, 2010). Due to waning iron stores between the ages of 4 and 6 months, the American Academy of Pediatrics (AAP) recommends exclusively breastfed infants be supplemented with 1 mg/kg per day of oral iron until iron-fortified foods (iron-fortified cereal) are introduced into the diet (Baker et al,

2010). Preterm infants who are breastfed should have 2 mg/kg per day of supplemental elemental iron daily until age 12 months (Baker et al, 2010). Infants, including preterm infants who are formula fed, should receive iron-fortified formula for the first 12 months of life. Partially breastfed infants (more than half their nutrition from breast milk) should receive 1 mg/kg per day of iron. The early addition of solid foods to the infant's diet may impair the ability to absorb iron, and solid foods should be introduced slowly, with conscious inclusion of foods high in iron. Cow's milk should not be introduced into the diet before age 12 months (Baker et al, 2010).

Conducting a good history of iron intake is a guide for whether screening for IDA should occur at the routine 9 or 12 month well visit. The AAP recommends all children have hemoglobin measured to screen for IDA at approximately age 12 months (Baker et al, 2010). Prematurity, low birth weight, lead exposure, or diet low in iron may indicate a need for earlier screening.

The Institute for Clinical Systems Improvement (ICSI, 2004) and the AAP (Baker et al, 2010) recommend an iron-rich diet for all children from birth to 6 years of age. Children between ages 1 and 2 are particularly prone to IDA (CDC, 2002). Toddlers require 7 mg per day of iron (Baker et al, 2010). Typically, toddlers may have somewhat picky eating habits and may consume large quantities of milk. Children age 1 to 3 years who do not have adequate dietary intake of iron should receive daily supplementation with iron in liquid, chewable, or, if in Canada, sprinkle form (Baker et al, 2010). If toddlers or preschoolers exhibit signs and symptoms consistent with anemia (tiredness, irritability, loss of appetite) or have a history of inadequate iron intake or drinking more than 32 oz of milk a day, they should be screened with Hgb and Hct tests (Baker et al, 2010). Lead poisoning can also contribute to IDA in young children; therefore, high-risk children should be screened for lead.

Iron needs increase during periods of rapid growth. Teenage girls are in a high-risk group because of their growth spurt, the onset of menstruation, and poor dietary intake of iron-containing foods (less than 15 mg of iron per day). Although IDA is more common in females, adolescent boys may be at risk during their growth spurt if they don't have adequate intake of iron (11 mg/d). Adolescents should be screened with Hgb and Hct tests at ages 12 to 14 years, based on a history of their risk factors, including dietary intake, vegan or vegetarian diet, skipping meals or disordered eating, history of heavy menstrual periods, participation in endurance sports, or intensive physical training (National Anemia Action Council, 2009).

Although anemia is common in older adults, in this population it is usually due to GI blood loss associated with ulcers, the use of aspirin or NSAIDs, or chronic disease rather than to iron deficiency. Ferritin levels increase with illness and inflammation; therefore, a ferritin of 45 ng/dL should be used to determine iron deficiency in the older adult (Bross, Soch, & Smith-Knuppel, 2010). Unexplained iron deficiency requires investigation for gastric malignancy or other source, as well as replacement of iron.

Women generally have smaller stores of iron than do men and have increased loss through menstruation, and their balance between intake and loss of iron is precarious. IDA occurs more frequently in nonpregnant women who experience menorrhagia. Pregnancy places a woman at risk of IDA because their iron requirement doubles due to the increased blood volume of the mother and iron need of the growing fetus (ODS, 2010). Women at risk should be screened for IDA at annual physical examinations, and pregnant women should have screening included as part of their regular prenatal care.

Prevention of IDA

Treatment of IDA begins with prevention, but iron deficiency cannot be overcome with increased dietary intake alone. Iron supplements are always required.

The primary goal of management for IDA is prevention. The key to prevention of IDA not due to a disease process is adequate nutrition. Prevention, for infants, starts with breastfeeding. The AAP recommends exclusive breastfeeding for the first 4 to 6 months of life (Baker et al, 2010) and that iron fortification of 1 mg/kg per day of iron be started at age 4 months and iron-rich foods be introduced at age 6 months (Baker et al, 2010). Preterm infants require iron supplementation of 2 mg/kg per day starting at age 1 month and continuing until age 12 months (Baker et al, 2010). Low-birth-weight infants or infants with hematological disorders require iron supplementation before age 6 months. The AAP recommends liquid or chewable forms of iron (Baker et al, 2010). Iron

sprinkles are available in Canada. Formula-fed infants should use an iron-fortified formula.

Children and adults need to eat sufficient amounts of iron-rich foods. Foods rich in iron that the body can readily absorb include raisins, lean meats, fish, poultry, eggs, legumes, soybeans, dark green leafy vegetables, blackstrap molasses, fortified cereals, and whole-grain rice. The iron in many vegetables is poorly absorbed, so vegetarians must pay special attention to their intake of legumes and rice. The recommended amount of iron for non-anemic pregnant women is 27 mg/d, with a recommendation that all pregnant women take a low dose (30 mg/d elemental iron) daily to prevent anemia (ODS, 2010). Table 27-3 presents iron intake recommendations for the prevention and treatment of IDA.

Learning energy conservation techniques, such as planning rest periods, pacing activities, keeping objects within reach when performing tasks, and sitting down when doing chores, are other important lifestyle modifications for the patient with IDA.

Drug Therapy

Once the decision is made to begin drug therapy, the choice of drug is based on age and gender variables. Figure 27-2 delineates the drug treatment algorithm for IDA. See Table 27-3 for the dosages of iron recommended for infants, children, adolescents, and adults and during pregnancy and lactation. Doses ranging from 60 to 185 mg of elemental iron have been used. Oral formulations of 325 mg (60 mg of elemental iron) are usually taken by mouth with each meal tid.

Table 27–3 Iron Intake Recommendations for the Prevention and Treatment of Iron Deficiency Anemia

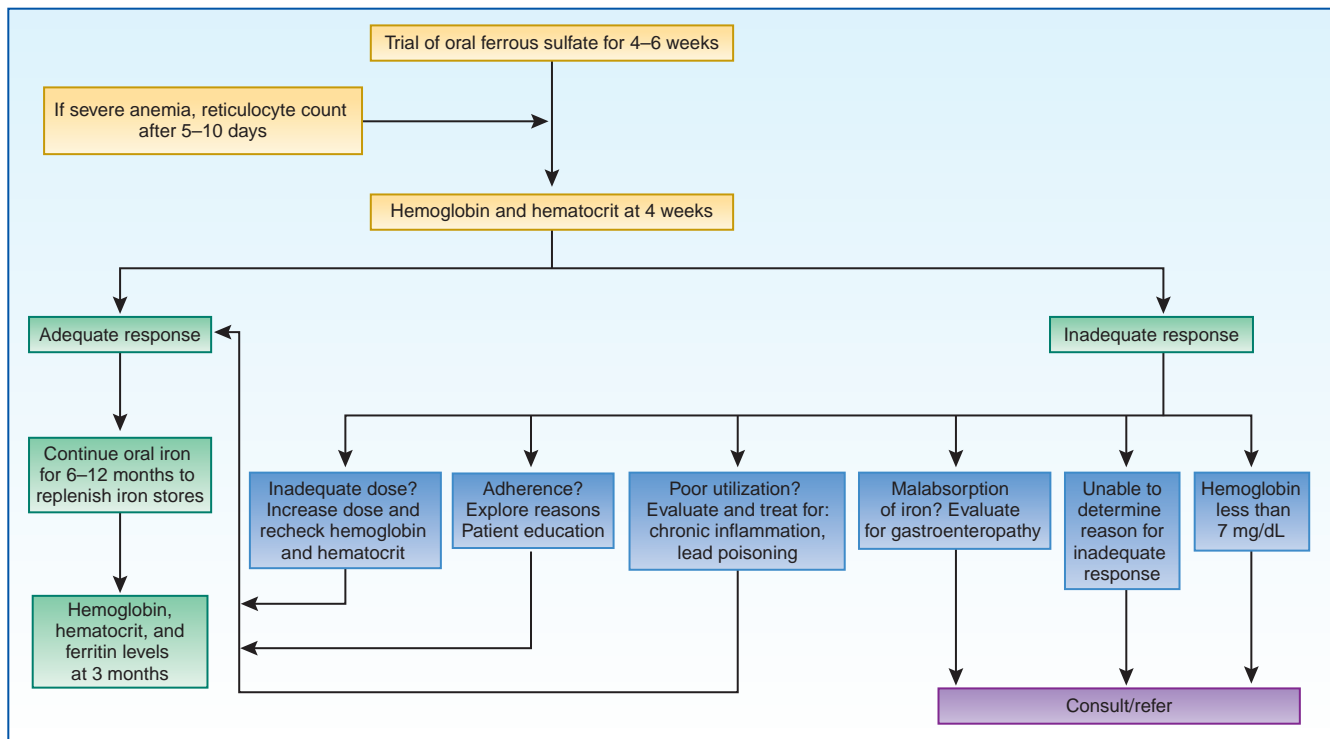
Risk Group	Prevention	Treatment
Infants	• Breastfeeding for first yr or iron-fortified formula • Preterm infants: 2 mg/kg of iron from 1 mo to 12 mo Breastfed infants 1 mg/kg per day of iron until adequate dietary intake of iron from foods • Begin iron-rich cereals or supplement at 6 mo • Screen for IDA at approximately 12 mo	Mild to moderate deficiency: 3 mg/kg/d in 1–2 divided doses Severe anemia: 6 mg/kg/d of elemental iron in 3 divided doses
Children 1–3 yr 3–12 yr Male 12–18 yr Female 12–18 yr All adolescents	7 mg/d of iron in diet 10 mg/d of iron in diet 11 mg/d of iron in diet 15 mg/d of iron in diet Diet should include iron-rich foods	1–3 yr: 6 mg/kg/d of elemental iron in 3–4 divided doses 3–12 yr: 3 mg/kg/d of elemental iron in 3–4 divided doses 12–21 yr: 150–250 mg of elemental iron/d Ferrous sulfate is best choice for oral iron Absorption enhanced by taking it on an empty stomach or with vitamins C and E; milk, antacids, tea, and food interfere with absorption
Adults 19–50 yr Male Female	8 mg/d of iron 18 mg/d of iron Diet should be high in iron-rich foods	150–250 mg of elemental iron/d (e.g., ferrous sulfate 300–325 mg tid or qid)
Adults 51+ yr	8 mg/d	
Pregnant and lactating women	30 mg of elemental iron daily during last two trimesters and while lactating	Ferrous sulfate 300–325 mg/d


Figure 27–2. Drug treatment algorithm for iron deficiency anemia.

Chapter 18 has a more detailed discussion of iron formulations. Although Chapter 18 includes ferrous sulfate, gluconate, and fumarate formulations, ferrous sulfate is the least expensive and the most easily absorbed. Slow-release and enteric-coated compounds have been advertised to reduce GI distress, and they require only once-daily dosing. However, they dissolve slowly and can bypass the proximal small bowel, where most absorption of iron takes place. Slow-release formulas are also significantly more expensive ($24.99 for 90 tablets of Slow Fe Slow Release Iron with 50 mg of elemental iron versus $4.49 for 100 tablets of generic ferrous sulfate with 65 mg of iron). There is no evidence to suggest that these formulations are worth the extra cost. If patients experience GI upset, it can be reduced by adjusting the dosage and by taking the drug with food.

Monitoring

The response to iron therapy is apparent within 10 days of initiation. The first change noted in blood values is an increase in the reticulocyte count as soon as 4 days after treatment is started, followed by a rise in Hgb concentration of 1 to 2 g/dL per day. If the anemia is severe (Hgb less than 8 g/dL), a reticulocyte count can be obtained 5 to 10 days after initiating therapy. If the anemia is not severe, Hgb, Hct, and ferritin levels are checked at 4 weeks. If the IDA is mild (Hgb 10 to 12 g/dL and Hct 30% to 60%), follow-up every 4 to 6 months is appropriate. Referral is almost never required unless there is an inadequate response to therapy in which the Hgb remains very low (Hgb less than or equal to 7 g/dL); there is a question of possible malabsorption that requires special GI testing; or the reason for the inadequate response is unclear.

Outcome Evaluation

Several weeks of therapy are required to bring Hgb levels back into the normal range, and replenishing iron stores may take months. Speed is not the issue, however, unless there is rapid blood loss. In that case, consultation or referral is appropriate. Hgb, Hct, and RBC indices should be evaluated at 4 weeks, 3 months, and annually. If the Hgb level does not return to normal limits within 6 weeks, the inadequate response should be evaluated. If the dose is inadequate, it may be increased. Starting with a lower dose and gradually increasing it reduces the likelihood of adverse reactions that may hamper adherence to the treatment regimen. Persistent, unrecognized blood loss should be sought with stool specimens for occult blood and ova and parasites. Referral to a gastroenterologist for x-rays and endoscopy may be necessary, and the source of the blood loss should be treated. If there is a history of poor weight gain, diarrhea and other GI symptoms, or surgery on the GI tract, malabsorption syndromes should be ruled out.

Poor iron utilization can result from chronic inflammation, lead poisoning, or sideroblastic anemia. Chronic inflammation can be demonstrated with elevated sedimentation rates, elevated iron and total iron-binding capacity levels, low percentage of iron saturation, and high ferritin levels. Lead poisoning is demonstrated with increased serum lead levels and basophilic stippling on RBC morphology. Sideroblastic anemia is usually found in infancy. Laboratory values reveal high ferritin levels, normal or high iron and total iron-binding

PATIENT EDUCATION

Patient education related to IDA should focus on:

1. Understanding the pathophysiology of IDA and its potential long-term effects.
2. Recognizing the importance of prevention and the role of diet and energy conservation.
3. Understanding the necessity of adherence to the treatment regimen.
4. Understanding the need for follow-up visits with the primary care provider because IDA can recur.

Stress to the patient that a diet with sufficient amounts of iron-rich foods may avoid the need for supplemental iron therapy but only after the IDA has been resolved. When diet alone is inadequate or when iron needs are very high, as in pregnancy, drug therapy is initiated. Patient education specific to drug therapy includes the following:

1. The reason for taking iron.
2. Doses and schedules for the drug.
3. Potential drug interactions and the need to inform other providers that they are taking iron.
4. Possible adverse reactions and ways to reduce them. The most common adverse reactions that lead to nonadherence are GI problems such as nausea and constipation. Taking iron with food reduces the total amount absorbed but can also reduce the nausea. Adequate fluids and fiber can prevent constipation. Stool softeners may be needed to treat constipation associated with iron therapy.

Additional patient education related to iron therapy is presented in Chapter 18.

capacity levels, and elevated bone marrow stores of iron. Each of these disorders must be treated before iron therapy can be successful. When the history, physical examination, and standard laboratory analyses do not lead to a determination of the cause of the inadequate response, or the initial Hgb level is less than 7 g/dL, consultation with or referral to a hematology specialist is appropriate.

Folic Acid Deficiency Anemia

Risk Groups

Several patient populations, including age-based, gender-based, and concomitant disease-based groups, are at risk for folic acid deficiency. Certain drugs are also associated with effects on dihydrofolate reductase, an enzyme critical to folate synthesis.

Infants who are fed powdered milk products or goat's milk develop this deficiency because these products are deficient in both folic acid and vitamin B_{12}. Older children who are exclusively vegetarian or who have severe nutritional deficiencies, absorption problems, or tapeworm

infestations are also at risk. Prolonged cooking of vegetables destroys folates and can result in deficiency if such foods are the only source of this vitamin. Older adults whose diets lack vegetables, eggs, and meat often develop folic acid deficiency. Supplementation of cereals with folic acid has been mandatory since 1998, resulting in a prevalence of folate deficiency of less than 0.1% in the general population (Odewole et al, 2013).

Women are not especially at risk unless they become pregnant. Pregnant women have increased folate requirements (800 μg daily versus 50 to 100 μg per day) and may become deficient, especially if their diets are lacking in folic acid–containing foods such as dark green vegetables. Evidence suggests that maternal folic acid deficiency is associated with increased risk for neural tube defects in the fetus.

Disease states associated with folic acid deficiency caused by impaired absorption include sprue, Crohn's disease, giardial infections, and short bowel syndrome. Disease states that result in deficiency because of increased demand include hyperthyroidism, hemolytic anemia, malignancy, and other chronic debilitating disorders. Alcoholics and patients with liver disease develop deficiency because of poor diet and reduced hepatic storage of folates. There is also evidence that alcohol interferes with the absorption and metabolism of folates. Patients undergoing renal dialysis lose folates from the plasma during dialysis, and that results in deficiency.

Drugs that interfere with folate absorption or metabolism include the antiepileptic drugs phenytoin, carbamazepine, and valproic acid, methotrexate (Folex), oral contraceptives, isoniazid (INH), triamterene (Dyrenium), trimethoprim (Trimpex), and pyrimethamine (Daraprim). Patients who take these drugs, especially on a long-term basis, should be monitored for folate deficiency.

Lifestyle Modifications

All patients should be instructed to eat foods high in folic acid. Foods high in folic acid include dark green leafy vegetables, bran, yeast, dried beans, fortified cereals, and nuts. Females should also be educated about the increased needs for folic acid prior to and during pregnancy. The U.S. Preventive Services Taskforce recommends folic acid supplements of 400 to 800 μg daily for all females planning or capable of becoming pregnant (2009).

Drug Therapy

Oral folic acid is well absorbed, and doses of 1 to 2 mg daily result in correction of the deficiency in 4 to 5 weeks. Hgb levels begin to rise within the first week, and the anemia is completely corrected in 1 to 2 months. Because of the potential teratogenic effects of folate deficiency in pregnant women, women of childbearing age should take prophylactic doses of 0.4 to 0.8 mg daily and continue this dose throughout any pregnancy. Folic acid supplementation to prevent deficiency should also be considered in the other high-risk patients mentioned previously. Detailed discussion of clinical use and dosing of folic acid is provided in Chapters 9 and 18.

Monitoring

Response to treatment is assessed after 2 weeks and then monthly until the condition stabilizes. A rapid rise in reticulocytes follows the initial treatment, with a peak in 5 to 8 days, an improving Hgb and Hct within 1 week, and a normal Hct within 2 months. The only monitoring required is to follow Hgb and Hct levels at regular intervals. The timing of such assessment is based on the acute versus chronic nature of the cause of the deficiency.

Pernicious Anemia (PA)

Risk Groups

The underlying disorder in PA is usually defective secretion of gastric intrinsic factor, which is necessary for vitamin B_{12} absorption. It is most common in northern Europeans but can occur in any age or ethnic group. Vitamin B_{12} malabsorption occurs in 10% to 30% of adults over the age of 50 because they have reduced pepsin activity and gastric acid secretion. This reduced activity interferes with the cleavage of vitamin B_{12} from dietary protein before it is absorbed. Partial or total gastrectomy and small bowel resection are the two most common iatrogenic causes of this problem. The former surgery removes the parietal cell–containing portion of the stomach that secretes intrinsic factor, and the latter surgery removes a portion of the bowel that absorbs the vitamin B_{12}–intrinsic factor complex. Diseases of the terminal ileum, fish tapeworm, thyroid diseases, and bacterial overgrowth in the small bowel from stasis can also cause PA. Nutritional deficiency is rare but may be seen in strict vegetarians after several years without meat, eggs, or dairy products.

Screen for PA any of these risk groups and other patients who present with the neurological symptoms of peripheral neuropathy, symmetrical paresthesias in the hands and feet

---

PATIENT EDUCATION

Patient education for folic acid deficiency anemia focuses on prevention as well as treatment. Diet and appropriate cooking methods are central to prevention, especially for strict vegetarians. The need for folic acid supplementation should be discussed with women of childbearing age. When diet alone is inadequate or folate needs are very high, as in pregnancy, drug therapy is initiated. Patient education specific to drug therapy includes the following:

1. The reason for taking folic acid.
2. The doses and schedule for the drug.
3. The fact that some drugs may potentially interfere with folate metabolism.
4. The need to inform their providers that they are taking supplemental folic acid.

More specific discussion of patient education is found in Chapter 18.

---

progressing to ataxia from loss of vibratory and position sense, memory loss, depression, agitation, personality change, or central visual scotomata. This is especially true for older adults, in which some of these changes may be confused with dementia.

Lifestyle Modifications

The underlying problem in PA is vitamin B_{12} deficiency. Patients should be taught to eat foods high in this vitamin, such as mollusks (e.g., clams), fortified breakfast cereals, liver, trout, salmon, milk, and eggs. These foods are listed in the order of highest to lowest amount of vitamin B_{12} (ODS, 2011). One serving of fortified breakfast cereal provides 100% of the daily requirement for vitamin B_{12},

Drug Therapy

Because the underlying problem in almost all cases of PA is malabsorption, therapy with vitamin B_{12} is required. Oral, IM, and intranasal replacements are available. Oral vitamin B_{12} is useful only for the rare case of nutritional deficit and for patients who cannot take the parenteral form. If the vitamin B_{12} deficiency is a nutritional deficit and not PA, 1,000 mcg of oral cobalamin is given until normal B_{12} levels are achieved, usually in 6 to 12 weeks. Intranasal cyanocobalamin (Nascobal), a synthetic vitamin B_{12}, may be used for maintenance therapy of patients with hematological remission after initial treatment. Once-weekly dosing of intranasal cyanocobalamin (one spray in one nostril) gives a 500 mcg dose. For PA, the parenteral route is often used, although oral therapy may also be effective (Oh & Brown, 2003). Vitamin B_{12} therapy is initiated with 1,000 mcg IM daily for 1 week followed by 100 to 1,000 mcg IM weekly for a month. Doses of 1,000 mcg may be used, as excess vitamin B_{12} is excreted in the urine. Because PA is not correctable, the patient must take vitamin B_{12} for life.

Parenteral, nasal, or oral therapy may be used once a patient's B_{12} levels return to normal. Parenteral therapy consists of 1,000 mcg of vitamin B_{12} monthly. Nasal therapy consists of 500 mcg of cyanocobalamin weekly. Oral therapy consists of 1,000 mcg daily for life. Oral therapy should be tried because of administration ease and cost.

The hematological response to parenteral vitamin B_{12} is rapid. The bone marrow usually returns to normal within 48 hours. Reticulocytosis begins on the second or third day and is usually maximum by the fifth to the tenth day. Patients usually show some other hematological improvements in 5 to 7 days, with deficiency resolving in 3 to 4 weeks. Hgb and Hct levels should return to normal within 1 to 2 months. It may take up to 6 months to resolve neurological symptoms. Correctable conditions require treatment of the underlying problem, and parenteral therapy continues temporarily. Sudden drops in serum potassium levels have been reported with vitamin B_{12} therapy. Serum potassium levels should be monitored and supplemental oral potassium given if needed.

Chapter 18 has a detailed discussion of rational drug selection and dosing for vitamin B_{12}. Although it is not urgent

to treat most cases of PA, the reversibility of neurological deficits is, to some extent, dependent on their duration. Patients with neurological symptoms should have this disorder promptly diagnosed and treated. When neurological symptoms are present, twice-monthly dosing is recommended for 6 months prior to beginning the usual monthly dose.

Monitoring

Reticulocyte counts, Hgb and Hct, iron, folic acid, and vitamin B$_{12}$ serum levels are obtained prior to treatment, between the fifth and the seventh day of therapy, and then frequently until the Hgb and Hct are normal. Relapse of symptoms is not uncommon in the presence of continuing therapy. Blood counts should continue at regular intervals throughout the patient's lifetime, based on individual response to therapy.

Because of the potential for sudden drops in serum potassium levels, these should also be monitored at the same time as Hgb and Hct levels are drawn. Liver function tests (LFTs) should also be done. If LFTs (aspartate transaminase [AST] and alanine transaminase [ALT]) are elevated before the start of cobalamin therapy, they should be evaluated every 2 to 4 weeks to monitor for liver dysfunction. If LFTs elevate after the start of therapy, more frequent testing might be required to assess for hepatotoxicity. The Schilling test is used for diagnosis but not as a monitoring tool. Referral to or consultation with a hematologist and gastroenterologist should occur with the diagnosis of PA.

Anemia of Chronic Disease

Risk Stratification and Screening

Anemia of chronic disease (ACD) is the most common form of anemia in older adults and is associated with several specific chronic diseases, including osteomyelitis, tuberculosis,

PATIENT EDUCATION

Patient education related to pernicious anemia (PA) should focus on:

1. Understanding the pathophysiology of PA and its potential long-term effects.
2. The importance of adherence to the treatment regimen.
3. The need for follow-up visits with the primary care provider in that PA and its symptoms can recur, even with continuing therapy.

Patient education specific to the drug therapy includes the following:

1. The reason for taking vitamin B$_{12}$.
2. The fact that the oral vitamin B$_{12}$ found in multivitamin tablets is not sufficient to treat the problem.
3. The doses and schedule for the drug.
4. The fact that patients need to take the drug for the rest of their lives.

rheumatoid diseases, hepatitis, carcinoma, myeloma, lymphoma, and leukemia. Anemias associated with renal failure occur secondary to erythropoietin deficiency, and the National Kidney Foundation (2006) has produced a separate guideline for diagnosis and management of this subset of ACD. Anemias associated with endocrine deficiency (e.g., thyroid, adrenal, or pituitary deficiency) reduce bone marrow responsiveness by not stimulating erythropoietin secretion. These disorders also have their own management.

Older adults with any chronic illness and patients of any age with these illnesses should be evaluated for the presence of anemia. ACD may also coexist with IDA. In these patients, ACD is usually mild and asymptomatic, but some patients may present with fatigue, shortness of breath, loss of appetite, weight loss, or light-headedness after mild activity. Because these symptoms may be the same as those seen with the underlying chronic illness, it is important to include evaluation for anemia in the work-up for these disorders (Bross, Soch, & Smith-Knuppel, 2010).

Hct in patients with ACD is rarely less than 25%; other laboratory findings are shown in Table 27-2. The criterion for the coexistence of ACD and IDA is a serum ferritin level of 20 to 50 nanograms (ng)/mL. Serum ferritin, however, may elevate in the presence of an acute inflammatory reaction and may not accurately reflect total body iron stores.

Treatment of ACD

There is no effective therapy directed specifically at ACD. Treatment of the underlying chronic disease is necessary to resolve the anemia. Sometimes, patients have a concomitant IDA that is amenable to treatment with iron, but otherwise, oral iron is not necessary. The main focus of therapy for ACD, besides treatment of the underlying disease, is energy conservation.

When ACD is caused by chronic renal failure, the cause is probably associated in part with decreased production of erythropoietin by the kidney. The target for successful treatment of this form of anemia is an Hgb level of 11 to 12 g/dL and an Hct level of 33% to 36%. To achieve this level, sufficient iron should be administered to maintain greater than 20% transferrin saturation and a serum ferritin level of 100 ng/mL or higher. In this case, administration of epoetin alfa (Epogen, Procrit) may lead to an increase of 6% to 10% in the Hct within 6 weeks. During the initiation of epoetin alfa therapy and while increasing the dose in order to achieve an increase in Hgb and Hct, the percentage of transferrin saturation and the serum ferritin level should be checked every month in patients not receiving iron and every 3 months in patients receiving iron until target Hgb and Hct are reached (National Kidney Foundation, 2006).

For patients with anemia associated with chronic renal failure or zidovudine-treated HIV, epoetin alpha is started at 50 to 100 units/kg in adults and 50 units/kg in children and dosed 3 times a week. The epoetin alpha dose is titrated to keep the Hgb level between 10 and 12 g/dL. Dosage is increased by 25% if Hgb is less than 10 g/dL and has not increased by 1 g/dL after 4 weeks of therapy or if Hgb decreases

below 10 g/dL. The epoetin alpha dose is decreased by 25% if hemoglobin approaches 12 g/dL or Hgb increases more than 1 g/dL in any 2-week period. The maintenance dose for patients on dialysis is individualized for each patient. The malignant diseases causing ACD may also require the use of this drug, which is discussed in Chapter 18.

Sickle Cell Anemia

This chapter does not discuss the total management of sickle cell disease (SCD). The reader is referred to NHLBI Evidence-based Management of Sickle Cell Disease (NHLBI, 2014) for a complete discussion and guidelines for management of common problems, such as pain and infection. However, it is important to remember that treatment of pain with NSAIDs carries with it the risk for GI bleeding, which may be a source of anemia beyond that associated with sickling. Hematuria can also occur secondary to renal abnormalities in SCD and may also contribute to anemia. This chapter focuses on management of the anemia and precipitants of sickling and the resultant ischemia.

Prevention

Prevention of the morbidity and mortality associated with the hemolytic anemia of SCD is focused on avoidance of the precipitants of a sickling crisis. Serious bacterial infections, especially those due to *Streptococcus pneumoniae, Haemophilus influenzae,* and *Mycoplasma pneumoniae,* are a major cause of sickling. Patients and their parents need to be taught early recognition of signs and symptoms of these infections, and early aggressive treatment is critical. Dehydration is another precipitant. Adequate hydration (2 qt/d or more in children and adults) should be stressed, especially during periods of elevated environmental temperature and physical activity. Exposure to cold, with its resultant vasoconstriction, can precipitate a sickling event and should be avoided.

Children with SCD should also receive all childhood immunizations as recommended by the Advisory Committee on Immunization Practices (ACIP) as discussed in Chapter 19. Additionally children with SCD need to be immunized with pneumococcal vaccine (PCV 13 and PPSV 23). Infants with SCD are considered high risk and are vaccinated with meningococcal vaccine (HibMenCY) and persons age 9 months to 55 years are vaccinated with MenACWY (NHLBI, 2014). All children with SCD should have an annual influenza vaccine, starting at age 6 months.

Although strenuous exercise may precipitate sickling, there is no evidence that most exercise is harmful, and the beneficial effects of exercise are well known. Patients with SCD are encouraged to participate in physical activities and set their own limits. Exercise capacity is reduced by as much as 50% in adults with SCD. Participation in noncompetitive recreational activities that do not involve strenuous exercise should be encouraged. Any activity, whether recreation or employment, resulting in exhaustion should be discouraged. Exercise under adverse conditions, such as

cold weather, high altitude, or cold water exposure, should also be avoided.

Dietary Counseling

Dietary counseling is an important part of patient care. Mothers should be encouraged to breastfeed their infants and give regular doses of iron supplementation per the AAP guidelines, although iron-fortified formulas are an acceptable alternative. Foods high in iron and folic acid should be encouraged in children and adults. Chapter 9 has more information on foods high in these nutrients.

Drug Therapy

Sickle cell patients should receive a daily multivitamin supplement (Tanyi, 2003). A diet rich in complex B vitamins and vitamin C and ingesting eight glasses of water daily to maintain hydration are critical.

Patients with SCA do not usually have concurrent IDA. Supplemental iron should not be prescribed unless the patient is documented to have reduced iron stores by specific assessments of the serum ferritin level or measurement of serum iron and iron-binding capacity. Children with SCA are often microcytic in the absence of iron deficiency. The incidence of the alpha thalassemia trait is also quite high in African Americans and may produce microcytosis in the absence of iron deficiency. Most patients eat poorly during painful crises, and daily supplements of 1 mg of folic acid should be prescribed during those times if not already being taken. The danger of masking a vitamin B_{12} deficiency is small, but African American patients are at risk. There is no evidence that any other form of vitamin supplementation is of value in SCD.

Infections also enhance susceptibility to vaso-occlusive events and their subsequent ischemia. Prophylactic penicillin is so effective in reducing the number of life-threatening episodes of pneumococcal sepsis in children under age 5. Most states screen newborns for SCD so they can be placed on penicillin by age 2 to 3 months. Oral penicillin VK 125 mg bid is given until age 3 years, then 250 mg bid is given until age 5 (NHLBI, 2014). Prophylaxis in older children has not been shown to be beneficial and may be unnecessary after *S. pneumoniae* and *H. influenzae* immunizations are complete and antibody titers are protective (NHLBI, 2014). Pneumococcal vaccination is also recommended for children and adults with SCD. Penicillin is discussed in more detail in Chapter 24.

A consensus statement from the National Institutes of Health published in 2008 states that evidence is strong for the use of hydroxyurea in the treatment of SCD in adults (Brawley et al, 2008). Although there is no drug to cure SCD, hydroxyurea (Droxia, Hydrea) has been shown to reduce the frequency of sickle cell pain crisis in adults, reduce the need for transfusions, and increase total hemoglobin and HgbF (NHLBI, 2014). SCD patients requiring hydroxyurea are usually managed by a specialist in hematology. The dosing schedule varies, but patients are usually started on 10 mg/kg initially, with the dose increased by

5 mg/kg every 12 weeks until the maximum dose of 25 to 35 mg/kg per day is reached, unless toxicity is observed. Toxicity is defined as absolute neutrophil counts lower than 2,000/mm³, absolute reticulocyte counts lower than 80,000/mm³, platelet counts lower than 80,000/mm³, or a fall in Hgb from greater than or equal to 7 g/dL to 4.5 to 5 g/dL if reticulocytes are lower than 320,000 or Hgb is lower than 4.5 g/dL. The BABY HUG study of hydroxyurea use in infants with sickle cell disease demonstrated significant improvement in pain, acute chest syndrome, hospitalizations, and transfusions; therefore the recommendation in the NHBLI guidelines is to start all infants with SCD on hydroxyurea at age 9 months (Lebensburger et al, 2012; McGann & Ware, 2012; NHLBI 2014).

Hydroxyurea may not be appropriate for all patients and should not be used for patients likely to become pregnant or those unwilling or unable to follow instructions regarding treatment. Hydroxyurea is a cytotoxic agent and has the potential to cause life-threatening cytopenia. The onset of leukopenia and thrombocytopenia may occur within 10 days of beginning therapy. White blood cell and platelet counts should be monitored prior to and periodically during therapy. Because hydroxyurea attacks rapidly growing cells,

stomatitis, anorexia, nausea, vomiting, and diarrhea may occur. Good oral hygiene and monitoring of nutritional status are important. Patients requiring hydroxyurea are usually managed by hematology. Patients and caregivers should be instructed not to handle the hydroxyurea tablets with bare hands; gloves should be worn.

Experimental drug therapy is being tried with erythropoietin to determine its capability in augmenting the production of fetal Hgb (HgbF). HgbF interferes with the polymerization of HgbS in solution and with the sickling of HgbS RBCs. Butyrate, a simple fatty acid widely used as a food additive, is also being investigated as an agent that may increase HgbF production. Their role in therapy, alone or in combination with hydroxyurea, is still unclear. Erythropoietin is discussed in Chapter 18.

Transfusions

With the mild to moderate anemia common to SCD, body systems except the eye and the spleen adapt fairly well to the reduced oxygen-carrying capacity of the blood. Most patients with SCD are relatively asymptomatic from their anemia and do not require transfusions to improve oxygen-carrying capacity. Transfusions may be used for specific indications

---

PATIENT EDUCATION

Patient and parental information related to sickle cell anemia should focus on the following:

1. Understanding the pathophysiology of SCD and the organs commonly damaged.
2. Recognizing the importance of prevention, especially the central role of prevention of infection and avoidance of precipitants of sickling.
3. Learning how to administer prophylactic antibiotics and other drugs.
4. Understanding the necessity of adherence to the treatment regimen.
5. Recognizing the need for regular follow-up visits with a primary care provider to manage this chronic disease.
6. Understanding the role of genetic counseling.

Prevention of sickling requires the parents and the patient to learn specific assessment skills. Any sign of illness in a child with SCD can be serious.

Patient education related to the administration of penicillin is discussed in Chapter 24.

Measures to minimize the risk of vaso-occlusive events beyond prevention of infection were discussed previously. The hazards of cigarette smoking and excessive alcohol intake and the benefits of a well-planned exercise program should be included.

Although IDA is not common for patients with SCD, prevention of IDA with a diet that includes sufficient amounts of iron-rich foods should be discussed. When iron is required, follow the patient education instructions for IDA.

Patient education specific to the use of hydroxyurea includes the following:

1. Take the drug exactly as prescribed, even if nausea, vomiting, or diarrhea occurs.
2. If a dose is missed, do not take it at all; do not double dose.
3. Notify the health-care provider of fever; chills; sore throat; loss of appetite; nausea; vomiting; diarrhea; bleeding gums; bruising; petechiae; or blood in the urine, stool, or emesis.
4. Avoid alcoholic beverages, aspirin, and NSAIDs, which may increase the risk of bleeding.
5. Inspect oral mucosa for erythema and ulceration. If it occurs, use a sponge brush and rinse mouth with water after eating and drinking. If mouth pain interferes with eating, contact the health-care provider for lidocaine-based mouthwash.
6. Encourage fluid intake of 2,000 to 3,000 mL of noncaffeinated fluid daily.
7. Review the need for contraception during therapy because of the teratogenic potential of this drug.

Patient education related to the other drugs used in treatment of SCD and its complications is presented in the Unit II chapters that include these drugs. Patient education related to the other complications of SCD is detailed in the NIH publications in the References section.

when the anemia is severe or to prevent chronic complications (NHLBI, 2014).

Monitoring

Hgb, Hct, reticulocyte counts, platelet counts, and white blood cell counts should be done frequently during the first year of life to establish the patient's baseline. After the first year, Hgb and Hct are relatively stable and need to be checked only once or twice a year in stable patients. Stable patients also require annual urinalysis, blood urea nitrogen (BUN), creatinine, and liver enzyme studies to monitor for evidence of organ damage. Before administration of transfusions, RBC antigens are needed. Patients with SCD are often difficult to crossmatch.

Most adults with SCD should have regular medical evaluations every 3 to 6 months. Blood counts, urinalysis, and routine chemistry tests should be done annually. With advancing age, complications such as chronic organ failure often require more frequent visits and more extensive laboratory evaluations. Attention focuses primarily on abnormalities in renal function and complications such as gallstones, aseptic necrosis, leg ulcers, and priapism.

Outcome Evaluation

The overall goal of therapy is the reduction in the number of sickling crises and prevention of organ damage. Hgb level goals are 9 g/dL or greater, but levels of at least 7 g/dL may be acceptable in asymptomatic patients. The goal for percentage of HgbS is 30% or less. Outcomes for chronic transfusion therapy were presented previously.

CHRONIC STABLE ANGINA AND LOW-RISK UNSTABLE ANGINA

Laura D. Rosenthal

Angina is a clinical syndrome typically characterized by deep, poorly localized chest or arm discomfort that is reproducibly associated with physical exertion or emotional stress and promptly relieved by rest or nitroglycerin. The pathophysiology behind it is an imbalance between myocardial oxygen supply and demand (ischemia) associated with coronary artery disease (CAD). Several million Americans suffer from ischemic heart disease, and more than 600,000 die each year from this disorder or its complications. Chronic stable angina is the form most commonly seen in primary care, but even these patients have a mortality risk of 1% to 4.5% annually.

Treatment includes lifestyle modifications and pharmacological and surgical interventions. Pharmacological management includes the use of aspirin, nitrates, beta-adrenergic blockers, long-acting calcium channel blockers (CCBs), angiotensin-converting enzyme (ACE) inhibitors, ranolazine, and low-density lipoprotein (LDL) cholesterol lowering with a 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitor (statin). These drugs are discussed in detail in Chapters 14 and 16. Concomitant disorders often include diabetes mellitus, hyperlipidemia, and hypertension, so the treatment regimen can be quite complex. Chapters 33, 39, and 40, respectively, discuss management of these specific disorders. The focus of this chapter is the long-term management of chronic stable angina and low-risk unstable angina that is usually done by primary care providers.

Several guidelines have been written about this management. The central guideline to which others refer or with which others are consistent is the American College of Cardiology/American Heart Association (ACC/AHA) guideline, published in 2007. The Institute for Clinical Symptoms Improvement (ICSI) guidelines published in 2011 and American College of Physicians guidelines published in 2012 all refer to the 2007 ACC/AHA guideline as a scientifically valid, high-quality review of evidence and agree with the findings of that guideline. The recommendations in this chapter are consistent with that guideline. Other guidelines that add to or differ from this guideline are also discussed.

PATHOPHYSIOLOGY

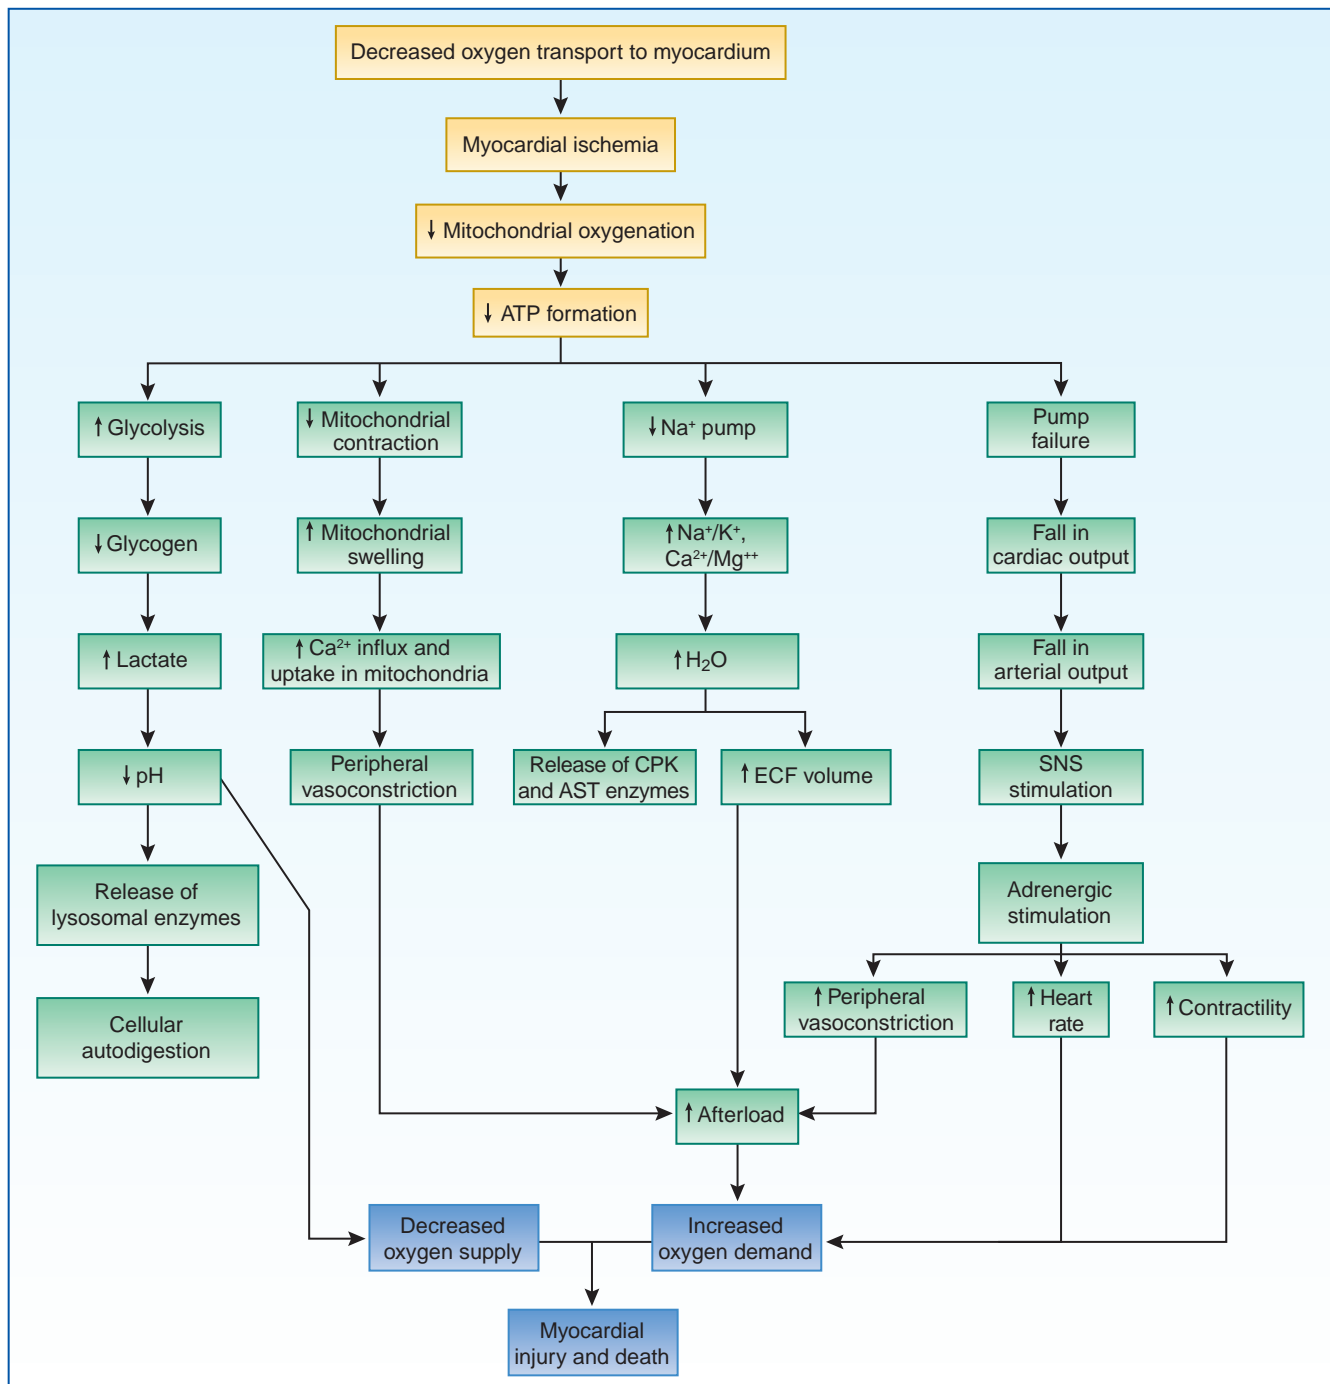
CAD, myocardial ischemia, and myocardial infarction (MI) form a pathophysiological continuum that impairs the pumping ability of the heart by depriving it of sufficient oxygen and nutrients. Figure 28-1 depicts the physiological changes that occur when the myocardium is deprived of oxygen. The coronary arteries supply oxygen to the myocardium. Oxygen extraction from these vessels is at maximum efficiency at all times, and there is little oxygen reserve during


Figure 28–1. Pathophysiology of myocardial ischemia.

periods of increased oxygen demand (McCance & Huether, 2014). Ischemia occurs when demand exceeds supply. One mechanism available to increase oxygen supply is to dilate the coronary arteries and bring more blood flow to the myocardium. Nitrates can do this in patients with normal hearts. Unfortunately, in CAD, usually associated with atherosclerosis and plaque formation, the coronary arteries are often maximally dilated already or unable to dilate secondary to plaque and calcium deposits. Most of the drugs available to treat angina decrease myocardial oxygen demand by decreasing the workload of the heart. The drugs accomplish this by decreasing afterload, preload, or both. The one exception to these mechanisms is ranolazine, whose mechanism involves reducing sodium-induced calcium overload in myocytes, which leads to myocyte dysfunction and angina.

In patients with ischemia, nitrates do not increase total coronary blood flow, but redistribute the blood to the ischemic areas. Although they have some ability to dilate the coronary arteries, nitrates are also able to facilitate movement of oxygen across the arterial–myocardial membrane. Their use in CAD relates as much to this action as it does to vasodilation.

The most common cause of CAD and resultant myocardial ischemia is atherosclerosis. The growing mass of plaque, platelets, fibrin, and cellular debris eventually narrows the lumen enough to impede blood flow. The growth of this mass is related in part to the action of angiotensin II, which acts as a growth factor for vascular cells. ACE inhibitors prevent the formation of angiotensin II and thus reduce this growth. The link between CAD and elevated plasma lipoprotein concentrations is well documented (see Chapters 36, 39, and 40). The fatty streaks that will eventually form the plaque have a lipoprotein/cholesterol base, the main component of which is LDL cholesterol. Statins have a major role in reducing LDL cholesterol concentrations and preventing plaque formation. Platelet aggregations release the prostaglandin thromboxane A_2, a potent vasoconstrictor capable of causing spasms of the coronary arteries. The use of aspirin in patients with CAD is associated with its role in irreversibly blocking thromboxane A_2.

Imbalances between myocardial supply and demand can result from a variety of conditions. Supply is reduced by the following:

- Hemodynamic factors such as increased resistance in coronary vessels, hypotension, and decreased blood volume. ACE inhibitors, beta blockers, direct renin inhibitors, and the dihydropyridine CCBs decrease peripheral resistance through their vasodilatory actions.
- Cardiac factors such as decreases in diastolic filling time, increases in heart rate, and valvular incompetence. Beta blockers and non-dihydropyridine CCBs decrease heart rate. The beta blockers have the further advantage of preventing the recurrence of MIs.
- Hematological factors such as the oxygen content of the blood, the acid–base status of the blood, and anemia.
- Systemic disorders, such as shock, which reduce blood flow or the availability of oxygen.

Demand is increased by the following:

- High systolic blood pressure, which increases the work the heart has to do to move blood from the left ventricle to the systemic circulation. One focus of anginal management is control of blood pressure. ACE inhibitors, beta blockers, direct renin inhibitors, and both types of CCBs decrease blood pressure.
- Increased ventricular volume, which increases the work the heart has to do because the left ventricle must move more blood. ACE inhibitors reduce sodium and water retention.
- Increased thickness of the myocardium (ventricular hypertrophy). The same mechanism that facilitated growth of the vessel walls in atherosclerosis also increases the thickness of the myocardium. ACE inhibitors play a major role here to decrease the remodeling. Beta blockers can assist in prevention of ventricular hypertrophy but play a smaller role.
- Increased heart rate resulting from exercise, stress, hyperthyroidism, fever, anemia, hyperviscosity of the blood, or negative feedback systems' response to decreased cardiac output. Beta blockers can assist in decreasing heart rate resulting from conditions such as hyperthyroidism and from negative feedback patterns secondary to decreased cardiac output.
- Conditions that heighten the myocardium's contractile response. Beta blockers and CCBs both have negative inotropic effects.

Ischemia caused by the imbalance between myocardial oxygen supply (MOS) and myocardial oxygen demand (MOD) produces pain referred to as angina. There are three types of angina: chronic stable angina, unstable angina, and Prinzmetal's angina. Chronic stable angina (exertional angina) is caused by narrowing of the arterial lumen and hardening of the arterial walls so that the affected vessels cannot dilate in response to the increased MOD associated with physical exertion or emotional stress. Research indicates that 75% to 80% of ischemia can be asymptomatic (silent ischemia) (Conti, Berry, & Petersen, 2012; Dweck, Campbell, Miller, & Francis, 2009). Diabetes mellitus and hypertension are associated with an increased prevalence of silent ischemia (Conti et al, 2012; Dweck et al, 2009). Ischemia with or without pain has the same prognosis, because it is the presence of ischemia, not angina, that determines outcome. In both cases, the myocardium is at risk.

On the cellular level, the myocardium becomes cyanotic within the first 10 seconds of impaired oxygen supply, and ischemic electrocardiographic (ECG) changes occur. Deprived of oxygen, the myocardial cells convert to anaerobic metabolism, and lactic acid accumulates. Myocardial nerve fibers are irritated by this lactic acid and transmit a pain message to the cardiac nerves and upper thoracic posterior nerve roots. Under ischemic conditions, cardiac cells are viable for about 20 minutes. The supply–demand imbalance must be resolved during this time to prevent permanent damage.

PHARMACODYNAMICS

Nitrates affect the supply–demand equation on both sides. Low doses of nitroglycerin preferentially dilate the veins more than the arterioles. The resulting decrease in venous return to the heart decreases left ventricular end-diastolic pressure (preload), resulting in decreased wall tension and an increased transmyocardial gradient. This increased gradient improves perfusion between the coronary arteries on the outside of the heart and the subendocardium on the inside of the heart, resulting in increased oxygen supply to the myocardium. Higher doses of nitrates dilate arterial vessels, which decreases systemic vascular resistance (afterload). Additionally, the higher doses cause further dilation of venous vessels, which results in venous pooling and decreased venous return to the heart. MOD is reduced by the reduced cardiac workload. Nitrates also dilate coronary arteries to some extent, but doing so is difficult in severe atherosclerotic arteries, and this effect is now thought to be only a small part of their action in relieving ischemia.

Beta blockers affect the supply–demand equation on the demand side. Both $beta_1$-selective agents and nonselective beta blockers decrease the force of myocardial contractility

and decrease heart rate and conduction velocity. Beta blockers also decrease systemic vascular resistance and blood pressure (afterload). All of these effects reduce myocardial oxygen demand and thus relieve anginal pain.

CCBs primarily affect the supply–demand equation on the demand side of the equation. By blocking calcium influx into cells, the dihydropyridines cause arterial smooth muscle relaxation, which results in peripheral vasodilation, decreased afterload, and ultimately decreased MOD. They also accomplish this at doses that do not affect cardiac smooth muscle. The dihydropyridines have the potential to cause coronary vasodilation, but again, because the coronary arteries are usually already maximally dilated in patients with angina, this will result in only a small, if any, increase in MOS. The non-dihydropyridine calcium channel blockers (Verapamil and diltiazem) depress the rate of sinoarterial (SA) node depolarization and slow atrioventricular (AV) conduction, resulting in a decreased heart rate as well as decreased contractility in cardiac smooth muscle. These two actions result in negative chronotropic and inotropic effects and ultimately decrease MOD. They accomplish this at doses that have only a small impact on vascular smooth muscle and consequently little effect on vasodilation.

ACE inhibitors also affect both the MOS and the MOD sides of the equation. Through their action on the renin-angiotensin-aldosterone system, ACE inhibitors prevent the formation of angiotensin II, a potent vasoconstrictor. This action decreases peripheral vascular resistance and thereby MOD, as the heart has decreased afterload against which it must pump. Reduced formation of angiotensin II also decreases the thickening of coronary artery walls, resulting in increased MOS (McCance & Huether, 2014) and decreases the thickening of ventricular walls, resulting in decreased MOD. They also reduce the secretion of aldosterone, which reduces the retention of sodium and water, thereby reducing extracellular fluid volume and preload.

Direct renin inhibitors (DRIs) decrease plasma renin activity, thus blocking the conversion of angiotensinogen to angiotensin I. Because of the lack of angiotension I, there is less available for conversion to angiotensin II. This decreases peripheral vascular resistance, thus decreasing MOD. As with ACE inhibitors, this also decreases the thickening of coronary artery walls, resulting in increased MOS. Aliskiren (Tekturna) is the only approved direct renin inhibitor available currently. Aliskiren causes less cough and angioedema than the ACE inhibitors but is still contraindicated in pregnancy.

Ranolazine has antianginal and anti-ischemic effects that do not depend on reduction in heart rate or blood pressure. At therapeutic levels, ranolazine inhibits the cardiac late sodium current. Through inhibition of the late sodium current, the pathophysiological cycle of myocardial ischemia and dysregulation of intracellular ion homeostasis that leads to angina is avoided.

Aspirin inhibits the synthesis of thromboxane A_2 in the production of platelets. This action reduces platelet aggregation to stop the cycle of vasoconstriction and platelet buildup. Research has demonstrated a role for low-dose aspirin for

male patients older than 50 as an adjunct to risk factor management to prevent a second heart attack. Women have more adverse effects than help if aspirin is taken prior to age 65. Women get more assist for cerebral vascular events than CV events from aspirin.

Finally, statins should be included in the treatment regimen for angina. Their role is on the MOS side of the equation; reduction in LDL cholesterol levels plays a significant role in decreasing the formation of atherosclerotic plaque. This plaque is central to the narrowing of the arterial lumen.

GOALS OF TREATMENT

The immediate goals are to treat to complete, or near complete, elimination of anginal chest pain and return to normal activities; maintain the patient at a symptom level of the Canadian Cardiovascular Society (CCS) classification of angina class I with minimum adverse effects; and keep blood pressure less than 130/85 mm Hg and pulse less than 70 beats per minute (Veterans Health Administration, Department of Defense [VA/DoD], 2003). The ultimate goals of therapy are to reduce the risks of MI and death. Although the clinical course of some patients may extend for 15 or 20 years, most patients with chronic stable angina are at increased risk for cardiovascular morbidity and mortality. Patient prognosis is strongly affected by the number and locations of coronary artery stenosis, the severity of the ischemia, and the presence of other CAD risk factors, such as smoking, hypertension, hypercholesterolemia, low high-density lipoprotein (HDL) cholesterol, diabetes mellitus, and age and gender considerations. Achievement of these goals is accomplished through improving oxygen supply and decreasing oxygen demand.

RATIONAL DRUG SELECTION

Angina is associated with MI and sudden cardiac death in the mind of provider and public alike. This presents a two-edged sword in therapeutic management: recognition of the potential complications, leading to consistent adherence to the treatment regimen, versus denial of the seriousness of the disorder, leading to lack of adherence to the treatment regimen. The health-care provider can improve adherence by placing angina in a realistic perspective and tailoring treatment options to each patient's needs. For effective management, the choice of treatment should be low cost, limited in complexity, and with the fewest possible adverse reactions. To achieve these treatment outcomes, lifestyle modifications and pharmacological therapy are chosen based on risk stratification, grade of angina, and specific patient variables.

Risk Stratification
Major Risk Factors
The major risk factors for CAD are age, family history, smoking, hypertension, hypercholesterolemia, low HDL

cholesterol, and diabetes mellitus. These risk factors are used in the Framingham equations for calculating the 10-year risk for the development of coronary heart disease (Anderson et al, 2007) and in the new risk equations that aim at uncovering a 7 year risk (Stone et al, 2014). In addition, conditions that decrease oxygen supply and increase oxygen demand are also major risk factors for ischemic heart disease. These include heart failure (see Chapter 36), anemia (see Chapter 27), hypertension (see Chapter 40), hyperthyroidism (see Chapter 41), valvular heart disease, and morbid obesity.

Noncardiac Factors

There are also noncardiac disorders that mimic angina because their primary symptom is chest pain. These include pulmonary embolism, pneumonia, pneumothorax, gastro - esophageal spasm or reflux, cholecystitis, peptic ulcer, pancreatitis, rib fractures, herpes zoster, and panic disorder. Some of these disorders also decrease oxygen supply and can cause angina. These disorders should be ruled out before deciding a patient has angina.

Women often have symptoms of angina that are atypical and may include fatigue, shortness of breath without chest pain, nausea and vomiting, back pain, jaw pain, dizziness, and weakness (ICSI, 2011). A study of cardiovascular outcomes in women with nonobstructive CAD (Gulati et al, 2009) found that women with traditional or atypical symptoms and signs suggestive of ischemia, but without obstructive CAD, were still at elevated risk for cardiovascular events compared with asymptomatic women. In addition, a large observational study from the National Registry of Myocardial Infarction revealed that in patients hospitalized with MI, women were more likely to present without chest pain and had higher mortality than men within the same age group (Canto et al, 2012). This elevated risk for females should not be overlooked.

Classification System for Grading Angina

The New York Heart Association (NYHA) and the CCS have devised a classification system for grading the severity of angina (Table 28-1). The lower the class, the more likely the patient's angina can be controlled by lifestyle modification and intermittent nitroglycerin (Table 28-2). The higher the class, the more likely the patient will require multiple drug therapy. The ACC/AHA guidelines have a classification system that incorporates the NYHA/CCS system and additional data. Table 28-3 depicts this classification system.

Treatment Algorithms

It is not within the scope of this book to discuss the testing involved in the diagnosis and grading of angina; however, a thorough history including questions about symptoms and when they occur related to exercise, about smoking, a physical examination, laboratory testing for possible causes of the symptoms (e.g., anemia or thyroid disorders), and a resting 12-lead ECG should be obtained. For those with abnormal ECG findings, referral to or consultation with a cardiologist is recommended. The treatment protocol discussed in this chapter assumes accurate diagnosis of angina with the appropriate diagnostic tools. Once the diagnosis is made, protocols are based on the grade or class of angina and the risk profile.

All appropriate patients with angina should be on aspirin 81 to 162 mg/d (Anderson et al, 2007; ICSI, 2011; Scottish Intercollegiate Guidelines Network [SIGN], 2007). Aspirin is known to be effective for reducing mortality in patients with CAD and has been associated with a decrease in nonfatal MI, nonfatal stroke, and vascular death (Vandvik et al 2012). In multiple studies, aspirin was associated with preventing reinfarction and significantly reduced recurrent ischemic events (Antithrombotic Trialists' Collaboration, 2009).

Table 28–1 **Grading of Angina by the New York Heart Association and the Canadian Cardiovascular Society**

Class	New York Heart Association	Canadian Cardiovascular Society
Class I	Proven coronary artery disease without symptoms	Ordinary physical activity, such as walking or climbing stairs, does not cause angina. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.
Class II	Angina only with unusually strenuous physical exertion	Slight limitation of ordinary activity. Angina occurs on walking or climbing stairs rapidly; walking uphill; walking or stair climbing after meals; in cold wind; under emotional stress; or only during the few hours after awakening. Walking more than two blocks on the level and climbing more than one flight of ordinary stairs at a normal pace and in normal conditions does not cause angina.
Class III	Angina during routine physical activity	Marked limitations of ordinary activity. Angina occurs on walking one to two blocks on the level and climbing one flight of stairs in normal conditions and at a normal pace.
Class IV	Angina during minimal activity or rest	Inability to carry on any physical activity without discomfort. Angina may occur at rest.

Table 28–2 Risk Profiles Associated With Angina

Risk	Lifestyle Risk	Physiological Risk
Low	• Nonsmoker • Normotensive • Low cholesterol • Negative family history	• Mild stable angina (class I–II) • Good exercise tolerance tests • Normal ventricular function on echocardiography
High	• Smoker • Hypertensive • Hypercholesterolemia • Positive family history	• Severe angina (class III–IV) • Unstable angina • Poor exercise test performance • Impaired ventricular function
Uncertain	• Obesity • Sedentary lifestyle • Type A personality • Emotional stress	• Silent ischemia

Table 28–3 American College of Cardiology/American Heart Association Risk Stratification in Patients With Chronic Stable Angina

Class	Description
Class I	• Disabling (CCS III and IV) chronic stable angina despite medical therapy • High-risk criteria on noninvasive testing regardless of anginal severity • Angina and have survived sudden cardiac death or serious ventricular dysrhythmias • Angina and symptoms of CHF • Clinical characteristics that indicate a high likelihood of severe CAD
Class IIa	• Significant LV dysfunction (ejection fraction <45%). CCS Class I or II angina and demonstrable ischemia but less than high-risk criteria on noninvasive testing • Inadequate prognostic information after noninvasive testing
Class IIb	• CCS Class I or II angina, preserved LV dysfunction (ejection fraction >45%) and less than high-risk criteria on noninvasive testing • CCS Class III or IV angina, which improves to Class I or II with medical therapy • CCS Class I or II angina, but intolerance to adequate medical therapy
Class III	• CCS Class I or II angina patients who respond to medical therapy and have no evidence of ischemia on noninvasive testing • Patients who prefer to avoid revascularization

CHF = congestive heart failure; LV = left ventricular.

If aspirin is contraindicated, clopidogrel (Plavix) 75 mg daily may be an effective substitute (Chen et al, 2011; Kaiser Permanente Care Management Institute, 2008; Vandvik et al, 2012). One large (19,000 patients) randomized controlled study of patients with a history of ischemic heart disease, MI, or atherosclerotic peripheral arterial disease found clopidogrel demonstrated a reduction in myocardial infarction when compared with aspirin 325 mg daily but failed to show a significant difference in reduction of stroke or total mortality (Vandvik et al, 2012).

There is no data to support the use of dual antiplatelet therapy (aspirin and clopidogrel) for secondary prevention of nonfatal MI or total mortality in patients with CAD who are greater than 1 year post MI with stent placement (Vandvik et al, 2012).

Patients with angina only on exertion, a normal resting ECG, and symptoms that can be controlled by rest and intermittent nitroglycerin (ACC/AHA class III) should be started on lifestyle modifications and have any concurrent aggravating factors or disease processes treated. For example, hypertension itself can cause angina, and elevated cholesterol contributes to the continued development of atherosclerosis. Severe anemia, hyperthyroidism, hypoxic lung disorders, diabetes mellitus, and critical valvular stenosis need to be treated and brought under control. Patients with known CAD, age 65 and older, with ECG changes on exertion, and with diabetes are considered high risk for unstable angina and should be started on both lifestyle modifications and drug therapy (Fraker & Fihn, 2007).

Lifestyle Modification

Fundamental to the management of all types and grades of angina is the reduction of risk factors through lifestyle modification. Lifestyle modifications may prevent the

development of complications commonly associated with myocardial ischemia and have little cost. Even when they cannot control angina alone, they may reduce the number and dosage of drugs required for angina management and prevent the need for surgical intervention. All patients should be advised to stop smoking, maintain appropriate levels of blood pressure and cholesterol; follow the Dietary Approaches to Stop Hypertension (DASH) diet for control of hypertension, including the recommendation for cholesterol management and achieve, to the extent possible, their ideal body weight. Table 28-4 discusses the main lifestyle modifications appropriate for patients with angina. They are similar to those appropriate for patients with hypertension and hypercholesterolemia.

When these initial therapies have not resulted in improved exercise tolerance or decreased episodes of angina, or when the patient is ACC/AHA class I or IIa on the grading scale, initial drug therapy is begun. Figure 28-2 delineates the drug treatment protocol for chronic stable angina and low-risk unstable angina.

Drug Therapy

Initial Therapy for Symptomatic Patients

ACE inhibitors and beta-adrenergic blockers are the mainstays of initial drug therapy for patients with angina (ICSI, 2011; Kaiser Permanente Care Management Institute, 2008). The second-generation dihydropyridine CCBs (amlodipine and felodipine) and long-acting nitrates can be used for treatment of angina in patients when beta blockers and ACE inhibitors are ineffective or contraindicated (Kaiser Permanente Care Management Institute, 2008; Qaseem et al, 2012). Short-acting, sublingual nitrates can be used in patients with mild, stable CAD for immediate relief on an as needed basis (ISCI, 2011; Quaseem et al, 2012). Each drug class has a group of patients for whom they are best suited and a group for whom they are contraindicated. Detailed discussions of each of these classes of drugs are given in Chapters 14 and 16. The focus here is on their role in angina management.

ACE inhibitors are recommended by the American College of Physicians (Quaseem et al, 2012) and in other guidelines (ICSI, 2011; Kaiser Permanente Care Management Institute, 2008) for all symptomatic patients with chronic stable angina to prevent MI or death and to reduce symptoms. Anderson (2007) also recommend this drug class but limit it to patients who have diabetes, hypertension, chronic kidney disease, or left ventricular dysfunction. They recommend that ACE inhibitors be considered in CAD patients even without left ventricular dysfunction. They have been shown to improve outcomes for CAD patients through their ability to both increase MOS and decrease MOD. ACE inhibitors are discussed in more detail in Chapter 16. Table 28-5 shows concomitant diseases for which they are more useful and for which they are contraindicated.

Table 28–4   Lifestyle Modifications

Attain Ideal Body Weight.

Excess weight increases cardiac workload and increases oxygen demand. It is also associated with hypertension, and loss of as little as 10 lb can significantly reduce blood pressure.

Increase Aerobic Physical Activity Within the Limitations of Angina.

The overall goal of anginal therapy is to restore optimal exercise capacity. The presence of angina, however, indicates an imbalance in oxygen supply and demand and denotes possible damage to the myocardium. Start with a level of activity that does not produce pain, and gradually increase the activity level by 1 min each day as long as there is no angina. Even limited activity is preferred to no activity. Daily activity is preferred to intermittent activity.

Reduce Daily Sodium Intake to No More Than 1,500 mg.

Sodium helps the body retain water, which increases the amount of blood volume. This increases cardiac workload and increases oxygen demand. It is also associated with hypertension. Reduced intake of this level can often be achieved by not adding salt during cooking or on the table and by watching hidden sources of salt, such as canned foods.

Maintain Adequate Intake of Dietary Potassium (Approximately 60 mEq/d).

The heart is heavily dependent on potassium for contractility.

Reduce Intake of Dietary Saturated Fats and Cholesterol.

Cholesterol and saturated fats are implicated in the development of atherosclerosis, which narrows coronary arteries and makes angina worse. The level of reduction depends on serum cholesterol levels. Hypercholesterolemia requires lower levels than those required for patients with normal cholesterol levels. Start with the American Heart Association Step 1 diet (http://www.nhlbi.nih.gov/guidelines/obesity/e_txtbk/txgd/4321.htm).

Stop Smoking.

Nicotine is implicated in several ways in making angina worse. Absorbed nicotine increases blood pressure and heart rate, thus increasing myocardial oxygen demand. Nicotine also causes vasospasm, and the rise in carboxyhemoglobin from smoke inhalation reduces oxygen supply. Even passive smoke inhalation can reduce exercise tolerance in patients with angina. The low doses of nicotine found in nicotine replacement therapy (NRT) do not significantly elevate blood pressure or heart rate, and NRT may be used to aid in smoking cessation.

Limit Alcohol Intake.

For men and heavier patients, alcohol intake should be no more than 2 oz (30 mL) of ethanol (e.g., 24 oz beer, 10 oz wine, 2 oz 100-proof whiskey)/d. For women and lighter-weight patients, the intake should be no more than 1 oz/d.

Table 28–5 Drug Choice Based on Concomitant Disease States

	Effect on Concomitant Disease States	
Drug Choice	Favorable Effects	Unfavorable Effects
Nitrates	Heart failure Hypertension	Migraine headaches MI
Beta-Adrenergic Blockers	Heart failure Arrhythmias, atrial tachycardia Hypertension "Stage fright" Migraine headaches Hyperthyroidism	Advanced AV block Uncontrolled or severe reactive airway disease Claudication/Raynaud's disease (can use beta$_1$-selective drug) Diabetes mellitus (may try beta$_1$-selective drug)
	Post-MI	Depression
ACE Inhibitors	Diabetes mellitus Heart failure Hyperlipidemia Hypertension	Contraindicated in pregnancy Bilateral renal artery stenosis Angioedema history
Direct Renin Inhibitors	Hypertension	Contraindicated in pregnancy Bilateral renal artery stenosis Angioedema history
HMG-CoA Reductase Inhibitors (Statins)	Hyperlipidemia Hypertension	Contraindicated in pregnancy Myopathy history
Calcium Channel Blockers Dihydropyridines	Hypertension, isolated systolic hypertension Systolic heart failure Raynaud's disease, peripheral vascular disease	Peripheral edema
Verapamil	Atrial tachycardias Hypertension Migraine headache MI	Advanced AV block Constipation Heart failure Concurrent use with beta blockers may cause additive bradycardia
Diltiazem	Atrial tachycardia Diabetes mellitus MI	Advanced AV block Heart failure
Amlodipine	Atherosclerosis Heart failure	

ACE = angiotensin-converting enzymes; AV = atrioventricular; HMG-CoA = 3-hydroxy-3-methyl glutaryl coenzyme A; MI = myocardial infarction.

Angiotensin II receptor blocker (ARB) therapy is recommended for patients with CAD and diabetes with hypertension and for those with left ventricular systolic dysfunction when these patients are intolerant to ACE inhibitors. For other patients who are intolerant to ACE inhibitors, there is insufficient evidence to recommend for or against ARB therapy (Kaiser Permanente Care Management Institute, 2008). ARBs can be added to ACE inhibitor therapy for clinical reasons, such as uncontrolled hypertension or insufficient vasodilation, but it is not recommended as a routine combination. The combination of an ACE inhibitor and an ARB does not reduce all-cause mortality and may increase undesired side effects.

Beta blockers with no intrinsic sympathomimetic activity (ISA) properties are recommended as initial therapy by all the guidelines for all patients, with or without previous MI, unless specifically contraindicated. They especially decrease

MOD and are the drugs of choice for exertional angina (ACC/AHA all classes). Because they do not improve myocardial oxygen supply, their main role is in preventing recurrence of MIs in patients with CAD. They are especially useful for patients with exertional angina whose lifestyle involves frequent vigorous activity, patients with resting tachycardia (e.g., hyperthyroidism), and for patients who have concomitant diseases that might benefit from beta blockade. The Kaiser guidelines (2008) make a strong recommendation for giving a beta blocker to CAD patients with left ventricular systolic dysfunction (NYHA classes I through IV). Table 28-5 shows these concomitant diseases.

Beta blockers are contraindicated for patients with severe, uncontrolled reactive airway diseases and vasospastic angina. For patients with mild to moderate reversible airway disease or chronic obstructive pulmonary disease, cardioselective beta blockers may be used as long as the airway disease is

stable and well controlled (Kaiser Permanente Care Management Institute, 2008). The most cost-effective and convenient beta blockers are atenolol (Tenormin) and metoprolol succinate (toprol XL), both with once-daily dosing, a low adverse reactions profile, and beta$_1$ selectivity. Beta blockers are discussed in more detail in Chapter 14

Most guidelines recommend lipid-lowering therapy with statins for all CAD patients who have LDL cholesterol levels greater than 100 mg/dL except the Veterans Health Administration (2003), which does not mention LDL levels, and Kaiser guidelines, which call for LDL less than 70 mg/dL in patients with CAD. Treatment of elevated LDL cholesterol is discussed extensively in Chapter 39 and the drugs themselves are discussed in Chapter 16.

Nitrates and CCBs are appropriate for symptom man - agement and specific indications. Nitrates are the oldest and best studied of the antianginals, are cost-effective, and have a variety of routes of administration that allow flexibility for the patient. They are more effective than beta blockers in relieving and preventing anginal episodes in patients with vasospastic angina. Nitroglycerin 0.3 to 0.4 mg sublingual tablets or translingual spray is used for immediate symptom relief. All patients with angina should carry some form of rapid-acting nitrate with them at all times. They should be instructed to use this medication at the first sign of angina, even if they are uncertain if the symptoms are angina. If symptoms have not improved after 5 minutes of taking one dose of this drug, the patient should call 9-1-1 for medical attention. This recommendation has been updated from the previous recommendation of taking up to three doses before calling EMS. This change encourages earlier contacting of EMS by patients with symptoms suggestive of ACS. Self-medicating with prescription drugs, including nitrates, has been documented as a common cause of delay in calling EMS among patients with ACS (Anderson et al, 2011). Chapter 16 has specific information on the treatment protocol and storage of nitroglycerin in its various forms.

For patients who respond well to sublingual or translingual nitroglycerin and who experience angina episodes more than "rarely," and who are intolerant of beta blockers, long-acting oral or transdermal nitrates are generally indicated. Among the available drugs, the most cost-effective are isosorbide mononitrate (Imdur) given daily or nitroglycerin transdermal patches applied daily with a 10 to 12 hour nitrate-free interval to prevent nitrate tolerance. The timing of the nitrate-free interval should coincide with the time of fewest episodes of angina, which is typically at night. The administration schedule that seems most effective is 7 a.m. and 2 p.m. daily. Headache is the most common adverse reaction but resolves over time. Starting with low doses and slowly increasing the dose reduces the incidence of headache.

CCBs, like the nitrates, decrease MOD. They are the initial drugs of choice when coronary artery vasospasm is suspected to be a contributing mechanism to the angina. They are also effective for patients with exertional angina who have fixed atherosclerotic CAD; when optimal doses of beta blockers or nitrates are ineffective, contraindicated, or poorly tolerated; and when a concomitant disease might benefit from the use of a CCB. Table 28-5 shows these concomitant diseases. Studies have also shown one CCB, amlodipine (Norvasc), to be effective in inhibiting vascular smooth muscle cell proliferation in atherosclerosis, and it may have a protective mechanism in preventing or retarding the progression of atherosclerosis (Ikeda et al, 2009; Martin-Ventura et al, 2008). It also has the advantage of a long half-life that allows once-daily dosing without resorting to a sustained-release form.

When initial therapy with low to moderate doses of these drugs is not adequate to control angina or to reduce progression from a lower class (ACC/AHA class I or IIa) to a higher one (ACC/AHA class IIb or III), two choices are possible. One is to increase the dose of at least one of the drugs. This is always done with consideration for the potential adverse reactions associated with that drug. In some cases, the addition of another drug to minimize the adverse reactions and provide an additive effect to maximize benefits may be more appropriate than significant increases in the initial drug. The second option is to substitute a drug from a different class. Nitrates and CCBs are both effective, for example, in vasospastic angina, but not all patients respond well to nitrates. Ranolazine has been evaluated in patients with chronic symptomatic angina despite treatment with the maximum dose of other antianginal agents. Statistically significant decreases in angina attacks were observed. This drug may be used concurrently with any of the antianginal classes discussed above and with antiplatelet and lipid-lowering drugs.

Multidrug Therapy

Combinations of beta blockers and calcium channel blockers have been shown to be more effective than the individual drugs used alone. Both amlodipine and felodipine (dihydropyridine CCBs) work especially well in groups of patients who demonstrate improvement while on this combination. Their effects on reducing MOD are complementary, making it possible to use lower doses of both drugs, and many of their adverse reactions cancel out. Lower doses also reduce the risk of hypotension. Patients not adequately controlled by either drug alone tend to benefit from the addition of the second drug. They are a questionable combination for patients with left ventricular dysfunction because together they may induce heart failure or bradycardia. Verapamil and diltiazem also should be avoided in this combination.

Combinations of a long-acting nitrate and a beta blocker are also safe, effective, and low in cost. Their effects are additive, permitting lower doses of both drugs, and their adverse reactions often cancel out. The beta blocker slows any reflex tachycardia caused by the nitrate, which helps to reduce MOD.

Combinations of long-acting nitrates and CCBs are rarely used because of the high risk for hypotension and because their adverse reaction profiles are additive. This combination is usually reserved for refractory cases of vasospastic angina.

When the drug combination greatly improves angina, it is worthwhile to attempt gradual reduction of prior drug

doses over time. For example, if the addition of a beta blocker to high-dose nitrate therapy greatly improves angina, gradual reduction in the nitrate doses can be tried.

Patients with severe (classes III–IV) angina frequently require at least three drugs from different classes. When this level of regimen is required, referral to a cardiologist is appropriate.

Drug Therapies That Are Not Helpful and/or Are to Be Avoided

According to ACC/AHA (2007) and Kaiser (2008), the following therapies are not helpful in treating angina based on evidence: vitamins C and E supplementation, chelation therapy, garlic, acupuncture, and coenzyme Q_{10}. Kaiser guidelines (2008) also mention folic acid, coenzyme Q_{10}, vitamin B_6, and vitamin B_{12} as being ineffective. Studies reviewed by Mente, deKoning, Shannon, and Anand (2009) showed varying degrees of evidence of causal links between dietary factors and coronary heart disease. No other guidelines specifically mention therapies that are ineffective.

Additional Patient Variables

Older Adults

The treatment protocol for angina is the same for older adults as it is for other adults, with consideration for the usual changes in pharmacokinetics in this age group. Lifestyle modifications are always first-line therapy because of their safety and cost. When drugs are chosen, consideration should be given to the risks for CAD and MI, which are higher in older adults. Older adults, however, may have chronic airway diseases, and nonselective beta blockers may be contraindicated if this concomitant disease is severe or uncontrolled. Congestive heart failure is also common and particularly lethal in older patients. ACE inhibitors and beta blockers have important roles in this disease process, whereas the negative inotropic effects of some non-dihydropyridine CCBs may make this disorder worse. The dihydropyridine CCBs amlodipine and felodipine do not have the negative inotropic effect and therefore do not seem to worsen heart failure in older adults. Hypertension and hypercholesterolemia are also more common in older adults. Table 28-5 shows the appropriate drug class selection for each of these disease processes.

Women

Initiation of hormone replacement therapy in postmenopausal women for the purpose of reducing cardiovascular risk is no longer recommended in the guidelines but is a current topic of debate in new literature. Data from the Women's Health Initiative indicated that this therapy may increase risk for some and was not helpful in others. Recent studies reveal that timing and duration of hormone replacement therapy may affect outcomes in women, but further research must be completed (Harman et al, 2011). The Heart and Estrogen/Progestin Replacement Study (HERS) (Miller & Oparil, 2003; Vittinghoff et al, 2003) concluded that women with coronary disease are at high risk for MI even in the absence of other risk factors.

Their risk increases up to 6-fold when many risk factors are present. Established drugs for secondary preventions, including aspirin, beta blockers, and lipid-lowering agents (statins), are underutilized in these women, especially those at highest risk.

Women of all ages are at higher risk for silent myocardial ischemia. Studies that have included significant percentages of female patients with CAD have found that taking aspirin produced the same lowering of all-cause mortality and lower incidence of nonfatal MI and stroke as found in men. The same findings have not proven true in women without CAD who are less than 65 years of age. Therefore, routine aspirin is not recommended in women without diagnosed CAD who are younger than 65 (Mosca et al, 2011). There is no gender-based difference in the treatment protocol for angina. There may be differences based on concomitant disease states such as hypertension and hypercholesterolemia (discussed in Chapters 39 and 40). Premenopausal women are at higher risk for anemia that may affect MOS. Treatment for anemia is discussed in Chapter 27.

Concomitant Diseases

Drugs used to treat angina may improve the management of some diseases and worsen others. Selection of an angina drug that treats a concomitant disease can simplify the overall therapeutic regimen, reduce cost, and increase the likelihood of adherence. It is not within the scope of this book to discuss all possible concomitant disease states, but those most common in patients with angina who might benefit from appropriate drug selection to treat the angina are discussed here.

Myocardial Infarction

Angina is usually associated with CAD, the major underlying mechanism behind MI. Both aspirin and beta blockers have been associated with MI prophylaxis and have the strongest evidence for their use. Aspirin is prescribed as for all patients with CAD. Diltiazem (Cardizem) in its long-acting form has been shown to decrease mortality for patients with non–Q wave MIs. Non-dihydropyridine CCBs should be avoided after MI for patients with poor ejection fractions (less than 40%) because of their negative inotropic effects. Nitrates tend to cause reflex tachycardia. The increased MOD associated with this tachycardia cannot be adjusted for with coronary arteries that are blocked and unable to be effectively dilated. They should be used with caution. ACE inhibitors are useful after MI to prevent heart failure and mortality. They are drugs of choice to treat angina in patients with diabetes or left ventricular dysfunction. Their action on angiotensin II produces antiatherogenic effects, and they diminish MOD and increase nitric oxide through their action on the bradykinin system. Post-MI patients who are given ACE inhibitors may also benefit from reduced angina. Both ACE inhibitors and beta blockers have been shown to decrease the cardiac remodeling that occurs with MI.

Heart Failure

Heart failure is commonly associated with higher grades of angina. Several drugs used to treat angina also reduce blood

pressure and improve myocardial function to reduce the risk for development of heart failure. ACE inhibitors are associated with decreased morbidity and mortality from heart failure and are first-line therapy for that disorder. Clinical benefits in heart failure include less dyspnea, improved exercise tolerance, reduced need for emergency care, and improved survival. A meta-analysis of five large randomized controlled trials of ACE inhibitors for symptomatic heart failure found an overall decrease in mortality of 28% (Flather et al, 2000). The greater benefit was found in patients with lower ejection fractions, but benefit was seen in all patients treated with ACE inhibitors (Flather et al, 2000).

Their "cousins," the angiotensin II receptor blockers (ARBs), are being used for treatment of heart failure in patients who cannot tolerate an ACE inhibitor. The negative inotropic effects of beta-adrenergic blockers were thought to make heart failure worse and were avoided in the past. More recent data about their role in reducing sympathetic nervous system discharge have moved them into first-line therapy in heart failure for patients with left ventricular systolic dysfunction (Hernandez et al, 2009). The beta blockers that are indicated or approved for use in patients with reduced (less than 45%) left ventricular function are carvedilol, metoprolol succinate, and bisoprolol. The dihydropyridines amlodipine and felodipine (Plendil) are the only CCBs demonstrated to be safe in treating angina with concomitant heart failure caused by advanced left ventricular dysfunction. Non-dihydropyridine CCBs should be avoided in heart failure based on their negative inotropism. Lifestyle modifications are also central to heart failure prevention and management. Drugs and lifestyle modifications for heart failure are discussed in Chapter 36.

Hypertension

All patients with angina should have their blood pressure assessed and managed consistent with the JNC 8 guidelines to a goal of less than 150/90 mm Hg, or 140/90 mm Hg if diabetic (James et al, 2014). Lifestyle modifications are the first approach to treatment of both hypertension and angina. Emphasis is placed on control of weight; reduced intake of sodium, saturated fat, cholesterol, and alcohol; and increased physical activity for both disease processes. All drug classes used to treat angina are helpful in the treatment of hypertension. ACE inhibitors and direct renin inhibitors are useful in blood pressure control based on their vasodilating effects and their ability to reduce extracellular fluid volume. Both of these actions also assist in the treatment and prevention of angina. Beta blockers are no longer first-line therapy in hypertension. CCBs are acceptable for patients with hypertension especially African Americans. Chapter 40 discusses the use of these drugs in more detail.

Hypercholesterolemia

Because hyperlipidemia contributes to atherosclerosis and the narrowing of blood vessels that result in angina, all patients with angina should have their cholesterol checked by a lipid panel with a goal of reducing LDL from baseline levels. Though specific target values are not suggested in the ATP IV, striving for LDL levels less than 100 mg/dL for most patients and less than 70 mg/dL for those in the very-high-risk category has evidence to imply better outcomes (Boekholdt et al, 2014). Factors that favor a decision to reduce LDL-C levels to less than 70 mg/dL are those that place patients in the category of *very high risk.* Among these factors are the presence of established cardiovascular disease (CVD) plus (1) multiple major risk factors (especially diabetes); (2) severe and poorly controlled risk factors (especially continued cigarette smoking); (3) multiple risk factors of the metabolic syndrome (especially high triglycerides greater than or equal to 200 mg/dL plus non-HDL-C greater than or equal to 130 mg/dL with low HDL-C [40 mg/dL]); and (4) on the basis of PROVE IT (a research trial), patients with acute coronary syndromes (Cannon et al, 2004).

To avoid any misunderstanding about cholesterol management in general, it must be emphasized the newest guidelines do not outline specific goals for everyone, but places emphasis on treatment for those at highest risk (Stone et al, 2014). As with hypertension, lifestyle modifications are the first-line approach to treatment. The only class of antianginal drugs that negatively affects hypercholesterolemia is the beta blockers. Nonselective beta blockers can increase triglycerides and LDL cholesterol and reduce the level of HDL. New evidence has shown that cardioselective beta blockers do not have as significant an effect on serum lipids (Singh, Singh, Singh, Jain, & Singh, 2012; Wai et al, 2012). Because of the availability of cardioselective beta blockers, these should be considered for use when there are other compelling reasons for the use of a beta blocker, such as MI prophylaxis

Peripheral-Vascular Diseases

The vasoconstrictive effects of nonselective beta blockers have an adverse effect on peripheral blood flow that may limit their use for patients with concomitant peripheral-vascular disease (PVD). Although these drugs are not contraindicated, caution is advised when prescribing this drug class to patients with severe PVD. The peripheral vasodilating effects of the dihydropyridine group of CCBs have resulted in their having an off-label use in the treatment of Raynaud's disease. They are the drugs of choice for patients with concomitant PVD.

Diabetes Mellitus

Diabetic patients with angina should make every effort to optimize glycemic control with a goal of achieving a near normal A1c (Fraker & Fihn, 2007). ACE inhibitors are the drugs of choice for patients with diabetes. Not only are they recommended by all the treatment guidelines used in this chapter, but they are also recommended by JNC 8 and the American Diabetes Association (ADA) guidelines (2015). CCBs are also useful because of their lower effects on glucose metabolism. They have also been shown to have some degree of renal protection.

Beta-adrenergic blockers decrease insulin secretion and may mask the signs of hypoglycemia. The one sign of hypoglycemia that is not masked is diaphoresis, and patients with diabetes who are taking these drugs should be taught to test

their blood glucose levels in the event of a diaphoretic episode. If a beta blocker must be used to treat angina for compelling reasons, blockade of these warning signs are associated with beta$_2$ blockade, and use of a beta$_1$-selective drug reduces but does not eliminate this issue. The use of beta blockers is important enough in the treatment of CAD in diabetic patients that its use in this group should not be avoided.

Elevated levels of plasma homocysteine were demonstrated to be a strong and independent risk factor for congestive heart disease events in studies of patients with type 2 diabetes or previous myocardial infarction (Agoston-Coldea, Mocan, Gatfosse, Lupu, &Dumitrascu, 2011; Soinio, Marniemi, Laasko, Lehto, & Ronnemaa, 2004). To date, research involving lowering plasma homocysteine levels through administration of vitamin B$_6$, B$_{12}$, and folic acid has not demonstrated a benefit in the prevention of cardiovascular disease.

Asthma and Chronic Airway Diseases

Beta blockers in both oral and topical ophthalmic forms may exacerbate asthma and other chronic airway diseases. Although they may exacerbate disease, they should not be avoided unless the patient has severe or uncontrolled airway disease. If they are to be used, the choice of a beta$_1$-selective oral agent and the occlusion of the nasal-lacrimal duct while administering the ophthalmic form minimize this issue. Appropriate calcium channel blockers are a good alternative for those patients with severe or uncontrolled airway disease.

Other disease processes that are affected positively or negatively by the drugs commonly used to treat angina are shown in Table 28-6.

Erectile Dysfunction

Erectile dysfunction (ED) is related to endothelial dysfunction and vascular damage, similar to hypertension and angina. Treatment of hypertension has also been associated with erectile dysfunction and may affect patient compliance with treatment of hypertension. The latest evidence, although very limited, states that beta blockers and thiazide diuretics are the drug classes most associated with erectile dysfunction (Baumhakel, Schlimmer, Kratz, Hacket, & Bohm, 2011; Manolis & Doumas, 2012). Nebivolol is the beta blocker least apt to cause ED and may even improve ED symptoms (Baumhakel et al, 2011). ACE inhibitors and ARBs have been shown to increase frequency of sexual contacts when compared with beta blockers (Baumhakel et al, 2011). No clinical trials have evaluated the effects of CCBs on erectile function.

It must be noted that phosphodiesterase-5 inhibitors (sildenafil, Viagra; vardenafil, Levitra; tadalafil, Cialis) used to treat erectile dysfunction, when taken in combination with nitrates used for chest pain, can cause severe vasodilation resulting in hypotension and syncope. In patients with CAD not taking nitrates on a regular basis, their administration in case of need should be 24 hours after the administration of sildenafil or vardenafil and 48 hours after the

administration of tadalafil. In patients taking nitrates on a daily basis, the use of phosphodiesterase-5 inhibitors is contraindicated (Chrysant & Chrysant, 2012).

Cost

The cost of antianginal drug therapy should be considered in drug selection, especially because patients are often on multiple drugs and a significant proportion of patients who are older may be on fixed incomes. In general, generic formulations are acceptable and cheaper than brand-name drugs.

Nitrates are the cheapest of the antianginals. Among the nitrates, nitroglycerin sublingual is significantly cheaper than the translingual spray. For patients with dry mouth, however, the sublingual tablet may not dissolve completely. As a result the spray, which does not have this problem, may be more appropriate regardless of cost. The spray has a much longer shelf-life and may actually be closer in price if the patient uses the drug rarely. Isosorbide mononitrate comes in an extended-release form; isosorbide dinitrate must be taken multiple times daily. If a once-daily dosing schedule is needed, the simplified regimen using isosorbide mononitrate should be considered.

Table 28–6   Drugs Commonly Used: Angina

Drug	Brand Name
ACE Inhibitors	
Captopril	Capoten
Enalapril	Vasotec
Lisinopril	Prinivil, Zestril
Ramipril	Altace
Trandolapril	Mavik
Direct Renin Inhibitors	
Aliskiren	Tekturna
Beta-Adrenergic Blockers	
Atenolol	Tenormin
Metoprolol succinate	Toprol XL
Calcium Channel Blockers	
Amlodipine	Norvasc
Diltiazem	Cardizem
Felodipine	Plendil
Nifedipine sustained release	Procardia XL
Nitrates	
Isosorbide dinitrate	Isordil
Isosorbide mononitrate	Imdur
Nitroglycerin (sublingual)	Nitrostat

ACE = angiotensin-converting enzyme; XL = extended release.

The beta blockers are in the middle in cost. An older drug, propranolol (Inderal), is relatively inexpensive, but its lipid solubility increases the adverse reactions profile, and it must be taken 2 to 4 times each day. It is a nonselective beta blocker, along with labetalol, nadolol, and timolol. Lack of selectivity results in more adverse reactions. In patients without reduced left ventricular systolic function, the drugs of choice are atenolol or metoprolol succinate. They are among the least expensive; are beta $_1$ selective; have a long half-life, enabling daily dosing; and have low lipid solubility, which results in a low adverse reaction profile.

CCBs and ACE inhibitors are the most expensive antianginals. Both classes have generic forms of some of the drugs that are less expensive. Short-acting forms are also less expensive but must be taken several times each day. Generically available, captopril is the only short-acting ACE inhibitor. Diltiazem is among the least expensive CCB; Verapamil is the least expensive, but it has limited use, and almost 100% of patients who take it develop constipation. This constipation usually requires an additional medication (stool softener) to treat the problem; therefore by the time the cost of the second drug is added in, all cost savings are lost. Amlodipine is a formulation that is also available in generic formulation. The expense needs to be weighed against its range of uses, once-daily dosing, reduced peripheral edema, decreased incidence of reflex tachycardia, and antiatherogenic properties. Aspirin brands do not appear to have significant advantages over generics. Enteric coating makes this drug more expensive, and there have been recent questions about inconsistent bioavailability with enteric coating. Therefore, use of the generic nonenteric-coated aspirin will be the most efficacious and cost-effective preparation.

MONITORING

The most important monitoring parameters are the presence, characteristics, and timing of angina episodes. Precipitating factors such as exercise, effort that involves use of the arms above the head, cold environment, walking after a meal, emotional stress, anger or anxiety, or coitus need to be reviewed. Patients should be evaluated every 4 to 6 months during the first year of therapy. After the first year, annual evaluations are recommended if the patient is stable and reliable enough to call or make an appointment when anginal symptoms become worse or other symptoms occur. The American College of Physicians (Qaseem et al, 2012) stresses the need for effective communication between providers when patients are comanaged by the primary care provider and a cardiologist.

The ACC/AHA (Anderson et al, 2007) and the American College of Physicians (Qaseem et al, 2012) recommend five questions that should be answered during the follow-up of any patient receiving treatment for chronic stable angina:

- Has the patient's level of physical activity decreased since the last visit?
- Have the patient's anginal symptoms increased in frequency or become more severe since the last visit?

If they have, has the patient decreased physical activity to avoid precipitating angina?
- How well is the patient tolerating therapy?
- How successful has the patient been in modifying risk factors and improving knowledge about ischemic heart disease?
- Has the patient developed any new comorbid illnesses or has the severity or treatment of known comorbid illnesses worsened the patient's angina?

Answers to these questions are as important as any diagnostic testing in determining whether the management plan needs alteration. Check with the patient first.

Initial laboratory studies should include an ECG and fasting lipid profile. Further tests in patients with chronic angina are based on history and physical findings and may include chest x-ray, CT angiography of the coronary arteries, or transthoracic echocardiography (Woodard et al, 2012); complete blood count (CBC); and tests for diabetes, thyroid function, and renal function (ICSI, 2011). Any further laboratory tests are largely based on the need to monitor concomitant disease states.

For ACC/AHA class III, low-risk angina patients, additional initial diagnostic tests may involve exercise treadmill testing and exercise echocardiography. After laboratory data and other monitoring parameters specific to the drugs they are taking have been taken and assessed, an annual 12-lead ECG, CBC, and blood chemistry tests are suggested. For ACC/AHA class I or II or high-risk angina patients, monitoring parameters should be determined in collaboration with a cardiology specialist. There is no clear evidence that routine, periodic testing of any sort is useful without a change in history or physical examination (Qaseem et al, 2012). The ACC/AHA (Anderson et al, 2007) consensus is that specific diagnostic tests, including chest x-ray, echocardiography, and stress testing, be done when specific changes occur in anginal symptoms, cardiac rhythms, congestive heart failure, or valvular heart disease. All of these tests require referral to a cardiologist, so it seems prudent that any significant changes in the areas mentioned trigger a consultation with a cardiologist to see if this testing is needed.

OUTCOME EVALUATION

Figure 28-2 shows the drug treatment protocol for angina management. Evaluation for angina control occurs throughout the protocol. The main indication for substitution of a drug from a different class or the addition of more drugs is inadequate control of angina or failure to reduce the grade or class to a lower grade or class of angina.

There are situations in which to worry about treating an angina patient and times when referral to a specialist is appropriate:

1. When chronic stable angina becomes unstable—Unstable angina means that it is new or accelerating or has become unpredictable in its characteristics or

Treat any concomitant diseases
Begin lifestyle modifications
Start patient on aspirin 81–325 mg/day

↓

Angina not under control
or grade not reduced

↓

Add sublingual or spray nitroglycerine (NTG)
for symptom management*

↓

Angina still not under control
or grade not reduced

↓

Initial drug choices

Add beta blocker
for all patients with
or without previous MI†

Add statin for all patients
with LDL >100 mg/dL

Add ACE inhibitor
for all patients with
LV dysfunction‡

↓

Angina still not under control
or grade not reduced

↓

Add drugs for patient with concomitant disease or therapies if not already taking
(see Table 28–5) or increase dose of one or more of initial drugs

↓

Angina still not under control
or grade not reduced

↓

Consider referral to cardiology specialist§

* If patient nitrate intolerant, may use calcium channel blocker for symptom relief.

† If beta blocker contraindicated or has unacceptable side effects, may use calcium channel blocker or long-acting nitrate.

‡ ACC/AHA recommends ACE inhibitors for diabetics and patients with LV dysfunction; American College of Physicians recommends for all with no restrictions.

§ ACC/AHA class I patients may require initial referral to cardiology specialist; consultation should occur whenever needed in planning care for all classes.

Figure 28–2. Drug treatment protocol for chronic stable angina and low-risk unstable angina.

precipitating factors. It is important to rule out the possibility that it is still stable angina but that changes in lifestyle or the onset of a concomitant illness is causing changes in the anginal symptoms. However, the time taken to rule this out should be very short, especially if ECG changes are noted. In general, patients with new-onset unstable angina should be referred to a specialist for urgent work-up.

2. When the patient has "ominous" findings on an exercise tolerance test—These tests are usually administered by

a specialist, who would probably be the first to notice the findings.

3. When a post-MI patient develops new-onset angina, especially with ECG changes—The more recent the MI, the higher the risk is. Urgent referral is required.

4. When an MI is suspected, based on anginal and other symptoms—Obtain an ECG, draw appropriate laboratory studies, and obtain a consultation with a physician.

5. When standard therapy is not successful in improving exercise tolerance and reducing the incidence of

PATIENT EDUCATION: ANGINA

Related to the Overall Treatment Plan/Disease Process

☐ Pathophysiology of angina and its prognosis

☐ Role of lifestyle modifications in improving prognosis and keeping down the number and cost of required drugs

☐ Importance of adherence to the treatment regimen

☐ Indications of complications that need to be reported and the need for regular follow-up visits with the primary care provider

Specific to the Drug Therapy

☐ Reason for taking the drug(s) and the anticipated action of the drug(s) on the disease process

☐ Doses and schedules for taking the drugs

☐ Possible adverse reactions and what to do when they occur

☐ Interactions between lifestyle modification and these drugs

Reasons for Taking the Drug(s)

Specific information related to angina includes reasons for the drugs being given. Antianginal drugs are given to reduce cardiovascular morbidity (especially MI) and mortality. Some drugs do both of these things; most do either one or the other. The expectation should be clear about what these drugs can and cannot do. Stable angina is a chronic condition that requires lifelong treatment, and so the regimen should be incorporated into the daily life of the patient. Even well-managed angina can become unstable and may require urgent management. Knowledge of when and how to use sublingual or translingual nitroglycerin is important.

Drugs as Part of the Total Treatment Regimen

Angina therapy is based on lifestyle modification. These modifications are not always easy to maintain, but they are equally as important as drugs in successful control of symptoms and prevention of complications. Among the lifestyle modifications is sodium restriction to reduce extracellular fluid volume, decrease afterload, and reduce MOD. Care should be taken not to reduce salt and fluid too quickly, which may result in fluid volume deficit, leading to hypotension and a reduction in MOS. Patients should be taught signs and symptoms of fluid volume deficit to report. None of the antianginal drugs directly reduces fluid volume, but all except aspirin have vasodilating actions that may make fluid volume deficit worse. Sodium reduction may also lead some patients to seek salt substitutes that have potassium as part of their contents. Changes in potassium levels can significantly affect myocardial functioning, so these substitutes should be used sparingly. Use of nonsalt herbal seasoning is encouraged.

   Another central lifestyle modification is regular aerobic exercise, such as walking or cycling. The amount and type of exercise must be carefully monitored and targeted to anginal symptoms. Patients can be referred to a cardiac rehabilitation program at the start of their exercise program so that their response can be monitored. Later, they can monitor their own response and determine the pace and amount of exercise that works for them. The key is gradually increasing regular aerobic exercise. Several of the antianginal drugs, especially the nitrates, have the potential to cause orthostatic hypotension. Exercise should be timed to avoid this adverse reaction, and adequate fluids should be taken while exercising.

angina symptoms, when a secondary cause of the angina that may require surgical intervention is suspected, or when the patient has complex concomitant disease processes—Consultation is appropriate. This may result in a referral, but it is generally not urgent.

PATIENT EDUCATION

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues.

ANXIETY AND DEPRESSION

Mary Weber • Krista Estes

According to the World Health Organization (WHO), major depressive disorder (MDD) is considered one of the top reasons for disability in the United States (WHO, 2012). Worldwide, it affects 350 million people across the life span, more women than men (Bromet et al, 2011; WHO, 2012). Depression, like many other chronic illnesses, can go undetected for many years, often leading to increased morbidity from other physical illnesses, substance use, and increased suicide rates (Rihmer & Angst, 2009). The most serious complication of MDD, a completed suicide, is often preventable. Suicide is a growing problem in the United States over the last few years, becoming more frequent than homicides, and in 2009 it was the 10th leading cause of death in those over age 10 (Centers for Disease Control and Prevention [CDC], 2009; Rihmer & Angst, 2009; U.S. Surgeon General, 2012).

Anxiety is a much more common and yet a misunderstood symptom. Approximately 18% of the U.S. population of adults in a given year will have an anxiety disorder (Kessler, Chiu, Demler, Merikangas, & Walters, 2005), and more women than men report having any type of anxiety disorder (McLean, Asnaani, Litz, & Hofmann, 2011). Disorders related to anxiety symptoms have changed over the years in the *Diagnostic and Statistical Manual (DSM)* and continue to evolve and change as more is learned about the neurobiology behind fear, panic, and worry. In 2013, the *DSM-V* (American Psychiatric Association [APA], 2013), differentiates between panic disorder (PD), generalized anxiety disorder (GAD) or "worry" disorder, obsessive and compulsive disorder (OCD), and post-traumatic stress disorder (PTSD). Each has a distinct set of symptoms, neurobiology, and some important differences in treatment. Anxiety disorders share

similar comorbidities with multiple chronic physical illnesses as well as depression, substance use, and increased suicide (Sadock & Sadock, 2010; Stahl, 2013).

Primary care providers (PCPs) are often the health-care providers to identify both depression and anxiety disorders and are instrumental in screening, early identification, assessment, treatment, and referral. This chapter will discuss the screening and identification of these disorders, current medications used to treat anxiety disorders and depression, the neurobiology that continues to evolve, evidence-based treatment strategies, and reasons for referral. For the purpose of this chapter, any clinician who provides individual, group, or family therapy will be referred to as a "mental health provider" and a psychiatric mental health nurse practitioner (PMHNP) or psychiatrist who prescribes psychiatric medication will be referred to as a "psychiatric provider."

ASSESSMENT AND SCREENING

According to the latest *DSM-V* (APA, 2013), definitions, the symptoms of what is called a major depressive episode must include at least a 2 week period of either a depressed mood or anhedonia (loss of pleasure in previously enjoyed people, places, and things). In addition to one or both of those symptoms, at least four of the following symptoms must be present: significant changes in weight not due to physical causes or self-restricting; sleep patterns that are different from baseline; fatigue or loss of energy that is new and not due to a medical condition; feelings of worthlessness or excessive or inappropriate guilt that occur nearly every day; as well as recurrent thoughts of death, wishing for death, up to and including plans to kill oneself (APA, 2013). As with all psychiatric disorders, medical disorders must always be ruled out first.

Assessment and screening for depressive disorders must include a work-up that excludes disorders such as hypothyroidism, anemia, kidney or renal impairment, cancers, or cardiac illnesses such as congestive heart failure. Additionally, other chronic illnesses such as HIV and hepatitis must also be ruled out because they can also cause some of the neurovegetative symptoms such as fatigue and weight loss (Sadock & Sadock, 2010). Careful assessment and screening will assist providers in early identification of a depressive disorder.

One of the most important screening tools is the Mood Disorder Questionnaire (MDQ), which can help the PCP rule in or out a depressive disorder or a bipolar disorder (APA, 2013; Hirschfield et al, 2000; Sadock & Sadock, 2010). The MDQ helps the provider differentiate whether an individual has had prior hypomania or mania episodes, which may be indicative of a bipolar disorder and would lead to a very different treatment strategy. For the individual with a positive bipolar screen, a referral to a psychiatric provider would be indicated. The Patient Health Questionnaire (PHQ-9) and the Center for Epidemiological Studies Depression Scale (CESDS) have also been used in primary care for depression screening (Kerr & Kerr, 2001). Both screening tools are not diagnostic of depression but can help as a waiting-room tool

prior to a visit to help screen for mood disorders. An evaluation, in addition to screening tools, has the best evidence to support the detection of depressive disorders given cultural and somatic issues that can make a screening tool difficult to interpret (Kerr & Kerr, 2001).

There are a number of diagnostic tools that have both reliability and validity in the diagnosis of depression as well as a way to measure outcomes of care. Some of these tools are available on the Web, and others are copyrighted and require permission to use in clinical practice. There is the Beck Depression Inventory (Beck, Ward, Mendelson, Mock, & Erbaugh, 1961) that has been translated into several languages, the self-administered Montgomery-Asberg Depression Rating Scale (MDRS-S) (Montgomery & Asberg, 1979), and The Inventory of Depressive Symptomatology (IDS): Clinician (IDS-C) and Self-Report (IDS-SR) ratings of depressive symptoms (Rush, Carmody, & Reimitz, 2006). Each of these can be used as tools by the patient and the clinician to help diagnose and then monitor progress of treatment. It is recommended that some type of consistent tool be used to evaluate the outcomes of care (Kurian, Grannemann, & Trivedi, 2012; Trivedi, et al., 2006; Zimmerman, Martinez, Friedman, Boerescu, Attiullah, & Toba, 2012).

Assessment of anxiety symptoms starts with differentiation of fear, worry, and panic. All of these feelings are "hardwired" in humans as part of the fight-flight response to danger (Stahl, 2013). However, when these symptoms cause distress leading to impairment at work, school, relationships, and general functioning, the provider must consider whether there is one or more anxiety disorders present, as they are comorbid with each other.

The first and most difficult differential diagnosis is panic disorder. A panic attack is described as a sudden, recurrent, and unexpected set of feelings and intense discomfort, both physical and psychological, that include palpitations, sweating, tremors, chest pain, shortness of breath, numbness and tingling, dizziness, light-headedness, and a fear of losing control or dying (APA, 2013). There are a number of physical causes of each of these symptoms that must be ruled out before a diagnosis of panic disorder is made. Common differential diagnoses for panic include hyperthyroidism, heart failure, cardiac arrhythmias, kidney or liver damage, anemia, a myocardial infarct, cerebral vascular accident or injury, disc disease, pulmonary embolism, and substance use disorders including alcohol withdrawal, amphetamine use, and other recreational drug use. There is a Hamilton Rating scale for Anxiety (Hamilton, 1959) that can help with identifying symptoms, as well as improvement, but it does not help differentiate whether the symptoms are physically based.

Another very common anxiety disorder is generalized anxiety disorder (GAD). This disorder is seen commonly in primary care and often overlooked and undertreated (Kessler et al, 2005; Parmentier, Garcia-Campayo, & Prieto, 2013). Symptoms of GAD include excessive worry that occurs more days than not, that is difficult to control, and that is associated with restlessness, difficulty concentrating, fatigue, irritability, and sleep disturbances (APA, 2013). As in panic, differentiating

physical causes of these symptoms, including hypoglycemia, hyperglycemia, asthma, COPD, and sleep apnea, is important before a GAD diagnosis is given.

Obsessive-compulsive disorder (OCD) is often not identified in primary care because of the shame and secrecy around some of the compulsive behaviors. The Yale-Brown Obsessive-Compulsive Scale (YBOCS) has been a good screening, assessment, and measurement tool (Goodman et al, 1989) that cde be used in primary care. Because of the complexity of treatment of OCD, it is recommended that the PCP refer these patients to a psychiatric provider for treatment.

Because of the variety of responses to distress following exposure to different levels of catastrophic events, the concept of PTSD has been reclassified as a number of disorders under Trauma and Stressor-related disorders (APA, 2013). As of 2013, the criterion for PTSD has now been expanded to include children and adolescents. There are criteria for children under 6 to include direct experience or witnessing or learning about traumatic events (APA, 2013). Other criteria continue to include recurrent, involuntary, and intrusive memories and nightmares, intense distress, and physiological reactions to triggers or cues of the stressor to make the diagnosis of PTSD (APA, 2013). Like many anxiety disorders, PTSD is often unrecognized in primary care. The post-traumatic stress disorder checklist (PCL) and the civilian version are used in both veteran populations and other adult populations to screen for the residual effects of a traumatic event but must be followed up with a full evaluation to determine if the disorder is present (McDonald & Calhoun, 2010).

There is a screening tool that has a child and parent report version to assess for potential traumatic events called the Traumatic Events Screening Inventory (TESI) (Ippen et al, 2002; Ribbe, 1996). The TESI and a revised parent version have been made more developmentally sensitive to young children (Ippen et al, 2002). This TESI tools allow the PCP to screen for events such as domestic violence, physical abuse, physical injuries, and hospitalizations. With the new *DSM-V* criteria, there will most likely be revised screening tools developed in the next few years.

One of the key screening and assessments necessary for those with either a mood and/or anxiety disorder is to assess for the presence of suicidality and level or severity of risk. According to the CDC (2010), suicide is the third leading cause of death among those aged 15 to 24 years, the second among those between 25 and 34, and the fourth leading cause of death for those aged 35 to 54. Assessment for the presence and risk of suicide is imperative in the early diagnosis of an anxiety or mood disorder as well as during treatment. The Substance Abuse and Mental Health Services Administration (SAMSA, 2009) has developed a five-step suicide assessment, evaluation, and triage method (see Table 29-1). The assessment includes identifying both risk and protective factors. Risk factors include prior suicide attempts, the presence of past psychiatric disorders including substance use disorders, family history of suicide attempts, significant stressors, and

Table 29–1 SAFE-T Assessment of Suicide Risk

Suicide Assessment Five-Step Evaluation and Triage	
Identify Risk Factors	What can be modified to reduce risk?
Identify Protective Factors	What factors can be enhanced?
Conduct Suicide Inquiry	Ask about suicidal thoughts, plans, behavior, and intent
Determine Risk/Level of Intervention	Determine risk. Choose appropriate intervention to address and reduce risk
Document	Assessment of risk, rationale, intervention, and follow-up

U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES Substance Abuse and Mental (HHS SAMSA); HHS publication number 09-4432, 2009.

access to firearms (SAMSA, 2009). Protective factors against suicide include having strong and positive relationships, feeling responsible for children or pets, strong social supports, religious beliefs, and a good ability to cope with stress (SAMSA, 2009). Assessment of risk also includes whether the individual has thoughts of death with no plan or intent, has thoughts of suicide with a plan but no intent, or has current suicidal thinking with a strong plan to die (SAMSA, 2009). All of these risk levels are important and need referral to a psychiatric provider immediately because even low-risk poses a significant risk for a completed suicide. Finally, it is essential to establish the appropriate level of care needed now, whether immediate hospitalization or referral with careful monitoring and a suicide-prevention plan in place. Specifics of a suicide prevention plan are discussed later in this chapter.

Assessment and screening for mood and anxiety disorders as well as risk factors for suicidal intent and behavior is just the beginning of treatment decisions. Anxiety disorders and depressive disorders have some distinct and overlapping neurobiology and often drive decisions about treatment. The next section will discuss the neurobiology of these disorders and how understanding these concepts will help the practitioner make good pharmacological decisions.

NEUROBIOLOGY

The neurobiology of depression has been evolving and changing over the last decade. In the classic monoamine theory of depression, the emphasis was on a deficiency of norepinephrine (NE), serotonin (5HT), and dopamine (DA). Although this theory corresponds to the use of the current antidepressants, there is little data to support it and some research results give conflicting evidence (Stahl, 2013). This theory has been supplemented with a more complicated view that involves how the neurotransmitter system regulates information processing in key areas of the brain that correspond to the symptoms of depression (Stahl, 2013).

Another theory about the cause of core symptoms of depression involves complex dysregulation of brain circuits in different parts of the brain. For example, the symptom of depressed mood is linked to problems in processing in the areas of the amygdala and the prefrontal cortex. Sleep and appetite are linked to dysfunction in the hypothalamus; fatigue is linked to NE and DA dysregulation in the prefrontal cortex and nucleus accumbens. Guilt, suicidality, and worthlessness theoretically are linked to dysregulation in the prefrontal cortex and the amygdala (Stahl, 2013).

There continues to be a significant amount of genetic research effort aimed at discovering why certain individuals develop depression and others never develop the illness. Although there is no specific gene or mutation identified, the information gathered suggests there are candidate genes that confer risk for depression that coupled with environmental stressors may contribute to the development of MDD (Stahl, 2013). There is also interest in both brain-derived neurotropic factors (BDNF) and vascular endothelial growth factor (VEGF) in the development of depression. Kotan, Sarandöl, Kırhan, Özkaya, and Kırlı (2012) described limited findings suggesting that BDNF levels might be associated with the recurrence of depression and that VEGF levels might be a determinant of the severity of depression. Although there are no medications to date that target these levels, research is pursuing leads in this area for newer medications.

The neurobiology of each of the anxiety disorders is more complex than traditionally described. Worry is a core symptom across most of the anxiety disorders. Worry and obsession have been linked to dysfunction of the corticostriatal-thalamo-cortical (CSTC) loops in the brain. Specific dysfunction of these loops may be what differentiates worry from panic and then from obsession (Stahl, 2013). In GAD, dysfunction of the circuits and the amygdala that are persistent may be the cause of persistent worry, whereas a repetitive loop may be involved in OCD (Stahl).

The neurobiology of PTSD is more complicated in that the dysfunction of the amygdala in interpretation of traumatic events and the hippocampus in the memory and re-experiencing of these events is also involved. Finally, malfunctioning of neurotransmitters that include the monoamines as well as gamma-aminobutyric acid (GABA), glutamate, and other complex circuits are involved in panic and phobias (Stahl, 2013). Neurotransmitters such as GABA, glutamate, NE, and 5HT have all been associated with the CSTC loops as well as information processing in the amygdala in all of the anxiety disorders. In this way, the neurobiology leads to more understanding of why certain medications that involve increasing GABA and 5HT have been helpful in the treatment of anxiety disorders.

EVIDENCE-BASED TREATMENTS OF MAJOR DEPRESSIVE DISORDER AND ANXIETY DISORDERS

Effectiveness trials of the use of antidepressants were conducted over several years, using individuals from primary care, university settings, and public mental health settings with MDD, including subjects with multiple comorbidities, to better reflect actual practice. The National Institute of Mental Health (NIMH) study was called the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study (Fava et al, 2006; Neirenberg et al, 2006; Trivedi et al, 2006). This was the first effectiveness research study to test the efficacy of one antidepressant and to answer the question of "What next?" This was also one of the first large randomized controlled studies in the treatment of MDD that looked at remission and not just response.

In the STAR*D trial, it was noted that it took up to 14 weeks of citalopram to reach a remission rate between 25% to 35% (Trivedi et al, 2006). The subject not remitted was then given the option of augmenting with a medication such as bupropion or switching to the same class of selective serotonin reuptake inhibitors (SSRI) or another class of antidepressant. After this second trial of the nonremitters, remission rates varied from 29% to 39% with no statistically significant difference between whether the approach was augmentation or switching within or between classes (Trivedi et al, 2006). There were a number of important findings from this large NIMH study: the goal of treatment of MDD is remission; titrate to optimal doses to reach remission; achieving remission may take up to 14 weeks; and the fact that the patients' treatment was augmented or switched on the first failure of an antidepressant doesn't matter—there is still a chance to remit with another trial of medication (Trivedi et al, 2006).

There are also a number of algorithms, such as the Texas Implementation of Medication Algorithms (2008), for the treatment of MDD and clinical guidelines from the American Psychiatric Association (2010) that support the results of the STAR*D study. Figure 29-1 is a general algorithm on the treatment of depression using the latest evidence-based research. The major emphasis from this large effectiveness study as well as guidelines and algorithms is to treat to remission and use other options as available. Patients who experienced symptom remission have an improved long-term prognosis over patients with a partial response (Rush, Trivedi et al, 2006; Sadock & Sadock, 2010; Suehs et al, 2008).

Unfortunately, there are no large effectiveness studies looking at anxiety in general. However, there are many randomized controlled trials and review articles that support the use of antidepressants as the first-line treatment of GAD (Reinhold, Mandos, Rickels, & Lohoff, 2011). In a large systematic review (SR) studying the effectiveness of antidepressants in panic disorder (PD), it was found that the following antidepressants were significantly effective in the treatment of PD: citalopram, sertraline, paroxetine, fluoxetine, and venlafaxine (Andrisano, Chiesa, & Serretti, 2013). There are also practice guidelines from the APA on the treatment of specific anxiety disorders (http://www.psych.org/practice/clinical-practice-guidelines). Figure 29-2 is an evidenced-based algorithm on the general approach to the treatment of anxiety disorders.

In a meta-analysis and SR, Stein, Ipser, and Seedat (2006) reported that SSRIs are often the first-line treatment for

General Algorithim for the Treatment of Depression Based on STAR*D Effectiveness Research

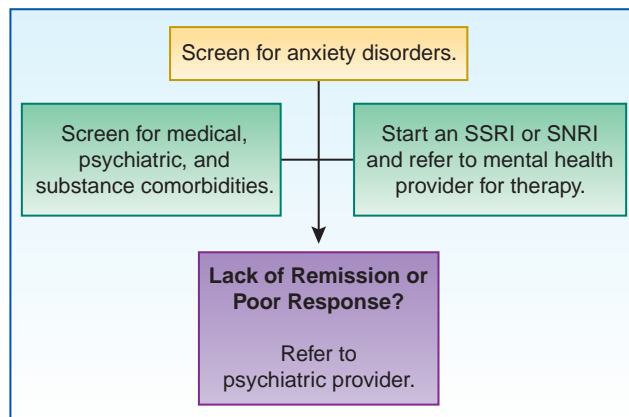
General Algorithim for the Treatment of Adults With Anxiety Disorders


Figure 29–2. General algorithm for the treatment of anxiety disorders.

PTSD, but there are significant gaps in evidence about this disorder. The Department of Defense (2010) reviewed the literature on SSRIs and alternative medications such as atypical antipsychotics in the management of this complicated illness. There are mixed results for all classes of medications with more of a symptom-based treatment approach for PTSD (http://www.healthquality.va.gov/Post_Traumatic_Stress_Disorder_PTSD.asp). For primary care, screening for these individuals and referral to a psychiatric provider is the most prudent given the significant comorbidities associated with PTSD (Sadock & Sadock, 2010).

There has been significant evidence mounting over the years for the role of exercise in many mental illnesses

(Weber, 2010). In a Cochrane SR of exercise and depression, exercise was found to be helpful in the reduction of depressive symptoms (Rimer et al, 2012). Although no SR of exercise in anxiety disorders has been published, there are a growing number of studies supporting the use of exercise as adjunctive treatment in anxiety disorders (Asmundson et al, 2013). In smaller studies, exercise has shown reduction in symptoms in GAD and panic disorder (Herring, Jacob, Suveg, Dishman, & O'Connor, 2012; Merom et al, 2008), OCD (Abrantes et al, 2012), and PTSD (Newman & Motta, 2007).

Cognitive behavior therapy as well as other types of therapies specific to disorders, such as exposure therapy, eye movement desensitization, and reprocessing (EMDR), and short-term psychodynamic psychotherapy have been found to be efficacious alone and as adjunct treatment in depression (Driessen et al, 2009), and anxiety disorders (Fjorback, Arendt, Ørnbølel, Fink, & Walach, 2011; Sadock & Sadock, 2010). Discussion of these techniques is beyond the scope of this chapter, but it is important for the primary care provider to refer individuals with anxiety and depressive disorders to mental health providers who can augment the pharmacological therapy with these interventions.

CLASSES OF MEDICATIONS

Classes of drugs used for anxiety and depression treatment include: nonselective norepinephrine-serotonin reuptake inhibitors (tricyclic and heterocyclic), serotonin-selective reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), norepinephrine-dopamine reuptake inhibitors (NDRIs), serotonin-agonist reuptake inhibitors (SARIs), norepinephrine-serotonin specific agonists (NaSSAs),

MAO inhibitors (MAOIs), and benzodiazepines (BZDs). Each class acts on neurotransmitters in a different way. The following is a review of the different classes of antidepressant medications.

Nonselective Norepinephrine-Serotonin Reuptake Inhibitors

Nonselective norepinephrine-serotonin reuptake inhibitors (NNSRIs) were previously referred to as tricyclic antidepressants (TCAs); they include such drugs as amitriptyline, clomipramine, imipramine, desipramine, nortriptyline, and doxepin. In presynaptic nerve terminals, this class of drugs inhibits the reuptake of NE and 5HT while also blocking serotonergic, α–adrenergic, histaminic, and muscarinic receptors. This increases the availability of NE and 5HT to bind to postsynaptic receptors, which results in an elevated mood, improved sleep, and weight gain (Stahl, 2011).

The NNSRI class of drugs is equally efficacious in treating depression as the other classes and is less expensive. However, these drugs are no longer considered first-line treatment due to their greater side-effect profile and risk of overdose and death. Sedation is a common side effect; therefore, it is recommended that these drugs be taken at bedtime (Stahl, 2011). Weight gain and autonomic side effects are also common (Stahl, 2011). Often less than a week's worth of these medications can produce life-threatening cardiac arrhythmia, hypotension, seizures, and extreme sedation, and death can occur (Stahl, 2011). Due to a narrow therapeutic index and risk for overdose, these medications should not be prescribed to anyone at moderate or high risk of suicide. In patients with other medical conditions, such as benign prostatic hyperplasia, epilepsy, preexisting cardiac arrhythmias, and unstable angina, exacerbation of their condition may occur (Khouzam, 2012). These drugs are generally not well tolerated by the elderly due to their anticholinergic side effects (Stahl, 2011).

Serotonin-Selective Reuptake Inhibitors

SSRIs are the class of drugs that include paroxetine (Paxil), fluoxetine (Prozac), sertraline (Zoloft), fluvoxamine (Luvox), citalopram (Celexa), and escitalopram (Lexapro). These drugs act by blocking the transport mechanism that returns unbound 5HT left in the synaptic cleft into the presynaptic neuron, thereby terminating the transmission of the message carried by that receptor. When the transport mechanism is blocked, more 5HT is available to bind to the postsynaptic serotonin receptor (Stahl, 2013).

Vilazodone (Viibryd) is a newer antidepressant to treat major depressive disorder in adults (Stahl, 2011). It is considered to be a serotonin partial agonist reuptake inhibitor (SPARI) with $5HT_1$ a partial agonist activity. Its activity is hypothesized to increase serotonin from several mechanisms (Stahl, 2011).

There is little evidence for superior effectiveness of one SSRI over another (Riley, McEntee, Gerson, & Dennison, 2009). To a significant degree, the SSRIs interact with many other drugs. They are highly protein bound and inhibit the CYP450 isoenzyme system to varying extents, leading to many potential drug interactions (Stahl, 2011). Patients who are taking several other drugs may benefit from a drug choice that has fewer drug interactions. For a chart of substrate and inhibitory drugs in the CYP450 system, see Table 29-2.

Table 29–2 ▓ **Four Cytochrome P-450 Isoenzymes and Potential Drug Interactions**

Isoenzyme	Substrates	Inhibitors
1A2	Acetaminophen, caffeine, theophylline, trimipramine, doxepin, clomipramine, amitriptyline, tacrine, propranolol, clozapine, trazodone, mirtazapine, alprazolam	Citalopram, fluoxetine, fluvoxamine, nefazodone, fluoroquinolones, grapefruit juice
2D6	Fluoxetine, sertraline, amitriptyline, clomipramine, desipramine, imipramine, nortriptyline, trimipramine, maprotiline, venlafaxine, nefazodone, trazodone, paroxetine, bupropion, flurazepam, Type I antiarrhythmics, dextromethorphan, oxycodone, codeine, haloperidol, perphenazine, risperidone, propranolol, alprenolol, timolol, metoprolol, indoramin, vilazodone (Viibryd)	Citalopram, fluoxetine, fluvoxamine, paroxetine, sertraline, nefazodone, trazodone, venlafaxine, amitriptyline, clomipramine, quinidine, fluphenazine, haloperidol, perphenazine, methadone
2C19	Citalopram, clomipramine, nortriptyline, desipramine, trimipramine, diazepam, omeprazole, phenytoin, fluoxetine, venlafaxine, phenelzine, vilazodone (Viibryd)	Citalopram, fluvoxamine, fluoxetine, paroxetine, sertraline, venlafaxine, mirtazapine, imipramine, tranylcypromine, diazepam, cimetidine, omeprazole
3A4	Loratadine, alprazolam, clonazepam, diazepam, midazolam, triazolam, estazolam, flurazepam, carbamazepine, amitriptyline, imipramine, clomipramine, bupropion, nefazodone, sertraline, trazodone, venlafaxine, citalopram, calcium channel blockers, amiodarone, disopyramide, lidocaine, propafenone, quinidine, erythromycin, acetaminophen, codeine, androgens, dexamethasone, estrogens	Fluvoxamine, fluoxetine, paroxetine, sertraline, nefazodone, venlafaxine, mirtazapine, diltiazem, verapamil, clarithromycin, itraconazole, ketoconazole, cimetidine, dexamethasone, grapefruit juice

SSRIs are commonly the initial drug of choice for patients with depression and many of the anxiety disorders. These drugs demonstrate equal efficacy to the nonspecific SNRIs with a safer and more tolerable side-effect profile. The more common adverse side effects include dizziness, sexual dysfunction, nervousness, nausea, sleep disturbance, and weight changes (Stahl, 2011). Serotonin syndrome is a potentially life-threatening condition resulting from excess serotonin agonist activity. This can result from too rapid titration of medication, overdose, a drug interaction, or an adverse drug reaction. This syndrome is more common than once thought. Medications such as tramadol, meperidine, St. John's Wort, and the over-the-counter medications dextromethorphan and decongestants often can interact with the SSRIs and cause serotonin syndrome (Stahl, 2013). The symptoms start out as diarrhea and diaphoresis and can progress to mental status changes, autonomic dysfunction, and neuromuscular abnormalities, up to death (Sadock & Sadock, 2010; Stahl, 2013). Treatment consists of discontinuation of the offending drug, supportive care, control of agitation, and possible hospitalization (Stahl, 2011; Wu, 2012).

In 2011, the U.S. Food and Drug Administration (FDA) issued a *Drug Safety Communication* stating that citalopram should no longer be used at doses greater than 40 mg per day because it could cause potentially dangerous abnormalities in the electrical activity of the heart. Its use at any dose is discouraged in patients at risk for QT prolongation. The revised labeling in 2012 describes what precaution needs to be taken when citalopram is used in these patients and those over the age of 60. Recommendations include the periodic use of ECG monitoring and/or electrolyte monitoring in patients with risk conditions, the discontinuation of citalopram in patients found to have persistent QTc measurements greater than 500 ms, and the limitation of the maximum recommended dose of citalopram to 20 mg per day for patients older than 60 years of age. The labeling recommendation for patients with congenital long QT syndrome who are at particular risk of torsade de pointes, ventricular tachycardia, and sudden death when given drugs that prolong the QT interval has been changed from contraindicated to not recommended (U.S. FDA, 2012).

Discontinuation syndrome may occur when a patient takes an NNSRI or an SSRI for more than 5 weeks and the dose is sharply reduced or stopped suddenly. Symptoms include agitation, anxiety, balance problems, bad dreams, concentration issues, dizziness, diarrhea, nausea, vomiting, electric shock-like sensations and flu-like symptoms (Stahl, 2011). This can occur in up to 30% of patients anywhere from days to weeks after stopping or reducing the medication and is more common in medications with a shorter half-life. Gradual tapering may prevent discontinuation syndrome symptoms (Wu, 2012). Fluoxetine has the lowest risk of causing these symptoms (Stahl, 2011). A few controlled studies as well as clinical experience has shown that among the SSRIs, discontinuation symptoms are more likely with paroxetine than with sertraline, citalopram, or escitalopram and all of the NNSRIs (Stahl, 2011).

Serotonin-Norepinephrine Reuptake Inhibitors

SNRIs block the reuptake mechanism of NE and 5HT, thus permitting greater availability of these neurotransmitters to bind with the respective receptors in the brain. Several SNRIs are available in the United States for the treatment of depression, including venlafaxine (Effexor and Effexor XR), duloxetine (Cymbalta), and desvenlafaxine (Pristiq) (Stahl, 2011). Levomilnacipran (Fetzima) is the newest medication approved in this class, but it should only be used in major depressive disorder (MDD) in adults and is not indicated for the treatment of fibromyalgia (FDA, 2013). Duloxetine was approved by the FDA to treat diabetic neuropathy in addition to depression (Riley et al, 2009). Prescribers are cautioned that there are other medications in this class that should not be considered interchangeable with these drugs. For example, Milnacipran (Savella) is pharmaceutically categorized as an SNRI but does not have FDA indication for depression; it is used for fibromyalgia treatment.

SNRIs elicit adverse reactions similar to those of SSRIs. In addition, common side effects include insomnia and elevated blood pressure. These drugs would not be the first choice for those with uncontrolled hypertension, preexisting sleep disturbance, and autonomic instability. As with the SSRIs, abrupt cessation should be avoided because discontinuation symptoms may occur (Stahl, 2011). Because of the addition of the norepinephrine neurotransmitters, these SNRIs are also found to be lethal in overdose, and limiting the quantity prescribed is warranted (Stahl, 2011).

Norepinephrine-Dopamine Reuptake Inhibitors

Only one NDRI is available in the United States: bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL). Its mechanism of action is not fully understood, but it has been found to increase NE and DA by weakly inhibiting their neuronal reuptake. Bupropion is indicated in the treatment of major depressive disorder, including seasonal affective disorder, and it can also be used as an adjunct in smoking cessation (Stahl, 2011).

Due to the short half-life of bupropion, more than once-a-day dosing for major depressive disorder may be required, which may have an impact on sleep. The use of the slow-release (SR) preparation (bupropion SR) or extended-release (XL) preparation once a day (bupropion XL) facilitates once-a-day dosing. The XL formulation, with a half-life of approximately 24 hours, is only intended for once-a-day dosing in the morning. The XL formulation, although now generic, is often more costly than the SR. The SR formulation has a half-life of 10 to 14 hours and can be dosed twice a day. If a second dose of the SR is required, it is usually recommended to give the second dose no later than 5 hours before bedtime because of the stimulating effect of the drug and the possible effect on sleep. There is an increased risk of seizures at high

doses so it is recommended that prescribers stay within the recommended maximum total daily dose of 450 mg and use should be avoided in patients at risk for seizures (Stahl, 2011). Bupropion has a dose-dependent increased risk for seizures in patients with eating disorders or those with chronic medical conditions that require the use of diuretics (Sadock & Sadock, 2010). Side effects may include dry mouth, sweating, tremor, and nervousness (Stahl, 2011). Due to a lack of direct effects on serotonergic neurotransmission, there is a lower incidence of sexual side effects (Sadock & Sadock, 2010; Thase et al, 2005). NDRIs are not effective in treating symptoms of anxiety because they may actually exacerbate anxiety and agitation (Riley et al, 2009; Sadock & Sadock, 2010).

Serotonin Agonist Reuptake Inhibitors

There are two SARIs: nefazadone and trazadone. They not only inhibit the reuptake of 5HT but also block the postsynaptic $5HT_2$ receptor subtype (Sadock & Sadock, 2010). With long term use, these drugs have the ability to increase serotonin release through the desensitization of $5HT_{1A}$ receptors. Both of these drugs also have a mild to moderate α_1-receptor antagonism (Stahl, 2011).

Nefazadone has an FDA Black-Box Warning related to hepatotoxicity; the drug is available only in generic form at this time. This drug has beneficial effects on sleep and is associated with minimal sexual side effects (Sadock & Sadock, 2010). On rare occasions, trazodone has been associated with priapism and anticholinergic side effects (Stahl, 2011). Both of these drugs are usually not recommended as a first-line antidepressant due to the potential side effects of sedation and orthostatic hypotension (Sadock & Sadock, 2010).

Norepinephrine- and Serotonin-Specific Agonist

Mirtazapine (Remeron) is a unique addition to antidepressants used to treat anxiety and depression. It is a 5HT agonist and reuptake inhibitor that blocks the reuptake of NE and the somato-dendritic reuptake of 5HT, resulting in an increase in 5HT available for release from the presynaptic neuron and more NE available in the synaptic cleft (Stahl, 2011). Mirtazapine specifically blocks the $5HT_2$ and $5HT_3$ receptors. This results in less sexual, gastrointestinal, and anxiogenic side effects (Sadock & Sadock, 2010). Unfortunately, it also blocks histamine, which contributes to the commonly observed side effects of drowsiness and weight gain at some doses (Sadock & Sadock, 2010). This may be an advantage for treatment in patients who are depressed with difficulty sleeping or patients with weight loss. Mirtazapine does not have the anti-muscarinic side effects of NNSRIs (Stahl, 2011).

Monoamine Oxidase Inhibitors (MAOI)

Monoamine oxidase is an enzyme found in nerve and other tissues, such as the liver and gut, that contributes to degradation

of the monoamines (DA, 5HT, and NE). In doing so, more of these neurotransmitters are available for postsynaptic binding (Stahl, 2011). The MAOIs block monoamine oxidase by binding to the enzyme and permanently inactivating it. Synthesis of replacement MAO requires about 2 weeks. This allows for levels of the catecholamines (DA and NE) and 5HT to rise, but it also decreases MAO availability for two other amines found in human diets, tyramine and phenylethylamine. MAO is a natural rate-limiting substance needed to detoxify tyramine in the human body before it causes such severe events as a sudden rise in pulse and blood pressure. Therefore, use of the MAOIs requires dietary restrictions of tyramine-containing foods, such as any aged meats and cheeses and fermented products (e.g., wine, beer, sauerkraut, soy sauce) (Stahl, 2011).

The MAOIs phenelzine, tranylcypromine, isocarboxazid, and selegiline inhibit MAO. Because there are significant dietary restrictions that, if neglected, can contribute to lethal side effects, these drugs are used less often than are other antidepressants and should only be prescribed by psychiatric providers (Sadock & Sadock, 2010). Hypertensive crisis is another potential major side effect of MAOIs. Patients may complain of occipital headache radiating frontally, sweating, photophobia, palpitations, stiffness in the neck, and nausea or vomiting. MAOIs can have dangerous interactions with many medications, including over-the-counter medications and herbal remedies. After discontinuing an SSRI or other serotoninergic, MAOIs must not be administered for 2 to 5 weeks (Stahl, 2011). This is considered a "wash-out" period.

Selegiline is available as a transdermal patch (Ensam), which avoids first-pass metabolism and produces less inhibition of the liver and gut MAO. This drug is associated with fewer food restrictions, but higher doses may cause an interaction with tyramine-containing foods and is a risk factor in elevated doses (Stahl, 2011). Transdermal selegiline is not FDA approved for use in children less than 12 years of age (Stahl, 2011). Given the risks, in depression treatment this drug should be given only by a psychiatric provider.

Benzodiazepines/GABA-ergics (BZDs)

The BZD medications are controlled substances occasionally used to treat acute anxiety. The legal implications of prescribing

controlled substances are found in Chapter 4. BZDs are no longer considered first-line agents for the treatment of anxiety disorders and have been replaced by the SSRIs and SNRIs. The BZDs are divided into short-acting agents: oxazepam (Serax) and triazolam (Halcion); intermediate-acting agents: alprazolam (Xanax), lorazepam (Ativan), estazolam (Prosom), and temazepam (Restoril); and long-acting agents: diazepam (Valium), quazepam (Doral), clorazepate (Tranxene), chlordiazepoxide (Librium), and flurazepam (Dalmane) (Stahl, 2011). BZDs act on the chloride ion channel of GABA-A receptors when they are bound to their adjacent BZD receptor. In doing so, they enhance GABA neurotransmission, which then lengthens hyperpolarization of the impulse, thus slowing down responses to successive impulses. The net effect is to decrease reactivity of the brain (Stahl, 2013). BZDs have five main effects: anxiolytic, anterograde amnesia, anticonvulsant, muscle relaxation, and sedation (Stahl, 2011).

The advantages of BZDs are rapid onset of action, tolerability, inexpensive in generic form, and little effect on the cardiovascular system. The disadvantages of the BZDs far outweigh the benefits for the treatment of anxiety disorders and will make depressive symptoms worsen. The use of BZDs is associated with dependence and withdrawal, risk of overdose, respiratory depression and death, sedation, interaction with alcohol, impaired motor coordination, and impaired cognition. A sign of dependence is the need for larger dosing to achieve therapeutic effect and inability to function without the medication (Stahl, 2011).

When used for a prolonged period of time, withdrawal symptoms may occur when benzodiazepines are stopped. If addiction or withdrawal is suspected, a referral to a psychiatric provider with experience in addiction is required to help the dependent individual withdraw safely (Sadock & Sadock, 2010). Abrupt discontinuation of long-term use of any benzodiazepine has been associated with seizures, and withdrawal may involve hospitalization (Sadock & Sadock, 2010). The two most common side effects of BZDs are drowsiness and confusion. Precaution should be used when prescribing these drugs to patients with liver disease and acute narrow-angle glaucoma. Sedative effects can be enhanced in patients who drink alcohol and take other CNS depressants (Stahl, 2011).

Buspirone (Buspar) is a nonbenzodiazepine GABA agonist that is FDA approved to treat anxiety disorders (Stahl, 2011). It does not act directly on the GABA receptor but as a partial agonist to the 5HT1A receptor. It also has some affinity for the DA2 receptors and 5HT2A receptors. Buspirone has minimal side effects and low risk of dependence, but the 3 to 4 week therapeutic lag time, multiple daily dosing, and subtle effects make it less popular among patients than are other anxiolytic agents (Stahl, 2011). It does not produce cognitive or memory impairment or disinhibition euphoria as the BZDs do but does interact with alcohol (Stahl, 2011).

ADVERSE DRUG REACTIONS

The adverse drug reactions seen with antidepressants can often be explained by understanding their action on the receptors in the CNS. The SSRIs are not specific for the receptor subtype to which 5HT binds. Instead, all the available SSRIs can bind with any 5HT receptor subtype. The binding of 5HT to the $5HT_2$ receptor may be implicated in the adverse sexual reactions of the SSRIs. With $5HT_2$ antagonists (e.g., nefazodone and trazodone) and the $5HT_{14}$ agonist buspirone (BuSpar), however, the sexual dysfunction effects are minimal (Kennedy & Rizvi, 2009). Because the SSRIs have minimum to no effect on norepinephrine, dopamine, histamine, or acetylcholine, there are few adverse reactions associated with blockade of these receptors (e.g., anxiety, restlessness, drowsiness, constipation, and orthostasis) (Stahl, 2011). Serotonin syndrome, another adverse reaction, was discussed earlier.

Reduced sexual desire, delayed or absent orgasm, premature ejaculation, and erectile disturbance can occur when taking any antidepressant, but they are most common with SSRIs (Stahl, 2011). These adverse reactions usually do not become evident for about a month, which may be more noticeable as the depressive symptoms are reduced. The patient may also have a primary reason for sexual dysfunction that needs to be evaluated. Educating patients about this possible side effect and informing them of other treatment options early can reduce the risk of patients decreasing their dosage or stopping treatment due to sexual dysfunction (Stahl, 2011). As the advanced practice nurse treating the patient, it is important to ascertain that the patient is experiencing sexual side effects due to the medication and not a co-occurring medical disorder or other reason. If the antidepressant is the cause of the sexual side effects, consider lowering the dose or changing to another antidepressant with less sexual side effects, such as bupropion. If the patient does not want to try a different medication and the lowered dose does not help, other strategies for male patients might include adding sildenafil or tadalafil (Stahl, 2011).

RATIONAL DRUG SELECTION

General Principles in Selecting an Initial Antidepressant

Clinical guidelines recommend that symptoms of depression and anxiety are best treated with a combination of medications and psychotherapy (Black, 2006; Eddy, Dutra, Bradley, & Westen, 2004; Mitte, 2005; Pampallona, Ballini, Tibaldi, Kupalnick, & Munizza, 2004; Rush, Trivedi et al, 2006; Thase et al, 2007). Many of the medications commonly used to treat anxiety are also used to treat depression (Posmontier & Breiter, 2012). For example, paroxetine is FDA approved to treat MDD, OCD, panic, GAD, and PTSD. Escitalopram is approved for the treatment of MDD and GAD. Sertraline is indicated for use in MDD, panic disorder, PTSD, and OCD. Fluoxetine is approved to treat MDD for ages 8 and older, OCD for ages 7 and older, bulimia, and panic disorder. Fluvoxamine has the approval to treat OCD and social anxiety disorder. Venlafaxine XR is indicated for MDD, GAD, and panic disorder (Stahl, 2011).

Research suggests that all antidepressants are equally effective; therefore the most important considerations are differences in onset of action and adverse events (Gartlehner et al, 2008). In one meta-analysis, the clinical effectiveness (a 50% reduction in symptoms after 8 weeks) of 12 new-generation antidepressants and patient acceptability (low dropout rates) in adults being treated for major depression were assessed. Escitalopram and sertraline were found to be the most effective (Cipriani et al, 2009). The Agency for Healthcare Research and Quality (AHRQ, 2012) did a comparative analysis and did not find differences in outcomes between antidepressants. Continued research and systematic reviews are needed to give providers more assistance in better rationales for antidepressant choice.

According to the APA practice guidelines (2010) for depression, the effectiveness of antidepressant medications is generally comparable between and within classes of medications. Therefore, it is suggested that a comprehensive psychiatric assessment be performed and initial selection of an antidepressant be largely based on the preference and prior response of the patient, clinical features, safety and anticipated side effects, coexisting medical conditions (both physical and mental), the pharmacological properties of the medications, and cost. For example, in an overweight individual, mirtazapine may not be the first choice because of the higher risks of weight gain. In addition, because mental disorders are often familial, it is helpful to know if anyone else in the family has similar symptoms and what medications have worked for them. When several choices are reasonable, select the medication that other blood relatives have had success with because they are likely to affect the patient in the same manner (Stahl, 2011). All of the antidepressants discussed in this chapter usually take 2 to 4 weeks to produce the full therapeutic effect, with gradual improvement beginning with the vegetative symptoms, then arousal symptoms, before the relief of mood symptoms. Refer to the general treatment algorithm for depression (Fig. 29-1).

Anxiety

As discussed above, anxiety is a normal emotion in response to threat or anticipation of harm. The total body responds through the autonomic system by preparing the body to flee the situation, remain and fight, or remain and freeze (Cash & Glass, 2011). Clearly, anxiety serves an adaptive purpose, and to automatically medicate anxiety may be countertherapeutic. When a patient maladaptively responds to stress and meets criteria for one of the anxiety disorders, the provider should consider medication and therapy (Cash & Glass, 2011; Sadock & Sadock, 2010).

The primary neural pathways involved in anxiety include 5HT, NE, and GABA. Therefore, pharmacological intervention can use nonselective norepinephrine-serotonin reuptake inhibitors, SSRIs, and/or SNRIs, or serotonin agonists. (Sadock & Sadock, 2010; Stahl, 2011). SSRIs and SNRIs can be used for GAD, PTSD, obsessive-compulsive disorders, and panic attacks. They usually take 2 to 4 weeks to provide the full therapeutic effect. Anxiety symptoms often resolve earlier than depressive symptoms, and they usually require a much lower dosage. For all anxiety disorders, starting low and going slow is the best way to avoid excessive serotonin adverse effects (Stahl, 2011). Refer to Figure 29-2 for a general algorithm for the treatment of anxiety disorders.

Buspirone does not produce tolerance or dependency. It requires about 2 weeks to reach the full therapeutic level, which may be intolerable to those with severe anxiety. Behavioral strategies can complement the medication effect, especially while waiting for the full therapeutic medication effect. It cannot be taken as needed and must be taken on a regular basis, usually more than once a day. Buspirone seems to be especially effective with patients who have generalized anxiety disorder.

Post-Traumatic Stress Disorder

There is evidence that cognitive behavioral therapy (CBT) (Mueser et al, 2007) and eye movement desensitization and reprocessing (EMDR) (van den Berg & van der Gaag, 2012) have been effective for the treatment of PTSD. Some patients may further benefit from medication in addition to psychotherapy (Sadock & Sadock, 2010). Medications prescribed to treat PTSD symptoms act primarily upon 5HT, NE, GABA, and DA neurotransmitters associated with the fear and anxiety circuitry of the brain. The FDA has approved two SSRIs, sertraline and paroxetine, for PTSD treatment. All other medication uses are off-label, although there is growing evidence supporting the use of the SSRI fluoxetine (Prozac) and for the SNRI venlafaxine (Effexor). Caution is needed in treatment of individuals with PTSD because comorbidity with traumatic brain injury or other mood and substance disorders is common (Department of Defense, 2010). More studies are needed at this time (National Center for PTSD, 2012).

Obsessive-Compulsive Disorder

Treatment of OCD is most effective when medication is combined with cognitive-behavioral therapy (Sadock & Sadock, 2010). OCD is typically treated with serotonin reuptake inhibitors. The mechanism by which these drugs work in the brain of an OCD patient is not fully understood despite numerous studies (Stein & Steckler, 2010). Clomipramine, a tricyclic antidepressant, and SSRIs (fluvoxamine, fluoxetine, sertraline, and paroxetine) have all been shown to be effective medications for OCD treatment. FDA-approved treatment for children with OCD includes fluoxetine and sertraline (Stahl, 2011).

MONITORING AND PATIENT EDUCATION

It is important to build a trusting relationship and be optimistic when discussing treatment options with patients. Make sure that the patient knows that recovery is possible

and that confidentiality will be respected. Information about treatment and support groups should be provided (National Institute for Health and Clinical Excellence, 2012). Once treatment is initiated, the patient's status needs to be frequently monitored for response to treatment, possible side effects, safety, increased suicidal thinking, and adherence to treatment at least every 1 to 2 weeks. This should begin 1 or 2 weeks after the initiation of therapy (Qaseem, Snow, Denberg, Forciea, & Owens, 2008). When considering frequency of follow-up appointments, consider the severity of the illness, co-occurring medical conditions, available support systems, progression of symptom change, and the patients' cooperation with treatment (Stahl, 2011). If a patient needs closer monitoring, refer to a psychiatric provider. (See Table 29-3 for recommendations about when to refer to a psychiatric provider.)

Currently, all antidepressants have a Black-Box Warning regarding an increased risk of suicidal thinking and behavior in children, adolescents, and young adults to age 24 (FDA Consumer Health Information, 2009). Because depression itself is associated with an increase in suicidal ideation, the chances of such ideation must be considered when making a choice about appropriate treatment (Sadock & Sadock, 2010). All patients who are prescribed an antidepressant and the parents of children or adolescents should be educated to monitor for an increase in suicidal ideation or behavior. It is especially important to assess for suicidality at the time of diagnosis, after initiating treatment, and as treatment progresses. The antidepressants begin to work on sleep, appetite, and energy, with mood as one of the last symptoms to remit. This puts all individuals being treated for depression and anxiety at risk for suicidal thinking.

The assessment, evaluation, and triage system discussed above and in Table 29-1 must be used every 1 to 2 weeks early in treatment and when increasing dosage (FDA Consumer Health Information, 2009; Sadock & Sadock, 2010). Immediate referral and possible hospitalization need to be considered if the patient persists in suicidal thinking (U.S. FDA, 2007). Some antidepressants, such as the NNSRIs and the SNRIs, can be lethal in overdose. When using these medications early on in treatment, consider dispensing weekly quantities and be aware of the possibility of hoarding. For patients who are having suicidal ideation, consider a safer medication in overdose, such as an SSRI (APA, 2010).

Planning ahead for the potential for suicidal ideation must always be considered as the treatment plan for each

individual is established. According to the U.S. Surgeon General's 2012 report on a Comprehensive National Strategy on Suicide Prevention, there needs to be support and treatment available at multiple points of entry. At the primary care provider and emergency department level:

- Screening improves the likelihood that the person will receive appropriate evaluation and treatment;
- Training on recognition of risk and quality of care increases the likelihood of a good outcome;
- The care provider accurately diagnoses and records the problems and ensures that the appropriate public health surveillance systems are notified or made aware of the diagnoses;
- The implementation of trauma-informed policies and practices ensures that the person is treated with respect and in a way that promotes healing and recovery;
- Easy access to mental health-care referrals for individuals with suicide risk increases the likelihood of a better outcome;
- Education efforts by health-care providers increase knowledge of the warning signs of suicide risk among the individual and his or her family and/or support network; and
- Continuous care and improved aftercare lead to better monitoring and follow-up of the at-risk individual over time (U.S. Surgeon General, 2012, p 12).

During the acute treatment phase, it is important to monitor the patient's response to ensure the treatment has been given for a sufficient duration, frequency, or dose. A patient needs about 4 to 8 weeks of optimal dosing of medication treatment to appropriately evaluate whether or not there is a partial response or no response at all. Treatment should be modified if remission has not been obtained in at least a 14 week period of optimal dosing or there has been little symptomatic improvement (Qaseem et al, 2008; Rush, Trivedi et al, 2006). If there is a mild-moderate response, increasing the dose or switching antidepressants or using of augmenting agents discussed earlier from the STAR*D results should be considered (Rush, Trivedi et al, 2006 Trivedi et al, 2006).

It is important to know when to refer someone who is not responding to treatment. Table 29-3 gives a list of possible reasons for referral to a psychiatric provider. Consider referring any individual with a poor response to two adequate trials of antidepressants, a chronic suicide history, comorbid PTSD, comorbid eating disorders, or if this person shows indications of a more complicated mood disorder. Refer to psychiatric providers immediately those with any psychotic disorder and those who are dependent on substances (Sadock & Sadock, 2010).

When reassessing and modifying a treatment plan, it is important to consider the patient's diagnosis, side effects, treatment adherence, psychotherapy, pharmacology, co-occurring conditions, and psychosocial factors (Stahl, 2011). Once the patient shows relief and response from the original symptoms and adverse reactions are tolerable, both the medication and psychotherapy should be continued for at least

Table 29–3   When to Refer

When to refer to a psychiatric provider
- Bipolar disorder
- Suicidality
- Psychosis
- Significant substance disorder comorbidities
- Comorbid PTSD or OCD
- Comorbid eating disorder
- Failure of two antidepressants
- Possibility of a personality disorder

4 to 9 months to reduce the risk of relapse (Qaseem et al, 2008). It is important to monitor for signs of relapse during this time. A patient's family can be helpful in the identification of relapse (Stahl, 2011).

Maintenance therapy may be necessary for some patients, especially those with a history of three or more major depressive disorders, a recurrent illness, or another medical and/or psychiatric disorder (Sadock & Sadock, 2010). If maintenance therapy is needed, the same treatment that was effective in the acute and continuation phases should be used. The patient should continue to be regularly monitored for signs of reoccurrence (Stahl, 2011).

When planning with the patient to discontinue antidepressant medication, it is important to select a target time when ordinary stresses are low; holidays, major family events, or return to school are not good times to discontinue medication. The medication should be tapered over at least several weeks. Relapse risk is high in the first 2 months after discontinuation. It is important to follow up with the patient during this time period. Educate the patient about the signs, symptoms, and potential for relapse as well as the need to restart treatment should this occur (Stahl, 2011).

COMORBIDITY OF MEDICAL AND PSYCHIATRIC DISORDERS

The diagnoses of anxiety and depressive disorders complicate the diagnosis and management of chronic medical diseases and contribute to poor outcomes. The choice of medication in treating depression and anxiety depends on the prominent symptoms the patient presents, comorbid conditions, other medications the patient is taking, and tolerance to adverse reactions (Stahl, 2011). Chronic illness and chronic disease progression can exacerbate concomitant depression and anxiety disorders. It remains important to treat these comorbid anxiety and depressive disorders, but slower titration and lower doses may be necessary if liver or kidney functions are compromised (Stahl, 2011).

Various studies indicate that migraines (Lake, Rains, Penzien, & Lipchik, 2005); pulmonary diseases such as asthma (Cooper et al, 2007); pulmonary hypertension, chronic obstructive pulmonary disease (COPD), and chronic bronchitis (Goodwin, Kroenke, Hoven, & Spitzer, 2003); fibromyalgia (Thieme, Turk, & Flor, 2004); cardiovascular diseases (Frasure-Smith & Lesperance, 2005) such as carotid atherosclerosis (Jones, Bromberger, Sutton-Tyrrel, & Matthews, 2003); irritable bowel disease (Mussell et al, 2008); and diabetes (Anderson, Freedland, Clouse, & Lustman, 2001) all have remarkable association with depression and/or anxiety (Howard, El-Mallakh, Rayens, & Clark, 2007).

Furthermore, frequent users of primary care and emergency services are twice as likely to have anxiety and depression than are mid- and low-range users (Ford, Trestman, Steinberg, Tennen, & Allen, 2004; Roy-Byrne & Wagner, 2004). Current research clearly demonstrates that treatment of depression and anxiety symptoms are an essential element of patients' general health state, their ability to cope with physical illnesses, and their quality of life with chronic illness. Primary care providers are the gatekeepers for these patients and recognition of the comorbidity can influence the outcomes for these patients if the PCP recognizes and treats the mental health features along with the physical health features.

SPECIAL POPULATIONS

There is growing evidence to support early detection of depressive and anxiety symptoms in children and adolescents and the use of developmentally appropriate assessment tools (Birmaher et al, 1999; Connolly, Bernstein, & Work Group on Quality Issues, 2007). The Screen for Child Anxiety-Related Disorders (SCARED) screening tool has both a child and parent version. (Birmaher et al, 1999). This is a short screening tool for children ages 8 to 11 that can help the PCP to look for generalized anxiety disorder and social or significant school phobias. It is recommended that questions be clarified with the child and that the tool be used with the adult caregiver (Birmaher et al, 1999). There is a recent systematic review that supports the use of cognitive behavioral therapy in children with anxiety disorders (James, James, Cowdrey, Soler, & Choke, 2013). Positive results from the screen should prompt the PCP to refer the child and parent to mental health providers for further evaluation.

According to the United States Preventive Services Taskforce (USPS, 2009), there is not enough evidence to support the use of routine screening for depression in children ages 7 to 11. Screening for adolescents ages 12 to 18 for MDD is recommended only when there is a system in place for accurate diagnosis, psychotherapy, and follow-up (USPS, 2009). The Guidelines for Adolescent Depression-Primary Care (GLAD-PC) was developed from 2005 to 2007. Its purpose is to provide a clinical guideline, information, recommendations, education resources, and tools for depression management of adolescents aged 10 to 21 in primary care. The guideline can be viewed at http://www.gladpc.org/ (GLAD-PC, 2010).

There is growing evidence for the use of antidepressants in children and adolescents for anxiety and depressive disorders. An SR of antidepressants for depressive disorders in children and adolescents provided some data to support the use of SSRIs in depressive disorders but also noted risks for increased suicidality (Hetrick, McKenzie, Cox, Simmons, & Merry, 2012). The evidence to support the use of SSRIs in children with OCD is not sufficient to support the use of medications in children with other anxiety disorders (Ipser, Stein, Hawkridge, & Hoppe, 2009). Fluoxetine is FDA approved for MDD and OCD in children 7 and older. Escitalopram is approved for MDD for children ages 12 and older (Stahl, 2011). Caution should be used when SSRIs are used in children and teenagers. One out of 50 report suicidal ideation as a result of treatment (Sadock & Sadock, 2010). As suicidal depressed patients begin to improve with treatment,

they begin to have the physical energy to carry out the act, whereas before they did not have the will to do so (Sadock & Sadock, 2010). These child and adolescent patients should be closely monitored for worsening depression and suicidal thoughts whenever treatment is initiated or the dose is adjusted (U.S. FDA, 2007).

Symptoms of depression and anxiety are not different in older adults. The evidence described above, including the STAR*D trial and other systematic reviews of anxiety disorders, support the use of antidepressants in elders with depression and anxiety disorders with remission the outcome of treatment. The major differences in treating older adults with anxiety and depression include starting low and going slow on dosages and being more aware of medical comorbidities and drug-drug interactions that occur more frequently with older adults (Sadock & Sadock, 2010). The American Geriatrics Society (2012) Beers Criteria for Potentially Inappropriate Medication Use in Older Adults cautions against BZD use because studies have found an increased sensitivity, which may result in an increased risk of falls, delirium, cognitive impairment, motor vehicle accidents, and fractures.

The one population that deserves special attention is the childbearing woman. There is some evidence of mild congenital abnormalities, an increase in low-birth-weight babies, and premature deliveries in those pregnant women taking antidepressants (Udechuku, Nguyen, Hill, & Szego, 2010). There has also been increased incidence of primary pulmonary hypertension in neonates in women treated with SSRIs (Udechuku et al, 2010). However, there is also evidence of poor neonatal outcome and poorer cognitive scores in children born to women with untreated depression (Guedeney, 2007; Tronick & Reck, 2009). This is a significant risk/benefit discussion that must take place prior to pregnancy. Once pregnant, the primary care provider needs to refer this woman to a psychiatric provider and an obstetrical provider so that a therapeutic plan can be created and used by all providers from pregnancy through the postpartum period (Sadock & Sadock, 2010).

Postpartum depression (PPD) is a significant illness with an impact on the mother as well as the infant (Deave, Heron, Evans, & Emond, 2008). In primary care, PPD is often undetected and untreated (Boyd, 2012). A recent review of the literature shows that PPD screening improves clinical outcomes (Gjerdingen & Yawn, 2007). Use of the Edinburgh Postnatal Depression Scale (EPDS) increases the diagnosis of PPD by approximately 20% (Georgiopoulos, Bryan, Wollan, & Yawn, 2001).

Finally, an ongoing debate is whether the breastfeeding woman who has significant anxiety and depression should take antidepressants. There are levels of risk that have been determined by the FDA, but these ratings can change with more evidence. The best plan is for the health-care provider and pregnant woman to review the U.S. National Library of Medicine, Drugs, and Lactation Database (LactMed) (http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm) for the latest information on risks to the infant from any drug while breastfeeding to make a decision based on the latest evidence.

OUTCOME EVALUATION

Outcome evaluation and appropriate referral points have been discussed in this chapter. Remission is the desired outcome of all treatment of anxiety and depressive disorders. Advanced practice primary care nurses are likely to see patients with depressive and anxiety symptoms in their practice, whether or not the patients directly identify their concerns as depression or anxiety. Therefore, it is important to assess possible physical reasons for the depressive and anxiety symptoms first. A thorough examination, including laboratory studies such as a complete blood count, liver and kidney function, and thyroid function, can help the practitioner rule out medical causes of symptoms that can mimic depression and anxiety symptoms, narrow the clinical options, and treat appropriately (Richardson & Puskar, 2012).

Medications target symptoms and the neural pathways in different parts of the brain. Some of the psychological and social symptoms, such as low self-esteem, social withdrawal, and poor communication, can be better treated with psychotherapy. Because the physiological, psychological, and social symptoms occur together in depression and anxiety, it would serve the patient best by not only prescribing medications but also discussing psychotherapy and referring the patient to a therapist to learn some new ways of coping with stress (Sadock & Sadock, 2010). When making a referral, it is equally important to inquire about the attendance and effectiveness of the referral at later appointments. If the patient has not followed up on the referral, the clinician should ask about this and offer additional referrals if necessary.

Working with the patient who is depressed and/or anxious can be challenging. Frequently, the primary care provider takes on the prescribing and medication management role while the patient is in therapy and after therapy is concluded. The primary care advanced practice nurse is in a pivotal position to assist the patient to find a therapist that best fits his or her own needs. It is important, therefore, to have readily available a list of therapists of both genders who are culturally diverse. When recommending therapy, the patient should ideally be provided with two or three names of therapists. Discussing with the patient the therapists' features that would make the patient feel the most comfortable (e.g., gender, discipline, geographical area, ethnicity) invites the patient to follow up on the referral. It is also helpful to tell the patient a little about each referral specific to therapeutic style (e.g., interactive, a good listener), theoretical orientation (e.g., cognitive-behavioral, interpersonal), and special interests (e.g., family conflicts, developmental transitions, sexual orientation). Of course, this requires that the advanced practice nurse know something about the therapists. That information is acquired through networking and collaboration.

Maintaining an open line of communication between the therapist and the PCP, with a patient's signed authorization for the release of information, reduces confusion in treatment direction. Respectful and collaborative consulting with mental health professionals yields rewarding outcomes for both patient and provider. Probably the greatest reward for the

PCP is seeing and hearing about the improvement the patient is making. It is tempting for both patient and primary care provider to attribute success to the medications, but to do so invalidates the power and capacity of patients. Medications can only help the brain return to its normal functioning. It is the whole person who makes the changes necessary for recovery to mental health.

● CLINICAL PEARLS ●

Treatment and Monitoring of Patients with Anxiety and Depression

1. Always evaluate a patient for hypomania or mania before starting an antidepressant because these conditions can worsen bipolar symptoms.
2. When there is any anxiety disorder, consider starting all antidepressants low and going slow.
3. Start low and go slow when treating older adults with depression and/or anxiety.
4. Always monitor for suicidal thoughts throughout the entire treatment.
5. Always discuss the risks of fetal damage with a woman of childbearing potential who is taking an antidepressant BEFORE she gets pregnant so that she knows the risks and benefits of treatment.
6. Always monitor for signs and symptoms of serotonin syndrome, especially asking about new medications prescribed or any over-the-counter medications taken.
7. Taper off antidepressants slowly; most have discontinuation side effects.
8. Withdrawal or discontinuation symptoms include dizziness, nausea, diarrhea, sweating, irritability, and increased anxiety. If these occur, raise the dose to stop symptoms and taper even more slowly.
9. Do not start monoamine oxidase inhibitors (MAOIs) within 14 days of stopping other antidepressants; do not start another antidepressant until 14 days after stopping an MAOI.
10. It is tempting for both the patient and primary care provider to attribute success to the medications, but to do so invalidates the power and capacity of patients.
11. Medications can only help the brain return to its normal functioning. It is the whole person who makes the changes necessary for recovery to mental health.

CONCLUSIONS

Primary care providers carry a major responsibility for screening, assessing, and providing overall health care for the majority of patients within the health-care system. This is complicated by the need to control costs, time efficiency, and range of services. Because many patients first seek help for any health problem from their primary care provider, the primary care provider also has an essential role in identifying mental health issues that influence health care and quality of life. By collaborating with mental health-care and psychiatric providers, including advanced practice psychiatric mental health nurse practitioners, the primary care providers can increase success rates in the treatment of both mental health and physical disorders. Some primary care settings include mental health-care providers as consultants and providers within the same clinic. This enhances collaboration and coordination of care and provides more satisfaction for providers and patients.

ASTHMA AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Benjamin J. Miller

Asthma and chronic obstructive pulmonary disease (COPD) are two of the most common chronic respiratory illnesses worldwide. According to the National Heart, Lung, and Blood Institute (NHLBI) and the World Health Organization (WHO), asthma affects more than 300 million people worldwide (Global Initiative for Asthma, 2013). COPD affects 6% of the adult U.S. population, is the third-leading cause of death, and is the 12th-leading cause of morbidity (Global Initiative for Chronic Obstructive Lung Disease [GOLD], 2014; Qaseem et al, 2011). This chapter discusses the pharmacological management of these two diseases.

ASTHMA

More than 22 million Americans, including 6 million children, have asthma (National Asthma Education and Prevention Program [NAEPP], 2007). Canada has similar statistics, with 2.3 million Canadians diagnosed with asthma in 2009 (Statistics Canada, 2010). This chapter focuses on the pharmacological management of asthma according to the current guidelines established by the NAEPP *Expert Panel Report 3: Guidelines* (2007). It includes a brief discussion of the pathophysiology of asthma to help explain the rationale for selecting appropriate medications. Monitoring and outcome evaluations are essential in asthma therapy

because adjustments can have a significant impact on a patient's activity level, and patient education is the key to having patients with asthma feel that they have control over a chronic illness. The overall goal of the asthma portion of the chapter is to enable the health-care provider to render optimal care for patients with asthma.

Pathophysiology

In the past, asthma was seen as episodic bronchospasm occurring in response to specific and nonspecific stimuli. It is now known that asthma is a chronic inflammatory disorder of the airways. The airway inflammation is present even between flare-ups and can significantly alter lung function. Based on this information, the NAEPP offers the following definition:

> Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role: in particular, mast cells, eosinophils, neutrophils (especially in sudden onset, fatal exacerbations, occupational asthma, and patients who smoke), T lymphocytes, macrophages, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of coughing (particularly at night or early in the morning), wheezing, breathlessness, and chest tightness. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment (NAEPP, 2007, p 9).

When asthma therapy is adequate, inflammation can be decreased over the long term, thereby preventing most asthma-related problems.

Chronic Inflammation

The lungs of patients who have died from asthma are visually noted to be overinflated. Both large and small airways are plugged with mucus and a mixture of cell debris, inflammatory cells, and serum proteins. Microscopic examination reveals extensive infiltration of the airway lumen and wall with eosinophils, mononuclear cells accompanied by vasodilation, evidence of microvascular leakage, and epithelial disruption (NAEPP, 2007). The airway smooth muscle is often hypertrophied, with new vessel formation, increased numbers of epithelial goblet cells, mucous gland hyperplasia, and deposition of interstitial collagen beneath the epithelium. These changes further support the theory of chronic inflammation in asthma.

A series of interrelated cellular mechanisms—mast cells, eosinophils, epithelial cells, macrophages, and activated T cells—have been shown to cause inflammation and affect lung function (Fig. 30-1). These cells can influence airway function by a number of routes. The release of histamine and leukotrienes can lead directly to bronchoconstriction. The release of proinflammatory cytokines from the mast cells, macrophages, and T cells activates the neutrophils, eosinophils, and macrophages, and this activation leads to the chronic inflammation associated with asthma. Cytokines can also cause the changes found on autopsy in patients with asthma: smooth muscle hypertrophy, increased vascular permeability, and mucus secretion.

Airway Hyperresponsiveness

Airway hyperresponsiveness is a hallmark of asthma, leading to the clinical symptoms of wheezing, chest tightness, and dyspnea after exposure to stimuli such as allergens, environmental irritants, viral infections, exercise, and cold air. The inclination of airways to narrow too easily and too much is a major aspect of asthma, along with the chronic inflammation noted previously. In the past, treatment of asthma focused on treating acute attacks with bronchodilator therapy. It is now known that the underlying inflammation influences the airway in such a way as to cause airway hyperresponsiveness. An allergen may trigger the release of a multitude of cellular mediators, cytokines, and chemokines, which results in increased smooth muscle responsiveness. Therefore, treating only the bronchoconstriction without treating the underlying inflammation leads to treatment failure if inflammation is present. Treatment of asthma and decreasing airway inflammation
Figure 30–1. Factors limiting airflow in acute and persistent asthma. Key: GM-CSF, granulocyte-macrophage colony-stimulating factor; IgE, immunoglobulin E; IL-3, interleukin 3 (and similar); TNF-α, tumor necrosis factor-alpha. (*Source:* Holgate, S. T., & Polosa, R. [2006]. The mechanisms, diagnosis, and management of severe asthma in adults. *The Lancet, 368,* 780–793.)

not only reduces symptoms but also decreases airway hyperresponsiveness.

Airflow Obstruction

Airflow obstruction is caused by a variety of changes in the airway. Acute bronchoconstriction and airway edema are two causes already discussed. Chronic mucous plug formation caused by increased mucus secretion can also influence airflow. It is now known that in some patients, airway changes are only partially reversible. Chronic inflammation leads to airway remodeling. Histological evidence indicates that there is an alteration in the amount and composition of the extracellular matrix in the airway wall. This change is not fully understood but suggests a rationale for early, aggressive treatment with anti-inflammatory therapy.

Understanding the role of inflammation and the cellular mechanisms involved has led to new treatment strategies. Understanding the multiple mechanisms involved in airway inflammation has led to treatment aimed at either multiple components (inhaled corticosteroids) or specific mediators of inflammation. For example, leukotriene modifiers are a treatment aimed at specific mediators. Leukotrienes are responsible, in part, for increased mucus production, bronchoconstriction, and eosinophil infiltration. Leukotriene modifiers, as described in Chapter 17, are either leukotriene receptor agonists (LTRAs) (zafirlukast and montelukast) or 5-lipoxygenase pathway (zileuton). Research continues to develop a better understanding of the pathology of asthma and treatment targeted at controlling the cellular changes that occur in acute and chronic asthma.

Classification of Asthma

According to *Expert Panel Report 3: Guidelines* (NAEPP, 2007), asthma severity in children 12 years or older and adults is determined by clinical features before treatment. There are four classifications of severity, based on need for medication to relieve symptoms, nighttime symptoms, and lung function:

1. Mild intermittent asthma: Symptoms occur less often than twice a week and the patient is asymptomatic between exacerbations; nighttime symptoms occur less than twice a month; and peak expiratory flow (PEF) is greater than 80% predicted. The use of short-acting beta$_2$ agonists (SABA) should be less than twice a week, unless used for exercise-induced bronchospasm (EIB).
2. Mild persistent asthma: Symptoms occur more often than twice a week but less often than once a day and exacerbations may affect activity; nighttime symptoms occur 3 to 4 times a month; and PEF is greater than 80% predicted. Patients with mild persistent asthma may use their short-acting beta$_2$ agonists more than twice a week but not daily, and not more than once daily.
3. Moderate persistent asthma: The patient is having daily symptoms; requires daily use of a beta$_2$ agonist; exacerbations affect normal activity; nighttime symptoms

occur more often than once a week; and PEF is greater than 60% to less than 80%.
4. Severe persistent asthma: The patient has some degree of symptoms all the time; extremely limited physical activity and frequent exacerbations; frequent nighttime symptoms, often 7 days a week; and decreased lung function (PEF less than 60% predicted). Table 30-1 outlines the classifications of asthma severity in patients aged 12 years or older.

In children, classification of asthma is based on severity and frequency of symptoms (NAEPP, 2007). Table 30-2 discusses classification of asthma severity and initiating therapy in children.

1. Mild intermittent asthma: Symptoms occur less often than twice a week and the patient is asymptomatic between exacerbations. Children aged 0 to 4 years have no nighttime symptoms, and children aged 5 to 11 years have nighttime symptoms less than twice a month and PEF is greater than 80% predicted. The use of short-acting beta$_2$ agonists should be less than twice a week, unless using for EIB. Exacerbations requiring oral systemic corticosteroids occur no more than once a year.
2. Mild persistent asthma: Symptoms occur more often than twice a week but less often than once a day and exacerbations may affect activity. In children aged 0 to 4 years, nighttime symptoms occur 1 to 2 times a month, and in children aged 5 to 11 years, nighttime symptoms occur 3 to 4 times a month; PEF is greater than 80% predicted. Patients with mild persistent asthma may use their short-acting beta$_2$ agonists more than twice a week but not daily, and not more than once daily. Children younger than age 4 years with mild persistent asthma have more than two exacerbations in 6 months requiring systemic steroids or four episodes of wheezing in a year lasting more than a day and risk factors for persistent asthma. Children aged 5 to 11 with mild persistent asthma have exacerbations 2 or more times a year.
3. Moderate persistent asthma: The child is having daily symptoms; requires daily use of a beta$_2$ agonist; and exacerbations affect normal activity. In children aged 4 years or younger, nighttime symptoms occur 3 or 4 times a month, and in children aged 5 to 11 years nighttime symptoms occur more than once a week but not nightly; PEF is greater than 60% to less than 80%. Children with moderate persistent asthma have exacerbations 2 or more times a year.
4. Severe persistent asthma: The patient has some degree of symptoms all the time; extremely limited physical activity; frequent nighttime symptoms (more than once a week in children younger than age 4 years and in older children often occurring 7 days a week); and decreased lung function (PEF less than 60% predicted). Children aged 5 to 11 with severe persistent asthma have exacerbations 2 or more times a year.

Table 30–1   Classification of Asthma Severity ≥12 Years of Age

Assessing severity and initiating treatment for patients who are not currently taking long-term-control medications

Components of Severity		Classification of Asthma Severity ≥12 years of age			
	Symptoms		*Persistent*		
		Intermittent	Mild	Moderate	Severe
Impairment **Normal FEV$_1$/FVC:** 8–19 yr 85% 20–39 yr 80% 40–59 yr 75% 60–80 yr 70%		≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2×/month	3–4×/month	>1×/week but not nightly	Often 7×/week
	Short-acting beta$_2$-agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily, and not more than 1× on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	• Normal FEV$_1$ between exacerbations • FEV$_1$ >80% of predicted • FEV$_1$/FVC normal	• FEV$_1$ >80% of predicted • FEV$_1$/FVC normal	• FEV$_1$ >60% but <80% of predicted • FEV$_1$/FVC reduced 5%	• FEV$_1$ <60% of predicted • FEV$_1$/FVC reduced >5%
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/year (see note)	≥2/year (see note)		
		Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV$_1$.			
Recommended Step for Initiating Treatment. (See "Stepwise Approach for Managing Asthma" for treatment steps.)		Step 1	Step 2	Step 3	Step 4 or 5 and consider short course of oral systemic corticosteroids
		In 2–6 weeks, evaluate level of asthma control that is achieved and adjust therapy accordingly.			

Key: EIB, exercise-induced bronchospasm; FEV$_1$, forced expiratory volume in 1 second; FVC, forced vital capacity; ICU, intensive care unit
Notes:
• The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
• Level of severity is determined by assessment of both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks and spirometry. Assign severity to the most severe category in which any feature occurs.
• At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

Goals of Therapy

The Expert Panel Report 3: Guidelines(NAEPP, 2007) clearly define the goals of asthma therapy:

Reduce Impairment

1. Prevent chronic and troublesome symptoms (e.g., coughing or breathlessness in the night, in the early morning, or after exertion).
2. Require infrequent use (less than twice a week) of inhaled short-acting beta$_2$ agonists for relief of symptoms (not including use for EIB).
3. Maintain (near) "normal" pulmonary function.
4. Maintain (near) normal activity levels.
5. Meet patients' and families' expectations of and satisfaction with asthma care.

Reduce Risk

1. Prevent recurrent exacerbations of asthma and minimize the need for emergency department visits or hospitalizations.
2. Prevent loss of lung function; for children, prevent reduced lung growth.

Table 30–2 Classification of Asthma Severity and Initial Therapy in Children

Components of Severity	Classifying Asthma Severity and Initiating Therapy in Children							
	Intermittent		Persistent					
			Mild		Moderate		Severe	
	Ages 0–4	Ages 5–11	Ages 0–4	Ages 5–11	Ages 0–4	Ages 5–11	Ages 0–4	Ages 5–11
Impairment								
Symptoms	≤2 days/week		>2 days/week but not daily		Daily		Throughout the day	
Nighttime awakenings	0	<2×/month	1–2×/month	3–4×/month	3–4×/month	>1×/week but not nightly	>1×/week	Often 2×/week
Short-acting beta$_2$-agonist use for symptom control	≤2 days/week		>2 days/week but not daily		Daily		Several times per day	
Interference with normal activity	None		Minor limitation		Some limitation		Extremely limited	
Lung function • FEV$_1$ (predicted) or peak flow (personal best) • FEV$_1$/FVC	N/A	Normal FEV$_1$ between exacerbations >80% >80%	N/A	>80% >85%	N/A	60%–80% 75%–80%	N/A	<60% <75%
Risk								
Exacerbations requiring oral systemic corticosteroids (consider severity and interval since last exacerbation)	0–1/yr (see notes)		≥2 exacerbations in 6 months requiring oral systemic corticosteroids, or ≥4 wheezing episodes/1 year lasting >1 day AND risk factors for persistent asthma	≥2×/year (see notes) **Relative annual risk may be related to FEV$_1$**				
Recommended Step for Initiating Therapy. (See "Stepwise Approach for Managing Asthma" for treatment steps.) The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.	Step 1 (for both age groups)		Step 2 (for both age groups)		Step 3 and consider short course of oral systemic corticosteroids	Step 3: medium-dose ICS option and consider short course of oral systemic corticosteroids	Step 3 and consider short course of oral systemic corticosteroids	Step 3: medium-dose ICS option OR step 4 and consider short course of oral systemic corticosteroids

In 2–6 weeks, depending on severity, evaluate level of asthma control that is achieved.
- Children 0–4 years old: If no clear benefit is observed in 4–6 weeks, stop treatment and consider alternative diagnoses or adjusting therapy.
- Children 5–11 years old: Adjust therapy accordingly.

Key: FEV$_1$, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroids; ICU, intensive care unit; N/A, not applicable
Notes:
- Level of severity is determined by both impairment and risk. Assess impairment domain by caregiver's recall of previous 2–4 weeks. Assign severity to the most severe category in which any feature occurs.
- Frequency and severity of exacerbations may fluctuate over time for patients in any severity category. At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and severe exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients with ≥2 exacerbations described above may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

3. Provide optimal pharmacotherapy with minimal or no adverse effects.

Rational Drug Selection

Asthma Step Therapy

The Expert Panel Report 3: Guidelines(NAEPP, 2007) recommends a stepwise approach to the pharmacological management of asthma. Management can begin at a higher level and gradually step down or start low and move up, depending on the patient's status when beginning treatment. The panel recommends that medications be categorized into two general classes: long-term-control medications to achieve and maintain control of persistent asthma and quick-relief medications to treat acute symptoms and exacerbations. Asthma severity determines the amount and frequency of medication, with suppression of airway inflammation the goal. One essential component of asthma treatment is the patient's cooperation in keeping a log of asthma symptoms. This patient self-assessment enables the provider to track the effectiveness of therapy and make treatment decisions based on medication use, nighttime symptoms, and PEF. Although step therapy is a helpful framework, the clinician must individualize therapy based on a patient's individual circumstances and response to therapy.

Initiating Control of Asthma

The *Expert Panel Report 3: Guidelines*(NAEPP, 2007) prefers an aggressive approach of gaining quick control with a higher level of therapy and then stepping down the care. A stepwise approach for managing asthma incorporates assessment of severity to initiate therapy or assessment of control to monitor or adjust therapy. New to the 2007 *Expert Panel Report 3: Guidelines* is the recommendation to assess asthma control and adjust therapy accordingly at regular intervals (NAEPP, 2007). Asthma control is "the degree to which the manifestations of asthma are minimized by therapeutic intervention and the goals of therapy are met" (NAEPP, 2007).

Once patients have received initial treatment for their asthma, they need ongoing monitoring to assess the degree of control. Control is based on level of impairment (symptoms, nighttime awakenings, interference with normal activity, SABA use, and spirometry or peak flows. Validated questionnaires can be used to measure level of impairment found in the *Expert Panel 3 Report: Guidelines* (Asthma Therapy Assessment Questionnaire, Asthma Control Questionnaire and Asthma Control Test) (NAEPP, 2007). Patients should be assessed regarding risk in relation to exacerbations. Table 30-3 outlines assessment of control in youths 12 years of age or older and adults; Table 30-4 is the assessment of control for children. The stepwise approach to treating asthma in adults is found in Table 30-5 and in children in Table 30-6. Drugs commonly used to treat asthma are shown in Table 30-7. Additional components of care include patient education and environmental control measures. See also Tables 30-7 and 30-8.

Mild Intermittent Asthma

Treatment for mild intermittent asthma symptoms consists of using short-acting inhaled beta$_2$ agonists as needed for symptoms, including patients who have asthma symptoms only when exposed to their asthma triggers (e.g., allergens, viral respiratory illness, chemical inhalants), people who have only exercise-induced asthma, and infants and children who wheeze with viral upper respiratory infections (NAEPP, 2007). Using short-acting beta$_2$ agonists more than twice a week may indicate a need to step up to step 2 therapy or to initiate long-term-control therapy. Education at this step is introducing the patient and family to the use of medication and teaching them about asthma, proper inhaler technique if appropriate, care during exacerbation of symptoms, and environmental controls to known allergens.

The *Expert Panel Report 3: Guidelines*(NAEPP, 2007) recommends that patients with mild asthma use their albuterol inhaler on an as-needed basis, which enables patients to feel that they have some control over their asthma. More frequent use (more than twice a week) indicates a need to step up therapy. Mild intermittent asthma is not inconsequential, as attacks can be severe, and it varies from patient to patient.

Mild Persistent Asthma

The recommended treatment for patients with mild persistent asthma is one long-term-control medication daily. The primary treatment is inhaled anti-inflammatory medication. Treatment is started with inhaled low-dose corticosteroids (ICS) for all age groups.

The suggested beginning dose of inhaled steroids is 80 to 240 mcg/d of beclomethasone HFA (QVAR) or 180 to 600 mcg/d of budesonide (Pulmicort Turbuhaler) or the equivalent. Sustained-release theophylline to serum concentrations of 5 to 15 mcg/mL is an alternative therapy, but it should be used with caution and with close monitoring of serum theophylline levels. Inhaled short-acting beta$_2$ agonists are used as needed to relieve symptoms. If symptoms persist, inhaled corticosteroids should be increased to 240 to 480 mcg/d of beclomethasone HFA (QVAR), which is three to six puffs per day of an 80 mcg/puff or the equivalent. If a patient is requiring daily use of inhaled beta$_2$ agonists and is using the medications correctly, then step 3 therapy is indicated. Patient education at this step is teaching self-monitoring and developing and reviewing the self-management plan.

An alternative to ICS is the use of mast cell stabilizers such as cromolyn (Intal) and nedocromil (Tilade). Mast cells are associated with asthma and other inflammatory processes. Specifically with asthma, there is hyperplasia of mast cells within the bronchial linings. With mast cell degranulation, histamines are released, resulting in bronchial constriction and acute asthma exacerbations. This class of medication prevents the breakdown of mast cells, thus stabilizing the bronchial epithelial cells, and has been found especially useful in exercise-induced bronchospasm or mild persistent asthma (Netzer, Küpper, Voss, & Eliasson, 2012; Schofield, 2014). A

Table 30–3 Assessing Asthma Control and Adjusting Therapy in Youths >12 Years and Adults

		Classification of Asthma Control (≥12 years of age)		
Components of Control		*Well Controlled*	*Not Well Controlled*	*Very Poorly Controlled*
	SYMPTOMS	≤2 days/week	>2 days/week	Throughout the day
	Nighttime awakenings	≤2×/month	1–3×/week	>4×/week
	Interference with normal activity	None	Some limitation	Extremely limited
	Short-acting beta$_2$-agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week	Several times per day
Impairment	FEV$_1$ or peak flow	>80% of predicted/ personal best	60%–80% of predicted/ personal best	<60% of predicted/ personal best
	Validated questionnaires			
	ATAQ ACQ ACT	0 ≤0.75* ≥20	1–2 ≥1.5 16–19	3–4 N/A ≤15
	Exacerbations requiring oral systemic corticosteroids	**0–1/year**	**≥2/year (see note)**	
		Consider severity and interval since last exacerbation		
Risk	Progressive loss of lung function	Evaluation requires long-term follow-up care.		
	Treatment-related adverse effects			
		Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
Recommended Action for Treatment (See "Stepwise Approach for Managing Asthma" for treatment steps.)		• Maintain current step. • Regular follow-up at every 1–6 months to maintain control. • Consider step down if well controlled for at least 3 months.	• Step up 1 step. • Reevaluate in 2–6 weeks. • For side effects, consider alternative treatment options.	• Consider short course of oral systemic corticosteroids. • Step up 1–2 steps. • Reevaluate in 2 weeks. • For side effects, consider alternative treatment options.

*ACQ values of 0.76–1.4 are indeterminate regarding well-controlled asthma.

Key: EIB, exercise-induced bronchospasm; ICU, intensive care unit

Notes:
- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2–4 weeks and by spirometry or peak flow measures. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.

ATAQ = Asthma Therapy Assessment Questionnaire
ACQ = Asthma Control Questionnaire
ACT = Asthma Control Test
Minimal Important
Difference: 1.0 for the ATAQ; 0.5 for the ACQ; not determined for the ACT.

Before step up in therapy:
—Review adherence to medication, inhaler technique, environmental control, and comorbid conditions.
—If an alternative treatment option was used in a step, discontinue and use the preferred treatment for that step.

Table 30–5   Stepwise Approach for Managing Asthma in Youths >12 Years and Adults

Stepwide Approach for Managing Asthma in Youths 12 Years of Age and Adults

Intermittent Asthma

Persistent Asthma: Daily Medication
Consult with asthma specialist if step 4 or higher is required.
Consider consultation at step 3.

Step 1
Preferred:
SABA PRN

Step 2
Preferred:
Low-dose ICS
Alternative:
Cromolyn, LTRA, Nedocromil, or Theophylline

Step 3
Preferred:
Low-dose ICS + LABA
or
Medium-dose ICS
Alternative:
Low-dose ICS + either LTRA, Theophylline, or Zileuton

Step 4
Preferred:
Medium-dose ICS + LABA
Alternative:
Medium-dose ICS + either LTRA, Theophylline, or Zileuton

Step 5
Preferred:
High-dose ICS + LABA
and
Consider Omalizumab for patients who have allergies

Step 6
Preferred:
High-dose ICS + LABA + oral corticosteroid
and
Consider Omalizumab for patients who have allergies

Step up if needed
(first, check adherence, environmental control, and comorbid conditions)

Assess control

Step down if possible
(and asthma is well controlled at least 3 months)

Each step: Patient education, environmental control, and management of comorbidities
Steps 2–4: Consider subcutaneous allergen immunotherapy for patients who have allergic asthma (see notes).

Quick-Relief Medication for All Patients
- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed.
- Use of SABA >2 days a week for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment.

Key: **Alphabetical order is usually more than one treatment option listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting beta$_2$-agonist, LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta$_2$-agonist.

Notes:
- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Zileuton is a less desirable alternative due to limited studies as adjunctive therapy and the need to monitor liver function. Theophylline requires monitoring of serum concentration levels.
- In step 6, before oral corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.
- Step 1, 2, and 3 preferred therapies are based on Evidence A; step 3 alternative therapy is based on Evidence A for LTRA, Evidence B for theophylline, and Evidence D for zileuton. Step 4 preferred therapy is based on Evidence B, and alternative therapy is based on Evidence B for LTRA and theophylline and Evidence D zileuton. Step 5 preferred therapy is based on Evidence B. Step 6 preferred therapy is based on (EPR—2 1997) and Evidence B for omalizumab.
- Immunotherapy for steps 2–4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.

Table 30–6 Stepwise Approach for Managing Asthma Long Term in Children

Stepwide Approach for Managing Asthma Long Term in Children 0–4 Years and 5–11 Years of Age

Step up if needed (first, check adherence, environmental control, and comorbid conditions)

Assess control

Step down if possible (and asthma is well controlled at least 3 months)

Children 0–4 Years of Age

	Step 1	Step 2	Step 3	Step 4	Step 5	Step 6
	Intermittent Asthma	Consult with asthma specialist if step 4 or higher is required. Consider consultation at step 3.				
Preferred	SABA PRN	Low-dose ICS	Medium-dose ICS	Medium-dose ICS + LABA or Montelukast	High-dose ICS + LABA or Montelukast	High-dose ICS + LABA or Montelukast + Oral corticosteroids ICS
Alternative		Cromolyn or Montelukast				

Each step: Patient education and environmental control

Quick-Relief Medication
- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms.
- With viral respiratory symptoms: SABA q 4–6 hours up to 24 hours (longer with physician consult). Consider short course of oral systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations.

Caution: Frequent use of SABA may indicate the need to step up treatment See text for recommendations on initiating dairy long-term-control therapy.

Notes
- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4–6 weeks, and patient's/family's medication technique and adherence are satisfactory, consider adjusting therapy or an alternative diagnosis.
- Studies on children 0–4 years of age are limited. Step 2 preferred therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.

Key: **Alphabetical order is usually more than one treatment option listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting beta$_2$-agonist, LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta$_2$-agonist.

Children 5–11 Years of Age

	Step 1	Step 2	Step 3	Step 4	Step 5	Step 6
	Intermittent Asthma	Consult with asthma specialist if step 4 or higher is required. Consider consultation at step 3.				
Preferred	SABA PRN	Low-dose ICS	Low-dose ICS + LABA, LTRA, or Theophylline *or* Medium-dose ICS	Medium-dose ICS + LABA	High-dose ICS + LABA	High-dose ICS + LABA + Oral corticosteroids
Alternative		Cromolyn, LTRA, Nedocromil, or Theophylline		Medium-dose ICS + LTRA or Theophylline	High-dose ICS + LTRA or Theophylline	High-dose ICS + LTRA or Theophylline + Oral corticosteroids

Each step: Patient education, environmental control, and management of comorbidities

Steps 2-4: Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma.

Quick-Relief Medication
- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed.

Caution: Increasing use of SABA or use >2 days a week for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment.

Notes
- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.
- Steps 1 and 2 medications are based on Evidence A. Step 3 ICS and ICS plus adjunctive therapy are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group: steps 4–6 are based on expert opinion and extrapolation from studies in older children and adults.
- Immunotherapy for steps 2–4 is based on Evidence B for house-dust mites, animal danders, and pollens: evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than adults.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.

Key: **Alphabetical order is usually more than one treatment option listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting beta$_2$-agonist, LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta$_2$-agonist.

Table 30–7 Drugs Commonly Used: Asthma and COPD

Drug	Dosage	How Supplied	Comments
Short-Acting Bronchodilators			
Albuterol HFA (Ventolin HFA, Proventil HFA, ProAir HFA)	*Inhaler* 2 puffs q4–6h 2 puffs 15 min prior to exercise	*Metered-Dose Inhaler* 90 mcg/puff	• May repeat dose in 5–10 min during exacerbations
Albuterol	*Nebulizer* (run over 10–15 min) *Adults:* Dilute 0.5 mL of 0.5% solution in 3 mL normal saline *or* give 1 unit dose Tablets: 2 mg, 4 mg *Children:* 0.01–0.03 mL/kg of 0.5% solution diluted in 2 mL normal saline *Oral* *Adults:* 2–4 mg tid or qid up to a max of 32 mg/d *Children 6–12 yr:* 2 mg tid or qid *Children <6 yr:* 0.1 mg/kg divided tid	*Solution for Nebulizer* 0.5% (5 mg/mL) 0.083 in unit-dose vial *Oral* Extended-release tabs: 4 mg, 8 mg Syrup: 2 mg/5 mL	• Check proper inhaler technique with every clinic visit

Table 30–7   **Drugs Commonly Used: Asthma and COPD—cont'd**

Drug	Dosage	How Supplied	Comments
Levalbuterol (R-albuterol, Xopenex)	*Nebulizer* 0.31 mg/3 mL 0.63 mg/3 mL 1.25 mg/3 mL *Adults:* 0.63 mg– 2.5 mg q4–8 h *Children:* 0.025 mg/kg (min 0.63 mg, max 1.25 mg) q4–8h *Inhaler* *Children ≥5 yr and adults:* 2 puffs every 4–6 h *Children <5 yr:* not FDA approved	*Nebulizer Solution* 0.63 mg of levalbuterol is equivalent in efficacy and side effects to 1.25 mg of racemic albuterol. The prod- uct is a sterile-filled preser- vative-free unit dose vial. *Inhaler* 45 mcg/puff	Levalbuterol has not been evalu- ated for continuous nebuliza- tion therapy
Terbutaline (Brethine)	*Oral* *Children >15 yr and adults:* 5 mg tid; maximum 15 mg/24 h *Children 12–15 yr:* 2.5 mg tid; maximum 7.5 mg/24 h *Parenteral* *Adults:* 0.5 mg SC in the lateral deltoid; may repeat in 15–30 min; maximum dose 0.5 mg in 4 h	*Oral* Tablets: 2.5 mg, 5 mg *Parenteral* 1 mg/mL	• Not recommended for children <12 yr • Terbutaline is used to control premature contractions in preg- nant women; use with care in the patient in the third trimester nearing her expected date of confinement (EDC), because it may affect labor
Bitolterol (Tornalate)	*Inhaler* *Children >12 yr and adults:* For bronchospasm: 2 puffs 1–3 min apart, followed by a third puff if needed For prevention of bronchospasm: 2 puffs every 8 h	*Inhaler* 0.37 mg/puff	• Not recommended for children <12 yr
Pirbuterol (Maxair inhaler)	*Inhaler* *Children >12 yr and adults:* 1–2 puffs q 4–6 h; maximum 12 puffs/day	*Inhaler* 0.2 mg/puff	Not recommended for children <12 yr
Long-Acting Bronchodilator Salmeterol (Serevent Diskus)	*Diskus Inhaler* *Children >4 yr and adults:* For asthma and control of bron- chospasm: 1 inhalation bid For exercise-induced asthma: 1 inhalation 30–60 min prior to exercise	*Discus Inhaler* 50 mcg/inhalation	**Not to be prescribed as monotherapy for persistent asthma.** Not to be used for short-term relief. Patients need to have a short-acting bronchodilator also prescribed for short-term relief and told not to use drug for acute exacerbations. If using salmeterol twice a day, do not use another dose for exer- cise-induced asthma; a short- acting bronchodilator or cromolyn should be used.
Formoterol (Foradil)	DPI 12 mcg/single-use capsule *Children ≥5 yr and adults:* Inhale 1 capsule q12h Note: Capsule is not to be swallowed	12 mcg capsule	Each capsule is for single use only; additional doses should not be administered for at least 12 h. Capsules should be used only with the Aerolizer inhaler and should not be taken orally. Efficacy and safety have not been studied in children <5 yr.

Drug	Dosage	How Supplied	Comments
Anticholinergic Agents			
Ipratropium bromide (Atrovent, Atrovent HFA)	*Inhaler* *Children >12 yr and adults:* 2–3 puffs qid; maximum 12 puffs/24 h 500 mcg per unit-dose vial *or* 0.25 mg/mL *Children:* 1–2 puffs q6h *Nebulizer* 1-unit dose *Adults:* 0.5 mg q30min for 3 doses, then 0.25 mg q6h *Children:* 0.25 mg q20min for 3 doses, then 0.25 mg q6h 0.5 mg/3 mL ipratropium bromide and 2.5 mg/ 3 mL albuterol *Adults:* 2–3 puffs q6h *Adults:* 3 mL q4–6h *Children:* 1.5–3 mL q8h	*Inhaler* 17 mcg/puff *Solution for Nebulizer* • Contraindicated in patients with soybean or peanut allergy.	• Can be mixed with albuterol 0.5% solution for nebulizer use if used within 1 h.
Tiotropium (Spiriva)	*HandiHaler* *Adults with COPD:* 2 inhalations of the powder contents of a single capsule once daily	DPI capsule: 18 mcg/capsule	Not approved for use in children. Approved for use in COPD.
Combination Inhaled Medications			
Albuterol/ipratropium bromide (Combivent)	*Inhaler* *Children:* 1–2 puffs q8h *Adults:* 2 puffs qid	*Inhaler* Ipratropium 18 mcg/puff combined with albuterol 90 mcg/puff	• Primarily used for COPD patients
	Nebulizer *Adults:* 3 mL every 30 min for 3 doses, then q2–4h prn *Children:* 1.5 mL q20min for 3 doses then every 2–4 h	*Solution for Nebulizer* Each 3 mL vial contains 0.5 mg ipratropium bromide and 2.5 mg albuterol.	• Simplifies medication regimen by combining two commonly prescribed medications • Not recommended for children
Fluticasone/Salmeterol (Advair Diskus)	DPI 100 mcg, 250 mcg, or 500 mcg/50 mcg *Adults:* 1 inhalation bid; dose depends on severity of asthma *Children:* 1 inhalation bid; dose depends on severity of asthma	Not FDA approved in children <12 yr. 100/50 for patient not controlled on low-to-medium dose inhaled corticosteroids. 250/50 for patients not controlled on medium-to-high dose inhaled corticosteroids.	
Budesonide and formoterol (Symbicort)	*Inhaler* *Children 5 to 11 yr:* Symbicort 80/4.5, 2 inhalation bid *Children ≥12 yr and adults:* Symbicort 80/4.5, 2 inhalations bid *or* Symbicort 160/4.5, 2 inhalations bid (medium dose steroid)	*Inhaler* Symbicort 80/4.5 containing 80 and 4.5 mcg of formoterol fumarate dihydrate per inhalation Symbicort 160/4.5 containing 160 mcg of budesonide and 4.5 mcg of formoterol fumarate dihydrate per inhalation.	

Table 30–7   Drugs Commonly Used: Asthma and COPD—cont'd

Drug	Dosage	How Supplied	Comments
Systemic Corticosteroids			
Prednisone	*Adults:* "Burst" therapy 40–60 mg/d in 1 or 2 doses *Children:* "Burst" 1–2 mg/kg/d in 1–2 doses; maximum of 60 mg/d	***Tablets*** 5, 10, 20 mg	If given in short "bursts" of 3–10 days, dose does not have to be tapered
Prednisolone (Prelone, Pediapred syrup)	*Children:* "Burst" 1–2 mg/kg/d in 1–2 doses; maximum of 40–50 mg/d	***Syrup*** Pediapred 5 mg/5 mL Prelone 15 mg/5 mL	Same as for prednisone
Inhaled Anti-Inflammatory Agents			
Cromolyn (Intal)	***Nebulizer*** *Children >2 yr and adults:* 1-unit dose qid, weaning down to bid	***Solution for Nebulizer*** 20 mg/2 mL ampule	• Must be used continuously for 3–4 wk before maximum effect is achieved • Very safe to use in children, with fewer adverse reactions than inhaled steroids
Nedocromil (Tilade)	***Nebulizer*** *Adults and children >2 yr:* 1 ampule via nebulizer qid	***Solution for Nebulizer*** 11 mg/2.2 mL ampule	
Inhaled Corticosteroids			
Beclomethasone dipropionate Beclomethasone HFA (QVAR)	*Adults:* *Low dose:* 80–240 mcg *Medium dose:* 240–480 mcg *High dose:* >480 mcg *Children:* *Low dose:* 80–160 mcg *Medium dose:* 160–320 mcg *High dose:* >320 mcg	QVAR MDI 40 mcg/puff 80 mcg/puff	
Budesonide (Pulmicort Flexihaler)	*Adults:* *Low dose:* 180–600 mcg daily (1 or 2 inhalations daily) *Medium dose:* 600–1,200 mcg daily (2–3 inhalations daily) *High dose:* >1,200 mcg daily (>3 inhalations daily) *Children:* *Low dose:* 200 mcg daily (1 inhalation daily) *Medium dose:* 200–400 mcg daily (2–3 inhalations daily) *High dose:* >400 mcg/d (>2 inhalations daily)	***Turbohaler DPI*** 90 mcg/puff 180 mcg/puff 200 mcg/puff	
Budesonide Inhalation suspension (Pulmicort Respules) for nebulization (child dose)	*Children 4 yr:* *Low dose:* 0.25 to 0.5 mg/d *Medium dose:* 0.5 mg to 1.0 mg/d *High dose:* 2.0 mg *Children 5–11 yr:* *Low dose:* 0.5 mg/d *Medium dose:* 1.0 mg/d *High dose:* 2.0 mg/d	***Suspension for Nebulizer*** 0.25 mg/mL 0.5 mg/mL	
Flunisolide (Aerobid)	*Children ≥12 yr and adults:* *Low dose:* 500–1,000 mcg daily (2–4 puffs daily divided in bid dose) *Medium dose:* 1,000–2,000 mcg daily (4–8 puffs divided bid)	***Inhaler*** 250 mcg/puff	Rinse mouth after use.

disadvantage to the mast cell stabilizers are that they take weeks to reach full effectiveness for asthma.

Leukotrienes are biologically active products of the arachidonic acid metabolism and result in inflammatory disorders including asthma. Antagonism of specific pulmonary receptors has provided a target for asthma therapy (Henderson, 1994). Medications in this class of therapeutics include montelukast (Singulair), zafirlukast (Accolate), and zileuton (Zyflo). Any of these medications may be used as alternatives to ICS in step 2 management of asthma.

Moderate Persistent Asthma

Patients with moderate persistent asthma require long-term preventive medication to maintain control of their asthma. The dose of inhaled corticosteroids should be 240 to 480 mcg of beclomethasone HFA (3 to 6 puffs per day of 80 mcg/puff) or low-dose inhaled corticosteroids combined with a long-acting beta-agonist bronchodilator (Advair). The long-acting beta-agonist salmeterol (Serevent) should not be prescribed without the concurrent use of inhaled corticosteroids because of increased risks of catastrophic events (asthma-related intubations and death), as discussed in Chapter 17. Quick relief of symptoms is obtained with short-acting inhaled beta$_2$ agonists. A more severe exacerbation may require oral corticosteroids. If control of symptoms is not achieved and the patient is adhering to the asthma plan, including correct inhaler technique, then increasing the treatment to step 4 is indicated. Having patients record their medication use and symptoms is essential at all steps but critical at step 3 because documentation is helpful in determining whether referral to an asthma specialist is indicated if the patient needs step 4 therapy.

Severe Persistent Asthma

Treatment for patients with severe persistent asthma symptoms requires step 4, 5, or 6 therapy. Step 4 therapy is daily medium-dose inhaled corticosteroids (240 to 480 mcg/d of beclomethasone HFA or the equivalent) and a long-acting beta agonist (arformoterol, formoterol, indacaterol, and salmeterol). An alternative approach is a medium dose of inhaled corticosteroid and a leukotriene modifier or theophylline. Step 5 therapy is daily inhaled high-dose corticosteroids combined with daily long-acting bronchodilators. The inhaled corticosteroid dose should be in the high range, which is greater than 480 mcg of beclomethasone HFA (more than 6 puffs/d at 80 mcg/puff) or the equivalent. Step 6 therapy for severe persistent asthma consists of high-dose corticosteroids combined with daily long-acting bronchodilators and oral corticosteroids.

If long-term oral corticosteroids are required, the lowest dose possible to achieve results should be used and on an alternate-day schedule if possible. Oral steroids are dosed at 2 mg/kg/d, not to exceed 60 mg/d. Inhaled corticosteroids are preferable to systemic corticosteroids, and the maximum dose should be used before long-term systemic therapy is initiated. Exacerbations require short bursts of high-dose systemic corticosteroids.

Severe persistent asthma requiring step 5 or step 6 therapy and associated with allergies may benefit from omalizumab (Xolair) therapy, which is a recombinant humanized mouse monoclonal antibody that binds to free immunoglobulin E (IgE) in the circulation and prevents them from responding to relevant allergens (dust mite, cockroach, cat, or dog) (NAEPP, 2007). It is administered every 2 to 4 weeks via subcutaneous route and has been demonstrated to reduce exacerbations and total emergency visits (Abramowicz, 2005; Bousquet, et al, 2005; Chiang, Clark, & Casale, 2005). All patients who require step 4 treatment need referral to an asthma specialist.

Emerging Therapies

Vitamin D

Recent reports indicate that persons with low vitamin D have a higher mortality from asthma (Zittermann, Gummert, & Borgermann, 2009), most likely due to the immunomodulator role that vitamin D plays (Rance, 2013). Low vitamin D levels may be responsible for the increase in childhood asthma, with 35% of children with mild-to-moderate persistent asthma presenting with low vitamin D levels (Brehm et al, 2010). Vitamin D decreases the allergic response by shifting the ratio of T1-helper cells to T2-helper cells to predominately T2-helper cells (Rance, 2013). There are no official recommendations for supplementing asthma patients with vitamin D, but measuring vitamin D levels in patients with asthma is warranted to determine if they are deficient. All asthma patients should consume at least the minimum daily intake for their age, which is 400 IU/d in infants 1 to 12 months and 600 IU/d in children age 1 year or older and adults through age 70 years. Adults over age 70 years are recommended to take 800 IU/d.

CFC Free Inhalers

Changes in the delivery of meter-dose inhalers from chlorofluorocarbons (CFC) to hydrofluoroalkanes (HFA) have resulted in a smaller particle size of delivery, which has enhanced the lung deposits from 20% to 50%, resulting in greater efficacy (Schofield, 2014).

Monitoring Control

Once control is achieved, patients need to be monitored every 1 to 6 months to determine if a step up or step down in therapy is indicated. Step therapy is meant to be a dynamic program of therapy in which changes in a patient's symptoms require movement up or down. To make appropriate treatment decisions, it is essential that patients be monitored frequently and that they maintain a self-assessment record. The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) says that the dose of inhaled corticosteroids may be reduced about 25% to 50% every 2 to 3 months to the lowest dose possible to maintain asthma control. Most patients with persistent asthma require daily medication to suppress underlying airway inflammation, and they may relapse if inhaled corticosteroids are withdrawn completely.

If at any time control of asthma symptoms is not achieved and sustained, the health-care provider has a number of actions to take. First and most important, the provider must review

and observe the patient's medication administration. Improper inhaler technique can create havoc in the management of asthma because the patient is not getting relief at increasing "doses" of medication. This problem can lead to unnecessary changes in therapy. The patient's inhaler technique should be reviewed at every visit because research has shown that technique deteriorates between visits (Self, George, Wallace, Patterson & Finch, 2014).

The provider needs to be aware that the prescribed regimen may not be followed at home. In a study of Medicaid patients age 2 to 17 years (N = 4262), 63% had discontinued their preventive asthma medications within 90 days of the prescription being written (Campo-Ramos Duran, Simon, Akinbami, & Schoendorf, 2014). Educating the patient on the necessity of taking preventive medication is critical to successful treatment.

Managing Exacerbations

A temporary increase in anti-inflammatory therapy may be needed to reestablish control or treat exacerbations. The need for oral steroids is characterized by increased need for short-acting bronchodilators or decreased PEF (20% or greater), reduced tolerance to activity, and increased nocturnal symptoms. A short "burst" of oral prednisone is often effective. The appropriate dose is 40 to 60 mg/d as a single or divided (twice a day) dose (1 to 2 mg/kg in children to a maximum of 60 g/d) for 5 to 10 days in adults and 3 to 10 days in children. If the steroid burst is successful (the PEF returns to normal and symptoms improve), then no other treatment is necessary. If the prednisone burst does not control symptoms, then a step up to a higher level is indicated. If frequent bursts of steroids are required, then higher-level care is needed. Doubling the dose of inhaled corticosteroids is not effective in treating asthma exacerbations (NAEPP, 2007).

Maintaining Control of Asthma

Factors that influence maintaining control of asthma include exposure to allergens, barriers to care (e.g., financial), and self-management issues. Allergy testing and referral to an allergy specialist may be necessary to maintain effective control of asthma symptoms. Families in crisis have difficulty in maintaining a complex medication regimen, and every effort should be made to simplify the treatment for all patients regardless of their resources.

Home Management of Exacerbations of Asthma

Home management of asthma exacerbations is an integral part of asthma management. Patients need to be educated to recognize early symptoms of decreasing lung function and to adjust their medications accordingly. The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) recommends the following home pharmacological therapy, which is described in detail in Figure 30-2.

First, assess severity. Patients at high risk for a fatal asthma attack require immediate attention after initial treatment. Patients at risk include those having previous severe exacerbations requiring intubation or intensive care unit (ICU)

admission for asthma, two or more hospitalizations or more than three emergency department visits in the past year, use of more than two short-acting beta-agonist canisters per month, difficulty perceiving airway obstruction or worsening asthma, or low socioeconomic status or inner-city residence.

Initial home treatment consists of increased frequency of inhaled beta$_2$ agonists, up to two treatments (2 to 6 puffs of MDI) 20 minutes apart or nebulizer treatment. If the response is good, the patient should continue the inhaled short-acting beta agonists and contact the provider to discuss whether a short course of oral corticosteroids is required. If the response is incomplete to initial therapy and persistent wheezing or tachypnea is present, the patient should be started on systemic oral corticosteroids, continue the short-acting beta agonists, and contact the provider urgently (the same day). If the response is poor to initial therapy, determined by marked wheezing and dyspnea, the patient should repeat the short-acting beta agonist immediately and start oral corticosteroids. If the distress is severe, the patient should be transported to the emergency department (consider calling 911).

Patients with good response to therapy need to continue more intensive therapy (step up in care) for several days until the PEF returns to normal. Patients should contact their health-care provider any time they begin oral steroids if the attack is severe or if emergent treatment is necessary.

Patient Variables

Pregnancy

Asthma affects between 3.5% and 13.9% of pregnant women in the United States (Kwon, Belanger, & Bracken, 2003; Louik, Schatz, Hernandez-Diaz, Werler, & Mitchell, 2010). Pregnant women with asthma need to be monitored closely for changes in lung function because the effects of pregnancy on the course of asthma are unpredictable and the asthma may worsen, improve, or remain unchanged (Hanania & Belfort, 2005; Louik et al., 2010). Adequate oxygenation is essential for the fetus to develop normally. Poorly controlled asthma can lead to low birth weight, increased perinatal morbidity, and prematurity.

In general, asthma therapy is the same for pregnant women as for other patients with asthma. They need to be educated and monitor their PEF throughout the pregnancy, with the *Expert Panel Report 3: Guidelines* (NAEPP, 2007) recommending monitoring of asthma status at prenatal visits. Any changes in PEF require prompt treatment and modification in pharmacological therapy. Most medications used to treat asthma are Pregnancy Class C, as noted in Chapter 17. Oral forms of beta$_2$ agonists should be used minimally in patients who are in labor, as terbutaline is a tocolytic (off-label use). Inhaled forms of beta$_2$ agonists are less likely to affect uterine contractions, and albuterol is the beta agonist of choice for pregnant women because of its safety profile (NAEPP, 2007).

Inhaled corticosteroids (ICS) are the long-term-control medications of choice, with budesonide the ICS with the most data available in pregnant women (NAEPP, 2007). Minimal data are available regarding the safety of

Assess Severity

- **Patients at high risk for a fatal attack require immediate medical attention after initial treatment.**
- Symptoms and signs suggestive of a more serious exacerbation, such as marked breathlessness, inability to speak more than short phrases, use of accessory muscles, or drowsiness, should result in initial treatment while immediately consulting with a clinician.
- Less severe signs and symptoms can be treated initially with assessment of response to therapy and further steps as listed below.
- If available, measure PEF—values of 50%–79% predicted or personal best indicate the need for quick-relief medication. Depending on the response to treatment, contact with a clinician may also be indicated. Values below 50% indicate the need for immediate medical care.

Initial Treatment

- Inhaled SABA: Up to two treatments 20 minutes apart of 2–6 puffs by metered-dose inhaler (MDI) or nebulizer treatments
- Note: Medication delivery is highly variable. Children and individuals who have exacerbations of lesser severity may need fewer puffs than suggested above.

Good Response

No wheezing or dyspnea (assess tachypnea in young children)

PEF ≥80% predicted or personal best

- Contact clinician for follow-up instructions and further management.
- May continue inhaled SABA every 3–4 hours for 24–48 hours.
- Consider short course of oral systemic corticosteroids.

Incomplete Response

Persistent wheezing and dyspnea (tachypnea)

PEF 50%–79% predicted or personal best

- Add oral systemic corticosteroid.
- Continue inhaled SABA.
- Contact clinician urgently (this day) for further instruction.

Poor Response

Marked wheezing and dyspnea

PEF <50% predicted or personal best

- Add oral systemic corticosteroid.
- Repeat inhaled SABA immediately.
- If distress is severe and nonresponsive to initial treatment:
  —Call your doctor AND
  —**PROCEED TO ED;**
  —Consider calling 9–1–1 (ambulance transport).

- To ED

Figure 30–2. Management of asthma exacerbations: Home treatment. Key: ED, emergency department; MDI, metered-dose inhaler; PEF, peak expiratory flow; SABA, short-acting beta$_2$ agonist (quick-relief inhaler). (*Source:* From National Asthma Education and Prevention Program [NAEPP]. [2007]. *The Expert Panel Report 3: Guidelines for the diagnosis and management of asthma.* Bethesda, MD: National Heart, Lung, and Blood Institute, National Institutes of Health.)

leukotrienes in pregnant women, but animal data do not indicate a concern for use during pregnancy (NAEPP, 2007).

Pediatric Patients

Approximately 6.8 million children (9.3%) in the United States have asthma (Centers for Disease Control, 2015). The Global Initiative for Asthma (2009) describes three categories of wheezing in children younger than age 5 years: transient early wheezing, persistent early-onset wheezing, and late-onset wheezing/asthma. Transient early wheezing is associated with

prematurity and parental smoking and is often outgrown by age 3 years. Persistent early-onset wheezing occurs before age 3 years and is characterized by recurrent episodes of wheezing associated with viral upper respiratory infections. The symptoms usually persist through school age and early adolescence. Children with early-onset wheezing have no evidence of atopy. Late-onset wheezing/asthma is often associated with atopy, often eczema.

Pediatric patients under age 5 years require special management strategies. The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) breaks out the treatment of children younger

than age 5 years to address the needs of the population. First, diagnosing asthma in infants and young children is difficult. Asthma is often underdiagnosed and undertreated in this age group because objective measures of lung function are difficult to obtain and treatment decisions are made on clinical assessment. Some health-care providers are reluctant to label children as having asthma, and often the child is given a label of chronic bronchitis, wheezy bronchitis, "happy wheezer," or the like and therefore does not receive adequate treatment. Note that not all wheezing and coughing are asthma, and the patient may have less common conditions such as cystic fibrosis, vascular ring, tracheomalacia, congenital heart disease, foreign body aspiration, and primary immunodeficiency.

As noted, among children younger than 5 years, the most common cause of asthma symptoms is viral respiratory infection. As most infants and toddlers contract repeated viral respiratory infections, susceptible children may have repeated episodes of asthma symptoms. Parents are often frightened and frustrated with these repeated exacerbations. Parental stress associated with frequent health-care visits, uncertain diagnosis, missed work because of the child's illness, or parental guilt about needing to work instead of being at home with the child can make working with these families a challenge for the provider. Open communication between health-care provider and parents should be used to clearly define roles and expectations of care." The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) stresses collaborating with parents and meeting their expectations regarding the care of their child with asthma.

Lieu and colleagues (1997) found that having a written asthma management plan and starting medications at the onset of a cold or flu lowered the odds of an emergency department visit in a case-control study of children up to age 14 with asthma in a large regional health management organization. The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) concurs with this older study and recommends parents can be taught how to identify and anticipate asthma symptoms, such as the beginning of a child's upper respiratory infection symptoms. Parents can learn to identify objective parameters of concern, such as respiratory rate or use of accessory muscles for breathing. Asthma education must be written and frequently repeated to stressed and often fatigued parents. It is best to provide in-depth teaching when the child is well so the parents can be at their optimal and not distracted by the child's condition.

The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) recommends that all children with asthma symptoms be given a therapeutic trial of bronchodilators, specifically inhaled short-acting beta$_2$ agonists. The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) includes a stepwise approach for managing infants and young children 0 to 4 years with asthma symptoms. Use of bronchodilators more than twice a week is an indication of the need for step 2 therapy: daily anti-inflammatory medication. Daily long-term therapy should begin with low-dose inhaled corticosteroids delivered via nebulizer or metered-dose inhaler (MDI) with holding chamber with or without mask. Alternative medications include cromolyn (nebulizer is preferred) or montelukast.

Step 3 therapy is indicated for moderate persistent asthma (symptoms daily or more than 3 to 4 nights/mo) and requires therapy with medium-dose inhaled corticosteroids. Poor response to the step 3 regimen indicates a need to step up to step 4 therapy, a combination of low-dose inhaled corticosteroids and a montelukast. If step 3 therapy is required, the *Expert Panel Report 3: Guidelines* (NAEPP, 2007) says that control should be established quickly with higher doses of inhaled corticosteroids and that therapy should be stepped down after 2 to 3 months to the lowest dose required to maintain control. Referral to an asthma specialist is essential for all children who require step 3 or higher care. Poor control at step 2 may also be a reason to consider referral.

Exacerbations caused by viral upper respiratory infections can be quite severe, and systemic corticosteroids may be needed often in this age group because of the number of viral upper respiratory infections that children get in infancy. A short burst of oral corticosteroids may be needed to establish control of asthma in children with moderate or severe asthma (NAEPP, 2007). A "burst" dose is 1 to 2 mg/kg/d (maximum 30 mg/d) of prednisone in two divided doses for 3 to 10 days. Table 30-6 discusses the stepwise approach to managing children with asthma.

Delivery of medication to infants and young children can be a challenge. There are several delivery devices available, but the dose of medication received can vary considerably among devices and age groups. Nebulizer therapy is preferred for children younger than 2 years. Nebulizers may be used in older children who are unable to use MDIs well enough to get therapeutic effects. MDIs with either a spacer or a face mask can be used. An MDI and spacer with face mask is an alternative strategy in infants if there is a need for portable treatment, such as for traveling or day care. It is also a good choice if the family is financially stressed and the cost of a nebulizer and medication is prohibitive. Prior to changing or stepping up therapy, patients and parents must be assessed for proper use of delivery devices. It should be noted that Pulmicort Respules (budesonide inhalation suspension) should be administered with a compressed-air-driven jet nebulizer, *not* an ultrasonic nebulizer.

The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) added a separate diagnosis and management category for children aged 5 to 11 years. The management of school-age children is similar to that of younger children, with the addition of theophylline as alternative long-term control medication in step 2 therapy and the use of long-acting beta-agonists combined with inhaled corticosteroids in step 3 or higher therapy (see Table 30-6). The U.S. Food and Drug Administration (U.S. FDA, 2010) recommends long-acting beta agonists not be prescribed without inhaled corticosteroids to children, and preferably a combination product (Advair) is to be prescribed.

Older children and adolescents often have to manage symptoms at school or otherwise away from parents, and the *Expert Panel Report 3: Guidelines* (NAEPP, 2007) recommends a written asthma action plan be shared with the school or day care. School-age children are developmentally interested in learning

and mastering new skills, and should be involved with their treatment plan. School-age and adolescent children need to be able to effectively administer inhaled medications. Therefore, as children with asthma get older and gain independence, the provider needs to observe the child's inhaler technique and make adjustments as necessary. Many schools do not allow students to carry and self-administer medications. The NAEPP (2007) has endorsed a resolution allowing students to carry and self-administer medications if the provider and parent consider it appropriate. The plan has to be worked out among the parent, the school, and the health-care provider.

Sports and physical activities are essential to a healthy lifestyle for children. Every attempt should be made to control asthma symptoms so that children can participate in physical activities. Treatment just prior to activity may prevent the cough and wheeze some children experience with exercise. Poor exercise tolerance is an indication of poorly controlled asthma and the need to modify the asthma management plan. Adding a long-term-control medication usually improves exercise tolerance. Guidance from the health-care provider can assist parents and children in choosing appropriate sports. Often, children allergic to pollens cannot play outdoor sports such as baseball or soccer yet can participate in swimming, basketball, and gymnastics without problems. Restricting physical activity should be a last resort.

Older Adults

Older adults with asthma symptoms often present with a variety of other disease processes. The provider must first determine how much of the airflow obstruction is reversible and how much is due to other obstructive lung disease (chronic bronchitis, emphysema). Often a trial of 2 to 3 weeks of systemic corticosteroids is necessary to determine the extent of reversibility of airway disease. Inhaled long-term-control medications can then be introduced if indicated.

The medications used to treat asthma have increased adverse effects in the older patient. Those with preexisting ischemic heart disease may also be more sensitive to beta $_2$-agonist adverse effects, including tremor and tachycardia. Concomitant use of anticholinergics, muscurinics, and beta $_2$ agonists may be beneficial in the older patient. Theophylline clearance is reduced, causing increased serum theophylline levels. Frequent monitoring of blood levels is necessary if theophylline is used for the older patient. Systemic corticosteroids can cause confusion, agitation, and changes in glucose metabolism. There is also a dose-dependent reduction in bone mineral content that may be associated with inhaled corticosteroid use. Low-to-medium doses appear to have no major effect on bone density. Older patients may be at more risk because of preexisting osteoporosis, lower estrogen levels (in women), and a sedentary lifestyle. Consider treatment with calcium and vitamin D supplements and, as appropriate, estrogen replacement for older patients on high-dose inhaled corticosteroid therapy.

Another concern in older patients is that the medications used to treat other chronic diseases may cause asthma exacerbations or require medication adjustments. Patients who are taking theophylline need to be assessed for medications that affect theophylline clearance. The nonselective beta blockers, including some beta blockers in eyedrops used to treat glaucoma, can result in mutual inhibition of therapeutic effects if used with beta $_2$ agonists. NSAIDs used to treat arthritis may cause asthma exacerbation. At each visit for asthma-related symptoms, it is essential to assess the patient's complete history, including all medications the patient takes.

Special Situations

Seasonal Asthma

Seasonal asthma is identified when patients appear to have asthma symptoms only in relationship to certain pollens and molds. Seasonal asthma is managed by the same stepwise approach to long-term management of asthma previously discussed. If the patient has predictable seasonal asthma—each spring, for example—long-term anti-inflammatory treatment should be initiated approximately 1 month before the anticipated onset of symptoms and continued through the season.

Cough Variant Asthma

Cough variant asthma is seen especially in young children. It is diagnosed when cough, usually at night, is the principal symptom. Daytime examination may be normal, thereby often delaying or confusing the diagnosis. A therapeutic trial of bronchodilator medication is often diagnostic of cough variant asthma. Monitoring PEF changes between morning and evening readings may also assist in the diagnosis. Management is according to the stepwise approach to long-term management of asthma.

Montelukast demonstrated in a small double-blind randomized controlled study to reduce cough 75.7% from baseline by week 4 in the treatment group, whereas the placebo group had a 20.7% reduction in cough (Spector & Tan, 2004). A more recent study of the use of montelukast for the treatment of cough variant asthma found a clinical significant improvement in health status, but no additional benefit over inhaled corticosteroids (Boom, Vaessen, Uil, Kerstjens & van den Berg, 2011).

Exercise-Induced Bronchospasm

EIB should be anticipated in all patients with asthma, with 50% to 90% of asthmatics having airways that are hyperreactive to exercise (Parsons & Mastronarde, 2005). Some patients (less than 10%) exhibit asthma symptoms only when exercising. Bronchospasm is due to hyperventilation of air that is cooler and dryer than that of the respiratory system, which causes loss of heat and water from the lungs. The diagnosis of EIB is made first by history of cough, shortness of breath, chest pain or tightness, or wheezing during or right after exercise. Formal diagnosis can be made in a laboratory or by having patients exercise strenuously enough to increase their heart rate to 80% of maximum for 4 to 6 minutes. Otherwise healthy patients can run in the hallway or stairway of the clinic if appropriate. The PEF measurements are taken before and at 5-minute intervals for 20 to 30 minutes. A 15% decrease in PEF is compatible with EIB.

The goal of EIB therapy is for patients to be able to participate in any activity they choose without asthma symptoms. Teachers and coaches need to be notified that a child or an athlete has EIB. The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) recommends the following treatment strategies:

1. Short-acting beta$_2$ agonists used just prior to exercise prevent EIB in 80% of patients for 2 to 3 hours. Salmeterol has been shown to prevent EIB for 10 to 12 hours. Long-acting beta agonists used daily will have decreased effectiveness; therefore, if daily pretreatment for exercise is needed, an alternative should be used.
2. Cromolyn and nedocromil inhaled shortly before exercise are also effective in preventing EIB but are not as effective as short-acting beta$_2$ agonists.
3. A lengthy warm-up before exercise may decrease the need for repeated medications if the patient can tolerate continuous exercise without symptoms.
4. Long-term-control therapy with inhaled anti-inflammatory medication may be indicated and helpful in reducing airway responsiveness and therefore decreasing EIB. Inhaled corticosteroids are recommended as first-line therapy for athletes who have persistent asthma to prevent worsening of symptoms during exercise.
5. A mask or scarf over the mouth may attenuate cold-induced EIB.
6. Leukotriene modifiers may attenuate EIB in up to 50% of patients.

Surgery

Surgery places patients with asthma at risk for complications both during and after a procedure. These complications include acute bronchoconstriction triggered by intubation, hypoxemia, and possible hypercapnia; impaired cough effectiveness; atelectasis; and respiratory infections. The more severe the patient's asthma before surgery, the higher the likelihood of complications will be. Prior to surgery, the asthmatic patient should have an evaluation that includes symptoms, review of medications, and pulmonary function testing. If possible, patients ought to be at their personal best PEF. A short burst of systemic corticosteroids may be necessary to reach ideal lung function. Patients who have received systemic corticosteroids in the past 6 months require IV hydrocortisone during the surgical period.

Monitoring

Monitoring patients with asthma is a continuous process, beginning with the initial diagnosis. The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) recommends ongoing monitoring of the following six areas: signs and symptoms, pulmonary function, quality of life and functional status, history of asthma exacerbations, pharmacotherapy, and patient–provider communication and patient satisfaction.

Monitoring Signs and Symptoms of Asthma

All patients should be taught to monitor and recognize their asthma symptoms. Recording symptoms and PEF on a self-assessment diary enables the patient and the provider to track asthma symptoms and determine if there is adequate control. Clinical signs of asthma should be assessed at each visit through physical examination and appropriate questioning of the patient. Questions should be asked about the recent past (e.g., In the past 2 weeks, how many times have you had nighttime symptoms?). Questions about longer periods give a more generalized response (e.g., Have your symptoms been better or worse since your last visit?). Assessment of symptoms should differentiate between daytime symptoms, nighttime symptoms, and symptoms that occur in the early morning and that do not improve after inhaling a short-acting beta$_2$ agonist.

Monitoring Pulmonary Function

Monitoring lung function is essential to diagnosis and management of asthma. Lung function can be monitored by spirometry and peak flow monitoring. The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) recommends that spirometry tests be done at the time of initial assessment, after treatment is initiated and PEF has stabilized to determine "normal" airway function for the individual patient, and then every 1 to 2 years to assess the maintenance of airway function. Spirometry may also be needed to check the accuracy of PEF readings before making major treatment decisions if there is a question about the reliability of the PEF. Peak flow meters are used for ongoing monitoring, not diagnosis, of asthma. Patients who have frequent exacerbations or require long-term therapy need to have a peak flow meter at home and be comfortable with its use. Monitoring PEF is essential to management of moderate to severe asthma in order to determine the severity of exacerbations and to guide treatment decisions. Daily PEF readings help to detect early changes in asthma status, help to evaluate response to changes in medication therapy, and provide a quantitative measure of airflow obstruction.

The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) does not recommend long-term daily peak flow monitoring of patients with mild intermittent or mild persistent asthma, although PEF may be helpful during exacerbations. Patients should be given in-depth teaching regarding peak flow meter use, which may require more than one visit or referral to a nurse clinician who can teach proper peak flow meter use. Patients need to establish their personal best PEF and use that reading as the basis of their action plan. The patient should use the same brand of peak flow meter or reestablish personal best PEF if changing brands because there is no universal normative value for peak flow meters and the PEF may vary between brands. Peak flow meters are usually covered by insurance if the provider writes a prescription for the item.

Monitoring Quality of Life and Functional Status

Monitoring quality of life and functional status is essential to determine if the goals of asthma therapy are being met. The *Expert Panel Report 3: Guidelines* (NAEPP, 2007)

recommends that the following areas of quality of life be periodically assessed:

1. Missed work or school because of asthma.
2. Reduction in usual activities.
3. Any disturbances in sleep due to asthma.
4. Any change in caregiver activities due to child's asthma (for caregivers of children with asthma).

Monitoring History of Asthma Exacerbations

Monitoring the history of asthma exacerbation is essential at every visit. The provider must question the patient and evaluate self-monitoring records to determine exacerbation, both self-treated and those treated by other health-care providers (e.g., emergency department visit, hospitalization). Changes in drug treatment are based on the exacerbation history.

Monitoring Pharmacotherapy

Monitoring the effectiveness of pharmacological therapy is key to successful asthma treatment. The following should be monitored: patient adherence to the regimen, inhaler technique, level of usage of as-needed inhaled short-acting beta$_2$ agonist, frequency of oral corticosteroid "burst" therapy, and changes in dosages of inhaled anti-inflammatory or other long-term-control medication. The provider must also determine if the patient is at the appropriate level of step therapy and if changes need to be made. At each visit, an up-to-date asthma action plan has to be reviewed and revised as appropriate.

Monitoring Patient–Provider Communication and Patient Satisfaction

Patient satisfaction and patient–provider communication should be assessed routinely. Two aspects of patient satisfaction should be assessed and addressed as appropriate: satisfaction with asthma control and satisfaction with quality of care (NAEPP, 2007).

Outcome Evaluation

Evaluating the effectiveness of asthma therapy is an ongoing process, as described in the Monitoring section. The best outcome for asthma patients is being able to accomplish their activities of daily living, whatever their lifestyle, with minimum asthma symptoms.

The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) recommends that referral to an asthma specialist be made if there are difficulties in achieving or maintaining control, if immunosuppressive therapy is being considered, or if a patient requires step 4 care (step 3 if patient is an infant or young child).

Patient Education

Patient education should include a written asthma action plan, which includes a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues. The *Expert Panel Report 3: Guidelines* (NAEPP, 2007) provides a systematic review of the evidence related to written asthma action plans compared with medical management alone and clearly recommends the use of a written plan based on the evidence to date in decreasing emergency department visits and hospitalizations.

The key to asthma patient education is to establish and maintain a partnership among the patient, the family, and the health-care team. Patients and families are being asked to manage complex medical regimens, detect and self-treat most

---

PATIENT EDUCATION

Asthma

RELATED TO THE OVERALL TREATMENT PLAN AND DISEASE PROCESS

BASIC FACTS ABOUT ASTHMA

Use a variety of teaching methods such as illustrations, videos, written pamphlets or books, and models. Repeat key facts at every visit until the patient and/or family demonstrates an understanding of asthma. An example would to be to show the patient a drawing of a normal airway and an airway affected by asthma. The provider can then demonstrate how different medications act on different components of asthma (bronchodilator relaxes smooth muscle, anti-inflammatory decreases inflammation, etc.). This information can be repeated when reviewing medications at each visit until a clear understanding is demonstrated.

MEDICATION SKILLS

This includes proper inhaler use, spacer use if appropriate, when to take quick-relief medications, and nebulizer use if appropriate.

SELF-MONITORING SKILLS

This includes self-assessment of symptoms, peak flow monitoring, and how to record symptoms and peak expiratory flow (PEF) on a self-assessment diary. Recognizing early signs of declining lung function is essential knowledge for the patient and family.

Environmental control and avoidance strategies will enable the patient and family to avoid possible asthma triggers. Discussion of how environmental exposure to allergens and irritants can worsen asthma symptoms and how to avoid triggers at home, work, and school will assist patients in learning self-management.

PATIENT EDUCATION—cont'd

PATIENT EDUCATION

SPECIFIC TO THE DRUG THERAPY

Reason for the drug being given and its anticipated action in the disease process.
Doses and schedules for taking the drug.
Coping mechanisms for complex and costly drug regimens.
Interactions between other treatment modalities and these drugs.

REASONS FOR THE DRUG(S) BEING TAKEN

Patient education about specific drugs is provided in Chapter 17.

DRUGS AS PART OF THE TOTAL TREATMENT REGIMEN

Information should be provided concerning drugs as part of the total treatment regimen and individualized to the patient's age and asthma severity.

Many educational resources are available, the best of which are from the National Institutes of Health (NIH) and the Global Initiative for Asthma. These documents include the following:

National Asthma Education Prevention Program (2007). *The Expert Panel Report 3: Guidelines for Management of Asthma.* Includes copy-ready patient handouts on use of peak flow meter, inhalers, and asthma action plans.
Global Initiative for Asthma (2009). Global strategy for asthma management and prevention. http://www.ginasthma.org. Includes a patient guide to asthma and interactive learning modules on asthma in adults and children.

INTERNET-BASED PATIENT EDUCATION RESOURCES ON ASTHMA

---

exacerbations (unless severe), and communicate appropriately with the team. Asthma education is cost-effective and can reduce morbidity for both adults and children.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD) is the term commonly used to refer to conditions of chronic airflow limitation that is not fully reversible. The airflow restriction is usually progressive and involves both the airways and lung parenchyma. Other terms used include *chronic obstructive airway disease* and *chronic obstructive lung disease.* The primary risk factor is cigarette smoking, although occupational exposure (grain, coal, asbestos) and air pollution are also known factors. Not all cigarette smokers develop COPD, so genetic factors may influence who will develop the disease. Four professional organizations have published guidelines regarding COPD: the American Thoracic Society (ATS), the European Respiratory Society (ERS), the Global Initiative for Chronic Obstructive Lung Disease (GOLD), and the American College of Physicians (ACP).

COPD is a heterogeneous disorder that includes primarily chronic bronchitis and emphysema but also comprises peripheral airway disease and asthmatic bronchitis. The diagnosis of obstructive lung disease is determined by spirometry tests of lung function. A positive diagnosis of COPD is made when the FEV in 1 second (FEV_1) and the ratio to the forced vital capacity (FVC) is less than 70%. COPD can be classified as mild, moderate, severe, or very severe by the ATS and the ACP (Table 30-9).

The differences between the clinical presentations of emphysema and of chronic bronchitis are clear, although patients can have components of both diseases. Patients with emphysema are older at diagnosis and often thinner than patients with chronic bronchitis (Table 30-10). The pathological changes in emphysema consist of permanent enlargement of the airspaces distal to the terminal bronchioles and destruction of the bronchiole wall. The primary symptom seen in emphysema is dyspnea. Chronic bronchitis is defined by chronic cough with copious sputum production for 3 months in 2 successive years (American Thoracic Society [ATS]/European Respiratory Society Task Force, 2004). Physical presentation differs in that patients with emphysema are typically barrel chested and breathe through pursed lips ("pink-puffers"), whereas patients with

Table 30–9 Stages of COPD

Classification	Definition by Spirometry
At Risk Patients who: smoke or have exposure to pollutants have cough, sputum or dyspnea have family history of respiratory disease	FEV_1/FVC >0.70 FEV_1 ≥80% of predicted
Mild	FEV_1/FVC <0.70 FEV_1 ≥80% of predicted
Moderate	FEV_1/FVC <0.70 50% ≤FEV_1 <80% of predicted
Severe	FEV_1/FVC <0.70 30% ≤FEV_1 < 50% of predicted
Very Severe	FEV_1/FVC <0.70 FEV_1 <30% of predicted, or FEV_1 <50% of predicted plus chronic respiratory failure

Source: Derived from American Thoracic Society, 2004; Qaseem et al, 2007.

Table 30–10 Clinical Features of Chronic Bronchitis and Emphysema

Characteristic	Chronic Bronchitis	Emphysema
Age at onset of symptoms	40–50 yr	50–60 yr
Primary symptoms	Cough	Dyspnea
Sputum	Copious, usually purulent	Scant, usually mucoid
Chest x-ray	Peribronchial thickening, often evidence of old inflammatory disease diaphragm	Hyperlucent, overinflated lung, flattened
Weight	Frequently obese	Thin, often marked weight loss
Total lung capacity	Normal or slightly decreased	Increased
Chest examination	Noisy chest, slight hyperinflation	Clear, may have slight end-expiration wheeze, marked hyperinflation
Cor pulmonale with heart failure	Common	Infrequent until end stages of disease

chronic bronchitis are typically obese and suffer from significant hypoxemia, cyanosis, and carbon dioxide retention ("blue-bloaters").

Pathophysiology

The pathophysiology of COPD is characterized by both acute and chronic inflammation. There are also changes in cellular proliferation, leading to tissue destruction, loss of structural ciliated columnar cells, squamous and goblet cell metaplasia, glandular and smooth muscle hypertrophy, and scarring. Clinically, these changes lead to worsened obstruction, hyperinflation of the lungs, increased sputum production, recurrent respiratory infections, and altered gas exchange. As the disease progresses, the patient experiences respiratory muscle fatigue, ventilatory disorders, cardiovascular compromise, and poor quality of life.

The immune response is implicated in the pathophysiology of COPD, with macrophages having a pivotal role in COPD exacerbations. Environmental triggers, including cigarette smoke, are suggested in stimulating Toll-like receptors (TLR), which initiate the innate immune response contributing to bronchial construction and mucous production. These receptors offer promising targets for pharmaceutical interventions (Bezemer et al, 2012; Rovina, Koutsoukou, & Koulouris, 2013).

Emphysema

Emphysema is closely linked to cigarette smoking and the damage to the respiratory tract from the chronic cellular changes smoking produces. The chronic, progressive destruction of the alveolar structures found in emphysema is thought to be caused by an imbalance between proteases and antiproteases in the lower respiratory tract. Proteases, specifically polymorphonuclear neutrophil (PMN) elastase and pulmonary alveolar macrophage (PAM) elastase, work unchecked to destroy alveolar structures and their elastin network. Cigarette smokers have increased numbers of PMNs and PAMs in their lungs, which result in the loss of elastic recoil and structural support found in the lungs of smokers with emphysema. These findings are also found in patients with genetic alpha $_1$ antitrypsin deficiency, which accounts for 2% of patients with emphysema. Alpha $_1$ antitrypsin functions as an antiprotease in the lung

to inhibit neutrophil elastase. Therefore, the same structural changes occur in these patients as occur in smokers with emphysema.

Chronic Bronchitis

Cigarette smoking is also the major contributor to the development of chronic bronchitis. Other inhaled irritants are also known to cause chronic bronchitis, among them dust, grain dust, fumes, and asbestos. Three direct effects of inhaling bronchial irritants contribute to the development of chronic bronchitis: (1) stimulation of mucus secretion in the airways, (2) impaired mucus clearance due in part to interference with ciliary activity, and (3) decreased resistance to bronchopulmonary infection because of altered alveolar macrophage function. Clinically, the patient presents with a chronic cough that is due to accumulation of the secretions. Airflow obstruction is due to inflammation of the airways and the thick secretions. The increased mucus is an excellent medium for recurrent bronchial infections, which cause further damage to the airways.

Goals of Therapy

The major goals of treatment for patients with COPD are to slow the disease process and maintain quality of life. Although medications such as antibiotics, bronchodilators, and corticosteroids are part of the treatment, other nonpharmacological measures have just as much impact. Most important, the patient must quit smoking. Nutrition and infection protection are key in maintaining optimal health. Exercise and pulmonary rehabilitation improve function and quality of life. A well-managed regimen of medication and nonpharmacological therapies enhances the outcome for patients with COPD.

Rational Drug Selection

The medication regimen for the COPD patient often includes different medications, each treating a different aspect of the disease. The ACP conducted an evidence-based review of therapies and made recommendations for treatment: maintenance monotherapy (long-acting beta agonists, long-acting inhaled muscarinics, or inhaled corticosteroids) for symptomatic patients with COPD and FEV_1 less than 60% of predicted; consideration of combination inhaled therapies for symptomatic patients with COPD and FEV_1 less than 60% of predicted (Qaseem et al, 2011). Drugs commonly used to treat COPD are shown in Table 30-7.

Bronchodilators

Beta Agonists

Bronchodilators are the mainstay of pharmacological therapy for COPD patients. They treat the reversible component of COPD and maximize airflow by relaxing the airway smooth muscle and improving lung emptying during tidal breathing (ATS/European Respiratory Society Task Force, 2004). Three types of bronchodilators are used in COPD management: $beta_2$ agonists, anticholinergic drugs, and methylxanthines (theophylline).

Inhaled $beta_2$ agonists have been the mainstay for COPD therapy, and short-acting $beta_2$ agonists should be prescribed for acute symptomatic relief of all persons with airflow obstruction. The ACP recommends long-acting beta agonists as monotherapy or in combination with an inhaled anticholinergic or inhaled corticosteroid (Qaseem et al, 2011). The long-acting beta agonists are effective in reducing COPD exacerbations and as of this writing may still be used for monotherapy in COPD patients, whereas they have received a Black-Box Warning not to be used as monotherapy in asthma (U.S. FDA, 2010). The long-acting beta agonists, salmeterol (Serevent) or formoterol (Perforomist), can be prescribed singly or in combination with an inhaled corticosteroid (Advair or Symbicort) or long-acting muscarinic antagonist (Tiotropium). In two large studies, the use of combination therapy was slightly better than single therapy in reducing the frequency of COPD exacerbations and hospitalizations. The combination of a short-acting beta agonist (albuterol) and ipratropium (an inhaled anticholinergic) reduces the duration of COPD exacerbations compared to albuterol alone (Qaseem et al, 2011).

Ultralong-acting beta agonists (Ultra LABA) activate the $beta_2$ receptors on the smooth muscle cells, resulting in activation of the cAMP pathway and muscle relaxation similar to short- and long-acting beta agonists. In 2011, the FDA approved the first Ultra LABA, indacaterol (Arcapta). Indacaterol is a once-daily long-acting bronchodilator that has an onset of 5 minutes and a duration of 24 hours (Reid & Pham, 2013). When combined with a long-acting muscarinic antagonist, the benefit is additive, resulting in an improvement of respiratory symptoms (Cope, Kraemer, Zhang, Capkun-Niggli, & Jansen, 2012).

Methalyxanthine

Theophylline is not included in the ACP 2011 recommendations, but is in the GOLD 2014 guidelines as a second-line drug, noting low-dose theophylline reduces exacerbations of COPD. Theophylline was historically a first-line agent used to treat asthma and COPD; however, the margin between therapeutic levels and toxic levels was small. Many patients developed toxicity and the use of theophylline decreased with the development of $beta_2$ agonists and anticholinergics. There has been a recent interest in theophylline, not only for the bronchodilator properties but also as a selective phosphodiesterase (PDE) inhibitor. Specifically, with blocking the PDE-3 resulting in bronchodilation and PDE-4 decreasing macrophage activation and inflammation, low-dose theophylline is showing promising results, especially in severe COPD patients who are resistant to steroids (Barnes, 2013; Hakim, Adcock, & Usmani, 2012).

Muscarinic Agents

Muscarininc agents that have anticholinergic properties, such as ipratropium bromide (Atrovent) and tiotropium (Spiriva), reduce the volume of sputum without changing the viscosity, which in addition to their bronchodilation effects may make them the drugs of choice in COPD. Tiotropium (Spiriva HandiHaler), a long-acting muscarinic antagonist (LAMA), is delivered as a dry inhalation powder once daily. Titropium has been found to reduce exacerbations and hospitalizations

of COPD patients compared with placebo and ipratropium (ATS/ European Respiratory Society Task Force, 2004; Qaseem et al, 2011). One caution is that the inhaled LAMA are not effective for immediate relief of bronchospasm because of their slow onset of action; therefore, regular dosing is necessary. Combining agents such as albuterol and ipra - tropium (Combivent) or formoterol and tiotropium (Symbicort) produces a greater change in spirometry over 3 months than either agent alone. The ACP recommendations note clinicians may consider combination inhaled medications for COPD if FEV_1 is less than 60% of predicted (Qaseem et al, 2011). Combination medications may be more convenient and economical for patients with COPD who require both medications. The combination of albuterol and ipratropium is also available in solution for nebulizer use (DuoNeb).

Recently, acridinium bromide (Tudorza Pressair) has been approved as a long-acting muscarinic antagonist (LAMA) for the treatment of COPD; it is delivered as a dry powder inhaler twice a day.

Corticosteroids

Corticosteroids have nonspecific anti-inflammatory activity at multiple points in the inflammatory process. Because of the cellular-level airway changes that define COPD, corticosteroids' effects are less dramatic in COPD than those seen in asthma. Yet corticosteroids are key components in the management of stable COPD and COPD exacerbations.

The use of daily inhaled corticosteroids (ICS) in the COPD patient has mixed results in clinical studies (ATS/European Respiratory Society Task Force, 2004; GOLD, 2014; Man & Sin, 2005; Qaseem, et al, 2011). The consensus of the expert panel groups based on the evidence to date is that inhaled corticosteroids do not modify the long-term decline in FEV_1 seen in COPD, but as both monotherapy and in combination with inhaled bronchodilators they decrease exacerbations and improve health status in patients with symptomatic COPD (GOLD, 2014; Qaseem et al, 2011). Therefore, the current ACP and GOLD guidelines recommend starting a patient on moderate- to high-dose inhaled corticosteroids (see Table 30-1). Combination therapy of ICS and a long-acting beta agonist, such as Advair (salmeterol/fluticasone), is more effective in decreasing exacer - bations than either agent alone (level A evidence in the GOLD report); therefore, combination therapy should be considered in any patient with moderate to severe COPD defined by FEV_1 less than 60% of predicted (GOLD, 2014; Qaseem et al, 2011).

Education about the slow onset of ICS is necessary so that patients do not become frustrated as the inhaled steroids are introduced. Patients need to be cautioned to rinse their mouths after inhaled steroid use to prevent oral candidiasis. There have been conflicting reports suggesting a higher incidence of pneumonia in patients receiving ICS; however, there is evidence to suggest causality (Hanania 2013).

Oral corticosteroids are useful in the short-term treatment of acute COPD exacerbation (ATS/European Respiratory Society Task Force, 2004; GOLD, 2014). There is level A evidence for the use of oral corticosteroids because they shorten recovery time, improve lung function, and decrease hypoxemia during the exacerbation (GOLD, 2009). If, in spite of maximum therapy with bronchodilators, the patient continues to have significant airway obstruction, a course of systemic corticosteroids is indicated. Prednisone is given as a dose of 30 to 40 mg daily for 10 days (ATS/European Respiratory Society Task Force, 2004; GOLD, 2009). At that time, the patient should have a 20% to 30% increase in pulmonary function (FEV_1). Some patients respond to a 10-day burst of cortico - steroids, and the medications can be discontinued. Other patients require a taper of medication to the lowest prednisone level required to prevent recurrent attacks and relieve bronchospasm. The prednisone dose is tapered over 1 to 2 weeks and then to 5 mg over 5 days. Tapering may lead to recurrence of symptoms, and patients should be educated regarding monitoring their symptoms and PEF during tapering. Long-term treatment with oral corticosteroids is not recommended in COPD (level A evidence), and patients should be transitioned to inhaled corticosteroids either as monotherapy or in combination with inhaled long-acting beta agonists (GOLD, 2014).

Phosphodiesterase-4 Inhibitors

An emerging therapy in the treatment of severe COPD associated with chronic bronchitis is phosphodiesterase-4 (PDE-4) inhibitors. This class of medications inhibits activation of the PDE-4 receptor sites located in the smooth muscles of the airways, resulting in bronchial relaxation and a decrease in the activation of the immune response (Lipari, Benipal, & Kale-Pradhan, 2013). Theophylline is a bronchodilator with nonspecific PDE-inhibition properties, but in 2011, roflumilast (Daliresp) was the first PDE-4 inhibitor approved by the FDA to prevent COPD exacerbation. Roflumilast is not intended as a rescue medication and should be taken daily as a 500 mcg tablet (Lipari et al, 2013; Reid & Pham, 2013).

Oxygen

For some patients, home oxygen therapy is necessary. Oxygen therapy can be used short-term during acute exacerbations or long-term in chronically hypoxemic patients. The goals of supplemental oxygen therapy are to correct arterial hypoxemia and prevent secondary organ damage; ideally, oxygen saturation should be greater than 90%. In patients experiencing an acute exacerbation of COPD, a drop in partial pressure of oxygen in arterial blood (PaO_2) to below 55 mmHg is an indication for short-term supplemental oxygen. Oxygen saturation of hemoglobin (SaO_2) has replaced arterial blood gas values in the outpatient setting. An SaO_2 of 88% corresponds with a PaO_2 of 55 mm Hg (McDonald & Khor, 2013).

Patients should be started on continuous oxygen therapy if they demonstrate persistent hypoxemia at rest (PaO_2 less than 55 mmHg or less than 88% oxygen saturation). These patients should be monitored to determine when oxygen therapy can be discontinued. For the chronically hypoxemic COPD patient, continuous home oxygen therapy for 15 hours or more per day is associated with increased survival rate in patients with severe airway obstruction (Qaseem et al, 2014). Patients with cor pulmonale or polycythemia with PaO_2 less than 59 mm Hg and less than 89% oxygen saturation require supplemental oxygen.

Patients on continuous oxygen therapy require arterial blood gas studies after 1, 3, and 6 months of therapy. Supplemental oxygen improves exercise tolerance, neuropsychological function, and quality of life—all key factors in the patient's emotional health in learning to live with this chronic disease.

Antibiotics

Patients with COPD have an excess of thick pulmonary mucus and decreased ciliary clearance of secretions; therefore, they are susceptible to repeated bronchial infections. Infection is considered present when the patient is producing a purulent sputum. The common organisms found in the sputum of patients with COPD patients are *Haemophilus influenzae, Streptococcus pneumoniae, Mycoplasma pneumoniae,* and *Moraxella catarrhalis.* The most common organism is *S. pneumoniae* (Rabe et al, 2007). Antibiotic choices have to cover these organisms until sputum cultures are available to determine sensitivity. Amoxicillin/clavulanic acid, macrolides, and double-strength sulfamethoxazole/trimethoprim are all appropriate first-line choices (Rabe et al, 2007). Resistant organisms require a change in antibiotic therapy after drug susceptibility studies are completed. Patients with moderate exacerbation who may require hospitalization or who don't respond to first-line therapy should be treated with a respiratory fluoroquinolone (levofloxacin, moxifloxacin, gemifloxacin). Length of treatment is 7 to 14 days.

Macrolide antibiotics have an immunomodulatory effect that has been effective for patients with moderate to severe COPD to prevent severe exacerbations (Kanoh & Rubin, 2010). Several small studies (Albert et al, 2011; Milstone, 2008; Spagnolo, Fabbri, & Bush, 2013) and one meta-analysis (Yao, Ma, Zhang, & Gao, 2013) have demonstrated a reduction in exacerbations and improvement of quality of life. The chronic use of macrolide antibiotics in patients with COPD has not been widely accepted because of FDA warnings regarding potential cardiac dysrhythmias, ototoxicity and antibiotic resistance. This therapy is under evaluation and may have a consensus for routine use in the future.

Leukotrienes

There are no data to support the use of leukotriene receptor antagonists in the treatment of COPD.

⊙ CLINICAL PEARL ⊙

Oxygen Therapy
One note of caution in providing oxygen therapy to some patients with COPD who have poor ventilatory capacity: These patients, known as "carbon dioxide retainers," no longer rely on rises in $PaCO_2$ as the primary drive to breathe. If these patients receive too much oxygen, raising their PaO_2 above their normal baseline, hypoventilation may occur. This results in CO_2 retention and the somnolence, lethargy, and coma that occur with carbon dioxide narcosis. Monitoring arterial blood gases is essential in all patients receiving oxygen therapy.

Alpha-Trypsin Augmentation Therapy

Patients who have emphysema related to genetic alpha $_1$ antitrypsin deficiency may benefit from augmentation therapy with an alpha$_1$-proteinase inhibitor (Prolastin, Aralast, Zemaira). These medications are administered weekly via IV. Patients with alpha$_1$ antitrypsin deficiency should be referred to a specialist for therapy.

Immunizations

Infection prevention is essential in management of patients with COPD, and vaccination against respiratory infections is an integral component in preventing illness in these patients. Protection against influenza virus is recommended annually. Optimally, the influenza vaccine should be administered between October and January, the earlier in the influenza season the better, to allow adequate antibody response. Patients with COPD also require a pneumococcal vaccine every 6 years regardless of age. Patients should be taught the importance of these vaccines so that they remember to get them.

Smoking Cessation

Smoking is a major contributor to COPD. Cigarette smoking results in severe destruction of lung tissue, and the damage is largely irreversible. To halt the progression of COPD, the patient must stop smoking. The benefits of smoking cessation include an eventual return to a nearly normal age-related rate of ventilatory function.

There are many new medications that can help the patient stop smoking. Smoking cessation is discussed in depth in Chapter 43.

Monitoring

Monitoring patients with COPD has four aspects related to pulmonary function and quality of life: signs and symptoms of COPD, pulmonary function, pharmacotherapy, and quality of life.

All patients should be taught how to monitor their symptoms for worsening pulmonary function. Patients with chronic bronchitis need to monitor their sputum for changes in color from their baseline to more purulent. Any symptoms of respiratory infection must be reported to their health-care provider so that appropriate antibiotic therapy can be started. During times of poor outdoor air quality, these patients need to remain indoors and report any signs of respiratory distress to their health-care provider. Patients with COPD may require increased use of bronchodilators or oxygen during these times.

Monitoring pulmonary function is done by spirometry, peak flow meter, oxygen saturation (pulse oximetry), and arterial blood gases. Patients can be taught to use a peak flow meter to monitor lung function at home and determine their need for changes in their medication regimen in times of illness or poor air quality. All patients with COPD need objective monitoring of lung function on a regular basis to identify worsening of function and, therefore, need for a change in their treatment regimen.

Patients should bring their medications on every visit to the health-care provider. MDI use should be reviewed and technique monitored with each visit. Patients who use more than the recommended amounts of beta$_2$ agonists need to be assessed closely to determine the reason for the increased use. Is the patient using the inhaler incorrectly or is the disease progressing? Increased use of inhaled bronchodilators is an indication for reevaluation of the medication regimen and a possible need for systemic steroids. Patients on supplemental oxygen therapy require arterial blood gases, as previously mentioned, at 1, 3, and 6 months after beginning therapy. Any change in respiratory status is an indication for repeat arterial blood gas determination. All patients require a written medication management plan that is reviewed at every visit.

Monitoring quality of life at every visit can determine if the treatment regimen is successful. Is the patient able to tolerate activities of daily living without assistance? Exercise tolerance, activity level, and nutrition all need to be evaluated.

The financial burden of a chronic illness such as COPD is significant, and referral to a social worker may be necessary to help the patient pay for prescribed treatment.

Outcome Evaluation

Successful management of patients with COPD includes their self-assessment of quality of life, as well as physical parameters of optimal treatment. As COPD is chronic and for the most part irreversible, outcome evaluation is based on the patient's having the best quality of life for the disease state. The successfully managed patient with COPD has optimal activity tolerance, which varies for each patient. Pharmacological management is aimed at decreasing bronchospasm and secondary infections. Therefore, the amount of bronchospasm and the number of infections determine if treatment is successful.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues. Patient education for the COPD patient centers on maintaining optimal pulmonary function and quality of life. Teaching self-management is the basis of successful treatment.

PATIENT EDUCATION

Chronic Obstructive Pulmonary Disease

RELATED TO THE OVERALL TREATMENT PLAN AND DISEASE PROCESS

The patient needs to be taught the following areas of self-management:

SMOKING CESSATION

This is a difficult area of education because of the physical and psychological addiction to cigarettes. Many patients have attempted to quit smoking previously and need to be encouraged to try again, using some of the pharmacological interventions available to aid in tobacco cessation.

PATHOPHYSIOLOGY OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

A basic understanding of the changes in the pulmonary system that occur with COPD will assist the patient in understanding the role that the different medications play in the treatment regimen.

MEDICATION SKILLS

Patients with COPD often have other chronic illnesses that require routine medications. Administering a complex regimen of multiple medications can be overwhelming, especially to older patients. Written schedules (in large print) and divided pill boxes are two strategies for medication management. Providing the patient with the generic and trade names of medications will decrease medication confusion. Having the patient bring all medications in for review will prevent medication errors. Often, the patient may be seeing other providers, including specialists who may also be prescribing medications. It is the role of the primary care provider to coordinate between specialty providers and monitor medications the patient is taking. Encourage patients to use a magnifying glass to read the generic names on the meter dose inhaler (MDI) canisters, as the canister color may change with different brands of the same medication.

SPECIFIC TO THE DRUG THERAPY

Reason for the drug being given and its anticipated action in the disease process.
Doses and schedules for taking the drug.
Coping mechanisms for complex and costly drug regimens.
Interactions between other treatment modalities and these drugs.

PATIENT EDUCATION—cont'd

REASONS FOR THE DRUG(S) BEING TAKEN

Patient education about specific drugs should be provided, including how to use inhalers appropriately.

DRUGS AS PART OF THE TOTAL TREATMENT REGIMEN

The total treatment regimen also includes teaching self-monitoring skills, including, if indicated, proper use of a peak flow meter.

Infection control measures are also taught. Patients with COPD are at high risk for respiratory infections. They need to be taught the importance of annual influenza vaccine and the need for a pneumococcal pneumonia vaccine every 6 years. They need to avoid crowds and people, especially children, with respiratory infections.

ADHERENCE ISSUES

Health-care providers should be aware of the potential problem of nonadherence with the treatment regimen and should discuss the importance of adherence with the patient and family members.

CONTRACEPTION

Teral Gerlt

Choosing a method of contraception (birth control) is an intimate process and one in which patients, male and female, often seek advice from their health-care provider. Unintended pregnancy rates remain high in the United States. Mosher, Jones, and Abma (2012) report that in the years from 2006 to 2010, just over 37% of all pregnancies in women age 15 to 44 were unplanned. Considerations that must be addressed include the safety of the method chosen, age of the patient, the health and medical conditions of the patient, ability to comply with method use, frequency of sexual relations, risk of sexually transmitted infections, and cost. The most important of these considerations after safety is compliance; any method that offers safety to the patient offers very little protection from pregnancy if use of the method does not fit the patient's lifestyle.

Many contraceptive options are available with varying efficacy rates (Hatcher et al, 2011). These options and their efficacy rates for first year of use are presented in Table 31-1. This chapter focuses on the pharmacological methods of contraception that offer the highest rates of effectiveness. Over the past several years, novel modes of delivery for contraceptive hormones have been introduced. The new delivery modes offer potentially lower rates of failure due to user error because they involve less frequent administration intervals, therefore increasing the user's ability to comply with proper use. Pharmacological methods include oral contraceptives (OCs), topical patches, vaginal rings, subdermal implants, injections, and intrauterine devices (IUDs). These methods include progestin-only preparations and preparations that include various combinations of estrogen and progestin.

PHYSIOLOGY OF THE NORMAL MENSTRUAL CYCLE

The menstrual cycle is regulated by positive and negative feedback in the hypothalamic-pituitary-ovarian axis. The pituitary gland releases stimulating and inhibiting hormones. Release of these hormones is regulated by pulses of gonadotropin-releasing hormone (GnRH) from the hypothalamus. GnRH pulses regulate follicle-stimulating hormone (FSH) and luteinizing hormone (LH) that in turn regulate the secretion of estrogen and progesterone from the ovary. The most obvious manifestation of this complex system is cyclic menstrual bleeding.

Table 31–1 Contraceptive Options

Method	Advantages	Disadvantages	Perfect Use Efficacy	Typical Use Efficacy
Estrogen/Progestin Combination Contraception				
Pills	Menstrual cycle control	Daily administration may be difficult for some users	>99%	91%
Patch	Menstrual cycle control Weekly administration	Patch may cause some local irritation Patch may fall off partially or completely	>99%	91%
Ring	Menstrual cycle control Once per cycle administration	User must be comfortable with vaginal administration	>99%	91%
Progestin Only				
Oral contraception	No estrogen; may be useful for users in whom estrogen is contraindicated	Daily administration may be difficult for some users Unpredictable bleeding pattern	>99%	92%
Progestin injectable contraception	Administration once every 12 wk Use of method discreet from others	Administration requires office visit Unpredictable bleeding pattern	>99%	94%
Progestin implant	Offers contraception for 3 yr	Insertion and removal requires office procedure Unpredictable bleeding pattern	>99%	>99%
Intrauterine Device (IUD)				
Copper	Hormone free Offers contraception for 10 yr	Insertion and removal requires office visit Dysmenorrhea and menstrual flow may be increased in first few months after insertion	>99%	>99%
Progestin-releasing	Decreased menstrual flow Offers contraception for 3 or 5 yr	Requires office visit for insertion and removal	>99%	>99%
Barrier Methods				
Male condom	Protection from most STIs Available without prescription	Use linked to coitus and partner-dependent	98%	82%
Female condom	Protection from most STIs Available without prescription	Use linked to coitus	95%	79%
Spermicide	Available without prescription	Use linked to coitus	82%	71%
Diaphragm	May be inserted several hours before intercourse	Available only with provider fitting and prescription Must be used with spermicide User must be comfortable with vaginal insertion technique	94%	88%
Cervical cap	May be inserted several hours before intercourse	Available only with provider fitting and prescription Must be used with spermicide User must be comfortable with vaginal insertion technique Lower efficacy for parous women	74%–91%	68%–84%
Vaginal sponge	Available without prescription Contains spermicide May be inserted several hours before intercourse	Lower efficacy for parous women	80%–91%	68%–84%

STIs = sexually transmitted infections.

The menstrual cycle is divided into four phases: follicular, ovulatory, luteal, and menstrual. During the follicular phase, FSH stimulates several follicles to develop, with one ultimately becoming dominant. The dominant follicle synthesizes enough estradiol to create negative feedback and decrease FSH levels. During the ovulatory phase, estradiol levels peak and exert positive feedback to induce an LH surge, which in turn facilitates release of the mature ovum. Estrogen also promotes proliferation of the endometrium, and development of progesterone receptors in the endometrium.

During the luteal phase, progesterone dominates; it is produced predominantly by the corpus luteum and prevents new follicle development as well as differentiation of the endometrium. If pregnancy does not occur, the corpus luteum degenerates. Once the corpus luteum degenerates, estrogen and progesterone levels decline, resulting in endometrial shedding or menstrual bleeding. Other gynecological organs are also influenced by estrogen and progesterone. The fallopian tubes exhibit increased proliferation, differentiation, and tubular contractility under the influence of estrogen; these processes are inhibited under the influence of progesterone. Cervical mucus water content is increased and penetration of sperm is facilitated by estrogen, whereas it is decreased by progesterone.

Estrogen exerts effects on other body systems, including positive effects on bone mass, increasing serum triglycerides, improving high-density lipoprotein (HDL) to low-density lipoprotein (LDL) ratios, and stimulating coagulation and fibrinolytic pathways. Progesterone increases body temperature, increases insulin levels, and may slightly depress the central nervous system (Chrousos, 2012).

PHARMACODYNAMICS

The major difference between endogenous estrogen and progestins and pharmacological preparations is their oral bioavailability. All orally available estrogen and progestins undergo first-pass metabolism in the liver. Currently, the vast majority of contraceptive preparations use ethinyl estradiol (EE) as the estrogen component. Mestranol is used in only three brands of OCs and must be metabolized into EE before it is able to bind with estrogen receptors. The last estrogen is estradiol valerate, a synthetic prodrug of 17ß-estradiol, used only in the quadriphasic Natizna.

Most progestins used in hormonal contraception are derivatives of testosterone. The alteration of testosterone not only makes them bioavailable but also changes their activity from androgenic to much more selective progestational activity. Currently, several different androgen-derived progestins are available in oral contraceptive preparations. Norethindrone, norethindrone acetate, and ethynodiol diacetate are first-generation progestins. Both norethindrone acetate and ethynodiol diacetate are converted to norethindrone in the body. As the amount of these progestins used in the formulations decreased, women experienced more spotting and breakthrough bleeding. In response, the second-generation progestins, norgestrel and levonorgestrel,

were developed. Levonorgestrel is the levorotatory form of norgestrel and its active metabolite. These progestins increased androgenic activity, thereby decreasing breakthrough bleeding; however, increasing the androgenic activity may lead to problems with acne, hirsutism, and dyslipidemia (Hatcher et al, 2011).

Desogestrel and norgestimate are third-generation progestins, which offer a decrease in androgenicity. Desogestrel undergoes conversion to its active metabolite etonogestrel, which is the progestin used in the vaginal ring and the subdermal implant. Norelgestromin is the primary metabolite of norgestimate and is available in the contraceptive patch. Decreased androgenicity theoretically reduced adverse effects on carbohydrate and lipid metabolism found in previous formulations, as well as lessening acne and hirsutism. Medroxyprogesterone acetate is available for injectable contraception.

Two fourth-generation progestins are now in use in the United States. Drospirenone is a derivative of spironolactone; as such, it has a mild diuretic effect as well as antimineralocorticoid effects. Drospirenone may cause hyperkalemia and should be used cautiously in women who are using drugs that cause a potassium-sparing effect, such as angiotensin-converting enzyme (ACE) inhibitors. Drospirenone should not be used in women with abnormal adrenal, renal, or hepatic function (*Drug Facts and Comparisons*, 2013; Speroff & Darney, 2011). The last progestin is dienogest, which displays properties of 19-nortestosterone derivatives as well as properties associated with progesterone derivatives, producing an anti-androgenic action (Speroff & Darney, 2011).

Mechanism of Pregnancy Prevention

Progestins are primarily responsible for the contraceptive effect in hormonal preparations. Progestins exhibit a negative effect in the hypothalamic-pituitary-ovarian axis, essentially suppressing the LH surge necessary for ovulation. They also cause thickening of cervical mucus, making penetration by sperm difficult. Tubal motility is slowed, delaying transport of the ovum and sperm. Finally, progestins cause atrophy of the endometrium, preventing implantation.

The estrogen component of hormonal contraception improves efficacy by suppressing FSH release, and therefore development of a dominant follicle. Estrogen also adds to cycle control, decreasing irregular bleeding patterns commonly found with progestin-only methods (Chrousos, 2012; Speroff & Darney, 2011).

GOALS OF TREATMENT

Treatment goals of pharmacological contraception are to use the safest, best-tolerated, and most effective method that the patient desires. In order to help the patient determine which contraception method may be best for her, the provider needs to be aware of any cultural or religious determinants, as well as partner acceptance.

In the last few years most of the research on new OCs has involved changing the type of estrogen and/or progestin in the formulations and the dosing pattern to decrease side effects and enhance ease of use (Sitruk-Ware, Nath, & Mishell, 2013). Natazia was released in 2010 and is the only four-phasic oral contraceptive on the market. It is the first OC to contain estradiol valerate, a synthetic prodrug of 17ß-estradiol and a new progestin, dienogest, which displays properties of 19-nortestosterone derivatives as well as properties associated with progesterone derivatives.

The only chewable OC on the market, Generess, combines 0.8 mg norethindrone and 0.025 mg ethinyl estradiol with four 75 mg ferrous fumarate placebo tablets. The 24/4 regimen is intended to decrease breakthrough bleeding and provide short, light, predictable periods (Shrader & Dickerson, 2008).

A combination OC, Zoely, utilizing natural estrogen (17β estradiol), and a new progestin (nomegesterol acetate), manufactured by Merck have been approved in the United Kingdom and several European and Latin American countries (Bahamondes & Bahamondes, 2014). The estrogen component, 17β estradiol, is structurally identical to endogenous 17β estradiol (Merck, 2014). Nomegesterol acetate has a 46-hour half-life, which increases efficacy (Merck, 2014). It has not received U.S. approval yet.

Safety

The fear over increased risk of breast cancer with oral contraceptive use is largely media induced. A meta-analysis of breast cancer data (Kahlenborn, Modugno, Potter, & Severs, 2006) suggests a small overall increase in breast cancer risk (OR = 1.19) across different use patterns. In studies that controlled for parity, the data indicated that the risk of breast cancer in nulliparous women was OR equal to 1.24, and length of hormonal contraceptive use did not increase risk. The most interesting finding was the increased risk of breast cancer in parous women who used OCs for more than 4 years prior to their first full-term pregnancy (OR = 1.52). However, Speroff and Darney (2011) put this in perspective by pointing out that because most of the women using OCs are in an age bracket during which breast cancer is very rare, the overall increase in breast cancer cases is relatively small.

A recently reported prospective study of over 116,000 women did find a RR = 1.33 of breast cancer with current use and no significant risk with past use (Hunter et al, 2010). One interesting finding was an increased risk (RR = 3.05) only in current use of a triphasic formulation containing levonorgestrel. When the use of this formulation was controlled for, it was found to account for the majority of breast cancer cases.

Current studies find no increase in the frequency of liver cancer in women who use OCs. Studies do show a negligible increase in the incidence of gallstones in current users, but the data point to this in women who have underlying asymptomatic disease and its acceleration, rather than an actual increase in the population.

Cardiovascular disease risk related to lipid metabolism is difficult to quantify because so many other risk factors are involved. Formulations with less than 50 mcg of estrogen seem to have no detrimental effects. In general, the cardiovascular risk factors other than OC use play the predominant role in the occurrence of ischemic stroke and myocardial infarction. Patients who smoke share an increased risk for heart attack, stroke, and thromboembolic phenomena (deep venous thrombosis [DVT] and pulmonary embolism) as they approach 35 years of age (Speroff & Darney, 2011). Findings from the Women's Health Initiative are discussed in Chapter 38 in relation to hormone replacement therapy. These findings should be considered in prescribing OCs, but the risk for these low doses of estrogen and progesterone were not part of this study.

Tolerance

More than 40 years of experience in prescribing OCs have provided much data with which to knowledgeably help patients decide when choosing an OC. Current OCs have less estrogen; therefore, they cause fewer of the pregnancy-like symptoms that had earlier been so distressing. The third- and fourth-generation progestins show fewer weight changes, improved complexion, and reduced mood swings. Improvements in packaging have also improved compliance by providing cues in the packaging for the day of the week each pill should be taken.

Effectiveness

The theoretical effectiveness is 99% or greater with most hormonal therapies. Patients have lower discontinuation rates and therefore fewer unwanted pregnancies if they are well educated about emergency hormonal contraception and use a backup method such as spermicide and condoms. Vomiting and diarrhea that accompany gastrointestinal illnesses can decrease oral contraceptive effectiveness by decreasing absorption; women should be advised to use a backup method for at least 7 days after a gastrointestinal illness (Speroff & Darney, 2011).

RATIONAL DRUG SELECTION

Guidelines

A good place to start in helping a patient choose a new hormonal contraceptive is to exclude those methods that are absolutely or relatively contraindicated because of existing health concerns and patient age. Deciding whether the patient has any contraindications to the use of estrogen narrows the choices considerably. Then review which delivery mode appeals to the patient based on her perceived ability to comply with the dosing regimen. Choices can then be fine-tuned based on acceptability of likely changes in bleeding pattern and side-effect profile. The provider should also discuss the theoretical and typical failure rates with the patient to ascertain if these are congruent with the patient's desire to avoid pregnancy. Other factors to consider are a patient's need for discreetness in the use of her method: a patient may wish to

conceal her contraceptive method from partners or other family members and taking a daily pill or wearing a patch may preclude these choices. Timing of a subsequent pregnancy should also be considered; for some methods a return to fertility is delayed after cessation of use. For patients who are satisfied with their current hormonal contraceptive choice, and for whom no new contraindications because of health issues are present, changing from a product or method to one that is newer to the market is unnecessary.

More than four dozen formulations of monophasic combined oral contraceptives (COCs), about two dozen multiphasic COCs, and several formulations of progestin-only pills (POPs), as well as several nonoral contraceptive hormone delivery methods, are available. Table 31-2 summarizes the name brand and generic hormone formulas currently available (Chrousos, 2012; *Drug Facts and Comparisons,* 2013; Hatcher et al, 2011; Shrader & Dickerson, 2008).

Table 31–2   Oral Contraceptives

Brand Name	Estrogen Dose (mcg)	Progestin Dose (mg)

If all OCs are similar in effectiveness and well tolerated, then choosing among them may seem difficult. In general, using a hormonal contraceptive with the lowest dose that still offers cycle control is best. Many experienced practitioners have a few favorite formulations that they use in clinical practice; they only venture from these choices if a patient has a particular side effect that may be improved by switching to another formulation based on increasing or decreasing the dose of its component drugs. This is also a good place for new practitioners to start when becoming comfortable with contraceptive counseling and prescribing. A short list should include one preparation that does not contain estrogen, an ultra-low dose, or 20 mcg EE pill (e.g., to use for women older than 35 years of age or those who smoke more than 15 cigarettes per day), a monophasic COC, a multiphasic COC, and a nondaily administration method for women who have difficulty with daily regimens. One factor that may influence what is on the short list is the availability of samples or products for purchase at the clinical site. Another influence may be patients' request for a particular brand-name product because of direct-consumer advertising practices of the drug companies. Additionally, the provider should be aware of what OCs are covered by the patient's insurance and what OCs are available on the $4 retail plans locally.

Cost

Cost can be a major barrier to contraceptive use for patients who do not have health insurance or prescription drug coverage. Most communities have county or private not-for-profit contraceptive centers with a sliding-scale fee schedule based on income to assist women without health insurance. The average cost for most forms of cyclical hormonal contraception is $30 to over $100 per cycle. Generic substitutions at lower prices are now available for many formulations, including formulations on the $4 retail plans. The cost of injectable contraception could be higher because of the office visit required for administration.

The initial cost of an IUD insertion may rule this out as an easy choice, but the cost spread over the life of the device may be less than that of other forms. Even for women who have prescription drug coverage, cost can be an issue.

Many insurance companies have implemented two- or three-tier co-payment schedules, resulting in higher costs for the client if a drug is not on the first-line formulary. The insurance companies are to provide formulary information to patients and providers to assist in decision making.

The Affordable Care Act (ACA) covers all prescription birth control methods as of 2014. The ACA spells out that barrier methods, hormonal methods, implanted devices (IUDs), emergency contraception, and sterilization procedures are all covered.

Patient Variables

Differences in a woman's physiological and psychological responses to estrogens and progestins make choosing OCs more art than science. However, taking a thorough personal and family history, performing a complete physical examination, and performing screening laboratory tests appropriate for patient age will identify those for whom OCs should not be prescribed. Patient variables that require withholding OCs or monitoring more closely are listed in Table 31-3.

The primary indication for using hormonal contraceptive preparations is to prevent pregnancy. These methods offer effectiveness and reversibility. In addition, users may experience the following noncontraceptive benefits (Hatcher et al, 2011; Speroff & Darney, 2011).

- Decreased dysmenorrhea, menstrual irregularities, and menstrual blood loss
- Lessening of acne and hirsutism
- Fewer ovarian cysts
- Significantly reduced endometrial and ovarian cancer risk
- Lower incidence of benign breast conditions such as fibrocystic changes and fibroadenoma
- Increased bone density
- Suppression of endometriosis for women who do not currently desire pregnancy

Drug Variables
Drug Interactions

Hormonal contraception that is administered orally undergoes first-pass metabolism in the liver; therefore, drugs that induce liver enzymes will decrease their contraceptive efficacy. Agents that treat tuberculosis, barbiturates, anticonvulsants,

Table 31–3 WHO Contraindications to Initiation of Combined Contraception with 35 mcg EE or Less

Risk	Contraindication
WHO Category 2 Contraceptive benefits usually outweigh risks; may require more frequent monitoring	Age >40 yr Smoker <35 yr BMI >30 due to increased VTE risk Hx HTN during pregnancy, BP now normal Known hyperlipidemia First-degree relative with DVT/PE Major surgery without prolonged immobilization Superficial thrombophlebitis SLE on immunosuppressive therapy or with severe thrombocytopenia Rheumatoid arthritis Sickle cell disease Valvular heart disease, uncomplicated Migraine without neurological aura, age <35 yr Unexplained vaginal bleeding, suspicious for serious underlying condition Cervical intraepithelial neoplasia Cervical cancer, awaiting treatment Undiagnosed breast mass Diabetes, insulin dependent or non-insulin-dependent, without vascular disease Asymptomatic gallbladder disease or postcholecystectomy Benign focal nodular hyperplasia of the liver Hx of cholestasis in pregnancy Ulcerative colitis or Crohn's disease Postpartum & breastfeeding, 4–6 wks PP with normal risk of DVT and >6 wks PP Postpartum & not breastfeeding, 3–6 wks PP with normal risk of DVT
WHO Category 3 Risks usually outweigh contraceptive benefits	Postpartum & breastfeeding, 3–4 wks and 4–6 wks with increased risk of DVT Postpartum & not breastfeeding, 3–4 wks with increased risk of DVT Age >35 yr and smoker <15 cigarettes/d Several drug interactions: protease inhibitors; anticonvulsants; lamotrigine; rifampin Multiple risk factors for coronary artery disease (based on age, smoking, diabetes, hypertension) Hypertension, adequately controlled and monitored • Systolic 140–159 or diastolic 90–99 Migraine without neurological aura, age >35 yr Hx of breast cancer, no disease >5 yr Diabetic with nephropathy, neuropathy, retinopathy Diabetic with vascular disease Diabetic >20 yr Symptomatic gallbladder disease Past COC-related cholestasis

and the herbal preparation St. John's wort have all been shown to increase liver metabolism of OCs; irregular bleeding and a decrease in contraceptive effectiveness may occur (*Drug Facts and Comparisons,* 2013). Common broad-spectrum antibiotics have not been shown to decrease serum concentrations of OCs. Penicillin and tetracycline are known to alter steroid metabolism in the gut because of changes in intestinal flora; this may potentially reduce their absorption

and effectiveness. Therefore, product labeling and *Drug Facts and Comparisons* (2013) still advise caution and the use of a backup method of contraception during and for 7 days after their use. However, both Hatcher and colleagues (2011) and Speroff and Darney (2011) agree that a backup method is not necessary unless accompanied by vomiting and diarrhea.

Another area of concern has been the effect of OCs on laboratory values. Previous thyroid test methods were affected by protein binding, but the new TSH is not. Lipid levels (cholesterol, triglycerides, and high-density lipoprotein cholesterol) may be affected by OCs. (Chrousos, 2012). A baseline lipid profile should be performed in women who have a significant family history or other risk factors for cardiovascular disease.

Adverse Effects/Contraindications

Many studies have investigated the incidence of venous thromboembolism (VTE) in COC users. The incidence of VTE is low in young women, one to three cases per 10,000 per year. VTE risk is increased by 2 to 5 times in COC users without other significant risk factors. The increase in risk is attributable to the estrogen component of COCs, which influences clotting factors and is dose-dependent. The incidence of VTE is extremely low; therefore, for any individual user this increase in risk still represents a very low chance of an adverse event. Risk factors such as inherited clotting disorders, strong family history of inherited clotting disorders, being older than 35 years, smoking more than 10 cigarettes per day, or obesity (body mass index [BMI] greater than 30) increase the risk 3 to 10 times. Such factors illustrate the need for screening patients diligently by taking a detailed family history before prescribing hormonal contraception.

In a MEGA (multiple environmental and genetic assessment of risk factors for venous thrombosis) case-controlled study, van Hylckama Vlieg, Helmerhorst, Vandenbroucke, Doggen, and Rosendaal (2009) found that overall, the use of COCs increases the risk of DVTs 5-fold over that of nonusers. The data also showed a significant difference in odds ratios in formulations using different progestins, but all using low-dose estrogens. Norethindrone and levonorgestrel had the lowest odds ratios of 3.9 and 3.6, respectively, whereas the odds ratio for norgestimate was 5.9, drospirenone 6.3, and desogestrel 7.3. These are third- and fourth-generation progestins that allow greater estrogenic activity, thereby increasing the risk. The authors' conclusion is "the safest option with regard to the risk of venous thrombosis is an oral contraceptive containing levonorgestrel combined with a low dose of estrogen" (van Hylckama Vlieg et al, 2009, p 7).

In a recently published comparison study of new users of low-dose COCs using levonorgestrel, norethindrone, or norgestimate versus a COC containing drospirenone, a transdermal patch containing norelgestromin, or a vaginal ring containing etonogestrel, Sidney and colleagues (2013) again found an increased risk of cardiovascular events with the use of drospirenone. The hazard ratio for drospirenone in relation to low-dose COCs was 1.77 for DVTs and 2.01 for arterial thrombotic events. Interestingly, the venous events were in women under 35 years and the arterial events were in women over 35 years.

Other major, but rare, adverse effects can occur with hormonal contraception: cholestatic jaundice, benign hepatic neoplasms, myocardial infarction, stroke, and neurological migraines. Patients should be counseled about the symptoms associated with these events and instructed to call their provider immediately if they experience them. Table 31-3 lists absolute and relative contraindications to hormonal contraceptives with 35 mcg of EE or less, as recommended by the World Health Organization (WHO) (2009).

Dosing Regimens

Combined Contraceptives

Oral contraceptive pills are traditionally dispensed in packages containing 28 pills, with the first 21 pills containing active synthetic hormone and the last 7 pills containing inert ingredients (or iron), during which withdrawal bleeding occurs. Several brands are available containing only the 21 active pills; the user then takes no pill for 7 days, during which withdrawal bleeding occurs. COCs come in many different formulations. The primary difference between brand names is the type and dose of progestin used. Monophasic preparations use the same dose of estrogen and progestin for each of the active pills. Biphasic preparations vary the dose of progestin, with an increase in the amount of progestin in the latter half of the active pills; these are rarely used today. More popular today are triphasic preparations, which vary the dose of estrogen, progestin, or both.

Several products now offer extended menstrual cycling. Seasonale, which contains active pills for 84 days, with 7 days off, produces withdrawal bleeding once every 3 months. Two newer products, Seasonique and LoSeasonique, are classified as monophasic but contain 10 mcg of EE in the last week of one cycle of dosing. Lybrel uses a continuous cycle without any hormone-free weeks for 1 year. Although these are the only pills using an extended-cycle dosing schedule approved by the U.S. Food and Drug Administration (FDA), other monophasic pills may be used similarly to space or manipulate the timing of menstrual periods, using the active pills continuously with less frequent intervals of inert pills (*Drug Facts and Comparisons,* 2013). The newest dosing regimen is monophasic COCs, having 24 active and 4 nonactive pills per cycle.

○ CLINICAL PEARL ○

Multiphasic Pills
Triphasic pill packs with pills of various colors may be confusing to some patients. If confusion is a concern, start with a monophasic OC for simple instructions.

Dosing Options

Numerous studies are under way experimenting with various dosing schedules, not only for COCs but also the patch and vaginal ring. The traditional monophasic 21/7 dosing schedule may soon be a thing of the past.

Starting Methods

COCs may be started in several different ways, each offering different advantages in the timing of starting the first and subsequent packs.

First-Day Start

The first pill is taken on the first day of the menstrual cycle. No backup method is needed using this initiation method because ovulation will be suppressed with the first cycle. Many pill packages allow the user to mark the start day to help keep track of pill taking, although many pill packages mark Sunday as the default start day.

Sunday Start

The first pill is taken on the Sunday following the start of menses; a backup method is recommended for the first 7 days. Starting on Sunday may offer the user the convenience of having menses occur only during the week.

Quick Start

The first pill is taken on the day of the office visit; a backup method is recommended for the first 7 days. This method can be used if the clinician is reasonably sure that the user is not currently pregnant (Hatcher et al, 2011).

Side-effect tolerance and compliance with daily pill taking are important factors in a woman's success with oral contraception. Missed pills occur much more frequently than either the user or prescriber realize. One study showed that 23% of women missed a pill the previous cycle; most were missed in the first week of the pack (Aubeny et al, 2004). Another study showed that 48% of women missed two or more pills in a 3-month period; the most common reasons were being away from home, forgetting, or not having a new pill available (Smith & Oakley, 2005). Helping the patient choose a time to take the pill when she is most likely going to be near the pill pack and helping her to associate pill taking with another daily activity may help increase compliance. The patient should also be instructed on what to do if pills are missed. Table 31-4 gives instructions for what to do about missed pills. Instructions are also found in the patient information included in each pill package (*Drug Facts and Comparisons,* 2013).

Side effects women experience may lead to discontinuation of OCs. Studies have found that discontinuation rates because of side effects are in the range of 17% to 34% and access issues are the most common reasons for discontinuation (Frost, Singh, & Finer, 2007; Westhoff et al, 2007). The majority of the side effects resolve with continued use (Hatcher et al, 2011).

> **CLINICAL PEARL**
>
> **LMP Notation**
> Last menstrual period (LMP) should be considered a vital notation to be displayed at the top of each chart note in a female patient's medical record.

Speroff and Darney (2011) state there are three major influences on continuation: the amount of side effects, concerns over medical risks (i.e., cancer, blood clots), and lastly nonmedical factors such as not understanding directions and complicated packaging. Good patient education in all aspects is essential for successful contraception.

Topical Patch

Ortho Evra is a topical patch that releases 20 mcg of EE and 150 mcg of norelgestromin, which is the primary active metabolite of norgestimate. Norelgestromin still undergoes liver metabolism; however, the resulting metabolite, levonorgestrel, is highly bound to sex hormone-binding globulin, limiting its biological impact (Speroff & Darney, 2011). The patch is applied once a week for 3 weeks, with 1 week being patch-free, during which withdrawal bleeding occurs. Patch use should be initiated on the first day of menses; if it is started on any other day, a backup method should be used for 7 days. Patch location should be rotated with each patch change, and it should be placed on skin that is clean and dry. It may be placed on the abdomen, upper torso, outer arm, or buttock. Side-effect profiles for the patch are similar to those for COCs, with the exception of skin irritation, which may occur at the application site (*Drug Facts and Comparisons,* 2013). There has been concern of decreased efficacy in women with high BMI; however, this is still uncertain. Speroff and Darney (2011) do recommend using continuous or extended schedules in this group of women for increased efficacy.

Vaginal Rings

NuvaRing is a soft, flexible plastic ring that releases 15 mcg of EE and 120 mcg of etonogestrel daily. The ring is placed in the vagina, left in place for 3 weeks, and then removed for a week when withdrawal bleeding occurs. It does not require fitting by a provider and is easily placed by the user. In addition, it releases steady, low doses of hormones, which offer better cycle control in the form of decreased breakthrough bleeding when compared to OCs (Oddsson et al, 2005). The primary advantage is the convenience of once-monthly self-administration, which may be particularly useful for the patient who has difficulty remembering to take a pill daily.

Table 31–4 **Instructions for Missed Oral Contraceptives**

Missed 1 active pill	Take pill as soon as you remember, taking two pills in 1 d if missed pill was d prior	Use backup contraception for 7 d
Missed 2–4 active pills	Take two pills for 2–3 d	Use backup contraception for 7 d
Missed 5 or more active pills	Start new pack on next start day (e.g., Sunday for Sunday starters)	Use backup contraception until 7 d of active pills taken

Other features of this method are the lower systemic exposure to EE, which is approximately 50% of what is typically seen in COCs with 30 mcg of EE (Timmer & Mulders, 2000) and 30% of those levels measured with patch use (van den Heuvel, van Bragt, Alnabawy, & Kaptein, 2005). Despite lower systemic levels of EE, ovulation is completely suppressed (Mulders & Dieben, 2001). As with COCs, evidence indicates that serum concentrations of EE are not affected by concomitant use of amoxicillin or doxycycline (Dogterom, van den Heuvel, & Thomsen, 2005).

As with all hormonal contraceptives, neither estrogens nor progestins should be used by women who have medical conditions that preclude their use. Other possible contraindications to use of NuvaRing are in women who have significant pelvic prolapse (Hatcher et al, 2011).

On the horizon are progestin-only vaginal rings that may be used for 3 months. These are currently on the market in several South American countries and used primarily for breastfeeding women. There is also research on a vaginal ring with the dual purpose of contraception and protection from STIs (Brache, Payán, & Faundes, 2013).

Progesterone-Only Contraceptives

Progestin-Only Pills

Two brand-name progestin-only pills are currently available: Micronor and Nor-QD. Three generics also contain 0.35 mg norethindrone. These pills contain no estrogen and are primarily used with special populations in which estrogen is contraindicated because of medical conditions or breastfeeding. Because these pills contain very low levels of hormone, users need to be particularly diligent with accurate pill taking. The primary contraceptive effect is through thickening of cervical mucus and prevention of sperm penetration, which occurs 2 to 4 hours after administration and diminishes after 22 hours of administration. If a pill is taken even a few hours late, a backup method is recommended for the following 48 hours. As with other progestin-only methods, common side effects are changes in bleeding patterns and breast tenderness (Speroff & Darney, 2011).

Injectable Progestins

Depot medroxyprogesterone acetate (DMPA), Depo-Provera, is a long-acting, injectable, progestin-only contraceptive. One injection of 150 mg IM is effective at suppressing ovulation for 12 to 13 weeks. DMPA also thickens cervical mucus and atrophies the endometrium (Hatcher et al, 2011). In 2005, Pfizer released a 104 mg SQ dose of DMPA that offers a lower overall hormone dose with no change in efficacy, even in patients with a high BMI. SQ administration can be done by the user without an office visit (Jain et al, 2004).

Injection offers the advantage of dosing once every 12 weeks, with very reliable efficacy. User errors can occur if the patient does not return for doses within the prescribed time, although it is acceptable to give a repeat dose up to 1 week late without clinical assessment to exclude pregnancy. DMPA will change a woman's bleeding pattern, causing an increased number of days of spotting or amenorrhea. This side effect may be unacceptable for some users and is the primary reason women discontinue use. Women in our society are socialized to believe that they need to have a monthly period. Patient education regarding expected bleeding pattern changes can increase the acceptance of these changes and contribute to the patient's success with this method. Weight gain may also be of concern for some patients; average weight gain is several pounds per year of use. Users of DMPA may also have a delay of return to fertility, on average 9 to 10 months (Hatcher et al, 2011).

Before initiating Depo-Provera the provider should exclude the possibility that the patient is currently pregnant. If a client discovers that she is pregnant after the drug's administration, the intramuscular injection cannot be reversed. The drug can be started while the client is menstruating, or if the client has had two negative urine pregnancy tests spaced 2 weeks apart, only if the client has not had unprotected intercourse during that time.

In 2004, the FDA issued a Black-Box Warning for Depo-Provera users in response to data showing a decrease in bone density with longer-term use. The warning states that it should not be used for more than 2 years consecutively if other alternatives are acceptable. Of particular concern is use in adolescents when bone accretion is still under way. Recommendations were made to assess bone density if women were to continue use for longer than 2 years (Omar, 2005). The Black-Box Warning applied to the lower SQ dose prior to published data. However, in a randomized 2-year study comparing IM DMPA with sub-Q DMPA, the authors found similar to slightly less bone loss in the first 2 years of use (Kauntiz, Darney, Ross, Wolter, & Speroff, 2009). Increasingly, however, data suggest that most if not all of the bone mineral density changes are reversed after discontinuation of the drug (Kauntiz, Arias, & McClung, 2008) and that increasing calcium intake and stopping smoking can significantly modify bone loss (Rahman & Berenson, 2010).

Intrauterine Progestin

Mirena is an intrauterine device that releases 20 mcg of levonorgestrel daily and can be left in place for 5 years. The local release of progestin creates only small levels of systemic circulating hormone, and the incidence of systemic side effects is small. Mirena causes thickening of cervical mucus and endometrial atrophy but has only a minimal effect on ovulation suppression. Changes in menstrual bleeding are common; many women experience a notable difference in menstrual flow or amenorrhea that may be more pronounced over time. Normal endometrial function typically returns within 1 to 3 months after discontinuation (Jensen, 2005).

In 2013, a second levonorgesterel intrauterine device, Skyla, was approved by the FDA. Skyla releases 14 mcg/d of levonorgesterel initially and declines to 5 mcg/d

after 3 years. Skyla is smaller in length and width than Mirena, has a smaller insertion tube, and has a silver ring at the top for visualization on ultrasound (Bahamondes & Bahamondes, 2014). The smaller size may make it easier to insert in nulligravida women. The efficacy is the same as the Mirena.

Many studies have found various noncontraceptive therapeutic uses for the Mirena. In a recent review article, Fraser (2013) found evidence for its use with menorrhagia of various etiologies. These include leiomyomas, adenomyosis, endometrial hyperplasia, and ovulation disorders. It is also effective for iron deficiency and pelvic pain with or without endometriosis.

Progestin Implants

Implanon provides contraception for up to 3 years and is the only implant currently available in the United States. It consists of one rod that contains 68 mg of etonogestrel, an active metabolite of desogestrel (Hatcher et al, 2011). Implanon has an overall serum progestin concentration that is lower than Norplant, which is no longer available in the United States, and has less variation (Speroff & Darney, 2011). Because it is only one rod, insertion and removal are simpler than with Norplant.

Emergency Contraception

Emergency contraception (EC) is a term used to describe methods of pregnancy prevention after an episode of improperly protected intercourse. EC should be taken as soon as possible, within 72 hours, but may be initiated within 120 hours (5 days). Improperly protected intercourse may occur if no method of pregnancy prevention was used, if the method used failed (condom broke or slipped off; diaphragm/cap/sponge became dislodged), or if the method was used improperly (missed pills).

Plan B One-Step (one tablet of 1.5 mg levonorgestrel) and Next Choice (two pills of 0.75 mg levonorgestrel) are progestin-only products packaged specifically for use as EC. These products are available over-the-counter for women over 17 years of age. The traditional dosing is to take one tablet 12 hours apart, but taking both doses at the same time does not decrease efficacy and is easier (Speroff & Darney, 2011). The newest EC is ella, a single 30 mg tablet containing ulipristal that requires a prescription. Existing pregnancy is the only contraindication to EC use; therefore, a urine pregnancy test should be performed before EC use.

CLINICAL PEARL

Depo-Provera and Osteoporosis
Counsel patients using Depo-Provera to increase dietary calcium intake and weight-bearing exercise. These interventions along with stopping smoking will mitigate bone mineral density changes.

MONITORING

Traditionally, hormonal contraception is provided during an annual examination, consisting of detailed personal and family histories, blood pressure measurement, general physical examination, breast and pelvic examinations, Pap smear, and sexually transmitted infection (STI) screening. These are important for evaluation of a woman's health; however, blood pressure measurement and personal and family histories provide the clinically relevant information necessary to initiate hormonal contraception safely. In fact, the latest American College of Obstetricians and Gynecologists (ACOG, 2012) and U.S. Preventive Services Task Force (USPSTF, 2012) guidelines concur that Pap smears should not start until age 21 and then, with negative results, every 3 years until age 29 is appropriate. Clinical breast exams may also only be every 3 years for women 20 to 39 years.

Monitoring for the adverse effects of OCs should be done initially at 3 months and then annually. Serious effects that could be caused by OCs include abnormal vaginal bleeding; hypertension; amenorrhea; unilateral numbness, weakness, or tingling, indicating possible cerebral spasm or occlusion; breast pain or mass; leg pain; chest pain; sudden loss of vision from possible thromboembolic phenomena; and jaundice (Hatcher et al, 2011).

In addition to screening for adverse drug effects, the provider should use these well-patient visits to screen for asymptomatic STIs, review breast self-awareness, and reinforce barrier protection for patients at risk for disease. Use of tobacco and alcohol are the two most common lifestyle habits that contribute to morbidity and mortality at all ages. Both have interaction effects on the organ systems of patients who use an OC. Patients with a chronic disease such as diabetes, seizure disorder, or migraine headache require more frequent monitoring visits based on their conditions.

CLINICAL PEARL

Emergency Contraception
During each office visit, provide patients under 17 with an emergency contraception prescription and instructions for use in case their primary contraception method fails.

OUTCOME EVALUATION

Symptoms of serious adverse effects require immediate evaluation and discontinuation of OCs until the cause of the adverse symptom rules out OC etiology. Symptoms that can be handled less urgently are irregular vaginal bleeding, amenorrhea, and mild-to-moderate blood pressure elevation. Breakthrough bleeding frequently occurs in the initial cycles of use of any OC formulation, is most common in the first three cycles, and usually resolves with continued use. If the patient has not

missed any doses, reassure her that breakthrough bleeding has not been associated with reduced efficacy. Some women may experience breakthrough bleeding after longer use; this is due to the decidualization and fragility of the endometrium, which is a progestational effect. Stopping the dosing regimen is unnecessary while resolving the problem. Use 1.25 mg conjugated estrogens or 2 mg estradiol for 7 days no matter where in the cycle spotting occurs. If this treatment is not effective, schedule an examination to rule out infection or other pathological causes. Amenorrhea is a common concern that may result after several months or years of OC use. Progestins atrophy the endometrium, and some women welcome scanty or no menses. Amenorrhea caused by DMPA may be a result of low estrogen levels (less than 30 mcg) (Speroff & Darney, 2011). For many women, no monthly cycle produces anxiety, which is usually relieved by a negative pregnancy test.

CLINICAL PEARL

Report of Bleeding
Patient reports of irregular or abnormal bleeding should be quantified with a menstrual calendar; have the patient differentiate between days on which spotting occurs and days on which bleeding is as heavy as her menses. Keeping a count of sanitary napkins or tampons used per day of bleeding may help further quantify bleeding. Bleeding may be excessive if a patient is using tampons and pads together and experiencing bleeding accidents. Serial hematocrit measurement several days or a week apart may assist in evaluating excessive bleeding. Excessive bleeding should be evaluated for underlying etiology, such as uterine cancer or polyps, thyroid disorders, or bleeding dyscrasias (Hatcher et al, 2011).

PATIENT EDUCATION

PATIENT EDUCATION

Overall Treatment Plan/Physiological Process
☐ Physiology of normal menstrual cycle.
☐ Need for follow-up visits: BP monitoring 3 months after initiation of methods containing estrogen, then annually. Breast and pelvic examinations, per national standards of care with client's age, history, and risk factors taken into consideration.
☐ Breast self-awareness education.
☐ Safe-sex practices, including male or female condom use in conjunction with hormonal contraception for STI prevention.
☐ Emergency contraception access and use, which can be used with failures of all methods.

SPECIFIC TO THE DRUG THERAPY
☐ How contraceptives prevent pregnancy through suppression of ovulation in the hypothalamic-pituitary-ovarian axis or endometrial and cervical changes.
☐ Doses and schedules for taking the drug. Specifically start method, active versus inactive pills, when to expect menses, what to do if pills are missed, suggestions for optimizing compliance with dosing schedule.
☐ Anticipated menstrual changes because of method use, such as lighter or shorter menses, amenorrhea, or irregular bleeding patterns.
☐ Common side effects with method use, such as breakthrough bleeding in first few cycles of OC use, breast tenderness, nausea, possible weight changes.
☐ Serious side effects, their symptoms, and how to access care in an emergency.
☐ Interactions between hormonal contraception and other treatment modalities or lifestyle habits. Emphasize the dangers of smoking with combined hormonal contraception at any age and the increased risk in women over age 35. Also advise patients to stop combined hormonal contraception 4 weeks before and 2 weeks after major surgery to prevent thrombus formation.
☐ Review time frame for return to fertility after discontinuation for specific method.

REASONS FOR TAKING THE DRUG(S)
Hormonal contraception offers very high efficacy; this may be particularly important for women between 15 and 35 years of age when fertility is highest. Methods can be used for long- or short-term deferment of childbearing, allowing control over timing and spacing of pregnancies.

DRUGS AS PART OF THE TOTAL TREATMENT REGIMEN
☐ Women who use hormonal contraception may also enjoy noncontraceptive benefits, such as less menstrual discomfort or lighter flow and the ability to predict or manipulate timing of menses for vacation or other social events.
☐ Use of hormonal contraception also confers protection against uterine and ovarian cancer (Speroff & Darney, 2011).

Continued

PATIENT EDUCATION—cont'd

PATIENT EDUCATION

ADHERENCE ISSUES

☐ Access to clinic appointments and prescription refills is one of the reasons for gaps in OC use. If medically indicated, give the patient a full year of refills.

☐ Counseling, education, and use of written materials can increase a patient's success with any method. Thorough patient education is the cornerstone of contraceptive success.

☐ The following are most important for patients taking OCs—they should take a pill every day in the correct order, and they should never just stop. If there are questions or concerns, they should always call the clinic first.

DERMATOLOGICAL CONDITIONS

Teri Moser Woo

The skin is the body's largest organ, and it is uniquely accessible for diagnosis and treatment. Primary care providers see patients with dermatological problems on a daily basis, with skin-related problems accounting for 5% of clinic visits and 74 million prescriptions for dermatologic agents (Centers for Disease Control, 2010).

The most common dermatological diagnosis reported in the National Ambulatory Medical Care Survey, 1993–2005, is dermatitis (13 million office visits per year), with skin and soft tissue infections diagnosed at 6.3 million visits per year (Pallin, Espinola, Leung, Hooper, & Camargo, 2009). This chapter addresses the pharmacological management

of common dermatological conditions seen in primary care. Accurate diagnosis of the condition is assumed.

DERMATITIS

Eczema (atopic dermatitis), contact dermatitis, diaper dermatitis, and seborrheic dermatitis are four common forms of dermatitis seen in primary care.

Eczema is a chronic skin disorder that affects all ages. It often begins in infancy and affects 10% to 15% of children. It may resolve during puberty, only to recur in adolescence or adulthood. The pattern of rash with eczema varies with age. Infants have the rash on the face, scalp, trunk, and the extensor surface of the extremities. In infants, the rash is usually acute or subacute, red, and vesicular. Eczema in adolescents and adults is usually chronic, with scaling, dryness, and lichenification on the flexure surfaces of the extremities, face, neck, hands, and upper chest. Eczema tends to worsen during the winter months.

Contact dermatitis is an acute inflammatory reaction of the skin to an irritant or allergen. It can be differentiated from eczema because it is generally not chronic or recurring and is usually distributed on exposed skin.

Diaper dermatitis (diaper rash) can occur in any patient who is incontinent and uses an occlusive barrier type of garment or diaper; however, it is most commonly seen in infants and toddlers.

Seborrheic dermatitis is a common inflammatory dermatitis characterized by erythematous, eczematous patches with yellow, greasy scale. It is usually localized to hairy areas and to areas with high concentrations of sebaceous glands. It can be found on the forehead, eyebrows, nasolabial folds, ear canals, neck, chest, intertriginous areas, the diaper or groin area, and intergluteal fold. In infants younger than 6 months, the scaling on the scalp without inflammation is commonly called cradle cap, and in adolescents and adults it is called dandruff.

Pathophysiology

Eczema

The exact etiology of eczema is unknown. Patients with eczema have high immunoglobulin E (IgE) antibody levels, but an exact immune cause has not been proved. A predisposition to pruritus and a reduced threshold of irritant responsiveness are believed to be key elements. Pruritus leads to increased scratching, which increases skin trauma, leading to increased itching (itch-scratch-itch cycle). Stroking the skin causes an abnormal reaction of dermatographism, a white line.

A high correlation exists between eczema and other atopic diseases, with 50% to 80% of children with eczema later developing asthma, allergic rhinitis, or hay fever. Often a positive family history for allergic disorders or asthma exists as well. The prevalence of eczema and skin allergies in children increased from 7.4% in 1997–1999 to 12.5% in 2009–2011 (Jackson, Howie, & Akinbami, 2013).

Contact Dermatitis

Contact dermatitis has two types: irritant and allergic. Both are usually confined to the point of contact with the irritant or allergen. This contact usually produces erythema, papules, and/or vesicles.

Irritant contact dermatitis is caused by contact of the skin with an irritating substance. The effect may be mild to severe. Irritating substances can be acid or alkali, solvents, or detergents. There is no immunological response as part of the inflammatory response in irritant contact dermatitis.

Allergic contact dermatitis is a delayed hypersensitivity response to an allergen. The allergen can be a variety of items in the environment, usually a small-molecular-weight substance that binds to the proteinaceous components of the skin to form a sensitizing antigen. Sensitization to the substance or allergen takes 10 to 14 days to develop after the first exposure. Dermatitis occurs within 1 to 7 days of subsequent exposure to the allergen. The most common allergens causing allergic contact dermatitis are certain plants (poison oak, ivy, and sumac), metals (especially in snaps, zippers, and jewelry), clothing (wool), cosmetics (fragrance or preservatives), topical medications (neomycin, anesthetics such as benzocaine, topical antihistamine), hair dyes, and soaps. Avoidance usually prevents the allergic response.

Diaper Dermatitis

Diaper dermatitis is an inflammatory disorder of the skin caused by a breakdown of the skin's natural barrier in the perineal or "diaper" area. The rash is often striking for its clear borders that coincide with the borders of the diaper or protective undergarment.

Forms of diaper dermatitis include irritant dermatitis, caused by chemical or mechanical irritation. Chemical irritation is caused by contact with urine and feces. Mechanical irritation is due to chafing of the diaper or undergarment on the skin folds. If the irritant dermatitis becomes chronic, the skin may appear dry. The rash may become more generalized and inflammatory, involving the creases and all the area that the diaper covers. The skin can become ulcerated or eroded with chronic irritation.

Infectious dermatitis may be caused by *Candida albicans* (candidiasis) and is usually a superinfection that can occur after a patient has had irritant dermatitis in the diaper area for 3 to 5 days. Candidiasis is suspected when there is a beefy red confluent rash with satellite lesions that are either red papules or pustules.

Other forms of diaper dermatitis include seborrheic dermatitis, psoriasiform napkin dermatitis, and atopic dermatitis. These disorders in the diaper area are treated the same as dermatitis on other parts of the body.

Seborrheic Dermatitis

The exact cause of seborrheic dermatitis is unknown. It is possibly related to increased production of sebum or an abnormal lipid composition of sebum. Seborrheic dermatitis is rare in children older than 6 to 12 months and in those who are prepubertal because the sebaceous glands are involuted

and dormant during this time and become active again with puberty. Saprophytic *Malassezia* colonizes the skin of many patients with seborrhea, with the inflammation of seborrhea thought to be a host response to the fungal infection (Weston & Howe, 2010).

Goals of Treatment

With all forms of dermatitis, the primary goals are to decrease the inflammation and discomfort caused by the dermatitis.

Rational Drug Selection

With all forms of dermatitis, rational drug selection is based first on decreasing the symptoms of an acute exacerbation and then on preventing, decreasing, and/or controlling the frequency and severity of further exacerbations.

Eczema

Acute Exacerbations

Topical Corticosteroids

Topical corticosteroids are adrenocorticosteroid derivatives incorporated into a vehicle suitable for application to the skin. The anti-inflammatory effect of topical steroids is related to their action on immune cells and by suppressing the release of proinflammatory cytokines. At the cellular level, they appear to inhibit the formation, release, and activity of the endogenous mediators of inflammation. When applied to inflamed skin, steroids inhibit the migration of macrophages and leukocytes into the area by reversing vascular dilation and permeability. This decreases edema, erythema, and pruritus.

Variable amounts of the drug are absorbed through the skin, depending on the drug used, the vehicle used, the amount of skin surface area the medication is applied to, and the condition of the skin. Absorption is enhanced by increased skin temperature, hydration, and application to denuded areas, intertriginous areas, or skin surfaces with a thin stratum corneum layer (face or scrotum). Occlusive dressings enhance skin penetration and therefore increase drug absorption. Infants and children have a higher proportion of body surface area to body weight, and therefore they absorb proportionally more medication. Following topical administration, corticosteroids enter the bloodstream and are metabolized and excreted the same as systemic steroids. Therefore, in infants and young children, the lowest effective strength of topical steroid is used to prevent systemic corticosteroid effects.

Topical corticosteroids are Pregnancy Category C. In pregnant patients, do not use corticosteroids extensively, for long periods, or in large amounts. Many topical steroids have been relabeled due to studies indicating many formulations cause hypothalamic-pituitary-adrenal (HPA) axis suppression in children; providers need to stay current with labeling changes, which may be found at the U.S. Food and Drug Administration (FDA) Web site, http://www.fda.gov.

The penetration of the topical steroid varies with the medication's vehicle. Ointments are more occlusive and usually more potent and are good for scaly areas. Creams are less occlusive and usually less potent. Lotions are usually the least potent and contain the most water. Table 32-1 presents the common topical steroids used for eczema. The potency of any steroid can be increased approximately 10-fold by occlusion with plastic wrap. Therefore, to increase the effects of a steroid, apply an occlusive dressing over the area. Do not use occlusive dressings more than 12 hours per day, or systemic steroid effects may occur. In young children, occlusive dressings are rarely used. A diaper is considered occlusive, and steroid use should be avoided in the diaper area unless a low-potency steroid is needed for short periods (e.g., 2 d).

Table 32–1 **Drugs Commonly Used: Dermatitis and Psoriasis**

Drug	Indication	Strengths Available	Dose	Comments
Topical Corticosteroids				
Low Potency				
Hydrocortisone (Hytone, Cortisporin, Cortaid)	Dermatitis	Cream, lotion, ointment: 1%, 2.5%, 0.5%	Apply a thin layer 2–4 times/d until healed.	Available OTC
Triamcinolone acetonide (Aristocort, Aristocort A, Kenalog)	Dermatitis	Cream, lotion, ointment: 0.025%	Apply a thin layer 3–4 times/d until healed.	Prescription required
Intermediate Potency				
Hydrocortisone valerate (Westcort)	Dermatitis	Cream, ointment: 0.2%	Apply a thin layer 2–3 times/d until healed.	Should be used with caution on the face; choose lower potency on face.
Hydrocortisone butyrate 0.1% (Locoid)	Dermatitis	Cream, ointment solution: 0.1%	Apply thin layer 2–3 times/d until clear.	Should be used with caution on the face; choose lower potency on face.
Mometasone furoate 0.1% (Elocon)	Dermatitis	Cream, ointment, lotion: 0.1%	Apply thin layer once daily. Maximum 3 wk therapy in children.	Cream & ointment for children ≥2 yr. Lotion not to be used in children <12 yr.

Table 32–1 Drugs Commonly Used: Dermatitis and Psoriasis—cont'd

Drug	Indication	Strengths Available	Dose	Comments
Triamcinolone acetonide (Aristocort, Kenalog)	Dermatitis	Cream, lotion, ointment: 0.1%	Apply a thin layer 3–4 times/d until healed.	Should be used with caution on the face; choose lower potency on face.
High Potency				
Betamethasone dipropionate, augmented (Diprolene)	Dermatitis	Emollient cream, lotion: 0.05%	Apply a thin film 1–2 times/d until healed; maximum of 45 g of cream or 50 mL of lotion/wk.	Avoid abrupt cessation if used for chronic conditions; not recommended in children ≤12 yr due to documented HPA suppression.
Triamcinolone acetonide (Aristocort A, Kenalog)	Dermatitis	Cream: 0.5%	Apply sparingly to affected area 2–3 times daily until healed.	Avoid abrupt cessation if used for chronic conditions; use with caution and sparingly in children.
Super-High Potency				
Betamethasone dipropionate augmented 0.05% (Diprolene AF)	Dermatitis	Ointment, cream: 0.05%	Apply thin film 1–2 times daily. Maximum: ointment 45g/wk, gel 50 g/wk.	Not recommended in children ≤12 yr. HPA axis suppression documented in children using this product (32%).
Topical Immunomodulators				
Pimecrolimus (Elidel)	Short-term or intermittent long-term treatment of mild to moderate atopic dermatitis	Cream: 1%	Apply to affected area twice daily.	Not recommended in children <2 yr. Pregnancy Category C. Not recommended in nursing mothers. Long-term safety has not been established.
Tacrolimus (Protopic)	Short-term or intermittent long-term treatment of moderate to severe atopic dermatitis	Ointment: 0.03%, 0.1%	Apply to affected area twice daily. Apply to dry skin. Do not occlude. *Children 2–15 yr:* use 0.03% strength.	Not a first-line therapy. Not recommended in children <2 yr. Pregnancy Category C. Not recommended in nursing mothers. Long-term safety has not been established. Do not use as first-line therapy.
Oral Corticosteroids				
Prednisone	Contact dermatitis (severe or if large skin surface area is involved)		*Adults:* 0.5–1 mg/kg/d (40–60 mg/d; maximum 60 mg/d). *Children:* 1 mg/kg/d; maximum 40 mg/d.	Dose is usually tapered after the first 10–14 d, with tapering taking 1–2 wk. Severe cases may need a 2 to 3 wk course; 2 wk is the minimum length of treatment for severe poison oak or ivy dermatitis.
Methylprednisolone (Medrol Dosepak)	Contact dermatitis (severe or if large skin surface area is involved)		Premeasured dose pack; dose is preset at 24 mg on day 1, tapering 4 mg/d to a dose of 4 mg on day 6.	Allows for easy tapering over 6 d. 6 d course may not be long enough for some patients.

Table 32–1 **Drugs Commonly Used: Dermatitis and Psoriasis—cont'd**

Drug	Indication	Strengths Available	Dose	Comments
		Antipruritic Agents		
Diphenhydramine (Benadryl)	Pruritus associated with dermatitis	Elixir: 12.5 mg/5 mL Chewable tablets: 12.5 mg Tablets: 25 mg	*Adults:* 25–50 mg every 4–6 h *Children 2–6 yr:* 6.25 mg; maximum 37.5 mg/24 h *Children 6–12 yr:* 12.5–25 mg q4–6h; maximum 150 mg/24 h	May cause drowsiness.
Hydroxyzine (Atarax)	Pruritus associated with dermatitis	Syrup: 10 mg/5 mL Tablets: 10, 25, 50, 100 mg	*Adults:* 25 mg 3–4 times/d *Children <6 yr:* 12.5 mg 3–4 times/d; maximum 50 mg/24 h *Children ≥6 yr:* 12.5–25 mg 3–4 times/d; maximum 50–100 mg/24 h	May cause drowsiness.
Cetirizine (Zyrtec)	Pruritus associated with dermatitis	Syrup: 1 mg/mL Tablets: 5, 10 mg	*Adults:* 5–10 mg once daily *Children 6–24 mo:* 2.5 mg once daily *Children 2–5 yr:* 2.5 mg initially; can increase dose to 5 mg/d either as one 5 mg dose or 2.5 mg q12h *Children ≥6 yr:* 5–10 mg once daily	Less sedation than other antihistamines. Should not be used concurrently with alcohol or other CNS depressants as it may potentiate the depressant effect.
Doxepin (systemic: Sinequan)	Pruritus associated with dermatitis	Capsules: 10, 25, 50, 75, 100, 150 mg	Dose range in 25–150 mg/d in single or divided doses; suggested starting dose is 75 mg/d, then titrate up or down as indicated. Use dose that achieves effect with fewest adverse effects.	Not recommended in children. Do not use within 14 d of monoamine oxidase inhibitors (MAOIs). May potentiate drugs metabolized by CYP2D6 (cimetidine, tricyclic antidepressants, SSRIs, phenothiazines, carbamazepine, quinidine, etc.); avoid these drugs during therapy. Contraindicated in patients with acute myocardial infarction (MI), urinary retention, or glaucoma. Pregnancy Category C; not recommend during pregnancy.
Doxepin (topical: Zonalon)	Moderate to severe pruritus associated with atopic dermatitis (eczema)	Cream: 5%	Apply a thin film to affected areas 4 times/d in 3 to 4 h intervals.	Interacts adversely with alcohol and MAOIs. Contraindicated in children. Pregnancy Category B. Patients with untreated narrow angle glaucoma and urinary retention should not use PO or topical form.
		Shampoos for Seborrheic Dermatitis		
Ketoconazole shampoo (OTC: Nizoral)	Seborrheic dermatitis	2% shampoo	Apply to wet scalp, massage for 1 min, rinse, and repeat; leave on scalp for 3 min, then rinse well.	See package. Pregnancy Category C. Not recommended in children.

Table 32–1 Drugs Commonly Used: Dermatitis and Psoriasis—cont'd

Drug	Indication	Strengths Available	Dose	Comments
Selenium sulfide shampoo (Selsun Blue, Head & Shoulders Intensive Treatment, Excel)	Seborrheic dermatitis	OTC: 1% shampoo Rx: 2.5% shampoo	Apply to wet hair and massage in for 2–3 min before rinsing completely; apply twice/wk until control is achieved, then weekly thereafter. For cradle cap: Apply 1% shampoo to scalp, avoiding eyes; rinse thoroughly.	See package. Advise patient that the shampoo will loosen crusted scales and that these scales may appear loose in the hair after the first few shampoos; brush to remove the scales from the hair; this will resolve after a few treatments.
Coal tar shampoo (OTC: Zetar, Neutrogena T/Gel, Tegrin Medicated, Denorex, Theraplex T)	Seborrheic dermatitis	1% Zetar, Theraplex T 2% Ionil T Plus, Ionil-T Therapeutic 1% coal tar shampoo, Neutrogena T/Gel 5%: Tegrin Medicated 7% Tegrin Medicated Extra conditioning 9% Denorex 12.5%: Extra Strength Denorex	Rub into wet hair and scalp and then rinse: repeat and leave shampoo in for 5 min, rinse well; may be used daily–weekly; follow package directions.	See package. Do not use if there are open infected lesions. May cause sun sensitivity for 24 h after application.
Pyrithione zinc (OTC: Head & Shoulders shampoo, Zincon, Danex, DHS, Sebulon, ZNP Bar)	Seborrheic dermatitis	1% shampoo: Head & Shoulders, Zincon, Danex 2% shampoo: DHS Zinc, Sebulon 2% soap: ZNP Bar	Shampoo: apply, lather, rinse, and repeat; use once or twice weekly. Soap: wet skin, lather, rinse, and repeat; use once or twice/wk.	See package.
Sulfur and salicylic acid shampoo (Fostex, Sabex, Sebulex)	Seborrheic dermatitis	5% sulfur and 3% salicylic acid: Maximum Strength Meted 3% salicylic acid and 5% colloidal sulfur: MG400 2% sulfur and 2% salicylic acid: Fostex Medicated Cleansing, Sebex, Sebulex	Follow package directions.	See package.
Coal tar (OTC: Zetar, Medotar, Pentrax MG217 Medicated, MG217 Dual Treatment, Fototar, Tegrin for Psoriasis, Oxipor VHC)	Psoriasis	Emulsion: 30% (Zetar)	Follow package directions.	May cause staining.
		Ointment: 1% (Medotar, Taraphilic), 2% (MG217 Medicated) Cream: 2% (Fototar) Lotion: 5% (MG217 Dual Treatment, Tegrin for Psoriasis); 48.5% (Oxipor VHC) Various generics: 20%	Rinse well after use.	Contraindicated if patient is taking tetracycline, psoralens, and topical retinoids. May cause contact irritant dermatitis. Pregnancy Category C.
Anthralin (Dithrocreme, Anthra-Derm, Dithro-Scalp)	Psoriasis	Cream: 0.1%, 0.25%, 0.5%, 1% Scalp cream: 0.25%, 0.5%	Begin with a low concentration (0.1%); apply a small amount to affected areas; rub in gently, avoiding healthy surrounding skin; leave on for 10 min, then wash off; after 1 wk, may increase to 15–20 min. Increase strength in incremental steps until lesions are healed and skin looks and feels normal.	May stain skin and clothes. Pregnancy Category C; safety in young children unknown. May alternate with other therapies (retinoids, topical steroids, UV light).

Table 32–1   Drugs Commonly Used: Dermatitis and Psoriasis—cont'd

Drug	Indication	Strengths Available	Dose	Comments
			Scalp cream: begin with low concentration (0.25%); apply to scalp after combing hair to remove scales; leave on for 10–20 min; use daily for at least 1 wk; increase strength if needed.	
Calcipotriene (Dovonex)	Psoriasis	Ointment, solution, cream: 0.0005%	Apply twice daily to affected area; rub in gently and completely. Treat for 6–8 wk; improvement usually noted after 1–2 wk.	Pregnancy Category C; should not be used during pregnancy or in children. Older patients have a higher incidence of adverse skin reactions. Rare reports of rapid onset of hypercalcemia.
Calcitriol (Vectical Ointment)	Psoriasis	3 mcg/g ointment	Apply twice a day a.m. & p.m. to affected areas. Maximum dose is 200 g/wk.	Pregnancy Category C; should not be used during pregnancy or in children. Hypercalcemia may occur.

OTC = over the counter; UV = ultraviolet; CNS = central nervous system; HPA = hypothalamic-pituitary-adrenal axis; SSRI = selective serotonic reuptake inhibitor.

There are many topical steroid preparations available, and it is impossible for any practitioner to be familiar with all of them. Familiarity with one or two agents in each category is reasonable. The most commonly used low-potency topical steroid is 1% hydrocortisone. Intermediate-potency topical steroids include hydrocortisone butyrate 0.1% (Locoid) and triamcinolone acetonide 0.1% (Kenalog). High-potency steroids include betamethasone dipropionate, augmented 0.05% (Diprolene lotion, Diprolene AF), and triamcinolone acetonide 0.5% (Kenalog). Super-high-potency topical steroids include betamethasone dipropionate, augmented 0.05% (Diprolene ointment or gel), and halobetasol propionate 0.05% (Ultravate). Providers need to know what medications are allowed from each category in the formulary or formularies they are using.

Oral Corticosteroids

Oral corticosteroids are occasionally used to treat severe eczema. Patients with eczema who receive oral cortico-steroids for another disease, such as asthma, see a striking improvement in their skin. Improvement in acute exacerbations is often dramatic, a mixed blessing in the treatment of this chronic illness. Patients often feel so good that they may have the false impression that the steroids "cured" their eczema. Given the major adverse effects observed with prolonged or frequently repeated corticosteroid therapy, routine use of oral steroids for eczema is contraindicated. If oral steroid therapy for severe eczema is considered, consultation with a dermatology specialist is indicated. A patient who is using oral steroids must understand that the effects are short-term and that oral steroid preparations cannot be used frequently. When the oral preparation is started, patients must be started on a comprehensive prevention routine to prevent severe exacerbations. They need to be warned that their eczema will return after the steroid effect wears off.

Immunomodulators

The immunomodulators are a class of topical medications used in the short-term or intermittent long-term treatment of atopic dermatitis. Pimecrolimus (Elidel) and tacrolimus (Protopic) are a second-line therapy after topical cortico-steroid treatment failure for atopic dermatitis. They act by interrupting the inflammatory process (Eichenfield et al, 2014). Tacrolimus has been found to inhibit T cells, Langerhans cells, mast cells, and keratinocytes in the epidermal cells. Pimecrolimus was specifically developed to treat inflammatory skin conditions; it inhibits the release of inflammatory cytokines and mediators from mast cells. The immunomodulator cream is chosen based on the severity of the eczema; tacrolimus (Protopic) is prescribed for moderate to severe eczema and pimecrolimus (Elidel) is prescribed for mild to moderate eczema. Neither product is to be used in children younger than 2 years, in immunocompromised patients, or in pregnant or lactating women (Pregnancy Category C). The immunomodulators have no steroid effects. Immunomodulators may be preferable to topical steroids on the face, skin folds, and anogenital area, or if the patient's eczema is recalcitrant to topical steroids or the patient has developed steroid-induced atrophy (Eichenfield et al, 2014).

The immunomodulator creams are applied twice a day to the affected area(s). Patients are to be instructed not to occlude the area. It may take 2 to 3 weeks for patients to notice improvement. Providers need to reexamine patients every 6 weeks. If using tacrolimus (Protopic) in children aged 2 to 15 years the

0.03% strength should be prescribed. See Table 32-1 for full prescribing information.

Both pimecrolimus and tacrolimus have received an FDA Black-Box Warning regarding the long-term safety of topical immunosuppressant calcineurin inhibitors due to rare cases of malignancy (skin and lymphoma) reported in patients using the topical forms of these medications. The FDA advisory states the following: "Animal studies have shown that three different species of animals developed cancer following exposure to these drugs applied topically or given by mouth, including mice, rats, and a recent study of monkeys" (U.S. FDA, 2006). Long-term studies are ongoing to determine risk, with interim results indicating no increase in malignancy rates (Eichenfield et al, 2014).

Antipruritics

Antipruritics are used to control the itching associated with eczema and to break the itch-scratch-itch cycle. Commonly used oral agents are the antihistamines diphenhydramine (Benadryl) and hydroxyzine (Atarax). These drugs have antipruritic and sedative actions. Pruritus can disrupt sleep; therefore, mild sedation can be helpful to prevent nocturnal itching, especially in children. Cetirizine (Zyrtec), a metabolite of hydroxyzine without its sedative effects, can be used during the day to achieve an antipruritic effect without sedation. Another antipruritic is the tricyclic compound doxepin (Sinequan), which has potent histamine$_1$- and histamine$_2$-blocking action.

Topical antipruritics can be used and should be considered if severe pruritus is present. Doxepin cream (Zonalon) can be used for moderate to severe pruritus associated with eczema. Care should be taken when prescribing doxepin for topical use because significant amounts can be absorbed systemically if it is used over 10% of the body surface area or if used for a long time. Drowsiness occurs in more than 20% of patients using doxepin cream, especially if it is used on more than 10% of the body surface area.

Available topical antipruritics that are safer to use than doxepin are Aveeno cream (colloidal oatmeal-based) and Moisturel emollient cream or lotion (petrolatum, glycerine-based). These over-the-counter (OTC) agents can be used liberally on large surface areas with no harmful effects.

Emollients

Emollients play a key role in both acute exacerbations of eczema and in long-term therapy. Wet dressings and emollients can be used to soothe the skin, reduce redness, and treat pruritus caused by eczema (Weston & Howe, 2010; Eichenfield et al, 2014). Emollients are applied to the skin and a wet cotton dressing is applied; then the dressing is covered with dry cloths or clothing. This can be done nightly to decrease pruritus and redness. The use of emollients is further discussed in the Long-Term Therapy section.

Antibiotics

Antibiotics may be necessary to treat secondary infections of *Staphylococcus aureus,* beta-hemolytic streptococci, a virus, or a fungus. If a bacterial infection is suspected, a culture should be obtained prior to beginning treatment. The likelihood of community-acquired methicillin-resistant *S. aureus* (MRSA) needs to be considered. For a patient with a localized infection, mupirocin (Bactroban) or retapamulin (Altabax) ointment can be used. Most infected eczema will require treatment with an oral antibiotic that is effective against *S. aureus* and streptococci. Cephalexin (Keflex), amoxicillin/clavulanate (Augmentin), and cefprozil (Cefzil) are all effective; treatment should be for 7 days. If there is recurrent bacterial infection, a 3-week course of treatment is necessary.

Long-Term Therapy

Eczema is a chronic disorder, and the patient often cycles between mild to moderate dry skin and exacerbations that can be mild to severe. Once an exacerbation quiets, patients must continue to care for their skin to prevent further exacerbations. The keys to long-term therapy are adequate hydration of the skin and avoidance of agents that cause exacerbations.

Emollients

Moisturizers, lubricants, and emollients help retain water in the skin. They are composed of petrolatum, lanolin, or other agents such as colloidal oatmeal in an emulsion. The emollient is applied 1 to 4 times per day after patients bathe. They pat their skin dry and then apply the lotion or cream liberally to all affected areas within 3 minutes after bathing. This procedure traps the moisture in the skin. Ointments provide the most occlusive barrier; creams are the next-best option. Lotions offer the convenience of easy application over large areas of skin but are not as occlusive as ointments and creams. Patients often decrease their use of emollients between exacerbations, and a review and reinforcement of their use during each clinic visit will increase compliance.

Of all the emollient products available, many are eliminated because they have additives such as perfumes or other chemicals, to which many patients with eczema are sensitive. Commonly used emollients are Aveeno cream or lotion, Eucerin cream or lotion, Lubriderm lotion, and Moisturel lotion. If the patient uses a lotion, make sure it does not contain alcohol, which is drying and irritating. Occasionally, patients are sensitive to the lanolin in Eucerin, which is a natural product derived from sheep's wool. Because large amounts are needed to be effective, expense can play a role in choosing an emollient. White petrolatum is inexpensive and a treatment option for patients with limited resources.

Nonpharmacological Measures

Nonpharmacological measures include hydrating baths and avoiding skin irritation and offending agents that cause exacerbations. Patients should be told to wear plastic or nitrile gloves when their hands may be exposed to harsh chemicals or detergents. They should avoid irritating fabrics such as wool. Soft cotton clothing allows the skin to breathe. Careful avoidance of perfumed lotions and soaps prevents flare-ups related to the additives in these products. Some patients have food sensitivities that exacerbate their eczema.

Baths are used to hydrate the skin. The patient should take a warm—not hot—bath for 20 minutes. The skin is patted dry, and emollients are applied immediately to maintain the

skin's hydration. The patient should use a mild soap for cleansing the groin and axillae, not harsh deodorant soaps. After a bath is also a good time to apply corticosteroid creams or ointments, if needed.

Contact Dermatitis

The treatment for both types of contact dermatitis is the same. If a small area of skin is affected, a topical corticosteroid cream is usually effective. If more than 10% of the skin surface must be treated or if the allergic contact dermatitis is severe, oral corticosteroids are used. Wet dressings or baths are soothing to the inflamed skin. Oral antihistamines may help control pruritus.

Topical Corticosteroids

Topical corticosteroid creams or ointments are effective in treating mild to moderate contact dermatitis. A low-potency (hydrocortisone 1% or 2.5% cream) or intermediate-potency (hydrocortisone valerate 0.2% or triamcinolone acetonide 0.1%) cream can be used. Intermediate- or high-potency corticosteroids should be used for plant dermatitis from poison ivy or oak (Prok & McGovern, 2014). See Table 32-1 for prescribing information. The patient should begin to experience relief in 2 to 3 days, with complete healing in 2 to 3 weeks.

Oral Corticosteroids

Oral corticosteroids (prednisone or methylprednisolone) are used if the contact dermatitis is severe or if a large skin surface area is involved. A 2 to 3 week course of therapy may be needed for severe cases, with 2 weeks usually the minimum length of therapy required for severe poison oak or ivy dermatitis. Oral prednisone is started at 1 mg/kg/d (maximum 60 mg/d) and tapered over 2 to 3 weeks, 40 mg/d during week 2 and 20 mg/d during week 3 (Prok & McGovern, 2014). A too short course may lead to rebound dermatitis when treating poison oak or ivy dermatitis (Prok & McGovern, 2014). See Table 32-1 for prescribing information.

Wet Dressings or Baths

Wet dressings or baths provide comfort. Aluminum acetate solution (Burow's, Domeboro) is an astringent wet dressing

---

CLINICAL PEARL

Dermatitis

- Occluding the surface with plastic wrap will increase penetration of the topical corticosteroid. Do not do this in children, as it will increase the systemic absorption of the steroid.
- For contact dermatitis, caution the patient using bath oils against slipping in the tub. Children should be supervised at all times when using bath dermatologicals, which can all cause the tub to be slippery. Older adults should also be monitored.
- For the patient with hand dermatitis, wearing cotton gloves overnight after applying a thick layer of **emollient** will increase absorption, and the patient will often see a significant improvement overnight.

---

applied for 30 minutes 4 times a day for relief of inflammation associated with contact dermatitis. Emollient baths that contain colloidal oatmeal solids (Aveeno) or oils (Alpha Keri Bath Oil, Lubriderm Bath Oil) can be used to provide relief from pruritus associated with contact dermatitis. Baths may be used as needed for comfort.

Diaper Dermatitis

Drug therapy in the treatment of diaper dermatitis is aimed at protecting the skin, decreasing inflammation, and treating *Candida* infection. Nonpharmacological interventions are also used to prevent irritant diaper dermatitis.

Barrier Medications

Barrier medications are used to protect the skin from the irritant effects of contact with urine and feces. Plain white petrolatum is an effective and inexpensive barrier agent. Vitamins A and D are added to petrolatum to create a barrier OTC medication, A&D Ointment. Zinc oxide is a commonly used barrier that has a drying effect as well. It is combined with a variety of other agents such as petrolatum (Diprotex, Diaparene, Bottom Better), cod liver oil and talc (Desitin), and balsam of Peru (Balmex), which is thought to promote wound healing. Plain zinc oxide is an effective barrier that is less expensive than the many diaper rash products. Barrier medications should be used at the first sign of irritation.

Anti-Inflammatory Medications

Anti-inflammatory medications are used to decrease the inflammation associated with diaper dermatitis. Because of the occlusive nature of diapers and undergarments, a low-dose hydrocortisone (0.5% or 1%) should be used for a brief period. Low-dose hydrocortisone can be used for 2 to 3 days in the diaper area safely if it is applied sparingly (pea-sized amount) and used 2 to 3 times a day. Stronger corticosteroid preparations or combination medications containing midpotency steroids with an antifungal (Lotrisone) should not be used in the diaper area.

Antifungal Medications

Candidiasis is treated with a topical antifungal agent that is effective against *C. albicans.* Commonly used medications are nystatin (Mycostatin), miconazole (Monistat-Derm), and clotrimazole (Lotrimin). All of these medications are applied twice daily until the *Candida* infection is clear. Miconazole and clotrimazole are available OTC and are usually not covered by insurance plans. Nystatin is available by prescription only and is usually covered by insurance. If a patient does not respond to the OTC products, a trial of nystatin is warranted.

Wet Soaks

Wet soaks or sitz baths are used to decrease inflammation and provide comfort from diaper dermatitis. Burow's solution soaks or compresses can be used if the rash is weepy. Commercial diaper wipes often contain alcohol, which stings, and they should be avoided during diaper dermatitis. A spray bottle of clean water allows adequate cleansing without further irritating the area.

Nonpharmacological Management

Nonpharmacological management includes exposure to air, frequent diaper changes, and changing the brand of diaper or protective garment. Expose the affected area to air by leaving the diaper off, or blow-dry the area with a hair dryer on low/cool setting held several inches away from the skin 2 to 3 times a day.

Seborrheic Dermatitis

The mainstay of treatment for seborrheic dermatitis is topical antiseborrheic shampoos. Topical corticosteroids may also be used for nonhairy areas such as the face.

Antiseborrheic Shampoos

Antiseborrheic shampoos should be used as prescribed to control dandruff. A variety of preparations are available to treat scalp seborrhea or dandruff. Selenium sulfide 1% shampoos (Selsun Blue, Head & Shoulders Intensive) and ketoconazole (Nizoral) are the most commonly prescribed shampoos for seborrhea and are available OTC. Selenium sulfide prescription formulas (Exsel, Selun) contain 2.5% selenium sulfide. Coal tar shampoos are available OTC and range in strength from 0.5% (DHS Tar) to 12% (Extra Strength Denorex) coal tar. Pyrithione zinc, the active ingredient in OTC shampoos such as Head & Shoulders, may also be used to treat seborrheic dermatitis. Bar soap containing pyrithione zinc is available for use on body areas with scalp seborrhea (ZNP Bar). Shampoos that combine sulfur and salicylic acid can also be used (Sebulex, Fostex). For treating cradle cap, low-strength selenium sulfide (1%) is generally recommended, and care should be taken to keep the shampoo out of the infant's eyes and to rinse the hair well. Table 32-1 presents prescribing information.

Topical Corticosteroids

Topical corticosteroids are used for inflammatory seborrhea that does not respond to medicated shampoo. Low-potency steroid lotion or gel is applied 2 to 3 times daily to affected areas. Ongoing use of topical steroids may be needed when seborrheic dermatitis recurs. Table 32-1 presents prescribing information.

Monitoring

Monitoring for all forms of dermatitis includes assessing the patient for effectiveness of therapy and determining if the patient has experienced any adverse effects or developed a secondary infection.

Outcome Evaluation

For all forms of dermatitis, effective management controls exacerbations and provides comfort measures to decrease pruritus or other symptoms. If the initial therapy has not controlled the exacerbation, increasing the potency of the initial medication or switching to another medication may be indicated. However, before switching to another medication, the provider should observe the patient's medication administration technique, which may be the problem.

Secondary skin infections, if they occur, should be treated promptly. Referral to a dermatologist may be necessary if therapy is not managing the dermatitis, if high-potency topical corticosteroids are indicated, or if the patient has an unusual presentation.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues.

PSORIASIS

Psoriasis is a chronic skin condition that affects 2% of the population worldwide (Menter et al, 2009). It is characterized by sharply defined, symmetrical, erythematous patches with a distinctive silver scale. There are two peak age ranges of onset: from 16 to 22 years and from 57 to 60 years. However, it may occur at any age. Men and women are equally affected, but it is more common in whites than in darker-skinned people. There is a positive family history for the disease in 30% of patients. The disease may remain localized to a few areas, or it may become generalized. The condition is lifelong and may occur in an intermittent or a continuous pattern.

Pathophysiology

The exact pathogenesis of psoriasis is unclear, although it is thought to be an immune-mediated disease (Feldman & Pearce, 2010a). There is a significant decrease in the amount of time that it takes for a psoriatic epidermal cell to travel to the skin surface and be cast off. A normal skin cell travels to the surface in 26 to 28 days; with psoriasis, the cells take only 3 to 4 days. This decreased time does not allow normal cell maturation to take place.

Lesions of active psoriasis can develop in areas of epidermal trauma. Surgical incisions, a sunburn, or scratch marks can all heal, leaving psoriatic lesions in their place (Koebner phenomenon). Exacerbations may be triggered by beta-hemolytic streptococcal infections, as well as by some medications (e.g., lithium, beta-adrenergic antagonists, angiotensin-converting enzyme inhibitors, antimalarial drugs, and indomethacin).

Extensor surfaces are affected more commonly, with other common sites being the intergluteal fold, the eyebrows, and around the ears. Nails may develop pits and ridges, may be thick and discolored, and have splinter hemorrhages.

Goals of Treatment

Although psoriasis is a chronic, lifelong, recurrent disease, the goal of therapy should be control of symptoms and clearing of psoriatic lesions. It should be emphasized to the patient that psoriasis is a treatable disease and that control is possible with continued, conscientious use of medication.

PATIENT EDUCATION

Dermatitis

RELATED TO THE OVERALL TREATMENT PLAN/DISEASE PROCESS

☐ Pathophysiology

☐ Role of preventive and nonpharmacological measures if appropriate

☐ Importance of adherence to the treatment regimen

☐ Self-monitoring of symptoms

☐ What to do when symptoms worsen

☐ Need for follow-up visits with the primary care provider

SPECIFIC TO THE DRUG THERAPY

☐ Reason for taking the drug and its anticipated action on the disease process

☐ Doses and schedules for taking the drug

☐ Possible adverse effects and what to do if they occur

☐ Interactions between other treatment modalities and these drugs

REASONS FOR TAKING THE DRUG(S)

☐ Patient education about specific drugs is provided in the appropriate chapter

SPECIFICALLY FOR ECZEMA

☐ Pathophysiology of eczema, that it is a chronic disorder requiring ongoing care, and that there is an itch-scratch-itch cycle that needs to be addressed, but that it is a recurring disease that can be controlled

☐ Avoidance of offending agents that cause exacerbations

☐ Appropriate use of **topical corticosteroids** should be demonstrated. With a sample, the provider can demonstrate how far a pea-sized amount of topical medication can be spread. The patient or caregiver applying the medication should be aware of the adverse effects of overuse of **topical corticosteroids**.

☐ Avoidance of irritants or agents that cause exacerbation of the eczema should be taught, with a written list of common irritants provided to the patient

☐ Long-term therapy (skin hydration and **emollient** use) versus acute therapy

SPECIFICALLY FOR CONTACT DERMATITIS

☐ Pathophysiology

☐ Appropriate application of **topical corticosteroids** should be demonstrated

☐ Appropriate use of **antipruritic medication**

SPECIFICALLY FOR DIAPER DERMATITIS

☐ The parent or patient should be educated about the underlying pathophysiology of diaper dermatitis, in that it is usually an irritant dermatitis caused by chemical irritation from urine or feces, complicated by mechanical irritation of the diaper or undergarment rubbing and chafing the skin.

☐ Describing the characteristics of a secondary infection with *Candida* will assist with early identification and treatment of this common complication in diaper dermatitis.

☐ Nonpharmacological management such as sitz baths, air drying, and frequent diaper changes should be discussed.

☐ If properly treated, the skin should return to normal in the area in 3 to 4 days. If the patient is not responding to treatment in 48 hours, then a reevaluation is necessary.

SPECIFICALLY FOR SEBORRHEIC DERMATITIS

☐ The patient should know that seborrheic dermatitis cannot be cured and can only be controlled and that treatment will probably need to be continued long-term in adolescents and adults. In infants with cradle cap, it will usually resolve around age 6 months.

☐ The patient should contact the health-care provider if signs and symptoms of a secondary infection occur.

DRUGS AS PART OF THE TOTAL TREATMENT REGIMEN

☐ The total treatment regimen includes pharmacological and nonpharmacological measures. Be sure the patient and/or family members are aware of the specific measures to be taken.

ADHERENCE ISSUES

☐ Health-care providers should be aware of the potential problem of nonadherence and should discuss the importance of completing the entire treatment regimen with the patient and/or family members.

Rational Drug Selection

The management of psoriasis consists of topical medication and phototherapy for mild to moderate psoriasis (less than 5% of the body involved) and the addition of systemic medications for severe psoriasis (more than 5% to 10% of the body involved) (Feldman & Pearce, 2010b; Menter et al, 2009). Not covered in this chapter because they are prescribed only by dermatology specialists are systemic treatments with immunosuppressants (alefacept [Amevive], efalizumab [Raptiva], cyclosporine [Neoral], ustekinumab [Stelara]), retinoids (acitretin [Soriatane]), methotrexate, and tumor necrosis factor blockers (etanercept [Enbrel], adalimumab [Humira], infliximab [Remicade]).

CLINICAL PEARL

Psoriasis

Psoriasis may affect a patient's self-esteem and may exacerbate depression. The patient's mood should be monitored. Referral to a support group or an organization such as the National Psoriasis Foundation (http://www.psoriasis.org) may be helpful.

Topical Therapy

Topical therapy for psoriasis consists of topical steroids, coal tar, or keratolytic shampoos for scalp involvement, keratolytic agents for thick plaques, anthralin, and calcipotriene. Topical immunomodulators may also be used.

Topical Steroids

Topical steroids are used to treat psoriasis because of their anti-inflammatory effects on the plaques. Moderate- to high-potency steroids are used because the lesions are generally steroid-resistant (Menter et al, 2009). The steroid cream or ointment is applied 2 to 3 times per day (see Table 32-1). Chronic topical corticosteroid use can cause tachyphylaxis and may have adverse effects such as atrophy and telangiectasia. Intermittent or "pulse" therapy minimizes some of these effects. If topical corticosteroids are used in the intertriginous areas or on the face, a low-potency medication should be chosen. Regardless of the topical steroid used, 2 to 4 weeks of continuous use is the limit, with gradual reduction in frequency of application to prevent rebound (Feldman & Pearce, 2010b). Patients should be discouraged from using steroids for longer periods. Topical corticosteroids should be reserved for psoriasis flare, and another medication used for ongoing therapy.

Coal Tar

Coal tar (Zetar, Medotar, Tegrin for Psoriasis) affects psoriasis by enzyme inhibition and antimitotic action. Tar preparations include creams, shampoos, ointments, lotions, gels, and oils. They range in strength from 1% to 20%. Tar has few adverse effects and is safer to use than topical steroids and anthralin, although tar has decreased in use in the United States (Menter et al, 2009). The major problem is that tar products are messy and can stain the skin and clothes. The tar preparation is applied to the affected areas once or twice daily. If using coal tar shampoo or bath emulsion, the patient should be instructed to rinse well after use. Tar preparations make the patient photosensitive; therefore, the patient should be instructed to avoid sunlight and ultraviolet light (see Table 32-1).

Anthralin

Anthralin (Dithrocreme, Dithro-Scalp) is an antimitotic agent that is used for chronic psoriasis. It has an antiproliferative effect. Although it is effective, anthralin has the disadvantages of being irritating and of staining skin and clothing. Anthralin's use has decreased over the past few years with the availability of preparations that are more cosmetically acceptable (Menter et al, 2009). Careful instructions for use increase the likelihood of a successful outcome with this difficult-to-administer medication.

When prescribing anthralin to a patient who has never used it, choose a low-concentration product (0.1%). The medication is applied to the psoriatic lesions and rubbed gently until the medication is absorbed. Take care not to get the anthralin on the healthy surrounding skin. It is important not to apply excessive medication, which increases the staining of skin and clothes. After the medication is rubbed in, it is left on 10 to 20 minutes; then it is washed off in the shower. After 1 week, the length of time the medication is in contact with the skin can be increased to 15 to 20 minutes. The strength of anthralin can be increased in increments (0.25%, 0.5%, 1%) as tolerated. Some patients require the medication to be applied and left on for 60 minutes to have improvement in their psoriatic lesions. Treatment should be continued until the lesions are completely healed (when nothing is felt with the fingers and the texture of the skin is completely normal). Table 32-1 presents prescribing information for anthralin.

Vitamin D_3 Derivatives

Calcipotriene (Dovonex) is a vitamin D_3 derivative that regulates cell differentiation and proliferation and suppresses lymphocyte activity. Calcipotriene is available in a cream, ointment, or solution preparation. It is effective and safe for short- or long-term treatment. Calcipotriene is applied in a thin film to the affected psoriasis plaques and rubbed into the skin gently and completely. In adults, the ointment is applied twice daily in the morning and evening. It is important that the patient does not exceed 100 g/wk of calcipotriene applied to the skin. Safety and efficacy in children have not been established. For the treatment of mild to moderate scalp psoriasis, the patient applies the topical solution twice daily. Improvement will be noted as soon as 1 to 2 weeks after treatment has begun. The patient should be reevaluated after 6 to 8 weeks. Calcipotriene may be used in combination with topical steroids, which is more effective than either treatment alone. Table 32-1 presents prescribing information for calcipotriene.

Topical calcitriol (Vectical Ointment) is a vitamin D_3 derivative similar to calcipotriene. Calcitriol inhibits keratinocyte proliferation and inhibits T-cell proliferation and other inflammatory mediators (Feldman & Pearce, 2010b). Calcitriol is applied to affected psoriatic plaques twice a day.

The maximum weekly dose should not exceed 200 g. Hypercalcemia may occur and calcitriol should be discontinued until normocalcemia returns.

Phototherapy

Patients with psoriasis respond very well to phototherapy. Phototherapy with ultraviolet-B (UVB) light is effective in managing psoriasis by reducing DNA synthesis of epidermal cells. UVB light treatment is easy for the patient to use and can produce long-lasting remissions of 2 to 4 months. UVB therapy is usually prescribed by a dermatologist. The use of commercial tanning beds is not recommended.

Systemic Medications

Systemic medications used for psoriasis are methotrexate, oral retinoids, immunosuppressants (alefacept [Amevive], efalizumab [Raptiva], cyclosporine [Neoral], ustekinumab [Stelara]), retinoids (acitretin [Soriatane]), and tumor necrosis factor blockers (etanercept [Enbrel], adalimumab [Humira], infliximab [Remicade]). They have serious adverse effects and therefore should be prescribed only by a dermatologist and only if the patient meets criteria determined by the American Academy of Dermatology. To try to decrease the adverse effects, the medications may be prescribed intermittently or on a rotational basis. Patients should be advised to avoid pregnancy before, during, and for a period of time after taking these drugs. The primary care provider will need to consult with the dermatologist and observe the patient for adverse effects if any of these medications are prescribed.

Monitoring

The patient who is being treated for psoriasis should be monitored for effectiveness of therapy and for adverse effects of the medication.

Outcome Evaluation

Psoriasis lesions should eventually clear, with the skin returning to the patient's normal look and feel. If the patient is using the medication correctly and there is unsatisfactory clinical response, or if skin irritation occurs, then either the medication needs to be changed or the strength increased. Skin irritation is a common adverse effect of psoriasis medications, especially if the patient gets the medication on the surrounding skin. Review proper administration technique prior to changing the therapy.

Patient Education

Successful treatment of psoriasis requires educating the patient on the following key points:

1. The patient should understand the pathophysiology of psoriasis: that it is a chronic disease but that remission is possible if adequately treated.
2. Proper application of topical medications will not only optimize treatment but also decrease adverse effects of the medications.
3. Many of the medications stain the skin and clothing. The patient should be aware of this problem and instructed on how to minimize the staining.
4. Some medications cause photosensitivity; therefore, the patient needs to understand the hazards of sun exposure and use protective clothing and sunscreen.

ACNE AND ACNE ROSACEA

Acne affects an estimated 17 to 28 million Americans, accounting for 4.4% of internist visits. It is the number-one condition seen by dermatologists, accounting for 18% of visits (Fleischer, Herbert, Feldman, & O'Brien, 2000). Acne can occur in girls as young as 9 or 10 years of age, with 70% to 87% prevalence in adolescents (Eichenfield et al, 2013), although acne can also occur in patients in their twenties to forties. Adolescent acne is more common in boys than in girls; however, adult acne is more common in women than in men. Males have a higher incidence of severe acne at all ages. Although acne may be a minor problem from a medical standpoint, studies have determined that acne has a significant impact on the patient's quality of life (Dalgard, Gieler, Holm, Bjertness, & Hauser, 2008). The practitioner needs to address the patient's concerns about acne with this in mind.

Pathophysiology

The underlying cause of acne is multifactorial. A genetic susceptibility appears to predispose some people to acne. Acne begins below the skin surface in the pilosebaceous unit of the sebaceous glands. In acne, the sebaceous glands are enlarged and sebum production is increased, probably because of adrenogenic hormones. In patients with acne, there is an alteration in the keratinization process in the follicular infrainfundibulum. This causes the extra sebum to occlude the hair follicle and produce microcomedones. These may enlarge with time and form closed comedones (whiteheads) or open comedones (blackheads). *Propionibacterium acnes (P. acnes)* organisms colonize the follicles and convert the triglycerides in the sebum into free fatty acids. Free fatty acids are a factor in the synthesis of chemoattractants that draw inflammatory elements, leading to the inflammation associated with acne. The patient may have superficial papules and/or pustules or deeper nodules, depending on the intensity of the inflammatory process.

Goals of Treatment

At this time, acne has no cure. The goal is to control the acne and keep visible lesions and medication adverse effects to a minimum. Management goals that will control acne are (1) controlling the inflammatory process associated with acne by altering the bacterial flora, and (2) decreasing the obstruction of the sebaceous ducts.

Rational Drug Selection

Acne treatment should be approached in a stepwise manner. If the acne is mild or moderate, a beginning therapy might include topical retinoids and/or topical antibiotics. If after 6 to 8 weeks this is not completely effective, an oral antibiotic might be added or a change in topical therapy initiated. For moderate to somewhat severe acne, the patient is usually started on an oral antibiotic and topical preparations combined. For severe, recalcitrant, nodular acne, the patient is prescribed isotretinoin (Accutane). Figure 32-1 presents an algorithm of the pharmacological management of acne.

Topical Agents

The topical agents used for acne can be divided into two categories: topical retinoids and topical antibiotics.

Topical Retinoids

Topical retinoids (tretinoin [Retin-A]), retinoid-like compounds (adapalene [Differin]), or retinoid prodrugs (Tazarotene [Tazorac]) are used to treat inflammatory and noninflammatory acne. They act to alter the abnormal keratinization process of acne that leads to microcomedome formation. Additionally, they

stimulate mitotic activity and increase the turnover of follicular epithelial cells, causing extrusion of the comedones. Clinically, this causes an initial worsening of acne, as comedones that were previously under the skin are extruded. This worsening is not a reason for discontinuation of treatment. Patients should be reassured that their faces will clear after approximately 6 to 8 weeks of treatment.

All retinoid preparations can cause some skin irritation, especially in fair-skinned patients or patients with sensitive skin. Irritation may be decreased in patients with sensitive skin by initiating 3-times-a-week or every-other-day therapy and increasing to daily use as tolerated (Eichenfield et al, 2013). Atopic people can be quite sensitive to these products. The patient should not use any harsh toners, astringents, scrubs, or cleansers while on topical retinoid therapy because these increase irritation. The patient's skin is more photosensitive when topical retinoids are used, and the patient should be advised to use noncomedogenic sunscreen for any sun exposure.

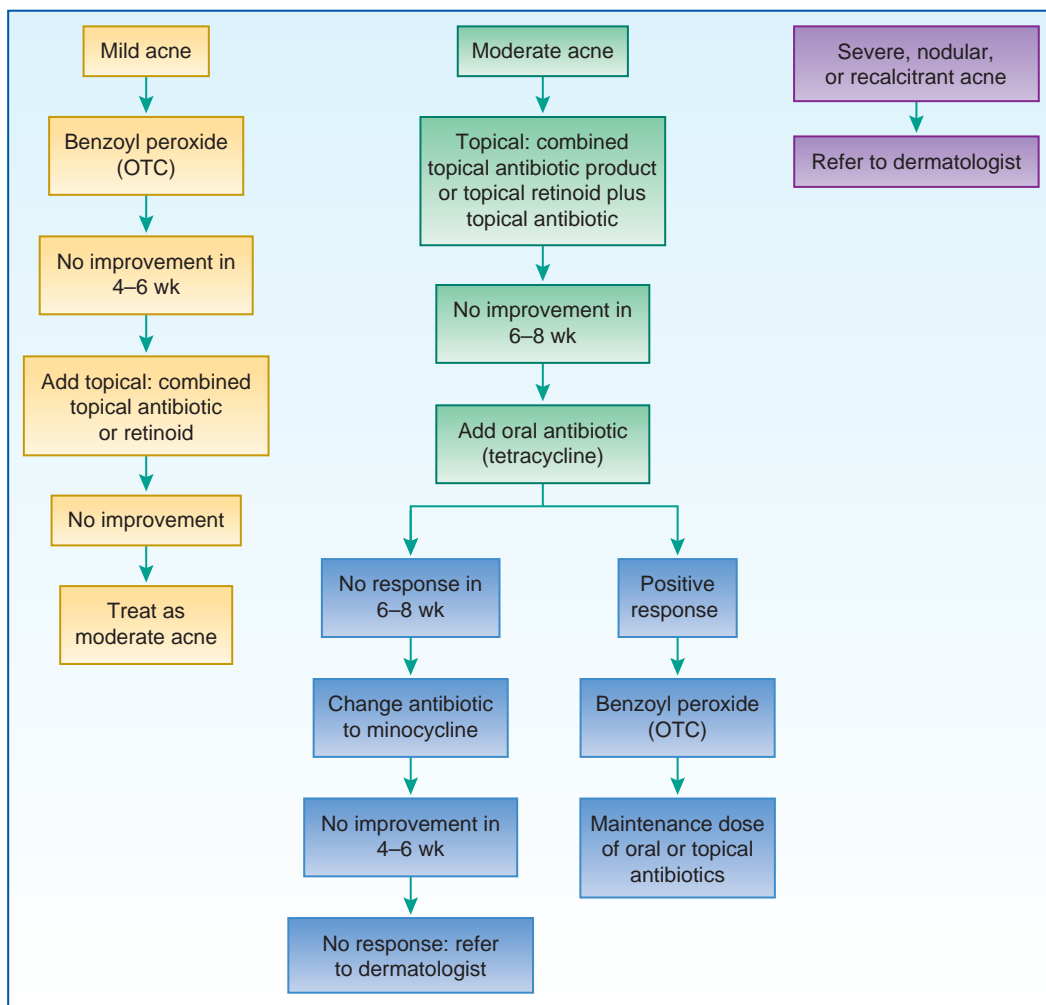
The patient should avoid the eyes and mucous membranes when applying these products. There may be transient stinging, burning, or pruritus immediately after applying topical


Figure 32–1. Algorithm: Pharmacological management of acne.

retinoids. Redness and peeling may occur with excessive application. If topical retinoids are used more than recommended, a dramatic increase in skin irritation occurs, but no improved response.

Table 32-2 presents the drugs commonly used to treat acne.

Topical Antibiotics

Topical antibiotics are thought to act to control acne by their bacteriostatic or bactericidal activity against *P. acnes.* They control the inflammatory process, probably by decreasing the free fatty acids that *P. acnes* produces. Applied topically,

Table 32–2 Drugs Commonly Used: Acne

Drug	Indication	Strengths Available	Dose	Comments
Topical Retinoids				
Tretinoin (Retin-A)	Acne	Cream: 0.025%, 0.05%, 0.1% Gel: 0.025%, 0.01% Liquid: 0.05%	Apply to affected areas once daily after washing face with a mild cleanser; begin with 0.025% cream and increase strength or to bid if needed. Sensitive-skin patients may need to dose every other night.	Wash hands after application. Normal use of cosmetics is permissible, but instruct patient to use noncomedogenic products. Pregnancy Category C; pregnant women should be switched to another product.
Adapalene (Differin)	Acne	Gel: 0.1% (alcohol-free) Lotion: 0.1% (30% alcohol)	Apply to affected areas once daily (HS) after washing with a gentle cleanser; avoid eyes, lips, and mucous membranes.	Avoid harsh soaps, cleansers, or alcohol-containing products, which increase skin irritation while using adapalene. Pregnancy Category C. May be used in children >12 yr.
Adapalene and benzoyl peroxide (Epiduo)	Acne	Adapalene 0.1% and benzoyl peroxide 2.5% gel	*Adults and children >12 yr*: Apply thin film once daily after washing. Reduce frequency if irritation occurs.	Avoid harsh soaps, cleansers, or alcohol-containing products, which increase skin irritation while using adapalene. Pregnancy Category C. May be used in children >12 yr.
Topical Antibiotics				
Benzoyl peroxide (Rx: Benzac, Desquam-X, Desquam-E) (OTC: Dryox, Fostex, Neutrogena AcneMask, Clearasil)	Acne	Liquid wash: 2.5%, 5%, 10% Bar: 5%, 10% Mask: 5% Lotion: 5%, 5.5%, 10% Cream: 5%, 10%	For cleansers, wash once or twice daily; rinse well and pat dry. For other forms, apply once daily; gradually increase to 2–3 times daily if needed; apply after cleansing skin.	Has a drying action that causes comedolysis and has a mild desquamation effect (irritating to the skin). Pregnancy Category C; topical application during pregnancy is generally considered safe.
		Gel: 2.5%, 4%, 5%, 10%, 20%		May be used in children >12 yr. Bleaches fabrics. Inactivates tretinoin and cannot be applied simultaneously.
Benzoyl peroxide/ clindamycin (Benzaclin, Duac)	Acne	5% Benzoyl peroxide 1% Clindamycin gel	Benzaclin: Apply to affected areas bid. Duac: Apply to affected areas once daily.	Has a drying action, causes comedolysis, and has a mild desquamation effect (irritating to the skin). Pregnancy Category C; topical application during pregnancy is generally considered safe.

Continued

Table 32–2 Drugs Commonly Used: Acne—cont'd

Drug	Indication	Strengths Available	Dose	Comments
				May be used in children >12 yr. Bleaches fabrics. Inactivates tretinoin and cannot be applied simultaneously. Rare reaction: colitis.
Erythromycin (Staticin, Akne-Mycin, A/T/S, Eryderm, Erymax, Ery-Sol, T-Stat, Erygel)	Acne	Solution: 1%, 2% Gel: 2% Ointment: 2%	Apply to affected areas bid after washing face with a mild cleanser.	Pregnancy Category B. Do not use concurrently with clindamycin.
Benzoyl peroxide/ erythromycin (Benzamycin)	Acne	Gel	Apply to affected areas once or twice/d (gel dries to a crusty white appearance; therefore, patient may prefer evening application; patient may use plain benzoyl peroxide in the morning if this is concern).	Pregnancy Category C. Bleaches fabrics. Must be kept refrigerated; stable for only 3 mo after mixed. Adverse effects include skin irritation and sun sensitivity.
Clindamycin (Cleocin, Clinda-Derm, C/T/S)	Acne	Gel, lotion, topical solution	Apply thin layer to affected areas bid.	Use with caution in patients with eczema. Although rare, there are reports of colitis with topical administration. If patient develops diarrhea, stop medication and investigate cause. Pregnancy Category B. Do not use in children <12 yr. Adverse effects include skin dryness and irritation, burning, and peeling.
Tetracycline (Topicycline)	Acne	Topical solution: 2.2 g/mL	Apply to affected areas bid; apply until skin is thoroughly wet (stinging and burning may occur but subside after a few minutes).	Pregnancy Category B. May be staining to clothes; yellowing of skin may be removed by washing. Assess patient for sulfite sensitivity. Topicycline contains sodium bisulfite.
Metronidazole (Metro-Gel, Noritate)	Acne rosacea	Gel: 0.75% Emollient cream: 1%	Apply a thin film bid to entire affected area after washing.	Improvement should be noted within 3 wk, but there may be continued improvement through 9 wk of treatment. Pregnancy Category B. Some mild skin irritation may be noted.
Oral Antibiotics				
Tetracycline (Achromycin)	Acne (long-term treatment)	Capsules: 250, 500 mg Tablets: 250, 500 mg	Initially, 500 mg bid for 1–2 mo. After control is achieved, dose may be lowered to 500 mg daily for 1–2 mo; then determine maintenance dose of 125–500 mg daily.	Must be taken on an empty stomach; poorly absorbed if taken with calcium-containing foods, milk, or antacids. Pregnancy Category D; do not prescribe to lactating women or children under age 8 (may cause staining of teeth).

Table 32–2   Drugs Commonly Used: Acne—cont'd

Drug	Indication	Strengths Available	Dose	Comments
Minocycline (Minocin)	Acne	Capsules: 50, 100 mg Tablets: 50, 100 mg	Initially, 100 mg bid, then wean to 50 mg daily after control is achieved.	Expensive. Must be taken on an empty stomach. Pregnancy Category D; do not prescribe to lactating women or children <8 yr.
Doxycycline (Monodox, Vibramycin)	Acne	Capsules: 50, 75, 100 mg	50–100 mg qd or bid	Take with a full glass of water and remain upright for 1 hour. May be taken with meals. Sunscreen must be worn.

antibiotics have an uneven, erratic penetration into the follicles. Therefore, they are usually used in mild acne, for maintenance after a course of oral antibiotics, or in conjunction with topical retinoids. There is a concern that resistant *P. acnes* may develop if topical antibiotics are overused.

The topical antibiotics that are approved for use include benzoyl peroxide, available by prescription (Benzac, Desquam-X, Desquam-E) or OTC (Dryox, Fostex, Neutrogena Acne Mask, Clearasil); erythromycin (Staticin, Akne-Mycin, A/T/S, Eryderm, Erymax, Ery-Sol, T-Stat, Erygel), clindamycin (Cleocin, Clinda-Derm, C/T/S); and tetracycline (Topicycline). A combination of benzoyl peroxide and adapalene (Epiduo Gel) is available. Ziana is a combination of clindamycin and tretinoin. The combination of benzoyl peroxide and an antibiotic erythromycin (Benzamycin) or clindamycin (Acanya, Benzaclin, Duac) is superior to either agent alone. Prescribing information is given in Table 32-2.

Oral Agents

Oral agents used for acne are divided into three categories: oral antibiotics, hormonal therapy, and isotretinoin (an oral retinoid). Oral antibiotics are prescribed for moderate to severe acne and are within the scope of practice of primary care providers. Isotretinoin is prescribed for severe nodulocystic acne but only by dermatologists because of its adverse effects.

Oral Antibiotics

Oral antibiotics are active against *P. acnes,* which helps transform comedones into inflammatory pustules and papules. Oral antibiotics do not affect existing lesions, but they prevent future lesions by decreasing sebaceous fatty acids by decreasing *P. acnes* colonization. They may also have an anti-inflammatory effect independent of their action against *P. acnes.* There is level I evidence for the use of tetracycline, doxycycline, minocycline, erythromycin, trimethoprim-sulfamethoxazole, trimethoprim, and azithromycin in the treatment of acne (Strauss et al, 2007). Azithromycin is effective against acne, but its routine use may lead to increased resistance (Graber, 2014). Increasing resistance to erythromycin has led to decreased use (Eichenfield et al, 2013). Doxycycline and minocycline are recommended due

to efficacy and once daily dosing (Eichenfield et al, 2013; Graber, 2014) Table 32-2 presents prescribing information for tetracycline (Achromycin V), doxycycline (Vibramycin) and minocycline (Minocin).

Hormonal Therapy

Hormonal therapy can be prescribed to women who require birth control who also have mild to moderate acne. Multiple oral contraceptives currently have FDA approval for use in acne: Ortho Tri-Cyclen, Ortho-Cyclen, Estrostep Fe, and Tri-Sprintec. The oral contraceptives appear to control the inflammatory component of acne. The patient is prescribed a premeasured-dose pack and takes one pill daily. Effects on acne are seen in 3 to 6 months of continued use. For full prescribing information, see Chapter 31.

> **CLINICAL PEARL**
>
> **Acne**
> Tell patients using **benzoyl peroxide** products that benzoyl peroxide can bleach clothes and towels. Advise them to use an old or white pillowcase on their bed and an old or white towel to dry their hands after using these agents.

Isotretinoin

Isotretinoin (Accutane) is the most potent agent for treating acne. It is reserved for severe, recalcitrant cystic acne. Its exact mechanism of action is unknown but thought to be related to decreased sebum production (by 90%) and isotretinoin's ability to decrease abnormal keratinization. Isotretinoin is prescribed for a period of 15 to 20 weeks and may need to be repeated. The toxicity profile and its ability to cause fetal malformations require that the prescriber provide extensive education and close monitoring throughout therapy. The adverse effects of dry skin, cheilitis, and pruritus are seen in almost all patients taking the drug. Patients may experience elevated serum triglycerides and clinical hepatitis, including elevated liver enzymes. Therefore, liver enzyme and lipid levels should be obtained before beginning therapy and monitored throughout therapy. Patients may develop depression

or suicide ideation; all patients taking isotretinoin should have their mood monitored.

The major concern is the use of the drug in women who may become pregnant; therefore, there are very stringent requirements and consent that must be met before the drug is prescribed. For female patients, a pregnancy test needs to be performed before beginning therapy and then monthly throughout therapy. Isotretinoin is Pregnancy Category X. It should not be prescribed to teenagers who have not completed their linear growth. Because of the toxic effects of isotretinoin, it is rarely prescribed by a primary care provider and is usually prescribed only by a dermatologist. All providers and female patients need to be registered with iPledge, a pregnancy-prevention program committed to preventing pregnancy while patients are taking isotretinoin. To register, go to http://www.iPledgeprogram.com.

Acne Rosacea

Acne rosacea, commonly referred to as rosacea, is a skin condition that usually affects middle-aged patients. It is a chronic inflammatory disorder that affects the blood vessels and pilosebaceous glands of the face. The patient often has a characteristic red-colored nose. An important hallmark characteristic is easy facial flushing and blushing associated with the ingestion of alcohol, spicy foods, or caffeine-containing beverages.

Patients with acne rosacea have papules and pustules superimposed on diffuse erythema and telangiectasia over the central portion of the face. Hyperplasia of the sebaceous glands, connective tissue, and vascular bed can lead to a large, bulbous red nose, called rhinophyma. The patient may also have ocular involvement that may require the care of an ophthalmologist.

Skin care includes use of a gentle facial cleanser and daily use of a sunscreen with a 30 sun protection factor (SPF) or greater to protect the skin (Del Roso et al, 2013a). Topical metronidazole (Metro-Gel, Noritate) and azeliac acid (Finacea) are FDA-approved to treat acne rosacea. The mechanism by which metronidazole works to improve the inflammation of rosacea is unknown but is probably related to its antibacterial effect. Likewise, the mechanism of action of azelaic acid to treat rosacea is unknown. Rosacea usually responds well to metronidazole or azeliac acid, but the antibiotic must be continued, because the rosacea will recur if the medication is discontinued (Del Roso et al, 2013b). Table 32-2 presents prescribing information.

PATIENT EDUCATION

Acne

RELATED TO THE OVERALL TREATMENT PLAN/DISEASE PROCESS

☐ Pathophysiology

☐ Role of preventive and nonpharmacological measures if appropriate

☐ Importance of adherence to the treatment regimen

☐ Self-monitoring of symptoms

☐ What to do when symptoms worsen

☐ Need for follow-up visits with the primary care provider

SPECIFIC TO THE DRUG THERAPY

☐ Reason for the drug's being given and its anticipated action on the disease process

☐ Doses and schedules for taking the drug

☐ Possible adverse effects and what to do if they occur

☐ Interactions between other treatment modalities and these drugs

REASONS FOR TAKING THE DRUG(S)

☐ Patient education about specific drugs is provided in the appropriate chapter.

SPECIFICALLY FOR ACNE

☐ The patient should understand that it will take at least 6 weeks to determine if treatment is effective. Tying this into the explanation of normal skin growth will help the patient understand why it takes so long for the medication to work.

☐ Whatever level of treatment the patient is started on, the patient needs to understand what alternatives there are if the chosen treatment is not effective.

DRUGS AS PART OF THE TOTAL TREATMENT REGIMEN

☐ The total treatment regimen includes pharmacological and nonpharmacological measures. Be sure the patient and/or family members are aware of the specific measures to be taken.

ADHERENCE ISSUES

☐ Health-care providers should be aware of the potential problem of nonadherence and should discuss the importance of completing the entire treatment regimen with the patient and/or family members.

Monitoring

The patient needs to be monitored for effectiveness and adverse effects of the acne medication.

Laboratory testing before and during therapy may be indicated for some patients. The primary care provider may be involved in obtaining and monitoring these tests. For female patients, especially those taking tetracycline, doxycycline, minocycline, and isotretinoin, pregnancy testing is recommended prior to beginning treatment and as indicated throughout therapy.

Outcome Evaluation

The patient needs to use an acne medication for at least 6 to 8 weeks before effectiveness can be determined. If there is no response after that time, then a change in therapy can be considered—either adding another medication or changing the regimen completely. Before determining the medication is not effective, review administration of the medication with the patient. The adverse effects associated with topical acne treatments include skin irritation and some redness and peeling. Mild symptoms usually improve if the frequency of administration is decreased slightly. If possible, the strength of the topical medication can be decreased if there is mild to moderate irritation. Severe skin irritation warrants discontinuing the medication and switching to another.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues.

SKIN INFECTIONS

Skin infections commonly seen in primary care include bacterial, viral, and fungal skin infections.

Bacterial skin infections are common and seen in patients of any age. The skin infections seen in primary care include impetigo, a furuncle (boil or abscess), perianal streptococcal infection, and cellulitis. All require prompt treatment with the appropriate antibiotic.

Many viral skin infections can affect the skin, often causing rashes. Herpes simplex virus infection, herpes zoster (shingles), and varicella (chickenpox) are the common viral infections seen in primary care.

Fungal skin infections can be divided into two types:*Candida* infections and dermatophyte infections. Dermatophyte or tinea infections include tinea of the scalp (tinea capitis or ringworm of the scalp), tinea of the skin (tinea corporis or ringworm), tinea cruris ("jock itch"), tinea of the feet (tinea pedis or athlete's feet), and tinea versicolor. Onychomycosis, a fungal infection of the nails, is another type of fungal skin infection.

Pathophysiology

Bacterial Skin Infections

The most common bacterial organisms found in skin infections are *S. aureus* and *Streptococcus pyogenes*. The organism usually enters through a break in the skin. The bacteria cause an inflammatory infectious process to begin.

Viral Skin Infections

Viral skin infections include herpes viral infections, varicella, and herpes zoster.

Herpes viral infections are spread by intimate contact between a person shedding the virus and a susceptible host. With inoculation into the skin or mucous membrane, herpes simplex virus (HSV) begins to replicate. The incubation period is 4 to 6 days. As replication continues, local inflammation and cell lysis lead to the distinctive vesicle with an erythematous region. The virus generally ascends the peripheral sensory nerves to the dorsal root ganglia. HSV replicates in the dorsal root ganglia and then enters an inactive or latent stage. The herpes virus is unique in that it establishes latency for varying periods of time. HSV can be reactivated and enter a replication cycle at any time. There are two HSV infections, HSV-1 and HSV-2, with HSV-1 generally associated with nongenital infection and HSV-2 associated with genital infection.

Varicella (chickenpox) is a highly contagious disease caused by the varicella zoster virus, a herpes virus. It is spread by direct contact, in droplets, and by airborne transmission. The virus infects individuals by the conjunctivae or respiratory tract, replicating in the nasopharynx and upper respiratory tract. It spreads systemically to cause a viremia, resulting in a disseminated vesicular rash after an incubation period of 10 to 14 days. The patient is contagious for 1 to 2 days prior to the rash eruption and until all the lesions are dry. After the rash clears, the virus enters a latent phase and remains inactive in the dorsal root ganglia.

Herpes zoster (shingles) is caused by reactivation of latent varicella zoster virus. The reason for the reactivation is unknown, although stress seems to have some impact. The incidence of the disease increases with age and immunosuppression. The patient usually experiences burning and pain along the dermatome prior to the vesicles erupting. The lesions are generally unilateral and appear along a dermatome, although there may occasionally be scattered lesions. The diagnosis is confirmed with Tzanck smear or viral culture.

Fungal Skin Infections

Candida infections are caused by *C. albicans,* which is commonly found on the skin and mucosal tissues in the oral, intestinal, and vaginal areas. Considered a normal flora in these areas, an overgrowth can lead to infection and erythema, ulceration, and characteristic white plaques. In the mouth, oral candidiasis is known as thrush. In women, a vaginal *Candida* infection is often referred to as

a "yeast infection." *Candida* is diagnosed by examination of scrapings from the area, using potassium hydroxide (KOH) preparation.

Dermatophytes are a group of fungi that live on the keratin of the stratum corneum, nails, and hair. Symptoms of dermatophyte infection include pruritus, scaling, occasional vesicles, and, in tinea corporis, characteristic annular lesions with raised edges and clearing in the center. Tinea versicolor can have clinical findings of multiple scaling, discrete macules that can be hypopigmented or hyperpigmented.

Onychomycosis is a fungal infection of the fingernails or toenails.

Goals of Treatment

The goals of treatment for skin infections are to decrease the severity of the infection or eradicate it (as appropriate), alleviate symptoms, and heal the skin area and return it to normal (as appropriate).

Rational Drug Selection

Bacterial Skin Infections

Impetigo

Impetigo is a bacterial infection (*S. aureus* or *S. pyogenes*) of the superficial layers of the skin, which begins as vesicles rupture, leaving a hallmark golden or honey-colored crust. Topical mupirocin ointment (Bactroban) or retapamulin (Altabax) for 5 days is used if the impetigo is mild (up to five singular lesions) (Stevens et al, 2014). The OTC ointments bacitracin and combinations of bacitracin, polymyxin B sulfate, and neomycin (Polysporin, Neosporin, Double Antibiotic Ointment, and Triple Antibiotic Ointment) are not recommended in the 2014 Infectious Disease Society guidelines for the treatment of skin infections (Stevens et al, 2014). Topical antibiotic ointments that contain neomycin (Neosporin) should not be used, as neomycin sensitivity is a concern. Oral antibiotics, such as cephalexin (Keflex) or dicloxacillin, are indicated if the patient has more than five lesions or ecthyma or if the lesions continue to worsen after 2 to 3 days of topical therapy (Stevens et al, 2014). Gram's stain and culture of exudate or pus is recommended to determine if MRSA is present. If MRSA is confirmed, treat with doxycycline, clindamycin, or sulfamethoxazole-trimethoprim (SMX-TMP) based on local resistance patterns (Stevens et al, 2014).

Furuncle

Treatment of a small furuncle, which is usually caused by *S. aureus,* may respond to warm packs and not need systemic antibiotics. A larger boil or abscess may require incision and drainage, as well as systemic antibiotics. Gram's stain and culture of the drainage will determine if the organism will be sensitive to the antibiotic of choice. Prior to Gram's stain results, an appropriate first-line antibiotic would be cephalexin or dicloxacillin (Stevens et al, 2014). Empiric therapy should include coverage for MRSA in areas of high prevalence. Antibiotics appropriate for MRSA include TMP/SMZ or

doxycycline, depending on local resistance patterns. Length of treatment should be 5 to 10 days, unless longer treatment is indicated by clinical progress.

Perianal Streptococcal Infection

Perianal streptococcal infection, a localized infection of the perianal area, usually occurs in children. The rash is caused by group A beta-hemolytic streptococci. The diagnosis is confirmed by a perianal swab and culture. The treatment of choice is penicillin, with erythromycin or cephalexin prescribed to penicillin-allergic patients.

Cellulitis

Cellulitis is a painful, erythematous, spreading bacterial infection involving the soft tissue. The patient can become quite ill if untreated, including developing sepsis. The causative organisms are most commonly *Streptococcus pneumoniae, S. aureus,* or, in children, *Haemophilus influenzae.* Treatment is with systemic antibiotics that are effective against these organisms. If the clinical assessment warrants it, an initial dose of an intramuscular or intravenous antibiotic (ceftriaxone, cefazolin, clindamycin) can be given, followed by oral antibiotic treatment. Oral antibiotic treatment with a broad-spectrum antibiotic such as dicloxacillin or a cephalosporin is indicated. Blood and tissue aspirate cultures will guide the practitioner in determining if the organism is sensitive to the antibiotic of choice. Close follow-up, usually within 24 hours, is indicated to determine if the clinical status is improving or worsening. The provider should consider MRSA if patients are not responding to initial therapy or have risk factors for MRSA. If MRSA is suspected, oral TMP/SMZ, clindamycin, or doxycycline (child younger than age 8 years) are the drugs of choice. Parenteral antibiotics (vancomycin) may be needed if cellulitis is severe or the patient does not respond to oral antibiotics within 24 to 48 hours.

Viral Skin Infections

HSV Infections, Varicella, and Herpes Zoster

The treatment of HSV infections, varicella, and herpes zoster includes the use of acyclovir (Zovirax), which can be used topically or systemically. Acyclovir has inhibitory action against HSV-1, HSV-2, and varicella-zoster virus. It decreases the duration of acute infections in HSV-2 infections and, when used to treat herpes zoster, shortens the time to lesion scabbing and decreases the length of viral shedding. When prescribed for patients with varicella, acyclovir decreases the number of vesicular lesions, shortens the time to healing, and decreases fever by the second day.

Other antiviral agents that may be prescribed include famciclovir (Famvir) and valacyclovir (Valtrex), which are the drugs of choice for recurrent outbreaks of HSV infection. Famciclovir can also be used for treatment of herpes zoster. It decreases the healing time by shortening the time to crusting and healing and decreases the length of viral shedding. Valacyclovir is a hydrochloride salt of L-valyl ester of acyclovir; is rapidly converted to acyclovir; and is active against HSV infections, varicella, and herpes zoster. See Table 32-3 for prescribing information.

Table 32–3 Drugs Commonly Used: Skin Infections

Drug	Indication	Strengths Available	Dose	Comments
Topical Antibiotics				
Mupirocin (Bactroban)	Bacterial skin infections	2% ointment (15, 30 g; available Rx only)	Apply to affected area tid until healed.	Pregnancy Category B Safe in children
Polymyxin B/neomycin/ bacitracin (Neosporin, Triple Antibiotics Ointment)	Bacterial skin infections	Triple antibiotic combination (available OTC)	Apply a small amount to affected area 1–3 times/d until healed.	Do not use if the patient has a neomycin sensitivity. Topical use is safe in pregnancy and in young children.
Polymyxin B/bacitracin (Polysporin, Double Antibiotic Ointment)	Bacterial skin infections	Double antibiotic combination (available OTC)	Apply a small amount to affected area 1–3 times/d until healed.	Topical use is safe in pregnancy and in young children.
Bacitracin (Baciguent)	Bacterial skin infections	Bacitracin only ointment (available OTC)	Apply to affected area 1–3 times/d until healed.	May use in patients with neomycin sensitivity. Safe during pregnancy and in young children.
Retapamulin (Altabax)	Bacterial skin infections	1% ointment	*Children age >9 mo and adults*: Apply to skin lesion twice a day for 5 days. May cover with gauze or bandage.	Safe during pregnancy and in infants age 9 mo and older. Not for intranasal use. Reevaluate if no improvement in 3–4 weeks after starting therapy.
Systemic Oral Antibiotics				
Cephalexin (Keflex)	Bacterial skin infections	Capsules: 250, 500 mg Suspension: 125 mg/5 mL, 250 mg/5 mL	*Adults:* 500 mg every 12 h for 7–10 d *Children:* 25–50 mg/kg/d divided qid or tid; treat for 7–10 d.	Inexpensive Pregnancy Category B Safe in children Well tolerated
Amoxicillin/clavulanate (Augmentin)	Bacterial skin infections	Tablets: 250 mg amoxicillin with 125 mg clavulanate; 500 mg with 125 mg	*Adults:* 500 mg of amoxicillin every 12 h *or* 250 mg every 8 h for 7–10 d	Broad-spectrum coverage Moderately expensive Pregnancy Category B
		Chewable tablets: 125 mg amoxicillin with 31.25 mg clavulanate; 200 mg with 28.5 mg; 250 mg with 62.5 mg; 400 mg with 57 mg; 125 mg with 31.25 mg/5 mL; 200 mg with 28.5/5mL; 250 mg with 62.5 mg/5 mL; 400 mg with 57 mg/5 mL	*Children >3 mo:* 25–45 mg/kg/d of amoxicillin divided every 12 h (use 200 mg/5 mL or 400 mg/5 mL strength suspension) or 20–40 mg/kg/d of amoxicillin if using 125 mg/5 mL or 250 mg/ 5 mL strength suspension; treat for 7–10 d; use higher amounts with more severe infections.	May cause gastrointestinal (GI) upset, especially at higher doses. Children's dose is based on amoxicillin content. Due to clavulanate content, two 250 mg tablets are not the same as one 500 mg tablet; suspension doses are also not equivalent. Children should not be given the 250 mg tablet until they weigh >40 kg.
Cefadroxil (Duricef)	Bacterial skin infections	Tablets: 1 g Capsules: 500 mg Suspension: 125 mg/5 mL, 250 mg/5 mL, 500 mg/5 mL	*Adults:* 1 g once/d for 10 d *Children:* 30 mg/kg/d divided into 2 doses every 12 h	Pregnancy Category B First-generation cephalosporin Convenient dosing
Cefprozil (Cefzil)	Bacterial skin infections	Tablets: 250, 500 mg Suspension: 125 mg/5 mL, 250 mg/5 mL	*Children ≥12 yr and adults:* 250–500 mg every 12 h for 7–10 d	Broad-spectrum coverage Expensive Pregnancy Category B *Children 2–12 yr:* 20 mg/kg/d divided into 2 doses 12 h apart for 7–10 d

Continued

Table 32–3 Drugs Commonly Used: Skin Infections—cont'd

Drug	Indication	Strengths Available	Dose	Comments
		Erythromycin estolate: 250, 500 mg tablets; 125 mg/ 5 mL, 250 mg/5 mL suspension Erythromycin ethylsuccinate: 200 mg chewable tablets; 400 mg tablets; 200 mg/5 mL, 400 mg/ 5 mL suspension	*Children:* 20–50 mg/kg/d qid for 10 d	May cause GI upset: take with food or milk.
Clindamycin (Cleocin)	Bacterial skin infections (MRSA)	Capsules: 75, 150, 300 mg	*Adults:* 150–300 mg qid	Pregnancy Category B
		Pediatric granules for oral solution: 75 mg/5 mL	*Children:* 8 mg/kg/d divided in 3–4 doses	May cause severe and possibly fatal colitis. Discontinue drug if significant diarrhea occurs.
Doxycycline (Doryx, Monodox) (Vibramycin)	Bacterial skin infections (MRSA)	Capsules: 50, 75, 100 mg	*Adults:* 100–200 mg/d in 1–2 divided doses	Contraindicated in children <8 yr
		Suspension: 25 mg/5 mL	*Children >8 yr:* 2–4 mg/kg/d in 1–2 divided doses maximum 200 mg/d	Pregnancy Category D Photosensitivity may occur.
Antivirals				
Acyclovir (Zovirax), topical	HSV infection, herpes zoster, varicella	3% ointment (3, 15 g)	Apply to lesion every 3 h 6 times/d for 7 d	Pregnancy Category C Use a finger cot or glove when applying ointment to prevent spread of virus.
Acyclovir (Zovirax), oral	HSV infection, herpes zoster, varicella	Tablets: 400, 800 mg	*Adults:*	Pregnancy Category C
		Suspension: 200 mg/5 mL	Genital herpes: Initial: 200 mg every 4 h 5 times/d for 10 d Chronic: 400 mg bid or 200 mg 3–5 times/d for up to 12 mo Intermittent: 200 mg q4h 5 times/d for 5 d; begin at first sign of occurrence Herpes zoster: 800 mg q4h 5 times/d for 7–10 d Varicella: 20 mg/kg 4 times/d for 5 d; maximum 800 mg/dose; begin within 24 h of first lesion *Children ≥2 yr:* Varicella: 20 mg/kg 4 times/d for 5 d; maximum 800 mg/dose; begin within 24 h of first lesion	Decrease dose in renal patients.
Famciclovir (Famvir B)	HSV infection, herpes zoster	Tablet: 135, 250, 500 mg	Genital herpes: Initial episode: 125 mg q12h for 5 d; begin as soon as symptoms appear Recurrent episodes: 125 mg q12h for 5 d Suppression therapy: 250 mg q12h for up to 12 mo Herpes zoster; 500 mg q8h for 7 d; begin within 72 h of lesions appearing	Not recommended in patients <18 yr. Decrease dose in renal patients. Pregnancy Category B. Register pregnant patients exposed by famciclovir by calling 800-366-8900 ext 5231.

Table 32–3   Drugs Commonly Used: Skin Infections—cont'd

Drug	Indication	Strengths Available	Dose	Comments
Valacyclovir (Valtrex)	HSV infection, herpes zoster	Caplet: 500 mg, 1 g	Genital herpes: Initial episode: 1 g daily for 10 d Recurrent episodes: 500 mg q12h for 5 d started within 24 h of first symptom of outbreak Herpes zoster: 1g q8h for 7 d; begin within 48–72 h of first lesions appearing	Not recommended in children. Decrease dose in renal patients. Pregnancy Category B. Register pregnant patients exposed by valacyclovir by calling 800-722-9292, ext 39437.
Antifungals Nystatin (Mycostatin, Nilstat)	Oral *Candida* infection	Suspension: 100,000 U/mL Pastilles: 200,000 U each	*Children and adults*: 2–3 mg in each inner cheek qid (total dose 4–6 mL); have patient hold medication in mouth as long as possible before swallowing; treat for 48 h after clinical cure to prevent relapse. *Infants:* 1 mL each cheek qid (2 mL/dose total) until 48 h after clinical cure; may apply medication to inner cheeks and tongue with cotton swab prior to administering the 1 mL dose via dropper.	Safe in pregnancy and in young children and even in debilitated infants Well tolerated, even with prolonged administration
Nystatin (Mycostatin, Nilstat, Nystex)	Cutaneous *Candida* infection	Cream, ointment, powder	Apply to affected areas 2–3 times/d until healed.	Safe in pregnancy and in children
Clotrimazole (Mycelex)	Oral *Candida* infection	Troches: 10 mg	*Adults and children >3 yr and adults:* 1 troche 5 times/d for 14 d; dissolve slowly in mouth	Not recommended in children Pregnancy Category C; not recommended for use in pregnancy May cause elevated liver function tests
Clotrimazole (Lotrimin, Mycelex)	Dermatophyte infections of the skin	1% cream (Rx and OTC); 1% solution (Rx and OTC); 1% lotion (Rx)	Apply to affected area bid for 2 wk. Tinea pedis: treat for 4 wk.	Pregnancy Category B Safe in children
Gentian violet	Oral *Candida* infection	Solution: 1%, 2% (available OTC)	Apply with cotton swab to entire inner surface of the mouth 2 times/d until healed	Stains everything it touches purple; warn patient/parents about staining of mouth; stain resolves within a couple of days of discontinuing therapy.
Fluconazole (Diflucan)	Oral *Candida* infection	Tablets: 50, 100, 150, 200 mg Suspension: 10 mg/mL 40 mg/mL	*Adults:* 200 mg first day, then 100 mg daily for 2 wk minimum *Infants and children:* 6 mg/kg on the first day, then 3 mg/kg daily for 2 wk minimum	Pregnancy Category C Interacts with cimetidine, hydrochlorothiazide, rifampin cyclosporine, phenytoin, and theo-phylline; monitor closely if patient is taking one of these medications with fluconazole.
Miconazole (Micatin, Monistat-Derm, Micatin)	Dermatophyte infections of the skin	2% cream (Micatin, Monistat-Derm); 2% powder (Micatin); 2% spray (Micatin Liquid) (available OTC)	Apply to affected area 2–3 times/d for 2 wk. Tinea pedis: treat for 4 wk.	Topical use safe in pregnancy and in children

Continued

Table 32–3 Drugs Commonly Used: Skin Infections—cont'd

Drug	Indication	Strengths Available	Dose	Comments
Tolnaftate (Tinactin, Ting, Aftate, Absorbine)	Dermatophyte infections of the skin, tinea pedis	1% cream, solution, gel, powder, spray powder, spray liquid (available OTC)	Apply to affected area bid for 2–3 wk; if skin is thickened, treatment may take 4–6 wk.	Safe for topical use in pregnancy Not recommended for use in children <2 yr
Terbinafine(Lamisil)	Dermatophyte infections of the skin	Cream	Apply to affected and immediate surrounding areas 1–2 times/d until symptoms are significantly improved (usually 1–4 wk). Tinea pedis: apply to affected and immediate surrounding areas until symptoms are significantly improved.	Pregnancy Category B; safety in children <12 yr has not been established. Clinical improvement may continue for 2–4 wk after therapy is stopped.
Sulconazole (Exelderm)	Dermatophyte infections of the skin	1% cream; 1% solution (Rx required)	Massage medication into affected area 2 times/d for 2 wk. For tinea pedis, apply for 4 wk.	Pregnancy Category C; use only if clearly needed.
Ciclopirox (Loprox)	Dermatophyte infections of the skin	1% cream; 1% lotion (Rx required)	Massage medication into affected area 1–2 times/d for 3 wk. For tinea pedis, apply bid for 4 wk.	Pregnancy Category C; safety in children <10 yr has not been established.
Ciclopirox (Penlac)	Onychomycosis of fingernails or toenails	8% topical solution (nail lacquer)	*Adults:* Apply thin layer to entire nail and surrounding 5 mm. Leave on 8 h before washing; once a week remove with alcohol. Trim and file nails while free of drug. Repeat for 4–8 wk.	Not recommended in children. Pregnancy Category B. Product is flammable.
Ketoconazole (Nizoral)	Dermatophyte infections of the skin	2% cream	Massage medication into affected area once/d for 2 wk. For tinea pedis, apply for 6 wk.	Pregnancy Category C May be used to treat cutaneous *Candida* infections
Econazole (Spectazole)	Dermatophyte infections of the skin	1% cream (Rx required)	Massage medication into affected area once/d for 2 wk minimum. For tinea pedis, apply for 4 wk minimum.	Pregnancy Category C; do not use in first trimester; use in second and third trimesters only if clearly needed.
Oxiconazole (Oxistat)	Dermatophyte infections of the skin	1% cream; 1% lotion (Rx required)	Massage medication into affected area 1–2 times/d for 2 wk. For tinea pedis, apply for 4 wk.	Pregnancy Category B; use only if clearly needed.
Griseofulvin Microsize (Fulvicin, U/F, Grifulvin V, Grisactin)	Tinea capitis, onychomycosis	Tablets: 250, 500 mg	Tinea capitis:	Pregnancy Category C; safe in children >2 yr
		Capsules: 125, 250 mg	*Adults:* 500 mg daily for 4–6 wk	
		Suspension: 125 mg/5 mL	*Children:* 11 mg/kg/d for 4–6 wk Onychomycosis: *Adults*: 750–1,000 mg daily in divided doses; treat fingernail infection for 4 mo; toenail infection for 6 mo. *Children:* 11 mg/kg/d; treat fingernail infection for 4 mo; toenail infection for 6 mo.	Renal, liver, and hematopoietic function tests need to be drawn and monitored every 8 wk if on prolonged therapy. Best absorbed if taken with a high-fat meal.

Table 32–3 **Drugs Commonly Used: Skin Infections—cont'd**

Drug	Indication	Strengths Available	Dose	Comments
Griseofulvin Ultramicro-size (Fulvicin P/G, Grisactin Ultra, Gris-PEG)	Tinea capitis, onychomycosis	Tablets: 125, 165, 250, 330 mg	Tinea capitis: *Adults:* 330–375 mg daily for 4–6 wk	Pregnancy Category C; safe in children >2 yr
			Children: 7.3 mg/kg/d for 4–6 wk Onychomycosis: *Adults:* 660–750 mg daily in divided doses; treat fingernail infection for 4 mo; toenail infection for 6 mo.	Renal, liver, and hematopoietic function tests need to be drawn and monitored every 8 wk if on prolonged therapy.
			Children: 7.3 mg/kg/d; treat fingernail infection for 4 mo; toenail infection for 6 mo.	Best absorbed if taken with a high-fat meal.
Ketoconazole (Nizoral)	Tinea capitis, onychomycosis	Tablets: 200 mg	*Adults:* 200 mg daily; may increase to 400 mg daily if inadequate clinical response; minimum length of treatment is 4 wk.	Monitor hepatic function prior to initiating therapy and monthly during therapy.
			Children ≥2 yr: 3.3–6.6 mg/kg/d	Pregnancy Category C; may be prescribed to children >2 yr. Not first-line treatment for onychomycosis because of possible hepatotoxicity. Use with caution if patient is taking medications that are primarily metabolized by the liver.
Itraconazole (Sporanox)	Onychomycosis	Capsules: 100 mg	*Adults:* Daily dosing schedule: toenails: 200 mg daily for 12 wk Pulse schedule: toenails: 400 mg daily for 1 wk/mo for 3–4 mo; for fingernails: 200 mg bid for 7 d, then 3 wk without medication, then 200 mg bid for 7 more days *Children:* Pulse schedule: 5 mg/kg/d for 1 wk/mo for 3–4 consecutive mo	Coadministration with astemizole is absolutely contraindicated because of secondary cardiotoxic effects. If used for more than 8 consecutive weeks, liver enzymes and electrolytes should be drawn prior to and every 8 wk during treatment. Pregnancy Category C; do not administer to pregnant women or women considering pregnancy. In children use griseofulvin as first-line therapy. Coadministration with astemizole is absolutely contraindicated because of secondary cardiotoxic effects. Coadministration with cisapride, midazolam, triazolam, simvastatin, and lovastatin is also contraindicated.

Continued

Table 32–3 Drugs Commonly Used: Skin Infections—cont'd

Drug	Indication	Strengths Available	Dose	Comments
Terbinafine (Lamisil)	Onychomycosis	Tablets: 250 mg	Fingernail infection: 250 mg daily for 6 wk Toenail infection: 250 mg daily for 12 wk	Not recommended for use in children; safety not established. Liver enzymes and complete blood count (CBC) should be monitored every 6 wk. Pregnancy Category B; delay treatment until after pregnancy.

HSV = herpes simplex virus; MRSA = methicillin-resistant *Staphylococcus aureus;* OTC = over the counter.

Three topical antiviral medications are available: acyclovir (Zovirax), penciclovir (Denavir), and the OTC product docosanol (Abreva). Acyclovir is indicated in the management of initial episodes of herpes genitalis and in limited, non–life-threatening, mucocutaneous HSV infections in immunocompromised patients. There is no clinical evidence for the benefit of using acyclovir in the immunocompetent patient, although decreased viral shedding may be noted. Topical acyclovir is applied to cover all lesions every 3 hours 6 times a day for 7 days. Penciclovir is indicated in the treatment of recurrent herpes labialis (cold sores) on the lips and face. Application to the mucous membrane is not recommended. In adults, penciclovir 1% cream is applied every 2 hours while awake, with treatment started as early as possible (during the prodrome or when lesions appear). Docosanol (Abreva) is the only OTC product available for the treatment of herpes labialis. It is applied to the cold sore 5 times a day until healed. Treatment should begin at first sign of outbreak. All of the topical products are most effective if started as early as possible, in the prodrome phase, and need to be applied with a glove or finger cot to prevent spread to other areas.

Comfort measures with antipruritics, such as antihistamines, and wet soaks are also part of the treatment plan for viral skin infections. Table 32-3 presents prescribing information.

Fungal Skin Infections

Oral Candidiasis

Oral candidiasis (thrush) is commonly found in infants and immunocompromised patients. Prompt treatment is essential to maintain adequate nutrition and for patient comfort. The treatment of choice is a topical application of an antifungal agent, such as nystatin (Mycostatin), clotrimazole (Mycelex), or gentian violet, or oral administration of the systemic antifungal fluconazole (Diflucan). Table 32-3 presents prescribing information.

Tinea Capitis

With tinea capitis (ringworm of the scalp), the patient presents with a characteristic bald patch, with crusting or scaling. *Microsporum* species usually present with broken hairs and a fine gray scale. *Trichophyton tonsurans* (black dot tinea) presents with tiny black dots that are the remains of broken hair shafts.

Treatment of tinea capitis consists of oral antifungal therapy with griseofulvin (Grifulvin V, Grisactin) and biweekly shampooing with a sporicidal shampoo (selenium sulfide or ketoconazole). Tinea capitis should always be treated with a systemic antifungal, never a topical agent. Treatment should continue for 6 to 8 weeks or until 2 weeks after the KOH or culture is negative. Close contacts should be empirically treated with sporicidal shampoo twice a week. Resistant cases can be treated with terbinafine, fluconazole, or itraconazole, based on the sensitivity as determined by culture. Table 32-3 presents prescribing information.

Tinea Corporis and Tinea Cruris

Tinea corporis (ringworm) is commonly caused by *Microsporum canis, T. tonsurans,* or *Epidermophyton floccosum.* The classic presentation is an annular lesion with raised borders and a clear center. There may be scaling and usually some erythema. The infection spreads by direct contact with an infected person or animal, with household pets being a common source of infection.

● CLINICAL PEARL ●

Thrush

Infants (and some older or very ill patients) are unable to hold nystatin suspension in their mouth. To achieve better results with nystatin administration, instruct the parents or caregivers to dip a clean cotton-tipped applicator into the nystatin solution, then rub the medication into the areas of thrush on the inner cheeks. Use a clean swab for each side and do not redip the applicator into the nystatin. After swabbing on the nystatin, the parent or caregiver can then administer 1 to 2 mL to each cheek.

Tinea cruris ("jock itch") affects the skin of the groin, upper thighs, and intertriginous folds. It is more common in males and rarely occurs before adolescence. It is caused by the dermatophytes *E. floccosum, Trichophyton rubrum, Trichophyton mentagrophytes,* and *C. albicans.* Tinea cruris is worse in hot, humid weather. The lesions are scaly with a raised border, erythematous, and slightly brown in color. Treatment for both

tinea corporis and tinea cruris is topical antifungal cream, with miconazole (Micatin, Monistat-Derm), tolnaftate (Tinactin), and clotrimazole (Lotrimin, Mycelex) the least expensive and most commonly prescribed. Other topical antifungals that may be used include terbinafine (Lamisil), sulconazole (Exelderm), ciclopirox (Loprox), ketoconazole (Nizoral), econazole (Spectazole), and oxiconazole (Oxistat). Table 32-3 presents prescribing information.

Tinea Pedis

Tinea pedis (athlete's foot) is caused by the dermatophytes *E. floccosum, T. rubrum, T. mentagrophytes,* and *C. albicans.* It is more common in males and rarely occurs before puberty. It can present in three forms: interdigital maceration, scaling, and fissuring; a "moccasin" distribution of persistent dry scale with minimal inflammation; or scattered pustules and vesicles on the sole and lateral aspects of the feet. The nonpharmacological management includes measures to keep the feet dry and well aired, such as wearing sandals whenever possible, wearing clean cotton socks, and drying the feet carefully after bathing. Pharmacological management is with topical antifungals, similar to those used for tinea corporis: miconazole, clotrimazole, tolnaftate, terbinafine, sulconazole, ciclopirox, ketoconazole, econazole, and oxiconazole. However, the length of treatment is usually longer than for tinea cruris. Table 32-3 presents prescribing information.

Tinea Versicolor

Tinea versicolor (pityriasis versicolor) is caused by *Pityrosporum orbiculare* (formerly called *Malassezia furfur*). Clinically, the infection appears as multiple scaling, discrete, oval-shaped macules that may be hypopigmented or hyperpigmented. The color of the macules ranges from salmon to brown, and they are usually seen on the trunk, neck, and shoulders. The infection is associated with warm, humid weather. Treatment consists of topical application of selenium sulfide shampoo (Selsun) or a topical antifungal, commonly one of the imidazoles (miconazole, clotrimazole, econazole). The patient should be educated to observe for recurrence, which up to 50% of patients experience. The shampoo is applied to the affected area and left on for 10 to 15 minutes every day for 1 week. It may also be used prophylactically once a month. The topical antifungal is used for 2 to 4 weeks and is rubbed into the affected area twice a day.

Onychomycosis

Onychomycosis is a fungal infection of the nail, either fingernail or toenail. The common dermatophyte that is found in onychomycosis is tinea unguium, with *Candida* infections also a cause. Effective treatment usually involves months of a systemic antifungal medication, commonly griseofulvin, ketoconazole, itraconazole, or terbinafine. Topical treatment is usually not effective, with the exception of ciclopirox nail lacquer (Penlac). Recent studies have demonstrated added effectiveness when topical ciclopirox and systemic antifungals are combined. Regardless of treatment modality, clearing of onychomycosis takes months of treatment. Table 32-3 presents prescribing information.

Monitoring

For all skin infections, the patient should be monitored to determine the effectiveness of the medication in treating the infection, compliance with the prescribed therapy, adverse effects, and the development of secondary infection.

Outcome Evaluation

For skin infections, improvement should be noted, usually within 24 to 48 hours. If not, a change in therapy may be indicated, with resistance suspected. Secondary skin infections, if they occur, should be treated promptly. Referral to a dermatologist may be necessary if therapy is not managing the infection.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues.

SKIN INFESTATIONS

Skin and hair infestation with arthropods, most commonly lice and scabies, is a frequently seen problem in primary care. Head lice infestation is at epidemic levels in school-age children, with 6 to 12 million people in the United States affected each year. Scabies can occur at any age and is more common when poor hygiene or crowded living conditions are present.

Pathophysiology

Lice

Pediculosis is infestation of the body with lice. The affected body area helps to determine what arthropod is present. The skin signs seen with pediculosis are pruritus, excoriation from scratching, adenopathy (occasionally) in the affected region, and the presence of lice or nits.

The common name for infestation with *Pediculus humanus capitis* is head lice (pediculosis capitis). The mite of head lice is usually visible, and the nits or eggs are visualized attached to the hair shaft. The female louse lays approximately four eggs per day and has a life span of 2 to 4 weeks. Head lice are spread by direct contact with another infected person or by indirect contact with a hairbrush, hat, or article of clothing that the lice or nits have been transferred to. Outbreaks in schools are seen when children share hats or hairbrushes. When outer garments are hung in a close group, which is often the case in school, the lice can travel from coat to coat and spread to an unsuspecting new household. Diagnosis is made by observing mites or nits.

Body lice (pediculosis corporis), the common name for infestation with *P. humanus corporis,* are uncommon. They usually are not seen on the body but on the seams of clothing and undergarments. They come onto the body to feed and

PATIENT EDUCATION

Skin Infections

RELATED TO THE OVERALL TREATMENT PLAN/DISEASE PROCESS

☐ Pathophysiology

☐ Role of preventive and nonpharmacological measures if appropriate

☐ Importance of adherence to the treatment regimen

☐ Self-monitoring of symptoms

☐ What to do when symptoms worsen

☐ Need for follow-up visits with the primary care provider

SPECIFIC TO THE DRUG THERAPY

☐ Reason for taking the drug and its anticipated action on the disease process

☐ Doses and schedules for taking the drug

☐ Possible adverse effects and what to do if they occur

☐ Interactions between other treatment modalities and these drugs

REASONS FOR TAKING THE DRUG(S)

☐ Patient education about specific drugs is provided in the appropriate chapter.

SPECIFICALLY FOR BACTERIAL SKIN INFECTIONS

☐ Explanation regarding the suspected cause of the infection and the rationale for the **antibiotic** treatment chosen

☐ Hand washing should be stressed to prevent spread of the skin infection to the patient or others.

☐ Give clear guidelines regarding notifying the practitioner if the infection is getting worse.

☐ Improvement should be noted in 24 to 48 hours; if not, a change in therapy may be indicated.

SPECIFICALLY FOR VIRAL INFECTIONS

Expectations of the medication. The healthy patient will have resolution of the vesicular lesions even without pharmacological intervention. Effective antiviral therapy decreases the time to scabbing and healing of lesions and decreases viral shedding time. In immunocompromised patients, the medication will help decrease the severity of the outbreak.

☐ Explain how the virus can become dormant and recur at a later time, even many years later.

☐ Patients using topical antivirals need to be instructed to use a glove or finger cot to apply the ointment to prevent getting the virus on their hands and spreading it; also, the patient may experience a transient burning when the medication is applied.

☐ It should be stressed to the patient and/or family members that the patient is contagious until the lesions are healed or scabbed over, even if antiviral agents are being taken; the patient should avoid contact with immunocompromised individuals and avoid sexual intercourse if the patient has genital herpes lesions.

SPECIFICALLY FOR FUNGAL INFECTIONS

☐ The patient and/or family members should understand how the fungal infection is spread and how contagious the infection is.

☐ Family members and pets should be checked for signs of infection and treated if indicated.

☐ The provider should stress the possibility of relapse if the medication regimen is not followed correctly and for the full treatment time.

DRUGS AS PART OF THE TOTAL TREATMENT REGIMEN

☐ The total treatment regimen includes pharmacological and nonpharmacological measures. Be sure the patient and/or family members are aware of the specific measures to be taken.

ADHERENCE ISSUES

☐ Health-care providers should be aware of the potential problem of nonadherence and should discuss the importance of completing the entire treatment regimen with the patient and/or family members.

leave hemorrhagic pinpoint macules where they extract blood. There is often excoriation from scratching. The common sites for body lice are the belt line, collar, and underwear areas. Diagnosis is made by examining the clothing and underwear for the presence of mites and nits.

Infestation with *Phthirus pubis* is commonly called pubic lice (pediculosis pubis). Patients often refer to it as crabs The mites are quite small and may need to be examined under a handheld magnifying glass because they may be mistaken for a freckle. The mites and nits are found on the pubic hair and

the hair of the perianal region. They may extend up to the hair on the abdomen and to the hair on the upper thighs. The eyelashes and axillary hair may also be involved. Pubic lice are never seen before pubertal hair development. They are often sexually transmitted. Diagnosis is made by observing the mite or nits in the pubic hair.

Scabies

Scabies is a highly contagious infestation with *Sarcoptes scabiei.* The female scabies mite burrows under the skin and lays eggs as she tunnels. The eggs hatch in about 2 weeks. The surface of the skin has characteristic curving burrows and excoriated papules. The burrows are in the horny layer of the skin and are seen most frequently on the sides of the fingers; the interdigital webs; and flexor surfaces of the wrists, elbows, axillae, and genitalia. In infants, the scabies mite can often be found on the entire body, including the trunk and face. There may be a secondary infection present.

The incubation period is 1 to 2 months after contact with another infested person or with unwashed clothing recently worn by an infected person. Bed partners can be infected even if there is no body contact. Often the first sign of infestation with scabies is intense pruritus, which occurs 2 to 6 weeks after the first exposure to the mite. The itching is caused by sensitization to the mite feces. Definitive diagnosis is made by scraping a burrow that reveals mites or eggs.

Goals of Treatment

The goals of treatment are to completely eradicate the arthropods and to educate the patient and family about the disease and how to prevent further infestations.

Rational Drug Selection

Pharmacological management of lice and scabies consists of the use of ectoparacides. The specific medication used varies by the type of infestation and the age of the patient. For head lice, there is a choice of OTC products and, in the case of resistance to OTC products, prescription lindane or malathion. Benzoyl alcohol (Ulesfia), ivermectin lotion (Sklice), and spinosad (Natroba) are prescription products that are FDA approved for head lice. There is also variety of nonpharmacological remedies. For body lice, the treatment of choice is lindane or permethrin 5% (Elimite) and washing infested clothing and bedding. Pubic lice are treated with lindane shampoo. Scabies is treated with permethrin or lindane. Nonpharmacological, environmental measures are a key part of the treatment of any infestation because patients can reinfect themselves or other family members and restart the infestation cycle.

Head Lice

Head lice can cause great distress to the family. It is necessary to treat head lice aggressively and completely to prevent recurrence. Unfortunately, resistance to some pediculicides has made treating head lice at times a clinical challenge. The OTC

products available include pyrethrins and permethrin. Benzoyl alcohol (Ulesfia), ivermectin lotion (Sklice), or spinosad (Natroba) may be prescribed for head lice. Malathion (Ovide) is a prescription drug used as a second-line agent for resistant head lice (Centers for Disease Control and Prevention, Division of Parasitic Diseases [CDC], 2013a).

Although all of the head lice treatments are relatively safe, they are classified as neurotoxic agents (except benzoyl alcohol), and they should be used exactly as directed on the package or prescription. To limit exposure, the medication should be washed off at a sink, rather than in a shower. Cool or lukewarm water should be used to minimize absorption caused by vasodilation. After treatment, the hair should be combed to remove all the nits. There are special combs available for this, or slow, patient combing can be effective. Advise parents to comb hair a minimum of 20 minutes, dividing hair in sections. Treat only family members who are actively infested. Do not treat head lice prophylactically.

With the use of malathion (Ovide) careful instruction should be given regarding the flammability of the product. Lotion and wet hair should not be exposed to open flames or electric heat sources, including hair dryers and electric curlers. Do not smoke while applying lotion or while hair is wet. Allow hair to dry naturally and to remain uncovered after application of Ovide lotion.

Pyrethrins

Pyrethrins are combined with piperonyl butoxide (RID, Pronto, A-200) and are available OTC. Pyrethrins are 100% insecticidal and 70% to 80% ovicidal. The shampoo is applied to dry hair and left on for 10 to 20 minutes, with the time varying by brand. It is important for the product to be applied to dry hair to enable the pediculicide to enter the insect's body better. The patient should be retreated in 1 week regardless of whether there is evidence of infestation. Pyrethrins have no residual activity and can be used in young children and pregnant women if used as directed.

Permethrin

Permethrin is a synthetic compound related to pyrethrins. It is available OTC in 1% cream (Nix) or prescription strength 5% cream (Elimite). Only Nix has FDA approval for use on head lice. It is 97% percent insecticidal and 70% to 80% ovicidal. Permethrin is a cream rinse that is applied after shampooing. It is important that the shampoo not have any conditioner in the formula, which makes the permethrin less effective. The cream rinse is left in the hair for 10 minutes before rinsing off. Treatment should be repeated in 1 week, regardless of whether signs of infestation are present. Permethrin cream rinse has residual activity against lice for up to 10 days.

Lindane

Lindane is a prescription product used as a second-line agent for head lice. The popular brand of lindane, Kwell, is no longer on the market, but multiple generic brands of the product are available. Lindane is 67% insecticidal and 45% to 70% ovicidal. Lindane is neurotoxic and should not be used in pregnant women or in infants. It is applied to dry hair,

working in small quantities of water to create a good lather. The shampoo is left on for 4 minutes. The amount of shampoo prescribed for short hair is 1 oz, and for long hair, 2 oz. The shampoo should be rinsed well. Lindane has no residual activity against head lice.

Malathion

Malathion (Ovide) is a pediculicide that is available OTC in the United Kingdom and has been recently reapproved as a treatment for head lice in the United States. Malathion is an organophosphate agent that acts as a pediculicide by inhibiting cholinesterase activity in vivo. It is very effective against head lice, with 96% mortality in 30 minutes (Downs, Narayan, Stafford, & Coles, 2005). Some residual remains and can kill newly hatched lice for up to 7 days.

Ovide is applied to dry hair in an amount sufficient to wet the hair and scalp. Hair should be allowed to dry naturally. Hands should be washed with soap after applying Ovide. Ovide is left on for 8 to 12 hours and then shampooed. After rinsing, use a nit (or fine-tooth) comb to remove dead lice and eggs. If lice are present in 7 days, Ovide may be repeated.

With the use of Ovide, careful instruction should be given regarding the flammability of the product. Lotion and wet hair should not be exposed to open flames or electric heat sources, including hair dryers and electric curlers. Do not smoke while applying lotion or while hair is wet. Allow hair to dry naturally and to remain uncovered after application of Ovide lotion.

Benzoyl Alcohol

Benzoyl alcohol (Ulesfia) was the first non-neurotoxin treatment for head lice. The active ingredient in benzoyl alcohol appears to stun the breathing spiracles of the lice open, enabling the vehicle to penetrate the respiratory mechanism (spiracles) and leading to asphyxiation.

Benzoyl alcohol (Ulesfia lotion) is applied to dry hair, completely saturating the hair and scalp and left on for 10 minutes. The lotion is rinsed off well with water. Treatment with another application of Ulesfia should be repeated in 7 days.

Ivermectin

Ivermectin lotion 0.5% (Sklice) causes the death of parasites by binding with the chloride channels, causing increased permeability of the cell membrane to chloride ions and resulting in paralysis and death of the parasite. It is not ovicidal. Ivermectin lotion can be used in patients 6 months or older and is applied to dry hair and left on for 10 minutes. After 10 minutes, the lotion is rinsed off with water. Retreatment is usually not necessary.

Spinosad

Spinosad suspension 0.9% (Natroba) is derived from soil bacteria and is approved to treat head lice in patients age 4 years or older. Spinosad causes neuronal excitation, causing the lice to become paralyzed and die. It kills live lice and unhatched eggs. The suspension is applied to dry hair and left on for 10 minutes, then rinsed with warm water. Retreatment is usually not needed.

Nonpharmacological Treatments

With the growing problem of resistance and concern over exposing children to repeated doses of pediculicides, there are anecdotal reports about the success of various nonmedicated therapies. Popular and safe remedies are hair conditioner, mayonnaise (full-fat variety), olive oil, and petroleum jelly. It is thought that they asphyxiate the lice by blocking their breathing apparatus or immobilize them and affect their ability to feed. A patient who would like to try these treatments should apply a thick layer of the product and cover with a shower cap. The product is left on from 1 hour to overnight, then shampooed out.

The provider may be asked by a frustrated parent about other nonpharmacological remedies. It is important to give the parent clear guidelines regarding the use of unproven and possibly dangerous interventions, such as using lamp oil or other flammable liquid. Products developed for animals, such as dog lice shampoo, are also not advised.

Using a nit comb will assist in removing nits, which will decrease the number of lice hatching. Parents will need support as they treat the head lice, which can be frustrating.

Body Lice

The treatment for body lice is topical pediculicides: lindane and permethrin (CDC, 2013b). Body lice live on clothing and underwear and come to the skin only to feed, so it is important to instruct the patient to wash all clothing and bedding in hot water to kill lice and nits that are on the clothing.

Lindane

Lindane is applied to the total body as a cream or lotion and left on for 8 to 12 hours (overnight). The amount needed for an adult is 2 oz. Lindane should not be used in infants. It is Pregnancy Category B but should not be used as a first-line medication in pregnant patients because there have been no adequate studies in pregnant patients. If it is prescribed during pregnancy, then it should not be used more than twice during a pregnancy.

Permethrin

Permethrin 5% (Elimite) may be used for body lice. It is slightly safer in pregnant patients and can be used in children as young as 2 months. Permethrin is applied from head to toe and left on for 8 hours (overnight), then showered off.

Pubic Lice

Lindane

Pubic lice are treated with an application of lindane 1% cream, lotion, or shampoo. A thin layer of cream or lotion is applied to the hair and skin surrounding the pubic area and left on for 12 hours. If lindane shampoo is used, the shampoo is massaged into dry pubic hair and left on for 5 to 10 minutes. If axillary or thigh hair is also infested, then use the cream or lotion. Reapply in 7 days if there is evidence of live lice. Sexual partners should also be treated concurrently. Bedding and clothes should be washed.

Pyrethrins

Pubic lice may also be treated with pyrethrins, which are permethrin 1%, pyrethrin lotion, or shampoo. Advise the patient

to thoroughly saturate hair with lice medication. Leave medication on for 10 minutes then thoroughly rinse off with water. Dry off with a clean towel (CDC, 2013c). Reapply in 7 days if there is evidence of live lice.

Sexual partners should be treated concurrently, and bedding and clothes should also be washed. Infestation of eyelashes by pubic lice is treated with petrolatum (Vaseline) ointment applied 3 to 4 times daily for 8 to 10 days. Nits should be removed by hand from the pubic area, axillae, and eyelashes.

Scabies

When treating scabies, the provider may choose among permethrin, lindane, or crotamiton (Eurax, Crotan). Crotamiton lotion or cream is only approved for use in adults. The provider may choose the drug based on patient age and the toxicity of the agent. All family members should receive treatment, even if asymptomatic, because they may be in the incubation period (4 wk), and so all members of the household need treatment to prevent recurrence. Although one treatment is curative, the inflamed burrows and pruritus may last for up to 3 weeks after treatment with a scabicide. Families need to be educated regarding this prolonged healing phase. Patients should not be re-treated unless living mites are observed.

Permethrin

Permethrin 5% cream (Elimite, Acticin) is the drug of choice for the treatment of scabies in young children and pregnant women. It is 90% effective against the scabies mite and can be used in infants as young as 2 months old and in pregnant women. The cream is massaged into the skin from the neck to the soles of feet. It should be left on for 8 to 14 hours and then washed off in the shower. Infants require special application of permethrin to the scalp, temple, forehead, hands, and feet. One to 2 oz of permethrin per family member are prescribed.

Lindane

Lindane 1% lotion or cream is used for scabies in children older than 6 months and in nonpregnant adult patients. It is applied in a thin layer from the neck down to the soles of the feet and left on for 8 to 12 hours (overnight) and then washed off thoroughly. If there are crusted lesions present, a tepid bath should be taken prior to application to soften the lesions. The patient should dry the skin thoroughly before applying lindane. Two oz of lindane per family member are prescribed.

Crotamiton

Crotamiton (Eurax) has scabicidal and antipruritic actions. The exact mechanism of action is not known. Crotamiton lotion or cream is massaged into clean skin of the whole body from the chin down. Medication should be applied under fingernails because scabies may remain under nails. A second application is advised 24 hours later. The medication is washed off in a bath 48 hours after the last application.

Topical Corticosteroids

Topical corticosteroids are used after scabies treatment to treat pruritus and inflammation associated with the scabies mite. Hydrocortisone 1% or 2.5% or a stronger corticosteroid, if indicated, is applied to affected areas twice a day until lesions are healed.

Monitoring

Patients and families need to be monitored for appropriate use of the medication and for effectiveness of treatment. The patient should be monitored for sensitivity to the medication prescribed. If medications are used appropriately, there is rarely an adverse reaction from them, although skin irritation or sensitivity may occur.

Outcome Evaluation

If effective treatment has been implemented, then the lice or scabies should be eradicated. Before resistance is assumed, the provider should review how the patient or family used the medication and if environmental measures were adequate.

Patient Education

Patient and family education is the key to effective eradication of lice and scabies. In prescribing treatment for lice or scabies, the following are key areas of education that need to be covered:

1. Explanation of how the patient was most likely infected with the lice or scabies and how they can be passed on to other family members or, in the case of pubic lice, sexual partners. The incubation period and early symptoms should be discussed to identify other contacts that may be infected, such as school contacts.
2. Proper use of the prescribed medication and environmental measures that may be taken should be explained. Written instructions should also be provided.
3. Environmental measures that should be taken for lice and scabies include washing sheets, towels, clothing, and headgear worn recently in hot water and laundry soap. They need to be tumbled in a hot dryer for at least 20 minutes to kill any remaining nits or scabies that may be on the clothing. Clothing that cannot be put in a hot water wash must be dry-cleaned or pressed with a hot iron. Remind parents to wash coats and car seat covers if indicated. Items that cannot be washed or dry-cleaned, such as stuffed animals, should be placed in a plastic bag for 3 to 4 weeks; for scabies, only 4 days is needed. Brushes and combs should be washed in hot water and soaked for 1 hour in disinfectant such as Lysol or rubbing alcohol and then rinsed with hot water. Vacuuming play areas, floors, rugs, and furniture will pick up any nits or lice that may have been transferred to these areas. Parents/patients should be told that insecticidal sprays or bombs are not necessary.

ALOPECIA ANDROGENETICA (MALE PATTERN BALDNESS)

Alopecia androgenetica (male pattern baldness) affects men and some women. It involves hair loss from the frontal, vertex, and occipital regions of the scalp in men and thinning of the hair in the frontoparietal area or diffuse hair loss in women.

Pathophysiology

Common male pattern baldness is genetically determined. The process can begin at any time after puberty. There is not actual hair loss, but a conversion of thick hair to fine, unpigmented vellus hairs, which are poorly seen.

The process is androgen-dependent. A male who has a disorder that lowers testosterone production will never go bald, regardless of genetics; a woman who has a masculinizing disorder that raises androgen levels will develop classic male pattern baldness.

Goals of Treatment

A realistic goal is to achieve moderate to dense hair growth with continued use of topical minoxidil (Rogaine) for at least 4 months. If treating with finasteride (Propecia), a realistic goal would be increased hair growth after 3 months of continued treatment.

Rational Drug Selection

Alopecia androgenetica can be treated topically with minoxidil or systemically with finasteride. Choosing between the two medications can often be a simple task based on the patient profile. If the patient is also being treated for benign prostatic hypertrophy (BPH), then finasteride is the drug of choice. For a female patient, minoxidil is the only choice available.

Minoxidil

Minoxidil, the first drug approved by the FDA to treat male pattern baldness, is available OTC. The patient may be seeking a recommendation from the prescriber or self-prescribing and seeking information regarding its use. It is important to note that minoxidil does not treat balding of the frontoparietal areas in men, only in women. Minoxidil is effective in treating balding on the vertex of the scalp in men.

Minoxidil 2% topical solution is applied to the scalp twice daily for the entire length of treatment. The patient applies 1 mL directly to the affected area of the scalp (vertex area in men and frontoparietal area in women). The medication should be applied to a dry scalp. Patients should be instructed to wash their hands after using their fingers to rub the medication into the scalp. Twice-daily application for at least 4 months may be needed to obtain observable hair growth. If the medication is discontinued, the hair in the treated area will shed in 3 to 4 months.

Minoxidil should not be used by pregnant patients (Pregnancy Category C) or by children under age 18 years. Minoxidil is generally well tolerated. The topical solution contains alcohol and therefore may be irritating upon application. Patients may be sensitive to minoxidil and develop contact dermatitis. Minoxidil topical solution used as directed has minimal cardiac effects, but if large amounts are applied there is a potential for cardiac adverse effects.

Finasteride

Finasteride is a type II 5-alpha reductase–specific inhibitor that inhibits the conversion of testosterone into 5-alpha dihydrotestosterone (DHT). Development of alopecia androgenetica is dependent on DHT, as is the prostate gland. Finasteride is also used in treatment of BPH. Finasteride is effective in treating vertex and anterior midscalp baldness in men. Hair regrowth is noted after 3 months of daily treatment, with full treatment effect achieved after 6 to 12 months of use.

The dose of finasteride is 1 mg once daily with or without food. Continued use is necessary to have continued benefit. If treatment is stopped, hair will return to untreated levels within 12 months.

Finasteride should be prescribed with caution in patients with hepatic dysfunction because the drug is metabolized extensively in the liver. It causes a decrease in serum prostate specific antigen (PSA) levels, even in the presence of prostate cancer. It is Pregnancy Category X. Finasteride exposure during pregnancy, even in small quantities, may produce abnormalities of the external genitalia in male offspring. Pregnant women or a woman planning a pregnancy should not handle crushed tablets. Finasteride may be potentially absorbed from the semen. When a male patient's sexual partner is pregnant or may become pregnant, the patient should either avoid exposing his partner to his semen or discontinue finasteride. There is a small possibility (3% or less) of developing decreased libido, erectile dysfunction, or ejaculation disorder while taking finasteride.

Monitoring

The patient being treated for male pattern baldness needs to be monitored for effectiveness of treatment and adverse effects of the medication. The major adverse effect seen with minoxidil is dermatitis or sensitivity to the topical solution, which is treated by discontinuing the medication. Topical steroids should not be used concurrently with minoxidil. The patient should also be observed for possible cardiac adverse effects.

Finasteride is generally well tolerated, and adverse effects are usually mild. If the patient experiences sexual dysfunction, then the drug should be discontinued. The patient should be monitored for prostate cancer with a digital rectal examination and PSA levels because finasteride causes a low PSA level, even in the presence of prostate cancer. If the patient's sexual partner is of childbearing age, he should be warned about the severe effects that finasteride can have on the developing fetus.

Monitoring for use of birth control, with condoms used to prevent semen exposure, is necessary if there is a possibility of the patient's partner becoming pregnant.

Outcome Evaluation

It may take 3 to 4 months to determine if minoxidil or finasteride is effective. The provider should schedule a follow-up appointment with the patient for 3 to 4 months after beginning therapy to determine effectiveness.

Patient Education

In treating a patient with alopecia androgenetica, the following key points should be covered in patient education:

1. The pathophysiology and cause of male pattern baldness.
2. Realistic expectations of therapy, including what type of hair loss the drug treats; how long therapy takes until effects are noticed; that if treatment is stopped, hair shedding will occur; and that the new hair initially may be fine and almost colorless, but with continued treatment the hair should develop the same color and texture as the rest of the hair on the scalp.
3. Caution that the patient should take the medication exactly as prescribed or as indicated by the instructions if taking OTC minoxidil.
4. Adverse effects of the medications, especially the hazards to women from finasteride exposure.

DIABETES MELLITUS

Kathy Shaw • Marylou Robinson

Diabetes and the ensuing complications remain a major cause of morbidity and mortality in the United States and around the world. According to the National Diabetes Fact Sheet, 29.1 million adults and children have diabetes (Centers for Disease Control [CDC], 2014). This number represents 9.3% of the U.S. population; 21 million people are diagnosed while 8.1 million remain undiagnosed. The prevalence of diabetes mellitus (DM) in the United States is growing year by year with many more young people impacted than ever before. Approximately 37% of U.S. adults have pre-diabetes and that number is growing (CDC, 2014).

The annual cost of DM care in 2012 was estimated to be more than $245 billion, with $176 billion attributed to direct medical care and $69 billion attributed to indirect care, which includes work loss, disability, and premature mortality (CDC, 2014). DM is the leading cause of blindness, lower extremity amputations, and end-stage renal disease, and a major cause of heart disease and stroke. Diabetes is the seventh leading cause of death in the United States, but that number may be underreported.

Diabetes mellitus is a chronic, progressive metabolic disorder from abnormalities in glucose, protein, and fat metabolism, which results in hyperglycemia. Diabetes is categorized into four clinical classes:

- Type 1 diabetes, which results from beta-cell destruction, leading to absolute insulin deficiency
- Type 2 diabetes, which results from a progressive insulin secretory defect or insulin resistance

- Diabetes due to other causes, e.g., genetic defects in beta-cell function, genetic defects in insulin action, diseases of the exocrine pancreas (such as cystic fibrosis), and drug- or chemical-induced causes (such as in the treatment of HIV/AIDS or after organ transplantation)
- Gestational diabetes mellitus (GDM), which is diagnosed during pregnancy but is not overt after delivery (American Diabetes Association [ADA], 2015).

Some patients cannot be clearly classified as having type 1 or type 2. Clinical presentation and disease progression may vary considerably in both types and diagnosis may be difficult for some individuals. Presentation and progression differ in age of onset, genetic predisposition, treatment options, and complications. Table 33-1 provides a brief comparison of the differences between type 1 and type 2, the two major types. This chapter focuses on the pharmacological management of type 1 and type 2 DM. Gestational diabetes, which requires consultation with an obstetrical provider, is briefly mentioned.

Diabetes mellitus is clearly interrelated with hyperlipidemia, hypertension, and coronary heart disease. Because these disorders go hand in hand with DM, treatment protocols now include management of all these disorders as part of diabetes management. This chapter discusses these disorders as they relate to diabetes mellitus.

PATHOPHYSIOLOGY

Type 1 Diabetes Mellitus

Several pathogenic processes are involved in the development of type 1 diabetes mellitus. Type 1, which accounts for 5% to 10% of all persons with diabetes, results from an autoimmune destruction of the beta cells of the islet of Langerhans of the pancreas and leads to absolute insulin deficiency (Bardsley & Magee, 2011). Type 1 was previously known as juvenile diabetes and insulin-dependent diabetes. Risk factors can be genetic, autoimmune, and environmental. Seventy percent of type 1 cases are diagnosed before the age of 30, although type 1 can occur at any age (Bardsley & Magee, 2011).

Type 1 diabetes has two subtypes: immune mediated (autoimmune disease) and nonimmune (idiopathic). Active autoimmunity directed at the pancreatic beta cells and their products are the first identification of type 1. Autoantibodies to

Table 33–1 Comparison of Type 1 and Type 2 Diabetes Mellitus

Characteristic	Type 1	Type 2
Age at onset	Usually during childhood or adolescence, but can occur at any age, even in eighth and ninth decades	Usually after age 40 and risk for it increases with age, obesity, and lack of physical activity
Type of onset	Signs and symptoms abrupt, but disease process may be present for years	Insidious and gradual
Genetic susceptibility	HLA-DR3 and DR4 and others; 50% concordance in monozygotic twins	Frequent genetic background, but no relation to HLA; almost 100% concordance in monozygotic twins
Environmental factors	Viruses, toxins	Obesity, nutrition; more common in women with prior gestational diabetes and in patients with hypertension or hyperlipidemia
Etiology	Unknown; postulated causes include heredity, autoimmune disease, and viral infections	Unknown; heredity is highly associated
Islet cell antibody and pancreatic cell-mediated immunity	Present at onset	Absent
Endogenous insulin	Secretion is markedly diminished early in disease; may be totally absent later	Levels may be low (insulin deficiency), normal, or high (insulin resistance)
Nutritional status	Thin, catabolic state	Obesity is common
Symptoms	Polydipsia, polyphagia, polyuria, fatigue, and weight loss	May be asymptomatic; polydipsia or polyuria may be present
Ketosis	At onset or during insulin deficiency	Resistant except during infection or stress
Control of blood sugars	Often difficult with wide glucose fluctuations	Variable
Dietary management	Essential	Essential; sometimes controlled with diet and exercise
Insulin	Insulin therapy required	Usually required as disease progresses
Metformin, sulfonylureas, and other oral agents	Not efficacious	Efficacious
Complications	Occur in a majority of patients after >5 yr, but reduced incidence for those with good control	Frequent, but reduced incidence for those with good control

tyrosine phosphatases IA-2 and IA-2 beta to islet cells, to insulin, and to glutamic acid decarboxylase (GAD65) are seen in 85% to 90% of patients with the immune-related subtype of type 1 diabetes. A small percentage (10% to 15%) of patients with type 1 DM have no known etiology (idiopathic). Most patients with idiopathic type 1 DM are African American or Asian American. This chapter focuses on the immune-related form.

Abnormalities at six genetic loci associated with type 1 DM have been identified to date. The most common is associated with mutation of the hepatic transcription factor (hepatocyte nuclear factor [HNF]-1 alpha) on chromosome 12. A second form involves the glucokinase gene on chromosome 7p. The latter form results in a defective glucokinase molecule. Because glucokinase converts glucose to glucose-6-phosphate, which then stimulates insulin secretion, defects in this gene result in increased levels of glucose needed to elicit normal levels of insulin secretion. Less common forms result from mutations in other transcription factors: HNF-4 alpha, insulin promoter factor (IPF)-1, and NeuroD-1. Genetic mutations that result in the inability to convert pro-insulin to insulin and some that affect insulin action rather than production have also been identified.

Susceptibility to type has been linked to these genetic mutations. Current theories maintain that islet-cell destruction occurs predominantly in persons who are genetically susceptible. When a person with the appropriate genetic characteristics is exposed to a trigger, the beta cells are destroyed directly or when an autoimmune process is triggered, which in turn destroys the beta cells. Environmental factors such as toxins, food antigens, and viral infections are suspected to be responsible for the induction of type 1 (Bardsley & Magee, 2011).

Type 1 has a long preclinical period. Signs and symptoms and clinical presentation of type 1 are abrupt, although a decline in insulin secretion begins long before the symptoms develop, possibly as long as 9 years before clinical presentation (Bardsley & Magee, 2011). Research has demonstrated the presence of islet-cell autoantibodies (ICA) for years before the occurrence of symptoms. ICAs precede beta cell deficiency and have been found in 85% to 90% of type 1 diabetes at the time of onset of clinical symptoms. Autoantibodies against insulin (IAA) have also been found. ICAs and IAA are probably the result of the beta cell

On The Horizon **CURE FOR TYPE I DM?**

Two recent research endeavors are exploring the use of older non-diabetic medications to intervene in early cases of DM I. Mice given verapamil essentially eradicated a protein that causes the death of beta cells. Trials funded by the Juvenile Diabetes Foundation with humans are planned to test this "cure" of type 1 DM (Shalev, 2014). Other researchers at Massachusetts General are exploring an interesting positive effect on pancreas recovery after administration of the old BCG vaccine originally developed to assist with TB care (Faustman et al, 2012).

destruction rather than its cause, and they tend to disappear with time.

The clinical difference between type 1 and type 2 is not always clear; there can be similarities between both types. Latent autoimmune diabetes in adults (LADA) is a slow, progressive form of type 1 that may be confused with type 2 and accounts for approximately 10% of older persons who require insulin. In LADA, there is a presence of autoantibodies that suggest it is an autoimmune disorder like type 1. However, there are differences such as T-cell reactivity, autoantibody clustering, and genetic susceptibility, which suggest different disease processes. In LADA, significant insulin resistance is present, which causes earlier beta cell destruction. Persons with LADA are usually over 35 years of age, are not obese, and require oral agents and progression to insulin within a relatively short period of time. Clinical presentation includes weight loss, unstable blood glucose, propensity for ketosis, and low C-peptide reserves (Bardsley & Magee, 2011).

Before hyperglycemia occurs, 80% to 90% of the function of insulin-secreting beta cells must be lost. DM may be precipitated by acute illness or stress at any time during the progressive decline in beta cell function, thus increasing the insulin demand of the damaged islet cells. Beta cell abnormalities are present long before the acute clinical onset of type 1 diabetes, and the event that precipitates the acute onset of symptoms may be far removed from the event that initiates the pathology.

Regardless of the cause, considerable evidence suggests that the pathology is probably disequilibrium between the relative excess production of glucagon by the pancreatic A cells and the lack of insulin produced by the beta cells. This ratio of insulin to glucagon in the portal vein, not the concentration of each hormone, controls hepatic glucose and fat metabolism, two major problems in type 1 diabetes. The recognition that the totality of the metabolic pathology is a factor of both of these hormones is leading to a different approach to diabetes management. Figure 33-1 depicts the pathological cause of the various symptoms of type 1 diabetes.

Due to lack of insulin production by the beta cells of the islet of Langerhans, treatment requires insulin replacement. If the disease progresses without treatment, diabetic ketoacidosis (DKA), weight loss, muscle wasting, and death may occur. Once treatment is initiated, the patient may enter temporary partial remission, despite the continued destruction of beta cells ("honeymoon phase"). Beta cell destruction eventually reaches a point at which hyperglycemia occurs again, and insulin therapy is required throughout the rest of the disease process. The assumption that C-peptides, an indication of native insulin production, would not be found in type 1 patients is being undermined by a report that up to one-third of type 1 patients have a small, clinically unimportant production of insulin (Wang, Lovejoy & Faustman, 2012).

Type 2 Diabetes Mellitus

Type 2 diabetes is much more common than type 1, affecting approximately 90% to 95% of persons with diabetes. Prevalence

Figure 33–1. Pathophysiology of type 1 diabetes.

of type 2 varies in the United States by ethnic group, with a higher frequency in Native Americans, Asian Americans, Latinos, Pacific Islanders, and African Americans (ADA, 2015). Other risk factors include obesity, sedentary lifestyle, hypertension, dyslipidemias, family history, gestational history, and age. Genetics have a strong influence, and a locus has been found on chromosome arm 7q that may be related to insulin resistance, one underlying alteration in type 2 diabetes (Bloomgarden, 2003). The offspring of parents who both have type 2 DM have a 15% chance of developing DM. Although there is disparity in incidence between ethnic groups for having DM, there is no racial disparity in rates of pre-diabetes that progresses to DM (Dagogo-Jack, Edeoga, Ebenibo, Nyenwe, & Wan, 2014). This means that without regard to genetic background, the risk of developing full DM is an equal to 11% per year for anyone diagnosed with pre-diabetes.

The pathogenesis of type 2 diabetes is complex and multifactorial, with symptoms that can vary greatly across patients. Plasma insulin levels in type 2 diabetes may be low, normal, or high. Although the specific etiology of type 2 is unknown, autoimmune destruction of beta cells does not occur. The main physiological alteration in type 2 DM is insulin resistance and/or decreased insulin secretion. Insulin resistance is a suboptimal response of sensitivity to insulin, especially in the liver, muscle, and adipose tissue. The result is an increased rate of endogenous glucose production secondary to increased glucagon levels. The gastrointestinal system also plays a role in regulating the secretion of insulin. Incretin peptides secreted from endocrine cells in the intestinal tract are released in response to the ingestion of food. Glucagon-like peptide-1 (GLP-1) and alterations in levels of the regulatory enzyme dipeptidyl peptidase-4 (DPP-4), which impacts the presence and duration of GLP-action, are recognized as factors in type

2 DM. GLP-1 is deficient in people with DM and pre-DM and contributes to the excessive hepatic glucose production, lack of postprandial glucagon suppression, and uncontrolled eating (Bardsley & Magee, 2011). Type 2 DM causes few and nonspecific pancreatic changes.

Many years of compensatory hyperinsulinemia may occur before the onset of clinical symptoms of diabetes. Eventually, the beta cell responsiveness to glucose stimulus diminishes and hyperglycemia prevails. Adipose tissue does not use glucose in response to insulin, resulting in obesity and a large amount of fat in the bloodstream, which results in increased plasma FFA levels. Increased visceral fat shows an inverse relationship with insulin sensitivity. Many people with type 2 DM are obese; obesity triples the risk for insulin resistance. Patients who are not obese by traditional weight standards may have an increased percentage of body fat distributed predominantly in the abdominal region. The gradual onset and progression of type 2 diabetes allows patients to adapt to the symptoms without realizing that the disease process is producing them.

Insulin resistance has also been linked to three other important disorders: hyperlipidemia, hypertension, and coronary artery disease. The Framingham Offspring Study (Bloomgarden, 2003) was among the first to suggest a central metabolic syndrome with high triglyceride levels, low high-density lipoprotein (HDL) levels, obesity, and hyperglycemia, which was also associated with hypertension. Because both dyslipidemia and hypertension are linked with atherogenesis, DM is an independent risk factor for coronary heart disease. Individuals with any one of these disorders should be screened for the others. Screening is discussed below.

Insulin resistance and the metabolic syndrome are also associated with a prothrombotic state that contributes to the vascular complications seen in this disorder. Insulin has a

direct antiplatelet effect, and loss of insulin results in increased adhesiveness and exaggerated aggregation and thrombus generation (Randriamboavonjy & Fleming, 2009).

Because an endogenous insulin supply exists early in the disease state, insulin may not be required initially. In older protocols, insulin was used later in the disease process or during acute illness or stress. However, current guidelines suggest that insulin may have a role earlier in the disease process, especially in light of the prevention of the three complications: dyslipidemia, hypertension, and atherogenesis. Oral hypoglycemic agents are also effective in addressing one or more of the metabolic defects in type 2 DM.

Maturity onset diabetes of the young (MODY) has a monogenetic defect in beta cell function that is inherited in an autosomal-dominant pattern, resulting in impaired insulin secretion but no defects in insulin action. It usually occurs in adolescence or early adulthood and accounts for approximately 1% to 5% percent of all diabetes. Persons with MODY are not usually overweight and do not have the features of metabolic syndrome that commonly occur in type 2 DM. MODY can often be treated with oral agents (Bardsley & Magee, 2011).

Complications

Long-term complications of all types of DM are based on target organ damage from micro- and macrovascular involvement. Microvascular involvement affects the eyes, heart, kidneys, and nervous system. Complications such as retinopathy with potential loss of vision, nephropathy leading to renal failure, peripheral neuropathy with risk of foot ulcers, amputation, and Charcot's joint and autonomic neuropathy with gastrointestinal, genitourinary, and cardiovascular symptoms and sexual dysfunction may occur. Macrovascular complications from DM occur in the form of atherosclerotic cardiovascular, peripheral vascular, and cerebrovascular diseases and increase the risk for hypertension, abnormalities of lipid metabolism, abnormalities of platelet function, and periodontal disease. The management of each of these complications is discussed below.

Pre-Diabetes

Individuals whose glucose levels do not meet the criteria for diabetes but are too high to be considered normal are classified as having pre-diabetes. These patients have impaired glucose tolerance (IGT) or impaired fasting glucose (IFG). Patients with these two disorders are at risk for diabetes and cardiovascular disease and may have insulin-resistance syndrome. The United States Diabetes Prevention Program (USDPP) showed that lifestyle modification and the administration of metformin (in adults) may prevent or delay the development of type 2 diabetes in patients with pre-diabetes (U.S. Diabetes Prevention Program Research Group, 2002; 2003).

Although discussion and research continue concerning the management of pre-diabetes, the current recommendations specify lifestyle change, which includes modest weight loss by increasing physical activity and making dietary changes and effectively managing known risk factors for DM and the complications. This therapy is more effective in the pre-diabetic state than after the disease state is reached. The biggest impact comes from diet and exercise even without weight loss (Senechal, Slaght, Bharti, & Bouchard, 2014). The current Standards of Medical Care in Diabetes also recommends that metformin be considered for those at high risk for developing diabetes, who are obese (BMI > 35) and under 60 years of age (ADA, 2015).

Diagnosis and Screening

Diagnostic Criteria for Diabetes and Pre-Diabetes

The diagnostic criteria for diabetes mellitus and pre-diabetes are shown in Table 33-2. There are four tests used for diagnosis, and the tests should be confirmed on a subsequent day, unless there are overt clinical symptoms. It is preferable to confirm with the same test or one that is considered more predictive; fasting plasma glucose (FPG) levels are the most reliable. If a repeated test is below the diagnostic criteria, the test should be repeated in 3 to 6 months (ADA, 2015). The criteria for such testing are listed in Table 33-3.

Table 33–2 Diagnostic Criteria for Diabetes Mellitus and Pre-Diabetes

Diagnostic Category	Diagnostic Criteria
Diabetes mellitus	Acute symptoms of diabetes plus casual plasma glucose concentration ≥200 mg/dL. *Casual* is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes are polyuria, polydipsia, and unexplained weight loss.
	Fasting plasma glucose ≥126 mg/dL. *Fasting* is defined as no caloric intake for at least 8 h.
	2-h postload plasma glucose in an oral glucose tolerance test ≥200 mg/dL. The test uses a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.
	Hb A1c ≥6.5%
Pre-diabetes	Fasting plasma glucose 100–125 mg/dL (IFG) *or*
	plasma glucose 140–199 mg/dL (IGT) 2 hr post-ingestion of standard glucose load (75 g) *or*
	Hb A1c 5.7%–6.4%

IFG = impaired fasting glucose; IGT = impaired glucose tolerance.

Table 33–3 **Criteria for Testing Asymptomatic Adults for Diabetes**

Individuals ≥45 yr and who have a BMI ≥25 kg/m² should be tested. If normal, the test should be repeated at 3 yr intervals.
Individuals <45 yr and who have a BMI ≥25 kg/m² and have additional risk factors should have more frequent testing.
Additional risk factors are the following: • Physically inactive • First-degree relative with diabetes • Members of high-risk ethnic group (African American, Hispanic, Native American, Asian American, Pacific Islander) • Delivered a baby weighing >9 lb or previously diagnosed with GDM • Hypertensive (B/P ≥140/90 mm Hg) • HDL cholesterol ≤35 mg/dL and/or triglyceride level ≥250 mg/dL • Have polycystic ovary syndrome (PCOS) • IGT or IFG on previous testing • Have other clinical conditions associated with insulin resistance (PCOS or acanthosis nigricans) • History of CVD

Screening Recommendations for Diabetes and Pre-Diabetes

Screening recommendations vary by specialty groups, but the most respected and used recommendations in the United States come from the ADA and therefore will be used here. The ADA (2015) recommends testing to detect pre-diabetes and type 2 diabetes in asymptomatic adults of any age who are overweight or obese (body mass index [BMI] greater than 25 kg/m²) and who have one or more additional risk factors for diabetes. In those without these risk factors, testing should begin at age 45 years. The Hb A1c, FPG, or 2 h 75 g OGTT (oral glucose tolerance test) are appropriate to test for diabetes or pre-diabetes (ADA, 2015).

Evidence from type 1 prevention studies suggests that measurement of islet autoantibodies identifies individuals who are at risk for developing type 1 DM. High-risk individuals, such as those with transient hyperglycemia or those who have relatives with type 1 diabetes, may be appropriate for this type of testing (ADA, 2015). Widespread screening of symptomatic low-risk individuals is not recommended.

In 2010, the ADA adopted the use of the Hb A1c with a threshold of ≥6.5% for diagnosis, provided the test is performed using a method that is certified by the National Glycohemoglobin Standardization Program (NGSP) and standardized or traceable to the Diabetes Control and Complications Trial (DCCT) reference assay. Point-of-care Hb A1c assays, for which proficiency testing is not mandated, are not sufficiently accurate at this time to use for diagnostic purposes (ADA, 2015). FPG or Hb A1c can be used for screening all age groups. The OGTT is impractical and expensive for general screening purposes; however, it is used to diagnose GDM.

Diagnostic Criteria for Pregnant Women

The ADA (2015) provides diagnostic screening criteria for pregnant women:

• Screen for undiagnosed type 2 diabetes at the first prenatal visit in those with risk factors, using standard diagnostic criteria.
• In pregnant women not previously known to have diabetes, screen for GDM at 24–28 weeks' gestation, using a 75 g 2 h OGTT and the diagnostic cut points as outlined below:
  • At 24–28 weeks' gestation in women not previously diagnosed with overt diabetes, perform a 75 g OGTT, with plasma glucose measurement fasting and at 1 and 2 hr.
  • The OGTT should be performed in the morning after an overnight fast of at least 8 hr.
• Screen women with GDM for persistent diabetes at 6–12 weeks' postpartum, using the OGTT and nonpregnant criteria (ADA, 2015).
• Women with a history of GDM should have lifelong screening for the development of diabetes or pre-diabetes at least every 3 years.
• Women with a history of GDM found to have pre-diabetes should receive lifestyle interventions and/or metformin to prevent DM.
• GDM diagnosis is made when any of the following plasma glucose values are exceeded: fasting ≥92 mg/dL, 1 h ≥180 mg/dL, or 2 h ≥153 mg/dL.

Screening Criteria for Children

The incidence of type 2 diabetes in adolescents has increased dramatically in the past 10 years, especially in minority populations. The ADA (2015) recommends testing asymptomatic children who meet the following criteria:

• Overweight (BMI >85th percentile for age and sex, weight for height >85th percentile, or weight >120% of ideal for height), plus any two of the following risk factors:
• Family history of type 2 diabetes in first- or second-degree relative
• Race/ethnicity (Native American, African American, Latino, Asian American, Pacific Islander)
• Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, polycystic ovary syndrome, small-for-gestational- age birth weight)
• Maternal history of diabetes or GDM during the child's gestation

Such testing should begin at age 10 years and occur every 3 years thereafter.

PHARMACODYNAMICS

General Diabetes Management and Glycemic Control

The treatment goals for both type 1 and type 2 DM are near-normal glucose levels. Recent studies show that tighter glycemic control can lead to higher mortality rates in some populations, especially older adults, those with comorbidities, and those who have preexisting complications. The current guidelines recommend an individualized approach that is both acceptable to the patient and provider while preventing both acute complications, such as hypoglycemia, and the development and progression of chronic complications from DM.

Insulin

Insulin is a hormone produced in the beta cells of the isles of Langerhans in the pancreas that is released by stimulation from an elevated blood glucose level (BGL). Administration of the exogenous insulin produces the same effect as the naturally occurring hormone. Currently, all insulin is manufactured to be chemically identical to human insulin through DNA technology.

Insulin lowers blood glucose levels by the following mechanisms (Sisson & Cornell, 2011):

- Promotes protein synthesis by increasing amino acid transport into cells
- Stimulates glucose entry into cells as energy source
- Increases storage of glucose as glycogen (glycogenesis) in muscle and liver cells
- Inhibits glucose production in liver and muscle cells (glycogenolysis)
- Enhances fat storage (lipogenosis) and prevents mobilization of fat for energy (lipolysis and ketogenesis)
- Inhibits glucose formation from noncarbohydrate sources, such as amino acids (gluconeogenesis)

The action of insulin is discussed in greater detail in Chapter 21. In summary, insulin receptors "open the gate" to allow utilization of glucose by the cells. The total number of insulin receptors can be mitigated by such factors as obesity and long-standing hyperglycemia, which may explain why weight loss can be a significant factor in diabetes management.

Current treatment recommendations for insulin indicate a regimen that most closely mimics endogenous insulin production; this regimen includes basal insulin, once or twice daily, and bolus insulin before meals or to correct hyperglycemia. Insulin regimens should be designed with basal, nutritional, correction elements, and work and activity schedules to achieve and maintain glucose control. Insulin preparations are categorized by onset, duration, and peak of action following subcutaneous injection: rapid, fast, intermediate, and long-acting. There are also various premixed combinations of intermediate-acting preparations with short- or rapid-acting preparations. See Table 33-4 and Chapter 21.

The two long-acting insulin analogs, glargine and detemir, are important breakthroughs in DM management and treatment. They can be used in conjunction with oral medications in type 2 or with rapid- or fast-acting insulin in both type 1 and type 2. Both provide peakless basal coverage but vary greatly in terms of how they work. Though marketed as 24 hour insulins, they do not fully meet that expectation. Until wider dissemination of a new class of ultra-long insulins, there are no better alternatives.

Glargine can be given at bedtime or at any time of day but should be given consistently at the same time each day. It cannot be mixed in the same syringe with other insulin nor can the syringe contain any other medication residue. Insulin detemir has a prolonged absorption and provides a more consistent 24-hour basal effect due to its albumin binding effect in the plasma and near the injection site. Insulin detemir cannot be diluted or mixed with any other insulin preparations.

Although insulin has been the drug of choice in managing diabetes in pregnancy, approaches to therapy vary greatly to include the use of metformin and glyburide. Women who have preexisting DM will have increased insulin requirements and should be treated aggressively. Women who have GDM and are obese will usually need higher insulin doses due to insulin resistance. The Endocrine Society now calls for all women who have had GDM to be tested for pre-diabetes

Table 33–4 Common Insulin Types, Onset, Peak, and Duration

Type	Insulin	Onset	Peak	Duration
Rapid-Acting	Humalog (Lispro) Novalog (Aspart) Apidra (Glulisine)	5–30 min	0.5 h–3 h	3–4 h
Short-Acting	Regular (Humulin R, Novalin R)	30–60 min	2–4 h	3–7 h
Intermediate-Acting	Isophane(NPH, Humulin N)	1–2 h	4–10 h	10–16 h
Long-Acting	Lantus (Glargine) Levimir (Detemir)	1–2 h 1–2 h	None	20–24 h 20–24 h
Fixed Combination	70/30 (NPH/regular ratio) 50/50 (NPH/regular ratio) 75/25 (NPH/lispro) 70/30 (NPH/aspart)	30–60 min 30–60 min 5–15 min 5–15 min	Dual	10–16 h

On The Horizon

ULTRA-LONG-ACTING INSULIN

An ultra-long-acting basal insulin analogue, insulin degludec, has just been approved. Duration of action nears 42 hours, so it might have an irregular dosing schedule. It is thought to have lower rates of nocturnal hypoglycemia compared to glargine. Its higher cost will be an issue. There are concerns about adverse CV effects.

CLINICAL PEARL

Rules for Fine-Tuning Insulin Doses

- The correction factor (CF) and insulin: carbohydrate ratio (I:C) for patients with either type 1 or 2 taking insulin.
- The rule of 1,500 enables the provider to find the CF or how much 1 unit of insulin will drop blood sugar for high blood glucose levels (usually greater than 140 to 150). First, calculate the total daily dose (TDD) of insulin as basal + bolus—about 50% of each. Then divide 1,500 by the TDD. For example, 1,500 divided by 30 units per day of insulin equals 50. One unit of rapid-acting insulin will drop glucose 50 points.
- The rule of 500 enables the provider to find the I:C ratio. Divide 500 by TDD. For example, 500 divided by 30 units per day of insulin equals 16.7. One unit will cover 16 to 17 g of carbohydrate (CHO). For ease of use, round down to 1 unit:15 g.

or continued diabetes with an OGTT 6 to 12 weeks after delivery (Blumer et al, 2013).

Various insulin regimens can be used for type 1, including short-acting (SAI) or rapid-acting insulin (RAI) boluses combined with intermediate-acting (IAI) or long-acting insulin (LAI) for basal. This can also be achieved with the premixed preparations.

Because of progressive beta cell dysfunction, insulin will usually be required in type 2 after a period of time. It is theorized that earlier use may "rest" the pancreas and reduce the intensity of the progression of DM, but this is not yet established as fact. Administration of basal insulin once or twice daily is preferred initially, either with IAI or LAI, to achieve desired normal glycemic patterns throughout the day and night. Glargine and detemir may have less nocturnal hypoglyemica than NPH; detemir may have slightly less weight gain. Both of the LAI are more expensive than NPH, which may be an important consideration (Inzucchi et al, 2012).

Providers should be aware of issues related to insulin use that can affect initiation, use, and adherence. Insulin is a necessary treatment for glucose toxicity and is the necessary replacement for insulin deficiency when oral agents alone become ineffective. One of the greatest obstacles to insulin use is patient and provider resistance. This inertia, or lack of intensification of treatment when warranted, is widely documented and must be overcome in order to provide optimal treatment for patients. In a systematic review of barriers to insulin progression in insulin-naïve and insulin-experienced users, Polinski and colleagues (2013) found that patient knowledge and experience with insulin were important attributes that impacted attitudes and willingness to intensify treatment with insulin. Only two articles on physician barriers were included in this review, but the consistent themes were the lack of knowledge, experience, and resources needed to provide insulin progression. Interestingly, providers overestimate patient resistance to injectable medication use (Peyrot et al, 2005).

Oral Agents

There are many pharmacological treatment options for type 2 DM. Oral agents are only effective for type 2 and most act on different aspects of the metabolic defects. Monotherapy with any of the agents will result in the reduction of Hb A1c by 0.5% to 2.0%. Combination therapy, either with two or more oral agents or an oral agent and insulin, results in a further decrease in the Hb A1c level (Sisson & Cornell, 2011). Insulin is the preferred treatment for pregnant women, but metformin or glyburide may also be used. Primary care providers should coordinate start of medications with an OB or endocrine specialist. Metformin is the only U.S. Food and Drug Administration [FDA] oral agent approved for use in children. There are multiple classes of orally administered drugs used for type 2, which have been discussed in Chapter 21, but are summarized here.

Biguanides

Biguanides are not considered hypoglycemic drugs; their pharmacological action does not increase insulin release from the pancreas or increase hypoglycemic effects. They are indicated as the initial drug of choice or as an adjunct in combination therapy. Metformin is the only drug in this class used clinically in the United States and is the only FDA-approved oral drug for use in children 10 years or older.

Metformin works primarily by decreasing hepatic glucose production by decreasing gluconeogenesis. It also increases peripheral glucose uptake and utilization, improves hepatic response to blood glucose levels so that the liver produces appropriate amounts of glucose, and decreases intestinal absorption of glucose. Insulin production is necessary for metformin to be effective. In contrast to some of the other drugs, patients taking metformin do not gain weight. In fact, they often lose weight. Because obesity is a major factor in the pathogenesis of type 2 diabetes, weight loss is an important action of this drug. Initial metformin therapy is indicated for type 2 DM with dyslipidemia, obesity, insulin resistance, and an elevated FPG. It can reduce Hb A1c by 1.5% to 2%.

Therapy is initiated at a low dose with slow titration to achieve desired glycemic control. The lowest dose is 500 mg once or twice daily, and the maximum dose is 2,550 mg. To reduce the gastrointestinal (GI) adverse reactions that are common with metformin, the dose is titrated up from 500 mg taken once or twice daily to the maximum effective dose. Beneficial side effects include weight loss, reduction

in LDL-C, total cholesterol, and triglycerides, and an increase in HDL-C. Gastrointestinal disturbances subside over time.

The Diabetes Prevention Program Research Group (2002) tested metformin and lifestyle modifications as methods for preventing the conversion of pre-diabetes to type 2 diabetes. Lifestyle interventions reduced the incidence of conversion by 58% and metformin by 31%. The cost effectiveness of the intervention was also investigated, and both metformin and lifestyle interventions were cost-effective across subjects, regardless of age, ethnicity, or gender and affordable in routine clinical practice. Therefore, the use of metformin is recommended for the prevention of the development of diabetes in patients with diagnosed pre-diabetes.

Sulfonylureas

Sulfonylureas increase endogenous insulin secretion by the beta cells and may improve the binding between insulin and insulin receptors or increase the number of receptors. Hypoglycemic effects appear to be due to increased endogenous insulin production and to improved beta cell sensitivity to blood glucose levels or suppression of glucose release by the liver. Sulfonylureas were the first class used to treat type 2 DM, but they are now considered secondary agents partially due to their hypoglycemic risks.

Sulfonylureas are absorbed quickly and completely and are not affected by food. They can reduce Hb A1c by 1.5% to 2%. Dosing should be started at the lowest dose and titrated as needed. Sulfonylureas are Pregnancy Category C with the exception of glyburide. A person who is not overweight and who does not have dyslipidemia is a good candidate for a sulfonylurea. Common side effects include hypoglycemia and weight gain. Less common side effects include skin rashes and mild GI disturbances. A newer concern is the link with additional risk for hypoglycemia with concurrent use of antibiotics (clarithromycin, levofloxacin, sulfamethoxazole-trimethoprim, metronidazole, and ciprofloxacin) (Parekh et al, 2014).

Alpha-Glucosidase Inhibitors

Alpha-glucosidase inhibitors do not act directly on any of the defects in metabolism seen in type 2 diabetes mellitus. They competitively inhibit and delay the absorption of complex CHO from the small bowel and lower BG levels after meals. Alpha-glucosidase inhibitors have no inhibitory activity against lactase and do not induce lactose intolerance. They are not associated with weight gain and diminish the weight-increasing effects of sulfonylureas when given in combination with them. Alpha-glucosidase inhibitor activity is effective on any CHO food intake, including liquid diets taken via a nasogastric tube. They have a limited role as adjunct therapy except in individuals who cannot take metformin. They can reduce Hb A1C by 0.5% to 1%.

Thiazolidinediones

Thiazolidinediones (TZD) are oral antihyperglycemic drugs that are best classified as insulin sensitizers. Pioglitazone

(Actos) and rosiglitazone (Avandia) are the only FDA-approved agents. Thiazolidinediones activate a nuclear receptor that regulates gene transcription, resulting in increased utilization of available insulin by the liver and muscle cells and adipose tissue. In addition, these drugs reduce hepatic glucose production so that the liver produces appropriate amounts of glucagon. TZDs are recommended in the guidelines for the two- or three-drug combinations. These drugs, especially rosiglitazone, should be used cautiously because of the potential for cardiovascular problems. The 2011 FDA imposed restriction on prescribing rosiglitazone-containing drugs has been lifted, but the requirement for close monitoring of heart failure signs and symptoms associated with a class effect of fluid retention remains (FDA, 2011). The fear of bladder cancer associated with these medications has not demonstrated a causal effect (Levin et al, 2015). There is a higher risk of bladder cancer in North American and European diabetic patients. There is not a dose response to cancer incidence. These agents can reduce Hb A1C by 1.5% to 2%.

Meglitinides

The meglitinides have a different mechanism of action from any of the other drugs used to treat type 2 DM. The meglitinides are short-acting insulin secretagogues. Two drugs, repaglinide (Prandin) and nateglinide (Starlix) are in this class. They work by closing the adenosine triphosphate (ATP)–dependent potassium channels in the beta cell membrane by binding at specific receptor sites. This potassium channel blockade depolarizes the beta cell and leads to an opening of calcium channels. The resultant influx of calcium increases the secretion of insulin. Because their time in the plasma is less than 2 hours, the effect is very short. Plasma insulin levels fall to baseline by 4 hours after dosing. The end result of their stimulation of insulin secretion is a lowering in postprandial blood glucose levels. To achieve this effect, they are dosed 3 times daily no more than 20 minutes before meals. They do not directly affect fasting blood glucose levels or any of the other defects in metabolism seen in type 2 diabetes. They are most useful in patients whose primary glucose alteration is postprandial hyperglycemia. These drugs are not commonly used because adherence is difficult, GI side effects can be distressing, and they are expensive. They can reduce Hb A1c by 0.5% to 1%.

Selective Sodium Glucose Co-transporter 2 (SGLT-2)

Canagliflozin (Invokana), dapgliflozin (Farxiga), and empagliflozin (Jardiance) inhibit renal SGLT-2 action, thereby blocking about 90% of the reabsorption of glucose in the kidneys and promoting excretion of excess glucose in the urine. This translates to nearly 250 calories a day. If blood glucose is high, then more is excreted in the urine. There is an osmotic fluid loss which can lead to intravascular volume depletion. Because the drug class also decreases renal hyperfiltration akin to ACE inhibitors, they are being evaluated for an indication to be nephroprotective (Cherney et al, 2014).

Major side effects are genital yeast infections in both genders related to the continuous presence of glucose in the urine. They can be used with some renal insufficiency which

helps cover patients previously on medications that must be stopped when GFR begins to decline. They are combined with many other agents to help reduce glycemic levels.

Incretin Therapy

Recent research and attention has been focused on new treatment options for type 2 DM: incretin hormones and their impact on glycemic control. Glucagon-like peptide-1 (GLP-1), a normally occurring hormone released from the gut after ingesting a meal, promotes satiety, decreases gastric emptying, increases glucose-dependent insulin release from pancreatic beta cells, and decreases glucagon release from pancreatic alpha cells (Sisson & Cornell, 2011). GLP-1 is rapidly inactivated by the enzyme dipeptidyl peptidase-4 (DPP-4).

Two therapies that block DPP-4 activity include the GLP-1 agonists and DPP-4 inhibitors. Both are effective therapies in the treatment of type 2 DM that do not cause hypoglycemia and can be used as monotherapy or in combination with metformin. When choosing between GLP-1 agonists and the DPP-4 inhibitors, the patient's age, the time from initial diabetes diagnosis, body weight, compliance, and finances should be considered (Dicker, 2011).

In recent studies, both drug groups have shown promise in lowering Hb A1c levels, contributing to weight stability, and providing protective cardiovascular function. Longitudinal studies have addressed the fear of negative cardiovascular impact; there appears to be no negative impact even in patients with renal insufficiency (Udell et al, 2014). A difference between these two classes is their mode of administration: GLP-1 agonists are injectable peptides, whereas the DPP-4 inhibitors are oral agents.

In the older population, DPP-4 inhibitors may be the best choice due to their glucose-lowering effect, the neutral effect on caloric intake, and therefore less negative effect on muscle and total body protein mass. In younger patients recently diagnosed with type 2 diabetes, abdominal obesity, and abnormal metabolic profile, treatment with GLP-1 agonists have a beneficial effect on weight loss and improve the metabolic profile. An additional factor to take into consideration when using these drugs is that DPP-4 inhibitors (in reduced doses) are safe for treating patients with moderate and severe renal failure, whereas GLP-1 is contraindicated in most of these patients (Dicker, 2011).

Dipeptidyl Peptidase-4 Inhibitors

The dipeptidyl peptidase-4 inhibitors (DPP-4) include sitagliptin (Januvia), saxagliptin (Onglyza), linagliptin (Tradjenta), and alogliptin (Nesina). All except linagliptin require considerations for renal dysfunction. The action of DPP-4 inhibitors is different from all other oral agents because they act on the incretin hormone system to have an indirect effect to increase insulin production. They improve glycemic control by increasing insulin synthesis and secretion, reducing glucagon, slowing gastric emptying by prolonging the action of the remaining GLP-1 hormones, and suppressing the appetite. One main advantage is the oral preparation. (See Chapter 21 for more detail.)

Glucagon-Like Peptide-1 Receptor Agonists (GLP-1s)

The first GLP-1 agonist receiving FDA approval was Exenatide (Byetta), a synthetic form of protein found in the saliva of the Gila monster. Exenatide and the other GLP-1 medications liraglutide (Victoza), albigutide (Tanzeum), and dulaglutide (Trulicity) activate GLP-1 receptors, which decreases fasting and postprandial glucose levels. They increase insulin synthesis and secretion in the presence of elevated glucose levels and improve first-phase insulin release, lowering glucagon, slowing gastric emptying, and reducing food intake. These drugs are given by subcutaneous injection for type 2 DM but are not a substitute for insulin. They have been noted to produce lower Hb A1c levels of 0.5% to 1.5% and weight loss. Liraglutide has been given formal FDA indication for obesity therapy; the others in the class may soon follow suit. They come in many combinations with other medications. The advent of long-acting, once weekly formulations has helped overcome much resistance to these being injectable medications. There are some concerns with medullary thyroid cancer (see Chapter 21).

Other Injectable Drugs

Amylin is a pancreatic hormone that is stimulated to release by the presence of a meal. Its role is to slow down gastric emptying rates, allowing a more gradual release of glucose into the system. The "satiety effect" suppresses appetite. The slower glucose absorption prevents a sudden postprandial spike. Pramlintide (Symlin) is an injectable amylin hormone derivative that mimics these natural effects. It is not popular due to a high rate of severe nausea and the need to inject prior to most meals (see Chapter 21).

GOALS OF TREATMENT

The overall goals for the treatment of diabetes are (1) near normalization of blood glucose, (2) prevention of acute complications such as hypoglycemia, (3) prevention of progression of the disease to target organ damage, and (4) appropriate patient-oriented self-management. Table 33-5 highlights the targets for glycemic control and prevention of complications (ADA, 2015). Although the American Diabetes Association/European Association for the Study of Diabetes [ADA/EASD] guidelines have targeted an Hb A1c of less than 7 (Inzucchi et al, 2012), the recommendation by the American Association of Clinical Endocrinologists/American College of Endocrinology [AACE/ACE] (2009) is a primary glycemic goal of an A1c of 6.5%, which must be individualized for the patient. The DCCT (1993), the Stockholm Diabetes Study of type 1 diabetes (Reichard, Nilsson, & Rosenqvist, 1993), the UK Prospective Diabetes Study [UKPDS] (1998), as well as the Kumamoto study (Ohkubo et al, 1995) conclusively demonstrated that in patients with type 1 diabetes, the risk for development or progression of retinopathy, nephropathy, and neuropathy is reduced by intensive treatment regimens when compared with conventional regimens. New data support complete normalization of glycemic levels may prevent microvascular complications even in type 2 DM. This is especially important

Table 33–5 American Diabetes Association Treatment Targets for Persons With Diabetes

Hb A1c	<7%
Preprandial Plasma Glucose	80–130 mg/dL
2-hour Postprandial Plasma Glucose	<180 mg/dL
Blood Pressure	<140–150 systolic patients with DM and HTN <90 diastolic mm Hg all patients with DM <130 systolic may be appropriate for some patients
LDL	<100 mg/dL (not a target; level per highest risk)
Triglycerides	<150 mg/dL
HDL	>50 mg/dL
Excess Urinary Albumin Excretion	<30

Key Concepts in Setting Goals:
- Individualize goals
- Special considerations for children, pregnant women, and older adults
- Less intensive glycemic goals for patients with severe or frequent hypoglycemia
- More intensive glycemic goals may further reduce microvascular complications at the risk of increasing hypoglycemia
- Postprandial glucose may be targeted if Hb A1c goals are not met despite reaching preprandial glucose goals
- Lipid goals should follow ATP IV guideline based on risks; initial evaluation at age 40.

Source: Adapted from American Diabetes Association. (2015). Standards of medical care in diabetes

considering many patients are not diagnosed for years. The microvascular system is thereby exposed to the destructive influence of heightened glucose levels for a long time. Earlier, more aggressive therapy at the time of diagnosis has long-term impacts with an unanticipated decrease in microvascular complications when compared to the traditional "easing into" more complex therapeutic approach used in the past.

However, there is less compelling evidence to support macrovascular risk reduction and glycemic control in type 2 diabetes. Several recent studies on macrovascular complications (ACCORD, ADVANCE, VADT) have actually shown increased cardiovascular disease (CVD) mortality in patients who were on the intensive control arm of the study in which the Hb A1c target was 6% (ADVANCE Collaborative Group, 2008; Duckworth, Abraira, & Moritz, 2009; Riddle et al, 2010). Because patients in all three trials had long-standing diabetes and either CVD or risk factors suggesting the presence of atherosclerosis, glycemic targets in the 6.4% to 6.9% range may play a greater role before macrovascular disease is well developed and a minimal or no role when it is advanced.

The ACCORD, ADVANCE, and the VADT studies were all large randomized controlled trials that did not conclude

tight glycemic control resulted in a reduction in cardiovascular events. The current theory is that early intervention may be the key; the UKPDS and the DCCT interventions were conducted early in the diabetes disease process, whereas the latter studies were conducted in patients who had longer durations of diabetes and preexisting illnesses. It should be noted that the ADVANCE trial did show evidence of benefits on microvascular and neuropathic complications. The ACCORD was stopped prematurely due to an increase in mortality in the control group.

APPROPRIATE TREATMENT

Initial Assessment

The initial assessment for patients with diabetes is complex and includes an extensive history about symptoms of the disease and the chronic complications associated with diabetes, current drugs being taken including over-the-counter (OTC) drugs, and alternative therapies that might affect glucose levels, family history of diabetes, CVD, cerebrovascular disease, or dyslipidemia, gestational history, and alcohol or drug use. Especially critical is assessment of risk factors for CVD, including smoking, hypertension, or dyslipidemia. After a thorough physical examination, which includes an inspection of the feet, laboratory data are collected. The results of this assessment will determine whether intensive or conventional therapy for glycemic control is better and whether treatment or referral for complications should be started early.

Setting a Glycemic Target

Many studies have shown that treatment regimens that reduce average Hb A1c <7% are associated with fewer long-term microvascular and neuropathic complications (ADA, 2015). For selected patients, a lower goal of 6.5% can be suggested if it can be achieved without significant hypoglycemia or other adverse effects of treatment. Such patients might include those with short-term duration of diabetes, long life expectancy, and no significant CVD (ADA, 2015). Glycemic targets recommended by the ADA and key concepts in setting these goals are shown in Table 33-5. Less stringent glycemic targets are recommended for patients with long-standing diabetes and/or advanced macrovascular and microvascular complications; older adults (65 years or older) in whom hypoglycemic awareness may be suppressed; children under 13 years; those with extensive comorbid conditions; those with severe or frequent hypoglycemia; and those with limited life expectancies of 5 to 15 years (ADA, 2015; ADA/EASD, 2012). Correlation between A1c levels and mean plasma glucose levels are shown in Table 33-6. Goals for children were tightened in 2014. The old goals of 8.5% for kids under 6, <8% for those 6–12 years of age and <7.5% for teens 13–19 have been supplanted with the target of <7.5% (ADA). Of course, individualization may be required based on the risks of hypoglycemia and comorbidities.

Table 33–6 Correlation Between Hb A1c Level and Mean Plasma Glucose Level

Hemoglobin A1c Levels	Mean Plasma Glucose (mg/dL)
6	126
7	154
8	183
9	212
10	240
11	269
12	290

Lifestyle Modifications

The incidence of DM and the incidence of obesity in the United States are increasing at approximately the same rate. This increased incidence of obesity is a primary culprit in the DM epidemic. Evidence from the USDPP (2002; 2003) found that even modest lifestyle changes, including eating less fat, modest weight loss of ~7% of body weight, and exercising 150 minutes weekly, cut the incidence of diabetes dramatically. Two studies of lifestyle modification have shown persistent reduction in the rate of conversion of pre-diabetes to type 2 diabetes in follow-up at 3 and 14 years' post-intervention (Li et al, 2008; Lindstrom et al, 2006). The recent questioning of dietary fat guidelines deals with a quality of evidence argument (Harcombe et al, 2014). There is a much evidence that reduction in fat has led to better outcomes in diabetes; therefore, it is suggested not to alter current therapeutic guidance until the national guideline authors make that suggestion.

Current ADA guidelines (2015) continue to support lifestyle changes that include a modest weight loss of 7% and increasing physical activity to 150 minutes of moderate-level cardiovascular exercise per week. Patients with pre-diabetes should receive an individualized consultation with a CDE or dietitian to provide guidance in healthy food choices, increasing physical activity, and moderate weight loss. Metformin therapy to prevent type 2 DM should be considered in those with IGT, IFG, or an Hb A1c of 5.7% to 6.4%, especially for those individuals with BMI greater than 35, less than 60 years of age, and women with prior GDM (ADA, 2015). Individuals with pre-diabetes should be reassessed at least annually for the presence of DM (ADA, 2015).

Lifestyle modifications should always be addressed with patients upon diagnosis of diabetes or pre-diabetes. To make these modifications more acceptable to many persons, it is suggested to place an emphasis on altered eating patterns, not "dieting." The traditional mantra of "diet and exercise" should be replaced with "exercise first" intervention. Severe dieting can create a loss of muscle (see below). Approximately 10% of patients with type 2 achieve glycemic targets with lifestyle modifications alone. All patients with DM should have an individualized consultation with a CDE for diabetes self-management education (DSME) to address lifestyle and behavior changes, which include:

- physical activity, healthy eating, tobacco cessation, weight management, effective coping
- disease self-management, which includes medication-taking management and self-monitoring of glucose and blood pressure when appropriate
- prevention of complications, including foot inspection; screening for eye, foot, and renal complications; and immunizations

Patients with pre-diabetes or diabetes should have individualized Medical Nutrition Therapy (MNT) through consultation with a registered dietitian familiar with the components of diabetes. Goals of MNT include the following:

- Attain and maintain recommended metabolic outcomes, including glucose and Hb A1c level; low-density lipoprotein (LDL) cholesterol, HDL cholesterol, and triglyceride levels; BP; and body weight.
- Modify nutrient intake as appropriate for the prevention and treatment of obesity, dyslipidemia, CVD, HTN, and nephropathy.
- Address individual nutritional needs, taking into consideration personal and cultural preferences and lifestyle while respecting the individual's wishes and willingness to change.
- For youth with type 1 diabetes, provide adequate energy to ensure normal growth and development and integrate insulin regimens into usual eating and physical activity patterns.
- For youth with type 2 diabetes, facilitate dietary changes that reduce insulin resistance.
- For pregnant and lactating women, provide adequate energy and nutrients needed for optimal outcomes.
- For older adults, provide for the nutritional and psychosocial needs appropriate to their age.

Regular exercise has been shown to improve glucose control, reduce cardiovascular risk factors, contribute to weight loss, and improve overall well-being. Exercise may also prevent type 2 diabetes in high-risk individuals (ADA, 2015). A regular physical activity program is recommended for all patients with diabetes who are capable of participating. Adaptations should be made if complications are present. Recommendations for patients with diabetes are moderate to intensive aerobic activity (50% to 70% of maximum heart rate) at least 150 minutes a week and resistance training at least 2 times a week unless it is contraindicated (ADA, 2015). Resistance exercise improves insulin sensitivity almost as much as aerobic exercise. Interval training of alternating 3 minute bursts of fast and slow walking may be more beneficial than walking at a steady rate (Karstoft et al, 2013). Before beginning an exercise program, patients should be evaluated for macro- and microvascular changes that may be worsened by exercise. A graded exercise test is appropriate only for symptomatic patients and those with cardiovascular disease who are older than 35 years, or older than 25 years with type 2 diabetes of

more than 10 years' duration, or type 1 diabetes of more than 15 years' duration; those with any additional risk factor for coronary heart disease; or those with microvascular disease, peripheral vascular disease, or autonomic neuropathy. Exercise is not recommended if the patient is in poor glycemic control.

Use of tobacco products is a concern in individuals with diabetes who are at higher risk for morbidity and premature death associated with the development of macrovascular complications. Smoking is also related to the premature development of microvascular complications in diabetes. Smoking cessation is a necessary lifestyle modification that should be addressed with all patients with diabetes. Table 33-7 lists the appropriate lifestyle modifications.

All members of the diabetes health-care team should be knowledgeable and supportive of the patient making lifestyle changes. Web sites that provide low- or no-cost diabetes meal planning and self-management educational materials include the American Diabetes Association (www.diabetes.org), National Institute of Diabetes and Digestive and Kidney Diseases (www.niddk.nih.gov), and the Academy of Nutrition and Dietetics (www.eatright.org/catalogue). Many of these resources are available in Spanish. Table 33-7 provides a summary of these recommendations.

Immunizations

Immunizations are safe and effective in preventing communicable diseases. People with diabetes and other chronic illnesses are at higher risk of mortality and morbidity from common communicable diseases than the general population. Therefore, it is recommended that all people with

Table 33–7 Lifestyle Modifications for Patients With Diabetes

Nutrition	
Type 1	• Eat at consistent times synchronized with the action of the insulin preparation and the consumption of carbohydrate. • Eat a bedtime snack consisting of 1–2 carbohydrate servings (15–30 g).
Type 1 and type 2	• Moderate caloric restriction if needed. • Space meals, spreading nutrient intake, especially carbohydrates, throughout the day. • Eat on a regular schedule. • Patients using insulin are encouraged to eat at consistent times synchronized with the action of the insulin preparation. • In the presence of reduced kidney function, total protein intake of 0.7–0.8 g/kg/d with 10%–20% of caloric intake from protein. • 7% of calories from saturated fats and minimum trans fat intake; the lessened attention to cholesterol intake for the general population may not apply to those with glucose metabolism issues. • Total carbohydrate content is more important than type of carbohydrate. The goal for most patients is 3–4 carbohydrate servings (45–60 g) per meal. 1–2 snacks per day may also be indicated and should include 1–2 carbohydrate servings (15–30 g). • Healthy eating to include carbohydrate intake from vegetables, fruits, whole grains, legumes, and dairy products should be advised over intake from other carbohydrate sources, especially those that contain added fats, sugars, or sodium. • Low-glycemic-load foods should not be emphasized over a well-balanced diet (Sacks et al, 2014). Fiber recommendations are the same as for persons without diabetes. High-fiber content in meals may slow the rate for glucose rise postprandially. • Sodium restriction, if any, is related to any concomitant hypertension. • Abstention from alcohol is advised. If consumed, it is best done with meals. No more than 2 drinks of alcohol/d for men and no more than 1/d for women (1 alcoholic beverage = 12 oz beer, 5 oz wine, or 1.5 oz distilled spirits).
Exercise	

Both types	• Exercise affects uptake of glucose by muscle and fat tissue and can affect plasma glucose levels. Time the exercise to coincide with caloric intake. May need to decrease basal and bolus insulin for extended exercise (e.g., all-day hike, ski, etc.). Persons with type 1 should exercise at the same time daily.
	  • Carbohydrate-based food should be readily available during and after exercise.
	  • Increase aerobic activity to 50%–70% of maximum heart rate for 30 min 5 days/wk; goal is 150 min/week. Obese or low-activity patients may need to start with as little as 3 min of activity/d and increase the activity by 1 min/d until the desired 20–30 min is achieved.
	  • Resistance training at least 2×/wk is recommended.
	  • Do not exercise if ketones are present. Monitor blood glucose before and after exercise. If BG ≤100 mg/dL, eat snack containing 10–30 g carbohydrate.
	  • Patients should learn their own glycemic response to different exercise conditions. They should keep records to understand their glycemic response.
	• Reduction of sedentary time to less than 90 minutes at a time (ADA, 2015).

Weight Loss	

Type 1 and type 2	• Weight loss is recommended for all overweight or obese individuals who have or are at risk for diabetes.
	  • Low-carbohydrate, low-fat, calorie-restricted, or Mediterranean diets may be effective for short-term weight loss (up to 2 yr).
	  • Monitor lipid profiles, renal function, protein intake (in those with nephropathy), and adjust hypoglycemic therapy as needed for patients on low CHO diets.
	  • Physical activity and behavior modification are important components of weight-loss programs and are most helpful in maintenance of weight loss.
	  • Moderate weight loss (7% of body weight), regardless of starting weight, has been shown to affect insulin sensitivity.

diabetes be immunized according to the following (ADA, 2015):

- Annual influenza vaccinations for all persons greater than 6 months of age.
- Pneumococcal polysaccharide vaccine should be given to all patients greater than 2 years of age. This should be administered as a one-time vaccination for those greater than 64 years if previously immunized if they were less than 65 and the vaccine was administered greater than 5 years ago.
- Hepatitis B vaccine should be given to all unvaccinated adults 19 to 59 years of age; consider vaccinating adults greater than 60.

Considerations in Special Populations

Children

Since the majority of all newly diagnosed cases of type 1 diabetes occur in patients younger than age 18 years, care of these patients requires integration of diabetes management with the growth and development needs of children, adolescents, and their families. Young patients with diabetes are best cared for by a team that can deal with these special needs. Glycemic targets may need to be modified because children younger than 7 years lack the cognitive capacity to recognize and respond to hypoglycemic signals. Considerations for level of control also should be undertaken with caution in children 2 to 7 years because hypoglycemia may impair normal brain development, but hyperglycemia is also neurotoxic. Overly aggressive dietary manipulation can contribute to lack of adherence, especially in adolescents. Schools and day-care settings must be involved in the treatment of diabetes, often participating in the administration of drugs. Treatment regimens must take all of these needs into account.

Children with type 1 diabetes also have a high risk for CVD and other complications from DM. The number of children with type 2 diabetes is currently too small to make a statement about their risk, but CVD is a strong risk factor in adults and likely exists for children as well. Management of complications is discussed in the Hyperlipidemia section.

Children may also develop type 2 diabetes. Prevention of the development of diabetes from pre-diabetes must take highest priority in children and should focus on decreasing the risk, incidence, and consequences of type 2 diabetes, especially in high-risk ethnic groups. Modifiable risks for type 2 diabetes in children that can be addressed with primary prevention include the prevention of obesity and the promotion of breastfeeding. The use of alcohol, tobacco, and drugs should be evaluated in all children and adolescents on diagnosis and reevaluated at every visit. Alcohol may increase hypoglycemic episodes caused by sulfonylureas or insulin and increase the risk of lactic acidosis in patients who use metformin. Family support is essential to the child or adolescent with type 2 diabetes. The whole family should be involved in dietary and activity changes, prevention of complications, as well as drug therapy management and self-monitoring of blood glucose.

For children, the goal weight should be the expected BMI for their age. Weight stabilization rather than weight loss is recommended for prepubertal children. Children who are morbidly obese may be referred to a specialist in weight reduction or a multidisciplinary child obesity clinic.

The BP goal is less than the 90th percentile on the basis of height and weight standards. Fasting lipid levels are best obtained after the initial metabolic stabilization (1 to 3 months after diagnosis). The lipid goals are LDL less than 100 mg/dL and total cholesterol less than 170 mg/dL. Treatment of children with dyslipidemia is discussed in Chapter 39 and hypertension is discussed in Chapter 40.

The Hb A1c goal for children depends on age and type of DM. Currently the only drugs approved for diabetes in children are metformin and insulin. Liver function tests should be performed before initiation of oral therapy. If multiple drugs are required, referral to a pediatric endocrinologist may be necessary.

Older Adults

Older adults (older than 65 years) are more likely to have type 2 diabetes and use oral agents to treat their disease. They may suffer severe consequences from a hypoglycemic episode, especially patients with significant atherosclerosis who may be vulnerable to permanent injury. Weight loss in overweight older adults should be carefully evaluated. In this population, low body weight has been associated with greater morbidity and mortality. Exercise training can significantly reduce the decline in maximal aerobic capacity that occurs with age, improve risk factors for atherosclerosis, slow the decline in age-related lean body mass, decrease central adiposity, and improve insulin sensitivity; all are beneficial in the older adult with diabetes.

Glycemia, glucose homeostasis, and the prevalence of diabetes all increase with age; therefore, this should be taken into consideration as glycemic targets for older adults are identified. Pani and colleagues (2008) examined a large cohort of patients without diabetes and found a positive correlation between increased Hb A1c levels and age. Current guidelines state that glycemic targets for older adults are generally more relaxed than younger adults. An Hb A1c of 7.5% is appropriate for the patient if cognitively intact, functional, and with a good life expectancy. The glycemic target can be less than 8.0% for those with complex needs such as multiple co-morbidities, ADL impacts, and mild cognitive impairment. They are further relaxed to less than 8.5% with moderate to severe cognitive impact, two or more ADL deficiencies, in skilled nursing facilities, and with end-stage chronic illness (ADA, 2015). There needs to be awareness of the risk for hypoglycemic and hyperglycemic complications (ADA). The presence of CVD risk factors should also be evaluated. Current research shows that more benefit may be received from the treatment of CVD and hypertension in older adults with DM than strict glycemic control. Although it is important and necessary to prevent complications from poor glycemic control, it is prudent to find the balance between adequate glycemic control and minimizing episodes of hypoglycemia.

The risk for hypoglycemic episodes in the older adult and the lack of hypoglycemic awareness due to physical, cognitive,

or pharmacological effects should be assessed regularly. Recent studies have noted that ED visits for hypoglycemia outnumber those for hyperglycemia. Additionally, the median time from first hypoglycemic episode to a CV event was 1.5 years without consideration of prior CV health (Khunti et al, 2015). Sulfonylureas may produce severe hypoglycemia. Second-generation drugs are less likely than first-generation drugs to have this adverse reaction. Glimepiride (Amaryl), a third-generation sulfonylurea, is least likely to cause this adverse reaction. Glyburide is the most likely to cause hypoglycemia and is not recommended for the elderly. TZDs should not be used in patients with heart failure because of the fluid-retention side effect. Metformin is often contraindicated in older adults because they may have renal insufficiency or heart failure. Alpha-glucosidase inhibitors, which are not part of the usual algorithm, have a good safety profile in this population, but are not well tolerated. The use of insulin requires that the patient or caregiver have good vision and motor skills and be cognitively intact. Regardless of the treatment regimen, all medications should be started at the lowest possible dose and titrated according to patient response and tolerance (ADA, 2015).

Race and Ethnic Groups

While minority populations are more likely to be diagnosed with DM, the rates of complications vary by ethnicity and race. According to the CDC, the age-adjusted percentage for Hispanics with diagnosed diabetes in the United States was 6.3% in 1997 and 12.8% in 2012. For that same time period, the age-adjusted percentage of diagnosed diabetes was 7.6% for whites, 13.2% for non-Hispanic blacks, and 9% among Asians. American Indians/Alaska Natives was 15.9% (CDC, 2014). These percentages are further broken down by regions and specific subsets of these populations. Interested providers are directed to the CDC report.

There are currently no specific guidelines addressing treatment for ethnicity or racial groups. The AACE evaluated the differences in diabetes presentation and complications across ethnic groups (Bloomgarden, 2003). Asian populations, who have low rates of obesity, have high rates of diabetes and cardiovascular disease. This runs contrary to the typical picture of the type 2 patient being obese; therefore, providers are cautioned not to dismiss the differential when screening for risks. This is especially so, because normal-weight diabetics actually have higher all-cause mortality (Carnethon et al, 2012). The prevalence of diabetes appears to be higher in the migrant population. Despite low obesity rates, increased intra-abdominal fat showed stronger correlation with hypertension and dyslipidemia than did insulin sensitivity per se and was a marker for diabetes risk. The prevalence of cardiovascular disease may be associated with the higher total and LDL cholesterol, higher triglycerides, lower HDL, and higher concentrations of homocysteine and lipoprotein(a) found in persons of South Asian ethnicity. These data suggest that treatment of hypertension and dyslipidemia and lifestyle modification are also necessary in this population.

The SEARCH for Diabetes in Youth Study Group (Liu et al, 2009) looked at Asian and Pacific Islanders younger than 20 years of age. This study found that most participants in the study who had type 2 diabetes were obese (Asian 71% and Pacific Islanders 100%), with a mean BMI greater than 33 kg/m². Of those with type 1 diabetes, Pacific Islanders were more likely to be obese, with a mean BMI of 26. The incidence of type 2 diabetes in these populations was almost double that of type 1 diabetes. The study group's recommendation is that a stronger public health effort needs to be focused on these youths in the area of type 2 DM and obesity.

Hispanics in the United States have a high incidence of obesity, high triglycerides, low HDL-C, hypertension, and high FPG. Predictors of conversion from pre-diabetes to diabetes in this population are high LDL and triglycerides and low HDL, high BP, and high BMI. Treatment of hypertension and dyslipidemia, and lifestyle modifications related to nutrition and weight loss are critical in this group. Metformin is indicated as an early intervention in this population to prevent conversion from pre-diabetes to diabetes.

African Americans have a greater prevalence of diabetes and hypertension than other ethnic groups. Treatment of both issues is essential in this population. Compared to others, African American adolescents have had a huge increase in development of type 2 diabetes. African American children have higher insulin secretion both before and during puberty and lower insulin sensitivity during adolescence. If the extrapolation is made that African American adults may continue this lower insulin sensitivity, then selecting drugs that improve insulin sensitivity to treat type 2 diabetes in African Americans of all ages is appropriate. Drugs with this characteristic include metformin and pioglitazone. Metformin is also a drug of choice related to the increasing prevalence of obesity among African Americans, particularly women.

The SEARCH study with African American youth (Mayer-Davis et al, 2009) looked at children from infancy to 19 years. This study found that the incidence of type 1 diabetes was high in this group, especially for those older than age 10. The study also found that both types of diabetes substantially affect adolescents in this ethnic group. Among adolescents with either type of diabetes, more than 90% were overweight or obese and 60% of those with type 2 diabetes came from households with an annual income of less than $25,000. Although lifestyle modifications are a major emphasis in this group, cost variables should especially be taken into account when choosing any drug for this population.

According to the CDC (2014), 24.1% of American Indians in the southwestern United States and 6% of Alaska Natives age 20 years or older who received care from Indian Health Services had diagnosed diabetes. The vast majority of youth had type 2 diabetes. These young people are likely to have poor glycemic control, a high prevalence of unhealthy behaviors, and evidence of a severely depressed mood. They have more metabolic factors associated with obesity and insulin resistance (abdominal fat, dyslipidemia, and a higher albumin-to-creatinine ratio). Intervention efforts should be targeted at primary prevention and efforts

to prevent or delay the development of chronic complications associated with metabolic factors. Failure to treat the depression will undermine any effort to increase self-management.

In non-Hispanic white youth, there are more cases of type 1 than type 2 diabetes; they have the highest rate of new cases of type 1 diabetes than any other group (CDC, 2014). In the SEARCH study, it was reported that 40% of the subjects in this study had elevated LDL echolesterol and less than 3% met traditional recommendations for the intake of saturated fat (Bell et al, 2009). Of those with type 1 diabetes, 18% were smokers, and 26% of those with type 2 smoked. Lifestyle and cardiometabolic risk factors require attention in this population.

Pharmacological Management

Diabetes is a lifelong disease that may have few symptoms until organ damage occurs. For this reason, health-care providers often find themselves prescribing lifestyle modifications or drugs to treat a problem that patients have no clear evidence that they have and at a point when they may not feel acutely ill. The choice of treatment should be low cost, limited in complexity, have the fewest possible adverse reactions and should be chosen based on the type of diabetes, the desired glycemic target, the severity of hyperglycemia, and specific patient variables.

Type 1 Diabetes

Patients with type 1 diabetes require insulin. The pattern of administration of insulin is based on the patient's blood glucose, dietary, lifestyle and exercise patterns. Regardless of the type of insulin used, appropriate therapy should mimic endogenous insulin secretion delivered before meals or to correct hyperglycemia. This can be achieved by intensive insulin therapy, split-mixed insulin therapy, or continuous subcutaneous insulin injections (CSII) (ADA, 2015). An insulin analog is recommended, especially if hypoglycemia is a problem for the patient.

The total daily insulin requirement is 0.3 to 0.5 units/kg body weight/d with titration to glycemic targets. Higher doses may be indicated during an acute illness. Adjustments should be made after reviewing patterns of control over at least 3 days, taking food intake and activity into consideration. Hypoglycemia is addressed first and then hyperglycemia. Make

adjustments up or down in increments of 1 unit until sensitivity to insulin is well understood (Texas Diabetes Council, 2010; Sisson & Cornell, 2011).

In the split-mixed regimen, insulin is given 2 to 3 times daily by splitting the dose—two-thirds given in the morning and one-third given in the evening. Two-thirds of the total daily dose (TDD) is administered before breakfast using a ratio of 1:2 rapid-acting (RAI) or short-acting insulin (SAI) to intermediate-acting insulin (IAI); one-third of the TDD is given at bedtime using a 1:1 or 1:2 ratio of RAI or SAI to IAI (Texas Diabetes Council, 2010; Sisson & Cornell, 2011). Another possibility is to use premixed 70/30 insulin with two-thirds of the dose in the morning and one-third of the dose in the evening.

When using the intensive insulin therapy approach, three to four injections are administered per day. This regimen involves 1:1 basal bolus dosing with LAI basal administered either at breakfast or bedtime with either RAI or SAI bolus doses before each meal. Prandial insulin should be matched to carbohydrate intake, preprandial blood glucose levels, and anticipated activity. Patients who are intelligent, motivated, and reliable can be taught to regulate their blood sugar with intensive control. Less capable patients risk hypoglycemic reactions on this regimen and might not be appropriate candidates or might need higher fasting blood sugar targets than more capable patients (Table 33-8).

Bolus premeal insulin doses should include the following:

- Insulin to cover carbohydrate ingested: 1 unit RAI covers 500/TDD g carbohydrate from meals.
- Additional insulin to correct high SMBG: 1 unit RAI lowers PG by approximately 1,800/TDD mg/dL (regular lowers PG by ~1,500/TDD).
- Adjustments should be made for exercise. Decrease 1 unit for every 30 minutes of moderate-intensity exercise (Texas Diabetes Council, 2010).

Initial and annual assessments of blood pressure (BP) and lipids are also done. If hypertension or hyperlipidemia are found, drugs to treat these conditions are also started early in diabetes management. Screening for other autoimmune disorders, such as thyroid dysfunction, celiac disease, and vitamin B_{12} deficiency should be done based on signs and symptoms.

Figure 33-2 shows the algorithm for management of type 1 diabetes. See Table 33-9 for commonly used insulin regimens.

Table 33–8 Basal Bolus Insulin

Rapid-Acting (RAI)	Short-Acting (SAI)	Intermediate-Acting (IAI)	Long-Acting (LAI)	Mix
Bolus	Bolus	Basal	Basal	Basal
• Correction • Preprandial	• Correction • Preprandial	• a.m./p.m. breakfast and dinner	• HS or breakfast	• a.m./p.m. breakfast and dinner
3–4×/d	3–4×/d	2×/d	1×d	2×d
Novolog Humalog	Regular	NPH	Lantus Levimir	70/30 (IAI/SAI) 50/50 (IAI/SAI) 75/25 (IAK/RAI)

Establish glycemic target

Adults without severe complications who are willing and able to use individualized algorithm, take up to 4 injections/day and test BG at least 4×/day.
Tight control/intensive therapy:
—FPG and premeal 90–130 mg/dL
—Postprandial <180 mg/dL
—HbA1c <7%

Children
Plasma blood glucose goal (mg/dL)

Age	Before meals	Bedtime	HbA1c
0–6	100–180	110–200	7.5%–8.5%
7–12	90–180	100–180	<8%
13–19	90–130	90–150	<7.5%

Patients who are at high risk for hypoglycemia; older adults; patients w/ late disease or advanced, severe complications; not motivated to follow complex regimen.
Conventional therapy:
—FPG 120–150 mg/dL
—Bedtime glucose 120–160 mg/dL
—HbA1c 7%–8%

Lifestyle modifications (see Table 33-7)
Plus insulin
1. Start w/ total daily dose 0.2–0.4 units/kg; usual 0.4–0.8 units/kg
2. 50% basal give once or twice daily (glargine, detemir preferred, or NPH)
3. 50% prandial—rapid acting preferred (aspart, lispro, glulisine, or R)
    a. Start with 1 unit/15 g carbohydrate OR
    b. Divide into equal doses if consistent carbohydrate OR
    c. Divide into 3 doses based on meal size
4. Correction dosing to be used in addition to meal dose for blood sugars >150
More advanced methods may be used as patient comfort increases. See text.

Hypoglycemia (<70)
Treat before addressing hyperglycemia
—Fasting: decrease basal dose
—Preprandial: decrease dose of rapid acting at preceding meal

Hyperglycemia
—Fasting: >130 increase long-acting dose
—Preprandial: >150 increase dose at previous meal
—Titrate both q 3 days

Contact by e-mail or phone 1–2×/wk initially by NP, RN, or CDE

FU visit at 1 month
—Review blood sugar patterns, activity, hypoglycemic episodes
—Continue dose adjustment as needed

Contact as needed by NP, RN, or CDE

FU visit at 3 mo
—Review as above
—HbA1c

Glycemic targets met?

Yes

—Continue regimen
—May advance to pump therapy or advanced carbohydrate counting. See Clinical Pearls.

No

—Review lifestyle, insulin regimen, and adherence
—Consider confounding variables
—Adjust insulin based on patterns

HbA1c and visit every 3 mo

Most Type 1 patients should be followed by a multidisciplinary endocrinology team.

Figure 33–2. Treatment algorithm for type 1 diabetes.

Table 33–9 ⊗ **Commonly Used Insulin Regimens**

Insulin Therapy Type Insulin	Schedule	Advantages	Disadvantages
Intensive Insulin Therapy Basal = LAI Bolus = RAI	Basal at breakfast or bedtime, or basal at evening meal Start 0.3–0/5 units/kg/d	Consistent insulin dose throughout the day with basal; bolus insulin only when food present	Requires 4 injections and pre-meal + bedtime SMBG. LAI not compatible with other insulin; requires separate syringe.
Split-Mix Insulin Therapy—3 injections Basal= LAI (or IAI) Bolus = RAI	Long-acting to = 50% TDD HS; 50% TDD RAI remainder of dose of mixed insulin at breakfast and evening meal. If using IAI, give before breakfast and HS. Start 0.3–0.5 units/kg/d	Consistent insulin dose throughout day with basal	Glargine not compatible with other insulin; needs separate syringe. Premeal SMBG
Split-Mix Insulin Therapy—2 injections **Basal = IAI** Basal/Bolus = SAI or RAI mix 2:1 ratio a.m., 1:1 ratio p.m.	Basal at breakfast and dinner or HS; bolus before each meal. 2/3 NPH, 1/3 SAI or RAI *or* Premix 70/30, 75/25, or 50/50	Consistent insulin dose throughout day	Multiple injections required and premeal SMBG. IAI may reduce risk of nocturnal hypoglycemia.
Basal = IAI or LAI 3	Start with 6–10 units or 0.1–0.2 unit/kg body weight/d at breakfast or HS to initiate therapy.	Start with low dose to reduce hypoglycemic risk.	**Type 2 only**
Basal = LAI + oral agent	Long-acting at bedtime or breakfast; oral agent 1–2 × daily	Once-daily dosing of insulin. Consistent insulin dose throughout day.	Requires injection as well as oral agent. **Type 2 only**

In any of the regimens using fast-acting insulin, rapid-acting insulin may be substituted.

CLINICAL PEARL

Type I Diabetes Treatment

- Most patients should see an endocrinologist and diabetes treatment team; treatment can be challenging and a team approach works best. Consultation with a Certified Diabetes Educator is a must.
- Make small changes gradually with close follow-up (every 1 to 2 wk) until adequate control is achieved.
- Ongoing follow-up has been shown to be very beneficial; this can be done by phone or electronically.
- It is normal to have wide variability in BGL even with adherence to the treatment plan. Variability does not necessarily mean nonadherence.
- Consistency in mealtimes, injection sites, and timing and frequency of exercise is vital.
- The treatment plan must be individualized with adjustments preplanned for anticipated sudden increases in physical activity such as summer sports camps or ski vacations.

Type 2 Diabetes

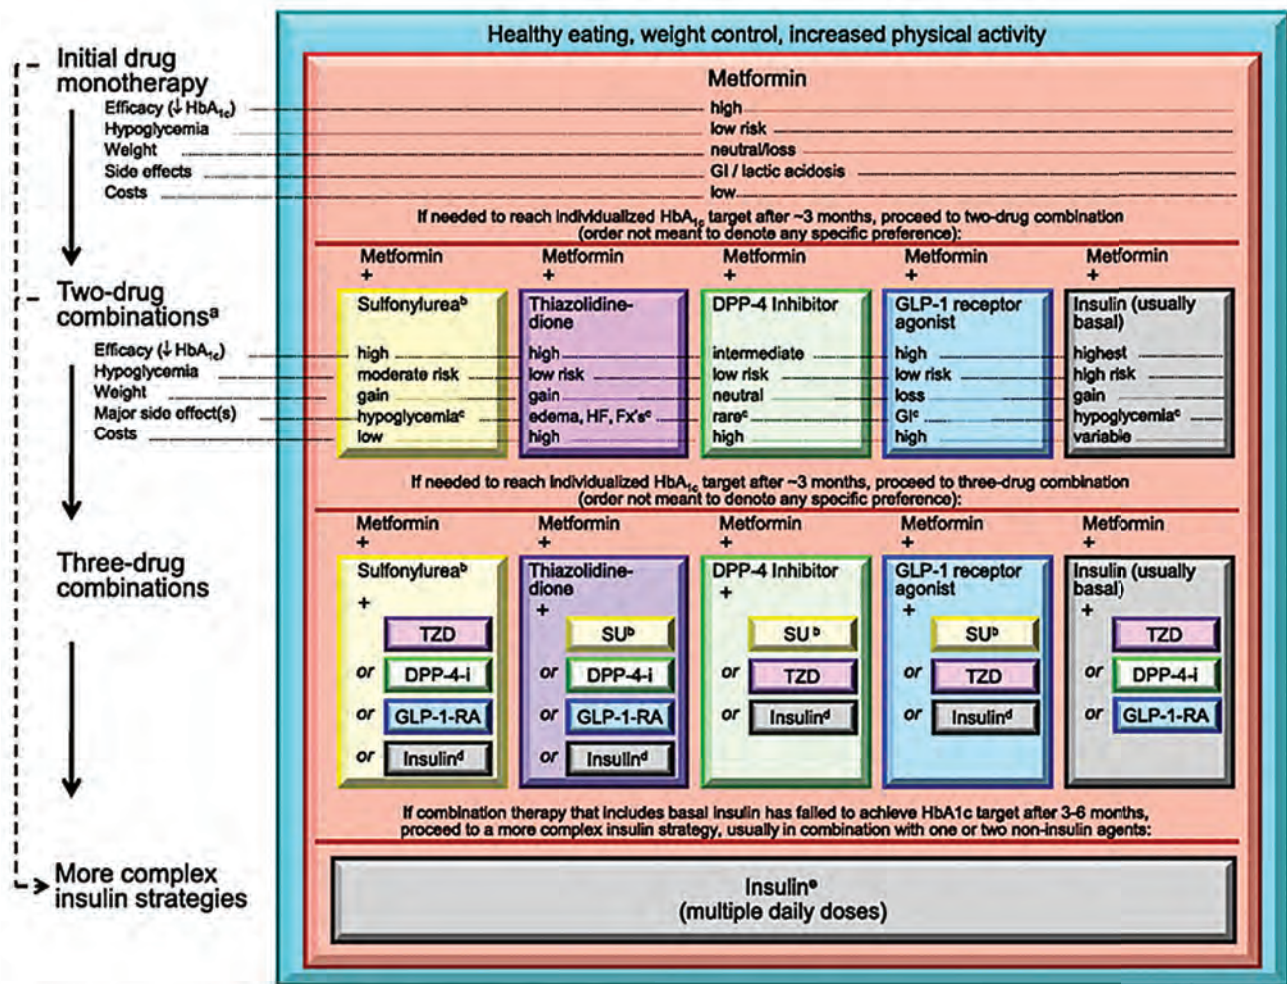
Type 2 diabetes can be a complex disease. Once a glycemic target is set, the algorithm for type 2 diabetes always begins with lifestyle modification and DSME. Intensive glycemic targets are often difficult to reach with lifestyle modifications alone, so monotherapy should be initiated after 3 months if there is no reduction in Hb A1c.

Using a stepped approach with the recommendations published by the ADA/EASD (2012), metformin is used initially unless there are major contraindications. Combination therapy with one or two additional agents are added if there is no reduction in the Hb A1c level in 3 months, with the goal of minimizing side effects (ADA, 2015). See Figure 33-3 for current treatment recommendations. Metformin should be continuously used regardless of the addition of other agents (Iznucchi et al, 2012).

The guidelines base the choice of a drug on the effectiveness of the drug in efficacy, reducing long-term complications, weight gain, major side effects, and expense. The ADA/EASD consensus document lists the various classes of antihyperglycemic drugs and provides information about these variables. Figure 33-3 shows the algorithm for management of type 2 diabetes. Please note Inzucchi published this prior to SGLT-2 medication inclusion into guidelines. The algorithm emphasizes the following:

- Achievement and maintenance of near normal glucose levels (Hb A1c less than 7%).
- Initial therapy with lifestyle interventions, which include diet, exercise, and education.
- First-line therapy begins with metformin.
- If glycemic goals are not achieved or sustained within 3 months on oral monotherapy at maximum dose, a second oral agent, a GLP-1 agonist, DPP-4 inhibitor, or insulin should be added (ADA, 2015).
- Early addition of insulin therapy in patients who do not meet target goals.

At some point in their disease, many patients with type 2 diabetes will require the addition of insulin and can use a variety of insulin regimens; many patients can be successfully

Antihyperglycemic therapy in type 2 diabetes: general recommendations.


Inzucchi S E et al. Dia Care 2012;35:1364-1379

a. Consider beginning at this stage in patients with very high HbA1c (e.g., > 9%).
b. Consider rapid-acting, nonsulfonylurea secretagogues (meglitinides) in patients with irregular meal schedules or who develop late postprandial hypoglycemia on sulfonylureas.
c. See (…)[text] for additional potential adverse effects and risks(…).
d. Usually a basal insulin (NPH, glargine, detemir) in combination with noninsulin agents
e. Certain noninsulin agents may be continued with insulin (see text).. Consider beginning at this stage if patient presents with severe hyperglycemia (>16.7–19.4 mmol/L [300–350 mg/dL]; Hb A1c >10.0–12.0%) with or without catabolic features (weight loss, ketosis, etc.).

Figure 33–3. General recommendations for antihyperglycemic therapy in type 2 diabetes. *Inzucchi et al (2012). Management of hyperglycemia in type 2 diabetes: A patient centered approach. Position Statement of the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD). Diabetes Care, 35(6), 1364–1379.*

managed on one injection of basal insulin alone, but because of the progressive nature of the disease, the addition of prandial insulin may be needed (Inzucchi et al, 2012). The likelihood of insulin requirements over time needs to be discussed early in the disease process with all type 2 patients. Once-daily injections, split mix, or intensive insulin therapy may be used. See Table 33-9 for common insulin regimens.

When initiating insulin in type 2, LAI or IAI is administered in a single dose at bedtime or in the morning; the typical starting dose is 6 to 10 units or 0.1 to 0.2 units/kg body weight/d. Larger doses, as high as 0.7 to 2.5 units/kg body weight/d, may be needed due to the presence of insulin resistance. The single dose is usually given in conjunction with one or more oral agents. The dose is increased by 2 units every 2 to 3 days until daily FPG levels are consistently within the glycemic goal range. If the FPG is greater than 180, the dose can be increased by 6 units every 3 days. If hypoglycemia occurs, the dose can be reduced by 4 units or 10%, whichever is greater. Once the FPG is in target range, testing of blood glucose before each meal will help determine the dose of additional injections of insulin to be added.

Type 2 can be controlled well with basal insulin alone; however, prandial insulin may be added with the use of SAI or RAI before meals or the split-mixed regimen as discussed under type 1. In the two- or three-injection regimen, IAI is administered before breakfast and before the evening meal or at bedtime with an SAI given before breakfast and dinner, using a 2:1 ratio in the morning and 1:1 ratio in the evening. LAI may also be used daily or twice daily at breakfast and bedtime. Premixed agents may also be used. Starting dose should be 0.3 to 0.5 units/kg body weight/d; if the current dose is greater than 0.5 units/kg body weight/d, use 80% of once-daily insulin and divide as two-thirds IAI and one-third RAI or one-half LAI with one-half RAI (Texas Diabetes Council, 2010).

In intensive insulin therapy, a 1:1 basal bolus is used with an LAI once daily or IAI at breakfast, evening meal, or bedtime with either an SAI or RAI used before meals as in type 1. The same guidelines should be used for premeal dosage calculations. The starting dose should be 0.3 to 0.5 units/kg body weight daily. The advent of glucometers that have an automatic insulin dose calculator might make this option available to many more patients who are unable or unwilling to undertake any of these regimens. See Table 33-9 for the commonly used insulin regimens.

Oral hypoglycemic agents have limited ability to reduce hyperglycemia; therefore, patients who initially present with blood glucose levels above 300, Hb A1c greater than 10, or with significant hyperglycemic symptoms, insulin therapy is strongly recommended to lower PG to less than 180 before oral agents are begun. This treatment is mandatory in the presence of catabolic features or ketonuria; the latter reflects profound insulin deficiency (Inzucchi et al, 2012). Treatment options are once-daily insulin or intensive insulin therapy.

As with type 1 diabetes, initial and annual assessments of BP and lipids are also done. Comprehensive CVD risk reduction should be a major focus of treatment, and drugs to treat these conditions are also started early in diabetes management. The guidelines for both BP and lipid control are discussed in the Complications section. A long time "Rule of 15" can be taught to reliable patients for milder hypoglycemia episodes. They should take 15 gm of carbohydrate and recheck their sugars in 15 minutes.

Severe Insulin Resistance Therapy: U-500 Insulin

In cases of long-term DM, the volume of insulin required in each injection can become larger and larger. The obesity epidemic has accelerated the number of patients who require larger doses for adequate control. In the rare cases when individual injections are over 200 units, the prescriber should consider a consultation with endocrinology to initiate use of a concentrated insulin. Typical insulin concentrations are 100 units per mL. A specialized insulin of 500 units per mL must be specially ordered from the manufacturer Eli Lilly.

Of key importance is understanding that the dosages are not simple arithmetic division of the U-100 doses by five. Presently, there are no insulin syringes for this concentration of insulin; therefore, a standard 1 cc (TB) syringe is used. The

concentrated insulin comes in 20 mL vials, not the standard 10 mL vials of other insulins. The drug is ordered and measured in volume, not units. There is significant risk of medication error unless a conversion chart is referenced for every dose adjustment. These can be downloaded from the Eli Lilly Web site. An example of the difference is that 50 units of U-500 is only 0.1 mL, 55 units is 0.11mL and 60 units is 0.12mL.

U-500 is a concentrated form of Humulin R insulin, but it cannot be used in IV titrations nor mixed together with other insulins like the U-100 formulation. Its onset is 30 to 45 minutes and peaks in 2 to 4 hours like its less concentrated counterpart. The duration of action can be the typical 8 hours, but in larger volume injections it can last for 24 hours; however, it is not to be considered a basal insulin. This extended duration of action can trigger severe hypoglycemia 15 to 18 hours after injection.

Concentrated insulin is given twice daily before breakfast and dinner if the standard daily dose is around 200 units/day. For patients who require 300 to 750 units daily, the U-500 can be dosed three times daily. Dose requirement between 750 and 2,000 units can be divided into 4 injections. U-500 can be used in insulin pumps for patients requiring 2,000 plus units a day. Manufacturer directions indicate the vial must be discarded after 31 days without regard to the amount of medication remaining.

PREVENTION AND MANAGEMENT OF COMPLICATIONS IN DIABETES

Obesity

Obesity contributes to diabetes by affecting insulin receptors, and it contributes to many of the complications associated with diabetes. Weight loss alone improves short-term glycemic levels and has the potential to improve long-term metabolic control. Metformin is the oral agent most associated with fostering weight loss and is the drug of choice in the treatment algorithm for patients with central obesity. The lack of weight gain associated with alpha-glucosidase inhibitors suggests that these drugs might also be helpful as adjunct therapy for patients with diabetes who are obese, but they are not currently included on the treatment algorithm. GLP-1 agonists, DPP-4 medications, and SGLT-2 medications have also been shown to promote weight loss or at least

On The Horizon | **U-300 INSULIN**

The FDA has just approved a U-300 insulin (Toujeo), which is a long-acting basal insulin with a lower glucose lowering effect per unit than glargine, but lower risks of hypoglycemia. Lower-volume injections will be beneficial. The precautions about mixing solutions in a syringe also pertain. This insulin uses units per dose like glargine; this is unlike the U-500 insulins, which are volume based.

not to contribute to weight gain. Sulfonylureas, TZDs, and insulin are associated with weight gain.

Post-bariatric surgical insulin and drug therapy requires specialty consultation. There can be wild swings in glucose levels. The six mini-meal dietary plan needs specific attention for insulin coverage that should be modified by the specialist. Many patients have a nausea and emesis pattern and dumping syndrome associated with initial overeating. It takes time to find a new rhythm. As the expected weight loss accelerates over time, the amount and degree of dose adjustments requires close coordination to avoid hypoglycemic episodes.

Concomitant disease processes also affect drug choice. Often these disease processes reflect target organ damage from diabetes. The pathophysiological changes associated with the disease process and/or the drugs commonly used to treat it contribute to determining the best drug therapy, especially for patients with type 2 diabetes. The ADA (2015) has specific recommendations for screening and management of chronic complications of diabetes based on concomitant disorders. They are discussed in the sections that follow.

Coronary Artery Disease and Heart Failure

CVD is the leading cause of morbidity and mortality in people with DM; 65% of deaths in persons with diabetes are due to CAD or cerebrovascular events. Stroke, MI, and sudden death are higher in people with diabetes.

Large epidemiological studies have shown that in patients with diabetes, hyperglycemia increases the incidence of CVD (UKPDS, 1998; Khaw et al, 2004). The UKPDS found that for every percentage point reduction in Hb A1c levels, there was a reduction in microvascular complications by 35%; and for every 1% reduction in Hb A1c, there was a 25% reduction in diabetes-related deaths, a 7% reduction in all-cause mortality, and an 18% reduction in combined fatal and nonfatal MI (ADA, 2002). In the EPIC-Norfolk study, it was found that an increase in 1% Hb A1c level was associated with a 20% to 30% increase in CVD events in both men and women (Khaw et al, 2004). It is also recommended that patients with IGF, IGT, and borderline Hb A1c levels be screened for CVD risks (ADA, 2015).

Despite earlier studies suggesting better glycemic control would reduce CVD, three recent studies, the ACCORD, VADT, and ADVANCE studies, did not show a reduction in macrovascular events with stricter glycemic control (6.4% to 6.9%) compared with the standard control of 7%. Decline in macrovascular events is more likely related to control of BP, lipid reduction, and smoking cessation.

All patients with known CVD should be treated with an angiotension-converting enzyme (ACE) inhibitor and statins (if not contraindicated); in patients with acute MI, beta blockers should be used for up to 2 years after infarction in individuals at lower risk of hypoglycemia (ADA, 2015). Atherosclerosis occurs earlier in patients with diabetes than in those without elevated glucose levels. A major mechanism is increased production of thromboxane, a potent vasoconstrictor and platelet aggregant. Aspirin blocks the formation of thromboxane by acetylating cyclo-oxygenase and has been used as both primary and secondary prevention for cardiovascular events.

According to the current ADA recommendations (2015), aspirin therapy (75 to 162 mg/d) should be used as a primary prevention strategy in patients with type 1 or type 2 diabetes at increased cardiovascular risk, including men older than 50 years and women older than 60 years who have additional risk factors such as family history, smoking, dyslipidemia, or albuminuria. The same dose should be used as secondary prevention for those patients with a history of CVD. If aspirin is contraindicated (e.g., known aspirin allergy), clopidogrel (Plavix) 75 mg/d should be used as antiplatelet therapy. Combination antiplatelet therapy is reasonable for up to 1 year after an acute coronary syndrome (ADA, 2015). Aspirin therapy is not recommended for patients at low risk, which includes men younger than 50 years and women younger than 60 years with no CVD risk factors. With the diagnosis of DM now considered a CV event equivalent, few diabetic patients should go without a basic consideration of aspirin therapy.

Metformin has been associated with improving cardiovascular risk through its action in improving lipid levels. However, patients with congestive heart failure who take metformin have an increased frequency of lactic acidosis. This drug is not recommended for HF patients with lower ejection fractions. Insulin may be required for these patients.

Among the oral agents, sulfonylureas are the most associated with risk of hypoglycemia, which may be difficult to recognize in patients concurrently taking beta blockers because beta blockers mask the signs and symptoms of hypoglycemia, with the exception of diaphoresis. Patients with coronary artery disease, heart failure, or hypertension are commonly treated with beta blockers. If sulfonylureas must be given concurrently with beta blockers, glimepiride is less likely to cause hypoglycemia than other drugs in the class.

In a recent RCT in China, in patients diagnosed with type 2 DM for more than 5 years with coronary artery disease for 3 years, treatment with metformin for 3 years reduced death from cardiovascular causes, death from any cause, nonfatal MI, nonfatal stroke, and arterial revascularization by 46% compared with use of glipizide (Hong et al, 2013).

ACE inhibitors are central to the management of heart failure and hypertension. ACE inhibitors and angiotensin II receptor blockers (ARBs) promote ventricular remodeling. These drugs also have been shown to significantly reduce the trajectory of diabetic nephropathy. All patients with diabetes and hypertension should be treated with either an ACE or ARB (ADA, 2015). When renal insufficiency progresses to moderate levels of GFR reduction, they must be discontinued.

Coronary artery disease is further discussed in Chapter 28, "Chronic Stable Angina and Low-Risk Unstable Angina," and heart failure is discussed in Chapter 36, "Heart Failure."

Hyperlipidemia

Having diabetes is now considered equivalent in cardiovascular risk to having established cardiovascular disease and is

listed by the National Cholesterol Education Program (NCEP) as an independent risk factor for coronary heart disease (CHD). The NCEP and ADA both recommend aggressive lipid management aimed at lowering LDL cholesterol, raising HDL cholesterol, and lowering triglycerides to reduce macrovascular disease and mortality in patients with DM. Patients diagnosed with type 1 in childhood have a high risk of developing early subclinical and clinical CVD. Adult patients with type 2 diabetes have an increased prevalence of lipid abnormalities. Although evidence is lacking on type 2 diabetes in children, the assumption is that they will also demonstrate these abnormalities.

Diabetes, particularly type 2, can cause a lipid abnormality with a high level of very-low-density lipoprotein (VLDL) and a low level of HDL (ADA, 2015). This is seen clinically as high triglyceride levels (200 to 400 mg/dL) and low HDL levels (less than 35 mg/dL).The target lipid levels recommended by the ADA are shown in Table 33-5. All patients with diabetes should have a fasting lipid profile at least annually. Children older than 2 years should have a lipid profile after the diagnosis of diabetes and when glucose control has been established. If values are normal, the test should be repeated every 5 years.

Lifestyle intervention, which includes MNT, increased physical activity, weight loss, and smoking cessation, may allow some patients to reach lipid goals. Each patient's age, type of diabetes, pharmacological treatment, lipid levels, and other medical conditions should determine the type of nutritional interventions used, with a focus on the reduction of saturated fat, cholesterol, and trans-fatty acids. Glycemic control can also positively impact plasma lipid levels, particularly in patients with very high triglycerides TG (ADA, 2015).

For those patients who have CVD or are over 40 years old with other CVD risk factors, pharmacological therapy is warranted. Statin therapy should be considered in addition to lifestyle therapy if LDL cholesterol remains greater than 100 mg/dL or in those with multiple CVD risk factors (ADA, 2015).

HMG-Co-A reductase inhibitors (statins) have consistently demonstrated the ability to reduce cardiovascular risk for adults and for children over the age of 10 years when the main goal is reduction of LDL cholesterol. These drugs have also been shown to improve endothelial function and cause regression of carotid intimal thickening (McCrindle et al, 2007; Wiegman et al, 2004). Their action is less prominent in reduction of VLDL and triglycerides, but they also have this action. Although other drugs will be discussed here, the current ADA recommendations (2015) stress treating all patients with DM with statins unless contraindicated.

Fibrates act more directly on VLDL and triglycerides (TGs), while also increasing HDL-C. They are most commonly used for lowering TGs but can be used concomitantly with statins to address multiple dyslipidemias. If used in combination, risks of serious side effects are increased, so close monitoring is necessary.

Ezetimibe is a cholesterol absorption inhibitor whose primary effect is reduction of LDL-C. It has been shown to be safe in combination with a statin to enhance the effects. Vytorin is a combination of simvastatin of varying doses and ezetimibe 10 mg. The initial systematic review of this combination, however, found that the drug was no more effective than either drug taken alone (Sharma et al, 2009). This finding provided additional support for the findings from the 2008 ENHANCE trial, which did not show a clinical outcome demonstrating efficacy for combined therapy of ezetimibe and simvastatin, although there was a decrease in LDL (Kastelein et al, 2008). The recent release of reviewed MPROVE-IT data has cast a more favorable light on the drug combination (Blazing et al, 2014). It has yet to be determined if use of ezetimibe will increase again. Because large changes in cholesterol fractions are rarely achieved by monotherapy with one drug class, providers should use individual patient response to select drugs to be used to treat hyperlipidemia.

Bile acid sequestrants affect LDL-C with a modest increase in HDL-C. They are not commonly prescribed to treat dyslipidemias in patients with diabetes. Not only do they increase TGs but they may pose problems for patients with diabetic gastroparesis. The increase in TG is especially of concern in diabetics because the pancreas is already under stress.

Nicotinic acid (niacin) has been used to increase HDL-C; it has a modest lowering effect on TGs and LDL-C. However, it is associated with increased BGL particularly in pre-diabetes or newly diagnosed patients. Although niacin is relatively inexpensive, it has unpleasant side effects for the patient and can also increase hyperglycemia (Cornell & Sisson, 2011). The recently appreciated increase in CV event risk has led to niacin falling out of favor for use.

Omega-3 fatty acids can be useful in lowering TGs with a secondary effect of increasing HDL-C. They can also increase LDL. Because these drugs cause increased bleeding, they should be used cautiously in patients on anticoagulant therapy or aspirin.

Interventions to improve glycemic control usually lower triglyceride levels but have little effect on HDL levels. Metformin has a modestly favorable impact on lipids because of its actions in the liver. In clinical studies, metformin alone or in combination with a sulfonylurea lowered mean fasting serum triglycerides, total cholesterol, and LDL and had no adverse effect on HDL. Therefore, it is an appropriate oral agent for patients with diabetes who also have lipid abnormalities. The combination of gemfibrozil with metformin and an NCEP lipid-lowering diet is the most efficacious in both controlling lipid and lowering blood glucose levels. TZDs may increase HDL and LDL, but the long-term effect of such changes is unknown. Acarbose (Precose), an alpha-glucosidase inhibitor, has also shown beneficial effects for patients with hypertriglyceridemias. Acarbose acts on the pathogenesis of these disorders, lowering production of endogenous triglycerides. Chapter 39 presents more information on treatment of hyperlipidemia.

Hypertension

Hypertension (HTN) is a common comorbidity in patients with diabetes, affecting 20% to 60% depending on age, obesity, and ethnicity (ADA, 2015). HTN is also a risk factor for CHD and microvascular complications such as retinopathy and nephropathy. In type 1 diabetes, HTN is often a manifestation of diabetic nephropathy. In type 2 diabetes, HTN is often part of a syndrome that includes glucose intolerance, insulin resistance, obesity, hyperlipidemia, and coronary artery disease. In both types of diabetes, the presence of HTN is associated with increased cardiovascular risk, especially for stroke and ischemic heart disease. Control of HTN has been demonstrated to reduce the rate of progression of diabetic nephropathy and hypertensive cerebrovascular disease.

Blood pressure should be measured at every routine visit with a health-care provider. According to ADA standards, which have changed from previous recommendations, the target for people with HTN and diabetes is <150 systolic; the target systolic BP <130 is appropriate for younger patients and for those for whom the goal can be achieved without difficulty. Diastolic BP should be treated to <90 mg Hg, per JNC-8 standards, but opinion in diabetic communities believes this might be too lenient in diabetic patients. Standard treatment for HTN should include pharmacotherapy and lifestyle modifications. These include MNT, increased physical activity, moderate alcohol consumption, and modest weight reduction.

Pharmacological treatment should be initiated with either an angiotensin converting enzyme (ACE) inhibitor or angiotensin II receptor blocker (ARB); if one drug is not tolerated, another should be initiated. Multiple drugs are usually needed to achieve BP targets in many patients (ADA, 2015). Some drugs used to treat HTN also address other complications of diabetes. ACE inhibitors have been shown to improve cardiovascular outcomes in high-risk cardiovascular patients even without HTN. In patients with congestive heart failure, ACE inhibitors are associated with better outcome than are ARBs. ARBs improve cardiovascular outcomes in patients with HTN, diabetes, and end-organ damage. ACE inhibitors reduce the risk for diabetic nephropathy through their reduction of intraglomerular pressure and a reduction in glomerulosclerosis. They have a unique, specific, and beneficial effect on the kidneys of both normotensive and hypertensive patients with diabetes. ARBs (lorastan [Cozaar] and irbesartan [Avapro]) have been approved for use in treating diabetic nephropathy.

Alpha adrenergic blockers are not usually prescribed for treatment of HTN in persons with diabetes. The alpha-blocker arm of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) was terminated after interim analysis showed that alpha blockers were substantially less effective in reducing congestive heart failure than diuretic therapy (Wright et al, 2009). Alpha blockers are beneficial for treatment of benign prostatic hypertrophy (BPH) and can be used as an option for men with BPH and diabetes (Cornell & Sisson, 2011).

Diuretics can also be used to treat HTN but are not typically the first-line treatment for HTN in diabetes. In low doses, diuretics may safely be used for patients with diabetes (AACE,

2006; ADA, 2015), but at moderate to high doses they adversely affect glucose metabolism. They may also potentiate orthostatic hypotensive changes in patients with diabetic autonomic neuropathy. Thiazide diuretics have been shown to increase peripheral insulin resistance and hepatic glucose release. Other side effects are changes in electrolytes, such as hypokalemia, hyperglycemia, hyperlipidemia, and hyper/hypocalcemia. Therefore, serum electrolytes should be monitored throughout therapy; baseline renal function and potassium levels are necessary when choosing therapy (Cornell & Sisson, 2011).

Beta blockers are not typically used to treat HTN in patients with DM as an addition or as first-line therapy but may be used for patients with existing cardiac problems (prevention of second MI). Beta blockers may inhibit release of insulin as well as mask hypoglycemic symptoms, such as tachycardia. Nonselective beta blockers can also reduce the B2-mediated hepatic glucose output, which could have negative impacts during a hypoglycemic episdoe. Beta blockers can also increase total cholesterol, LDL, and triglycerides, while decreasing HDL.

Nondihydropyridine calcium channel blockers (CCBs) can be considered for patients who are unable to tolerate ACE inhibitors or ARBs. CCBs are now used as first-line therapy for HTN in African Americans. HTN is discussed in more detail in Chapter 40.

On The Horizon — RENAL INSUFFICIENCY

Metformin and other medications are curtailed when creatinine values rise. Several recent calls to continue with drug use if monitoring for lactic acidosis is not yet FDA-approved.

Nephropathy

Diabetic nephropathy (DN) occurs in 20% to 40% of patients with diabetes and is the single cause of end-stage renal disease. Elevated urinary albumin excretion (30 to 300 mg/24 h) has been shown to be the earliest stage of diabetic nephropathy in type 1 diabetes and a marker for development of nephropathy in type 2. It is also a well-established marker for increased cardiovascular disease risk (ADA, 2015). Patients with elevated urinary albumin excretion are likely to progress to clinical albuminuria and a decreased glomerular filtration rate over a period of years (Remuzzi, Schieppati, & Ruggenenti, 2003). HTN may accelerate the decline in glomerular filtration rate and the progression to end-stage renal disease.

Screening for excessive urinary albumin excretion should be done with a random spot urine sample for albumin excretion in type 1 diabetes once a child is 10 years of age and has had diabetes for 5 years and in adults once they have had diabetes for 5 or more years. All patients with type 2 should have such screening at time of diagnosis.

Elevated or high levels of urinary albumin excretion (30 to 299 mg/24 h) in nonpregnant adults should be treated with an ACE inhibitor or ARB, but not both concurrently. Reduction in dietary protein is not recommended for patients with

DM and diabetic kidney disease (albuminuria >30 mg/24 h) because it will not alter glycemic response, cardiovascular risk, or rate of glomerular filtration rate (GFR) decline (ADA, 2015). Serum creatinine and potassium levels should be monitored when ACE, ARB, or diuretics are used. Continued monitoring of urine albumin excretion to assess response to therapy and progression of disease is indicated. Serum creatinine should also be measured at least annually in all adults with diabetes regardless of urine albumin excretion (ADA, 2015).

ACE inhibitors, ARBs, and non-dihydropyridine CCBs reduce the rate of urinary albumin excretion and may give false-negative tests. To diagnose DN, excessive albumin excretion should be confirmed by at least two tests over a period of 3 to 6 months. An estimate of GFR using the CKD-EPI is becoming standard in hospitals because it also has values specific for gender, ethnicity, and age. This tool to calculate GFR can be found at the National Kidney Foundation (www.kidney.org) and the National Kidney Disease Education Program (www.nkdep.nih.gov). A more expensive test of Cystatin-C may be more useful if determination of renal insuffiency stage is unclear with standard methods. A referral to a specialist experienced in the care of DN should be considered in advanced kidney disease or when difficulties in management issues develop.

To reduce the risk or slow the progression of nephropathy, the recommendations are to optimize glucose and BP control. Intensive management and maintenance of BP to target goals have been effective in reducing the rate of progression to end stage. In patients with type 1 diabetes, with or without HTN, ACE inhibitors have been demonstrated to significantly delay the progression of DN. In patients with type 2 diabetes, HTN, and albuminuria 30 to 299 mg/24 h, ACE inhibitors and ARBs have been shown to delay the progression to albuminuria greater than 300 mg/h. In patients with type 2 diabetes, HTN, macroalbuminuria, and renal insufficiency, ARBs have been shown to delay the progression to nephropathy (AACE, 2006; ADA, 2015). The non-dihydropyridine CCBs (diltiazem and verapamil) may reduce albuminuria 30 to 299 mg/ 24 hours to an extent comparable with ACE, but the dihydropyridine CCBs may increase it (AACE, 2006).

Neuropathy

There are two kinds of diabetic neuropathy: autonomic and peripheral. Diabetic autonomic neuropathy (DAN) is often insidious and screening for it may require several tests. A detailed history and physical should include screening for signs and symptoms, including resting tachycardia, exercise intolerance, orthostatic hypotension, constipation, gastroparesis, erectile dysfunction, sweat gland dysfunction, impaired neurovascular function, and the potential for autonomic failure in response to hypoglycemia. Cardiovascular autonomic dysfunction (CAN) is a CVD risk factor and is the most clinically important form of DAN.

Hypotheses of etiologies of DAN include metabolic insult to nerve fibers, neurovascular insufficiency, autoimmune damage, and neurohormonal growth factor deficiency (Vinik,

Maser, Mitchell, & Freeman, 2003). Hyperglycemic activation of the polyol pathway leading to accumulation of sorbitol and potential changes in the nicotinamide adenine dinucleotide (NAD) to nicotinamide adenine dinucleotide hydride (NADH) ratio may cause direct neuronal damage. Activations of protein kinase C induces vasoconstriction and reduces neuronal blood flow. Increased oxidative stress, with increased free radical production, causes vascular endothelium damage and reduces nitric oxide bioavailability. Immune mechanisms may also be involved. Reduced neurotrophic growth factors, deficiency of free fatty acids, and formation of advanced glycosylation end products also result in reduced neuronal blood flow. In summary, a multifactorial process is probably involved in DAN; multiple body systems are affected. Major clinical manifestations are shown in Table 33-10.

Screening for signs and symptoms of CAN should be performed upon diagnosis of type 2 and 5 years after the diagnosis of type 1. Special testing is not usually needed (ADA, 2015).

CAN is a serious component of DAN because it is associated with increased morbidity and possibly mortality. CAN is the most clinically significant type of DAN. Indications can include resting tachycardia (>100 bpm) and orthostasis (fall in systolic BP 20 mm Hg upon standing without an appropriate heart rate response). Recommendations include management of HTN, lipids, and glucose control because currently there are no treatment options for treating the underlying nerve damage (ADA). Glucose control can slow progression but does not reverse existing nerve loss or damage.

Autonomic involvement can affect GI dysfunction, manifested by gastroparesis, constipation, and diarrhea. Metoclopramide (Reglan), a prokinetic agent, is the most commonly used drug to treat gastroparesis; however, it has a relatively high incidence of adverse reactions, especially in children and older adults. This increased risk for adverse reactions is significant because gastric emptying problems are more common in older adults. Diet modification (liquids or softer diet) and referral to a dietitian can be helpful.

Table 33–10 **Major Clinical Manifestations of Diabetic Autonomic Neuropathy**

Body System	Manifestations
Cardiovascular	Resting tachycardia, exercise intolerance, orthostatic hypotension, silent myocardial ischemia
Gastrointestinal	Esophageal dysmotility, gastroparesis, constipation, diarrhea, fecal incontinence
Genitourinary	Neurogenic bladder, erectile dysfunction, retrograde ejaculation, loss of vaginal lubrication
Metabolic	Hypoglycemia unawareness, hypoglycemic-associated autonomic failure
Skin	Anhidrosis, heat intolerance, dry skin
Pupillary	Pupillomotor function impairment, Argyll Robertson pupil

Source: Adapted from Vinik, A., Maser, R., Mitchell, B., & Freeman, R. (2003). Diabetic autonomic neuropathy. *Diabetes Care, 26*(5), 1554–1555.

Genitourinary dysfunction includes reduced bladder contraction force, resulting in urinary stasis, increased risk for bladder infections, and impotence. Bladder contraction force can be enhanced by the use of a cholinergic agonist such as bethanechol (Urecholine). Erectile dysfunction has been successfully treated with alpha blockers that increase vascular blood flow. The phosphodiesterase type 5 inhibitors sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra) are used for treatment of this problem. Other interventions, such as intracorporeal or intraurethral prostaglandins, vacuum devices, or penile prostheses, can also improve the quality of life for the patient suffering from erectile dysfunction.

Peripheral diabetic neuropathy, also known as distal symmetric polyneuropathy (DPN), may result in pain, loss of sensation, and muscle weakness and is a major risk factor for development of ulceration and lower extremity amputations. All patients with DM should be screened for DPN at diagnosis and at least annually thereafter, with a thorough examination that includes inspection and assessment of peripheral pulses and testing for loss of protective sensation using simple tests, such as two-point sensation, vibration perceptions using a 128 Hz tuning fork, 10 g monofilament pressure sensation, and assessment of ankle reflexes (ADA, 2015).

In addition to maintaining glycemic control, therapies are also directed at management of other symptoms in DPN and prevention of complications. Neuropathic pain is often severe and intractable. Treatment is based on individual patient response. Tricyclic antidepressants have been used for their effect on the intrinsic pain-suppressing pathways. Nortriptyline (Aven, Pamelor) and desipramine (Norpramin) are more useful when the patient also experiences orthostatic hypotension. Gabapentin (Neurontin), an anticonvulsant, acts by stabilizing neuronal membranes. The impact is very subtle in most cases. Therapy is begun at low doses, followed by gradual titration. Cymbalta (duloxetine) and Lyrica (pregabalin) are both approved for DPN. These drugs are discussed in more detail in Chapter 29. Capsaicin cream (0.025% to 0.075%), a substance P inhibitor, is also helpful in reducing DPN pain. It is applied 3 or 4 times daily. Treatment should also include smoking cessation. Patients should also be educated on the importance of foot care, proper footwear and daily foot inspection.

Retinopathy

Diabetic retinopathy (DR) is a highly specific vascular complication of both type 1 and type 2 diabetes. DR is the most frequent cause of blindness among adults ages 20 to 74 years. After 20 years of diabetes, nearly all patients with type 1 and more than 60% of patients with type 2 have some degree of retinopathy. One study found that an earlier age of onset of type 2 diabetes significantly affected the development of DR, even more than disease duration and degree of hyperglycemia (Wong, Molyneaux, Constantino, Twigg, & Yue, 2008). This finding supports the importance of delaying or preventing the development of diabetes from pre-diabetes and the need for the more stringent metabolic targets for

younger patients. Additionally, other factors associated with increased risk of DR are hypertension and nephropathy, thus lowering BP has been shown to decrease risk for DR. Use of pioglitazone has been linked with macular edema, but it is unclear whether this is a drug effect or the fact that most patients on these medications have less controlled sugars, greater BP, and more obesity (Fugimoto, 2013).

Adults and children ages 10 years or older with type 1 diabetes should have an initial dilated and comprehensive examination by an ophthalmologist or optometrist within 5 years after the onset of diabetes. Patients with type 2 should have the examination shortly after the diagnosis of diabetes. These examinations should be repeated annually for both types, but if there is no evidence of retinopathy for 1 or more years, then exams may be extended to every 2 years (ADA, 2015). Women with diabetes who are planning pregnancy should have an eye examination in the first trimester with close follow-up throughout the pregnancy and 1 year postpartum (ADA, 2015). One of the main reasons for screening is the established efficacy of laser photocoagulation surgery in preventing vision loss.

The DCCT study clearly demonstrated that near-normal glycemic control reduced or prevented the development of retinopathy by 76% as compared with conventional therapy and reduced the progression by 54% (Kilpatrick, Rigby, & Atkin, 2008). Other large studies have also confirmed the protective effect of glycemic control in patients with type 2 diabetes (UKPDS, 1998; ACCORD Study Group and ACCORD Eye Study Group, 2010). It was also found that patients assigned to intensive BP control had a 34% reduction in progression of retinopathy and a 47% reduced risk of deterioration in visual acuity with a reduction of as little as 10/5 mm Hg in BP (UKPDS, 1998), although a more recent study found that tight targets (systolic <120 mm Hg) had little effect on DR (ACCORD Study Group, ACCORD Eye Study Group, 2010). The FDA has approved two vascular endothelial growth factor (VEGF) inhibitors, ranibizumbab (Lucentis) and aflibercept (Eyelea), for use by specialists to help treat diabetic macular edema.

CLINICAL PEARL

Pumps and Daylight Savings Time
Some pumps may not automatically adjust for changes in daylight savings time. This will not impact basal insulin rates, but bolus doses can be impacted. Time-zone travel can also impact timing of doses if the pump is not GPS-enabled.

Thyroid Function

The presence of thyroid disorders may cloud the diagnosis and complicate the treatment of diabetes. Patients with type 1 diabetes should be screened for thyroid peroxidase and thyroglobin antibodies at diagnosis. Thyroid-stimulating hormone (TSH) concentrations should be measured after metabolic control has been established. If normal, recheck

them every 1 or 2 years. Metformin may alter TSH levels in the first 3 to 6 months of use. The pituitary feedback loop may be impaired in patients with prior hypothyroid issues without overt signs of hyperthyroidism. The clinical significance is undetermined (Duntas, Orgiazzi, & Brabant, 2011).

Autoimmune Disorders

Individuals diagnosed with type 1 diabetes should be assessed for the presence of other autoimmune diseases such as thyroid dysfunction, celiac disease, and B_{12} deficiency (ADA, 2015).

ASSESSMENT OF GLYCEMIC CONTROL

The ADA (2015) recommends evaluation of glycemic control at the initial visit and as part of continuing care for patients with DM. There are two mechanisms for assessing glycemic control: Hb A1c and patient self-monitoring of blood glucose (SMBG).

Hb A1c

Hb A1c provides baseline data and should be used for ongoing evaluation of glycemic control. Because Hb A1c reflects mean glycemia over the preceding 2 to 3 months, it should be mea-sured at least twice a year if patients are meeting treatment goals or have stable glycemic control; it should be measured every 3 months if therapy has changed or if patients are not meeting treatment goals (ADA, 2015). Although the Hb A1c goal for most patients is generally less than 7% per ADA guidelines, a more stringent goal of 6.5% (AACE, 2009) may be established for some patients if there is no significant hypoglycemia or other adverse effects. Such patients include those who are young, have a long life expectancy, and no risk of CVD. Less stringent goals below 8% are appropriate for those individuals who have a history of hypoglycemia, advanced complications or comorbidities, or who have DM of a long duration with poor control. A level of 8.5% is considered acceptable for those in long-term care facilities with advanced dementia, limited life expectancy, and significant issues with ADLs.

Multiple long-term studies support glycemic control through the current recommendations for Hb A1c testing and goal setting to reduce the risk of both micro- and macrovascular complications (DCCT, UKPDS, VADT, ADVANCE, ACCORD). The availability of point of care (POC) Hb A1c testing may increase Hb A1c monitoring and providers' adherence to current guidelines. Egbunike and Gerard (2013) found that in a small sample size ($n = 41$) of chart reviews in a practice, the documentation of POC Hb A1c testing increased from 65.9% pre-implementation to 82.9% 3 months' post-implementation of POC testing in a practice.

There are a few instances when Hb A1c may be unreliable. See Table 33-11 for a list of factors that create some doubt of the values obtained. Of major import when considering the care for diverse patients, having hemoglobin composed of other than the standard hemoglobin A can make the value too high or too low based on the average RBC life span and altered glucose binding sites (Xavier & Carmichael, 2013). There are over 700 types of altered hemoglobin, including thalassemia variants and differing sickle cell presentations; persons with Afro-Caribbean heritage are especially of concern. Also, individuals who have had multiple transfusions have unreliably high values for several months because the donor cells are preserved with a dextrose medium. This is compounded by the possibility the transfusions were required due to acute blood loss, which triggers a falsely low reading. Spherocytosis, altered splenic function, chronic liver or kidney disease, HIV patients on antiretrovirals, and individuals who take mega doses of vitamin supplements (especially A and C) also have unreliable numbers. Having high triglycerides can give falsely elevated readings. In these circumstances, it is recommended that using the same laboratory, avoiding POC testing, and concurrent monitoring of other glucose markers, including postprandial and fasting values, become a required part of the treatment plan.

Self-Monitoring of Blood Glucose (SMBG)

Regular testing provides the patient and provider with more detailed information about daily glucose fluctuations and response to medication, meals, activity, and stress. It can be useful in guiding both in successful initial management. An important factor in this equation is whether the patient and/or caregiver has adequate instruction and ongoing evaluation of SMBG technique and knows how to use the results to problem solve. All patients on inhaled or insulin pump therapy should perform SMBG 3 to 6 times daily and at least preprandial, at bedtime, prior to exercise, when hypoglycemia is suspected, after treatment of hypoglycemia, and prior to driving. SMBG may be helpful for patients on oral therapy or on less frequent insulin regimens. Those who are stable can avoid daily measurements and check with symptoms or on a less vigorous schedule.

Table 33–11   Situations Where Hb A1c May Be Unreliable

Disease or Situation	Impact on Hb A1c Value
Acute blood loss within 3 months	Too low
Multiple transfusions within 3 months	Too high
Sickle cell Hg F; thalassemia Hg S	Too low
Hemoglobin S, G, D, C, & E	Too high
Vitamin A and C supplements	Too low
Liver disease	Too low
Hyperbilirubinemia	Too high
HIV on antiretroviral medications	Too low
High triglycerides	Too high
African Caribbean heritage	Too high

Based on National Glycohemoglobin Standardization Program information (www.ngsp.org) and Xavier & Carmichael (2013).

DIABETES MELLITUS

PATIENT EDUCATION

Related to the Overall Treatment Plan/Disease Process

☐ Pathophysiology of diabetes and the long-term effects of inadequate management on target organs

☐ Role of lifestyle modification, especially dietary therapy, in improving outcomes and keeping the number and cost of required drugs down

☐ Importance of adherence to the treatment regimen

☐ Need for regular follow-up visits with the primary care provider and other specialists

SPECIFIC TO THE DRUG THERAPY

☐ Reason for taking the drug(s) and the anticipated action of the drug(s) on the disease process

☐ Doses and schedules for taking the drugs

☐ Possible adverse reactions (especially hypoglycemia, DKA, and hyperosmolar hyperglycemic non-ketotic coma), how to prevent them, and what to do if they occur

☐ Interactions between lifestyle modifications and these drugs

REASONS FOR TAKING THE DRUG(S)

Patient education about specific drugs is provided in Chapter 21. Specific information related to diabetes includes the following: glycemic control and management of hypertension and hyperlipidemia are central to reducing morbidity and mortality from cardiovascular disease and preventing retinopathy and end-stage renal disease. The risks of these complications while maintaining the potential for a good quality of life with appropriate treatment must be discussed.

DRUGS AS PART OF THE TOTAL TREATMENT REGIMEN

Expectations should be clear about what the drugs can and cannot do. Dietary and other lifestyle modifications complement drug therapy and are equally important. Diabetes is a chronic, progressive disease. Self-management requires incorporating a combination of medications, healthy eating, exercise, stress management, and SMBG into the everyday life of the patient with diabetes.

ADHERENCE ISSUES

Nonadherence to the treatment regimen may result in increased risk for complications and reduced life expectancy. Healthcare providers should be aware of potential problems with nonadherence, discuss the importance of adherence at each follow-up visit, and assist patients in removing barriers to adherence such as lack of social support and cost of the treatment regimen. A team approach with the patient as an active partner should be maximized. Ways to deal with nonadherence are discussed in Chapter 6. Patient education booklets are available from the ADA, which can be accessed on the Internet at www.diabetes.org.

OUTCOME EVALUATION

Outcome evaluation is measured by glycemic targets and prevention or development of the complications of diabetes. Current recommendations stress the importance of establishing treatment goals and glycemic targets using a patient-centered team approach. Collaboration with specialists, CDEs, dietitians, and the primary care provider is critical throughout treatment.

Because diabetes is a self-managed disease, goals and glycemic targets should take into account patient characteristics, such as the patient's capacity to understand and carry out the treatment regimen, the risk for severe hypoglycemia, and other factors that may increase risk or decrease benefit (e.g., very young or very old, end-stage renal disease, advanced cardiovascular or cerebrovascular disease, or other concomitant diseases that will materially shorten life expectancy). In addition, children with diabetes require integration of factors associated with growth and development into their treatment regimen.

PATIENT EDUCATION

Patient education includes a comprehensive overview of all aspects of management of the disease, including medications, meal planning, monitoring as appropriate, exercise, problem solving, coping, and prevention of complications. All patients should be referred to a DSME program initially and on an ongoing basis as life events occur, living situation changes, and as the disease progresses.

Patient education should focus on understanding the pathophysiology of diabetes and prevention of complications, the role of lifestyle modification, improving outcomes and keeping the number and cost of required drugs manageable, the importance of adherence to the treatment regimen, the need for regular follow-up visits with the primary care provider, and regular screenings and preventive care. Special attention must be given to planning what to do in event of illness that impacts the ability to eat. A small cache of diabetic testing supplies and a rotating emergency stock of medications should be set aside for blizzard and other weather emergencies

and placed in a durable container in regions with tornados and earthquakes. Plans for extended vacations such as cruises and international travel need to include consideration of crossing time zones and erratic meal schedules for those on insulin regimens.

Many patients want information on the use of dietary supplements such as chromium and cinnamon. Though chromium is an essential nutrient, issues of deficiency are very uncommon and the evidence is not there to support its use. Cinnamon use requires much better quality studies before the conflicting results of smaller studies can be verified. The use of artificial sweeteners has also become of concern; these sugar substitutes may actually increase weight gain, metabolic syndrome, and CV disease, but they are credited with helping individuals overcome high consumption of full sugar foods. The evidence is not clear.

GASTROESOPHAGEAL REFLUX AND PEPTIC ULCER DISEASE

Teri Moser Woo

Primary care providers see a variety of gastrointestinal disorders, including gastroesophageal reflux disease (GERD) and peptic ulcer disease (PUD). Over the past few years, many of the medications used to treat these two disorders have become available over-the-counter (OTC), leading to patients' attempting to self-manage a disorder before they decide to seek care from their provider. This chapter discusses the continuum of care for GERD and PUD from simple OTC antacids to chronic acid suppression therapy.

GASTROESOPHAGEAL REFLUX DISEASE

GERD is a common problem in primary care and is listed as the primary diagnosis for 6,859,000 ambulatory care visits annually, a rate of 2,332 per 100,000 (National Institutes of Health, 2009a). The prevalence of GERD is 10% to 20% (Katz, Gerson, & Vela, 2013). The severity of the disease varies from occasional postprandial discomfort to severe esophageal inflammation, stricture, bleeding, and even esophageal carcinoma. Gastroesophageal reflux is common and is often called acid reflux because of the acid taste in the back of the mouth or "heartburn" for the burning sensation patients feel in their chest. A presumptive diagnosis is made based on these symptoms of heartburn and regurgitation (Katz et al, 2013). GERD may also present as chest pain, epigastric pain, laryngitis, asthma, or chronic cough (Katz et al, 2013). Persistent acid reflux can cause damage to the esophagus due to chronic irritation of the esophageal mucosa (National Digestive Diseases Information Clearing House [NDDICH], 2007).

Evaluation and management of GERD is based on the American College of Gastroenterology clinical practice guidelines. In most cases, the primary care provider can manage diagnosis and treatment. Ten to 15 percent of patients with GERD require referral to a gastroenterologist. Although the focus of this chapter is drug therapy, lifestyle modification is central to successful management of GERD and is also discussed.

Pathophysiology

GERD results from the reflux of chyme from the stomach into the esophagus. The physiological action of the lower esophageal sphincter (LES) is critical to maintaining a pressure barrier between the stomach and the esophagus. In patients with GERD, the resting tone of the LES tends to be less than normal, permitting transient relaxation of the LES 1 to 2 hours after eating. This relaxation allows gastric contents to regurgitate into the esophagus. Greenberger (2003) reports on a study that found that gastric juice can separate and form

layers over ingested gastric contents in a pocket. After a meal, this highly acidic, unbuffered gastric juice can reflux into the distal esophagus for a distance of 1.8 cm. The median pH of this refluxed gastric juice was 1.6, compared to the pH of 4.7 in the stomach. This acidic layer may be a key factor in the high prevalence of disease in the distal esophagus and explain why the acid that is usually neutralized and cleared from the esophagus by peristaltic action within 1 to 3 minutes cannot be overcome. About 1 to 2 hours after eating, a mean LES tone is restored, but the LES is a complicated region of smooth muscle and many factors can contribute to poor functioning of the LES.

The function of the LES is regulated by the interaction of hormonal, neural, and dietary factors. The hormone gastrin increases resting tone, whereas estrogen, progesterone, glucagon, secretin, and cholecystokinin all decrease sphincter tone. The vagus nerve and alpha-adrenergic stimulation help to maintain resting tone. Tobacco, alcohol, peppermint, chocolate, and foods with high concentrations of fat or carbohydrate all decrease LES tone.

Medications can increase or decrease LES tone. Drugs that increase LES tone include bethanechol (Urecholine), metoclopramide (Reglan), pentobarbital (Nembutal), histamine, and antacids. Some of these (metoclopramide, antacids) are used to treat GERD. Anticholinergics, theophylline, caffeine, meperidine (Demerol), and calcium channel blockers are among the drugs that decrease LES tone. Drugs also contribute to LES tone (Table 34-1).

Factors that increase intra-abdominal pressure can also contribute to GERD by affecting the pressure gradient. Vomiting, coughing, and bending all increase intra-abdominal pressure. Obesity increases intra-abdominal pressure and GERD increases as BMI increases (Katz et al,

2013). Increased abdominal pressure during pregnancy may contribute to GERD, but the underlying reflux cause is the increased circulating estrogen and progesterone, which affect LES tone.

Transient relaxation of LES tone is not the only factor in GERD. Decreased secondary peristalsis and defective mucosal resistance to caustic liquids have also been implicated. Disorders that delay gastric emptying increase exposure time to the acid. Such disorders include gastric or duodenal ulcers, which can cause pyloric edema; strictures that narrow the pylorus; and hiatal hernia, which can weaken the LES. These factors are also targets of treatments for GERD.

The severity of the esophagitis that results from GERD depends on the composition of the gastric contents, the length of time they are in contact with the esophageal mucosa, and the epithelial resistance to acid. If the chyme is highly acidic (see above) or contains bile salts and pancreatic enzymes, reflux esophagitis can be severe. Patients with decreased esophageal peristalsis have longer exposure times between the chyme and the esophageal mucosa. Delayed gastric emptying contributes to reflux esophagitis by lengthening the period during which reflux is possible and by increasing the acid content of chyme.

Reflux esophagitis causes an inflammatory response in the esophageal wall, which results in hyperemia, increased capillary permeability, edema, tissue fragility, erosion, and ulcerations. Fibrosis and basal cell hyperplasia are common and precancerous lesions (Barrett's esophagus) can be a long-term consequence (McCance & Huether, 2010).

Signs and Symptoms

Most patients complain of burning substernal pain that radiates upward, often aggravated by meals and by lying down and relieved by sitting up. The burning substernal pain can be confused with the chest pain associated with angina or myocardial infarction and cause considerable patient distress. Nocturnal aspiration of reflux contents can cause recurrent pneumonia, bronchospasm, and cough.

Sore throat, hoarseness, and halitosis are associated with reflux into the back of the throat. A reflex salivary hypersecretion is sometimes described, especially in children.

Dysphagia usually suggests long-standing GERD with acute inflammation, stricture, or both. Solid food may stick in the distal esophagus; repeated swallows and significant amounts of liquid may be required to ensure passage into the stomach.

Table 34-2 shows the signs and symptoms of GERD and potential complications. A predominance of heartburn, regurgitation, or both, occurring after meals (particularly large or fatty meals) are highly specific to GERD. Older adults, who may have decreased gastric acidity or decreased pain perception, may not report these symptoms despite significant disease. They are also more likely to self-treat. Infants and children also have slightly different signs and symptoms and they are discussed in the sections about these specific patient populations.

Table 34–1 Foods and Drugs That Influence GERD

Foods and Drugs	Action on LES Tone
Foods	
Chocolate, spearmint, peppermint, decaffeinated coffee, high-fat or high-carbohydrate meals, alcohol	Decrease LES tone
Acidic foods, citrus fruit and juices, caffeine	Increase gastric acid secretion
Fatty foods	Delay gastric emptying
Drugs	
Tobacco	Decreases LES tone and increases gastric acid secretion
Anticholinergics, theophylline, meperidine, calcium channel blockers	Decrease LES tone
Bethanechol, metoclopramide, pentobarbital, histamine, antacids	Increase LES tone

LES = lower esophageal sphincter.

Diagnosis

Signs and symptoms alone are rarely sufficient to diagnose GERD; however, guidelines differ on their recommendations for diagnostic testing. The American College of Gastroenterology (ACG) guidelines recommends no routine testing for straightforward GERD (Katz et al, 2013). The ACG recommends diagnostic testing if patients do not respond to twice-daily proton pump inhibitors (PPIs), or gastric malignancy or misdiagnosis is a concern. The ACG (2013) recommends endoscopy for elderly patients, those with noncardiac chest pain, those at risk for Barrett's esophagitis, and those nonresponsive to PPIs (Katz et al). The ACG guidelines indicate "alarm symptoms" of melena, persistent vomiting, dysphagia, hematemesis, anemia, or involuntary weight loss greater than 5% that warrant endoscopy. Diagnostic testing is done by a gastroenterology specialist. The treatment protocol presented here assumes appropriate diagnosis of GERD.

Pharmacodynamics

Each of the contributing factors to the development of GERD is a target for pharmacological management. Drugs can be used to increase LES tone, to reduce the amount of acid in the chyme, to improve peristalsis and thereby decrease the time chyme is available to produce reflux, and to decrease the exposure of the mucosa to highly acid material. The classes of drugs with these actions include antacids, histamine$_2$ blockers, cytoprotective agents, prokinetics, and PPIs. Figure 34-1 depicts the site of action of each of these classes of drugs.

Drugs to Improve Lower Esophageal Sphincter Tone

Metoclopramide and bethanechol improve LES tone and have a prokinetic function but are not considered for monotherapy in the treatment of GERD. They are most useful in combination with acid suppression for patients with gastroparesis. Metoclopramide and bethanechol have not demonstrated significant healing of esophageal lesions.

Antacids also serve a dual purpose: they improve LES tone and increase gastric pH. They are usually patient-initiated drug therapy, along with lifestyle modifications.

Drugs to Reduce the Amount of Acid

Two main classes of drugs are used to reduce acid secretion: histamine$_2$ receptor antagonists (H$_2$RAs) and PPIs. H$_2$RAs act on the parietal cells to decrease the amount of acid

Proton pump inhibitors bind to the enzyme H⁺, K⁺-ATPase and prevent acid from being secreted.

Proton pump inhibitors

produced. Because most of these drugs are available OTC, many patients may have used these drugs as self-initiated therapy before seeking care. Providers need to determine self-medication for GERD in the initial history. H₂RAs may be used as maintenance acid suppression or heartburn therapy in patients who do not have erosive GERD (Katz et al, 2013). The ACG guidelines recommend a trial of nighttime H₂RAs for patients taking daytime PPIs to treat nighttime reflux (Katz et al, 2013).

PPIs are standard first-line therapy for GERD and decrease acid secretion by almost 100%. PPIs improve esophageal healing to about 80%.

Drugs to Improve Peristalsis

A few patients continue to report symptoms despite reduced acid secretion. These patients may benefit from prokinetics, which improve both LES tone and peristalsis. Metoclopramide may provide some benefit but has limited usefulness because of adverse drug reactions.

Drugs to Decrease Mucosal Exposure

Two cytoprotective agents are available to decrease the exposure of the gastric mucosa to acid: sucralfate (Carafate) and misoprostol (Cytotec). Sucralfate acts largely as a Band-Aid

to cover sites having erosive damage but is more often used with ulcers. Misoprostol acts by increasing the production of cytoprotective mucus. Older adults or those taking multiple drugs may benefit from sucralfate. Misoprostol is reserved largely for use when NSAIDs are a contributing factor to the increased acid load. These drugs are not mentioned in GERD guidelines, although discontinuance of NSAIDs is mentioned.

The pharmacokinetics and pharmacodynamics of each of the categories of drugs are discussed in more detail in Chapter 20.

Goals of Treatment

Therapy for patients with GERD has four goals: (1) reduce or eliminate the symptoms; (2) heal any esophageal lesions; (3) manage or prevent complications such as stricture, Barrett's esophagus, or esophageal carcinoma; and (4) prevent relapse. Meeting these goals requires a combination of lifestyle modification and drug therapy.

Rational Drug Selection

Algorithm

For most patients, GERD is treated with PPI therapy. Figure 34-2 presents an algorithm for GERD treatment.

Lifestyle Modifications

Antireflux maneuvers, dietary changes, and cessation of smoking are central to the management of GERD regardless of the step. Antireflux maneuvers reduce back pressure on the LES from intra-abdominal contents. Dietary changes reduce the total volume and acid content of the stomach. Smoking reduces LES tone and increases gastric acid secretion. Box 34-1 lists appropriate lifestyle modifications.

Drug Therapy

Lifestyle modifications and OTC antacids are a logical first step for treatment of heartburn, dyspepsia, or mild nonerosive GERD. Most patients have tried an OTC antacid before they seek health care. This step alone may be sufficient. H_2RAs may be sufficient if symptoms are mild and no erosive disease is evident. Tachyphylaxis may occur with H_2RAs.

PPIs are first-line therapy for patients with moderate or severe GERD or erosive disease. PPI therapy continues for 8 weeks and 70% to 80% of patients should have complete relief with PPIs (Katz et al, 2013). There are no major differences in response between the PPIs (Katz et al, 2013). Maintenance PPI therapy should be prescribed for patients who have symptoms that recur after PPI therapy is discontinued or patients with complications such as erosive esophagitis or Barrett's esophagitis (Katz, et al). The patient should be reassessed in 6 to 12 months to determine if he or she can be weaned off therapy. Patients who do not respond to PPIs need to be referred to a gastroenterology specialist.

Patient Variables

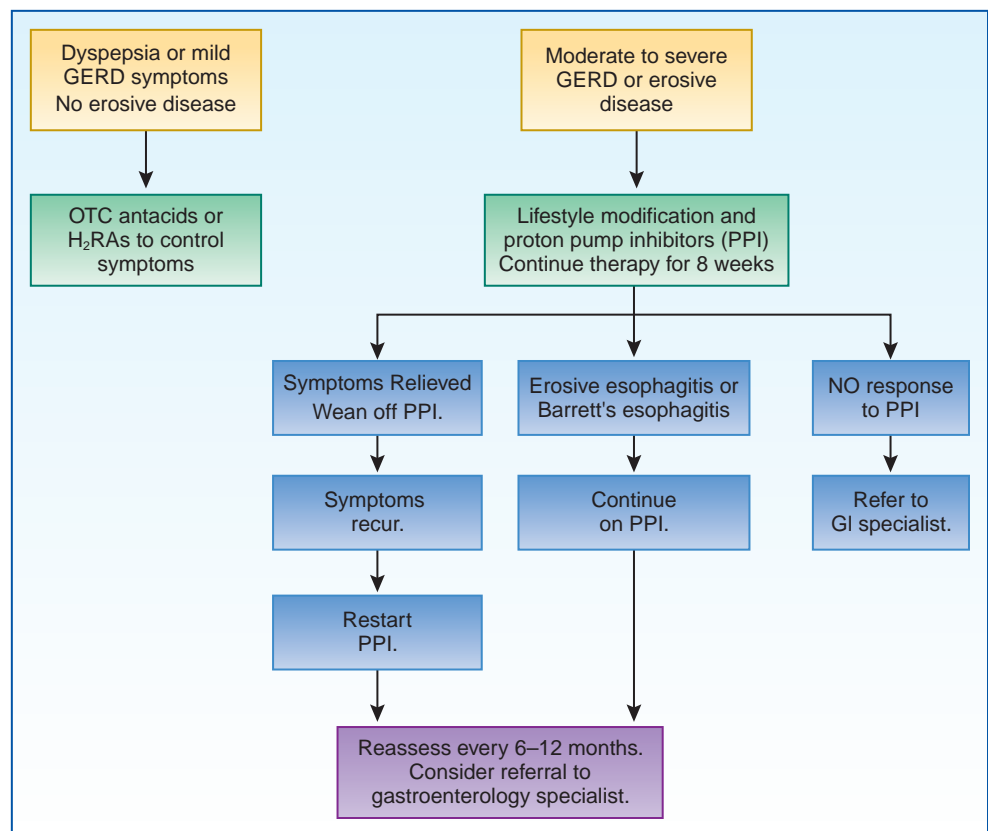
Patient variables are also considered in treatment choices. Primary among them is the age of the patient.


Figure 34–2. Algorithm for gastroesophageal reflux disease (GERD).

BOX 34–1 LIFESTYLE MODIFICATIONS IN GERD MANAGEMENT FOR ADULTS

Antireflux Maneuvers

- Sleep with the head of the bed elevated 6 to 8 inches with bed blocks or wedges or by using a hospital bed.
- Avoid the recumbent position within 3 hours after eating.
- Avoid bending over within 3 hours after eating.
- Avoid exercise, especially strenuous exercise, within 3 hours after eating.
- Attain and maintain appropriate body weight.

Dietary Considerations

- Avoid spicy, acidic, tomato-based, or fatty foods.
- Avoid chocolate, peppermint, onions, and citrus fruits and juices.
- Limit your intake of coffee, tea, alcohol, and colas.
- Eat moderate amounts of food at each meal. Do not gorge yourself.
- Avoid eating meals or bedtime snacks within 3 hours of going to bed.
- Reserve fluid intake for after or between meals.

Smoking Cessation

- Stop smoking. Smoking both lowers LES tone and increases the secretion of gastric acid.
- Smoking cessation is a high priority.

Weight Loss

- Weight loss may improve symptoms

Infants and Children

Gastroesophageal reflux (GER) occurs in up to 100% of 3-month-old infants, 4% of 6-month-olds, and 2% of 12-month-olds (Stansbury, 2004). Most (90% to 95%) outgrow GER by 12 to 18 months of age. Referral to a pediatric gastroenterologist is suggested if symptoms worsen or do not resolve by that age (Vandenplas et al, 2009). Given that most outgrow GER, aggressive management in infants is reserved for the few experiencing concomitant poor weight gain, feeding refusal, arching and crying during feeding, persistent irritability and pain, apnea, and cyanosis suggesting GERD.

In older children, symptoms that suggest GERD include lower chest pain, dysphagia, hematemesis, iron deficiency anemia, wheezing, aspiration or recurrent pneumonia, chronic cough, or stridor. The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) and European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) developed an international consensus on the diagnosis and management of GER and GERD and the consensus is used as the guideline for care (Vandenplas et al, 2009).

Diagnosis of GERD in both infants and children is usually done through a thorough history and physical exam with the symptoms being reported (Stansbury, 2004; Vandenplas et al, 2009). Any infant with poor weight gain and vomiting should first have a thorough physical exam and be assessed for adequate caloric intake. If caloric intake is adequate, the patient should have the following studies: a complete blood count (CBC), electrolytes, and blood urea nitrogen (BUN). The NASPGHAN/ESPGHAN do not recommend an upper GI series because of low sensitivity and specificity in infants and children (Vandenplas et al, 2013). Esophageal pH monitoring or combined multiple intraluminal impedance (MII) and pH monitoring are the most sensitive and accurate way to diagnose GERD in infants and young children (Vandenplas et al, 2013). Older children or adolescents may be empirically treated with an empirical trial of PPIs for 4 weeks (Vandenplas et al, 2013). No evidence supports empirical treatment of GERD in infants (Vandenplas et al, 2013). Children who present with atypical or extra-esophageal symptoms, do not respond to initial therapy, or have recurrent progressive symptoms should be referred to a gastroenterologist. In children with recurrent vomiting or regurgitation, or difficult or painful swallowing, endoscopy and other invasive tests may be required and referral is appropriate.

Lifestyle modifications are similar to those for adults. Table 34-3 lists the modifications for infants and children.

Infants With GERD

Consultation with a pediatric gastroenterology specialist is needed for infants with suspected GERD because of the

---

Table 34–3 Lifestyle Modifications in GERD Management for Infants and Children

Antireflux Maneuvers	Dietary Considerations
Infants	
• Keep infant in upright position during feeding and for 30 min after feeding. • Elevate head of crib mattress or bed 30 degrees. Do not use pillow. • Prone position postprandially when infant is awake, but not while asleep. • Consider commercial antiregurgitation (AR) formula if formula fed.	• Do not thicken formulas with rice cereal. • Try 2 wk on hypoallergenic formula. • In breastfed infants, consider cow's milk protein intolerance. A trial of withdrawal of cow's milk and eggs from maternal diet for 2 wk is warranted.
Children	
• Elevate head of bed. • Maintain weight according to guidelines or lose weight if indicated. • Stop smoking (parents or adolescents who smoke). • Do not eat within 1–3 h of going to bed.	• Avoid substances that can cause LES relaxation, including caffeine, chocolate, peppermint, garlic, citrus fruits, tomatoes, and alcohol.

LES = lower esophageal sphincter.
Source: Vandenplas et al, 2009.

difficulty in accurately diagnosing GERD. Empirical medication treatment without studies is not appropriate in infants (Vandenplas et al, 2009). A number of randomized controlled trials in infants have not found consistent improvement in symptoms (back arching, irritability, crying, fussing, vomiting) with either PPIs or H$_2$RAs (Davidson et al, 2013; Vandenplas et al, 2013). Neonates and infants with acid reflux confirmed by esophageal pH monitoring may be treated with esomeprazole, which is FDA-approved for infants down to 1 month of age (Davidson et al; Food and Drug Administration [FDA], 2011).

Children With GERD

Older children and adolescents need a history and physical examination to confirm the suspicion of GERD. Education regarding disease pathology and lifestyle changes should be implemented. No randomized placebo-controlled trials evaluating lifestyle changes or medications in treating heartburn or GERD in children have been done (Vandenplas et al, 2009). Therefore an approach similar to that used in adults with GERD should be used.

H$_2$RAs may be prescribed in infants and children with GERD, although this is not recommended by guidelines. Ranitidine (Zantac), cimetidine (Tagamet), and famotidine (Pepcid) have liquid formulations that make pediatric dosing easier and have been used successfully in children ages 3 months to 16 years.

Alternatively, a trial of 2 to 4 weeks of PPIs may be started in older children or adolescents. If the patient does not improve, treatment continues for 8 to 12 weeks. After 12 weeks of therapy, the PPI should be discontinued. If symptoms recur, the PPI should be restarted. If there is no response to the initial 2 to 4 week trial of PPIs, the patient should be referred to a gastroenterology specialist (Vandenplas et al, 2009).

The FDA has approved four PPIs for use in children: omeprazole (Prilosec), esomeprazole (Nexium), lansoprazole (Prevacid), and rabeprazole (Aciphex Sprinkle Delayed-Release Capsules*)*. Because the long-term effects of their use in children are not known, there is some concern regarding chronic acid suppression. Long-term PPI treatment has been associated with increased rates of community-acquired pneumonia, gastroenteritis, and entercolitis (Vandenplas et al, 2009). Long-term therapy with PPIs in children warrants consultation with a specialist.

Metoclopramide has adverse reactions in children, including restlessness, insomnia, somnolence, dystonia, and extrapyramidal symptoms. Some of the drug's anti-dopaminergic adverse reactions do not resolve with drug withdrawal. The NASPGHAN/ESPGHAN GERD guidelines do not recommend the use of prokinetics in most children (Vandenplas et al, 2009). Consultation with or referral to a pediatric gastroenterologist is suggested before these drugs are prescribed.

Older Adults

Gastroesophageal reflux is more common in the elderly than younger adults (Fock & Poh, 2010; Poh, Navarro-Rodriguez, & Fass, 2010). Older patients have an age-related decrease in upper esophageal sphincter pressure and delayed gastric emptying (Fock & Poh, 2010). More elderly patients have grade III–IV esophagitis yet are less likely to report classic symptoms of heartburn, regurgitation, or epigastric pain (Poh et al, 2010). Elderly patients are more likely to present with atypical symptoms of anorexia, vomiting, respiratory symptoms, and dysphagia (Poh et al, 2010; Scholl, Dellon, & Shaheen, 2011).

Antacids are generally safe in older adults, but antacids with constipation as an adverse reaction may be more problematic for them. In addition, many antacids have high sodium content, and some older adults are on low- to moderate-sodium diets. Among the H$_2$RAs, famotidine (Pepcid) is generally safe in the older population but should be used with caution in cases of renal insufficiency. Nizatidine (Axid) may cause asymptomatic ventricular tachycardia and carries a risk of hepatocellular injury. Ranitidine (Zantac) and cimetidine (Tagamet) carry risks for mental status changes in older adults (Poh et al, 2010). Because older adults are often taking several prescription and OTC drugs, the increased number of drug interactions associated with cimetidine also makes it a less attractive choice.

PPIs are generally safe in the elderly and provide rapid relief of symptoms and healing of erosive esophagitis (Poh et al, 2010; Scholl, Dellon, & Shaheen, 2010). Patients with hepatic impairment will have decreased clearance of PPIs and may need a dosage adjustment. Of concern are drug interactions associated with PPIs that are metabolized by CYP2C19 and CYP3A4, including interactions with warfarin, phenytoin, diazepam, and clopidrogrel (Poh et al, 2010). Patients taking PPIs and drugs with a narrow therapeutic range, such as warfarin or phenytoin, should be monitored closely during therapy. Elderly patients taking PPIs are at increased risk of community-acquired pneumonia, *Clostridium difficile* infections, and possible bone fractures in immobile patients (Scholl, Dellon, & Shaheen, 2011).

Among the prokinetics, metoclopramide has a risk for central nervous system (CNS) toxicity. In addition, it is contraindicated in congestive heart failure, renal failure, and hypokalemia, all of which are more common in older adults. Metoclopramide requires careful thought and monitoring in older adults.

Monitoring

Esophagitis is the cause of 5% to 10% of all cases of upper GI bleeding. Monitoring by complete blood count at annual exams is appropriate. The remainder of monitoring is clinical evaluation of symptoms.

Endoscopy to demonstrate the presence of lesions and their healing is the gold standard. It is shown in each algorithm at various steps of therapy. For patients requiring ongoing step 3 or 4 therapy, some specialists recommend endoscopy. Given its cost, others suggest endoscopy every 2 to 3 years because Barrett's esophagus is not reversible.

Long-term use of PPIs presents concerns. One concern is the development of precancerous cells due to hypochlorhydria, with enterochromaffin cell–like hyperplasia changes found in chronic PPI use (Lodato et al, 2010; Vandenplas et al, 2009). Another concern is an increase in hip fractures in at-risk patients who are on PPIs longer than 2 years and on higher doses of PPIs (Corley, Kubo, Zhao, & Quesenberry, 2010). Vitamin B_{12} deficiency is also a concern with chronic acid suppression.

Outcome Evaluation

Figure 34-2 shows the treatment algorithm for GERD. Outcome evaluation targets relief of symptoms. Evaluation also includes the other goals for therapy: healing of lesions, prevention of complications, and prevention of relapse.

Relapse rates are high for patients with GERD. Lifestyle modifications and some drug therapies are commonly required for life. H_2RAs or PPIs may be required chronically but at reduced doses. Return of symptoms for a patient who has been pain-free and is adherent to the treatment regimen suggests that the provider should increase the dosage of the current drug or move the patient to the next step in the algorithm and arrange for endoscopy evaluation.

Referral to a pediatric specialist is warranted for any infant younger than 2 months who presents with vomiting or other symptoms of GERD. Children and infants older than 2 months who are unresponsive to short-term (2 to 4 wk at each step) empirical treatment or have suspected or demonstrated complications also require referral.

Patients who have mild or typical symptoms and who respond to conservative treatment can be managed by the primary care provider. Patients who do not respond to 4 to 8 weeks of step 2 therapy should have a referral to a gastroenterologist, which means at least consultation with a gastroenterologist. Patients with erosive disease or who do not respond to step 3 therapy require referral to a specialist. These patients are at high risk for Barrett's esophagus, which carries with it a 30-fold greater risk for developing esophageal cancer than the general population.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for the drug being taken, drugs as part of the total treatment regimen, and adherence issues.

PEPTIC ULCER DISEASE

Peptic ulcer disease (PUD) is a common clinical problem estimated to have a lifetime incidence of 12% in men and 10% in women (Lew, 2009). PUD is listed as the primary diagnosis in 712,000 ambulatory care visits annually, and 1,473,000 visits annually have PUD listed as one of the diagnoses (National Institutes of Health, 2009b). The rate of hospital admission for uncomplicated ulcer has decreased significantly, but the incidence has not decreased, making this largely a disease that is treated in the primary care setting. Risk factors for PUD include smoking and habitual use of NSAIDs or alcohol, but the main culprit is *H. pylori* infection, which has been firmly established as a major cause of PUD. Reduction of stress and other factors that increase gastric acid secretion are still included in disease management.

Peptic ulcers fall into two categories: duodenal ulcers and gastric ulcers. Each has a slightly different pathology and treatment, although they share many aspects of both. They are addressed separately here.

Pathophysiology

PUD is a chronic inflammatory condition of the stomach and duodenum. It is the result of increased acid and pepsin secretion; impaired mucosal cytoprotection; use of NSAIDs; *H. pylori;* personal factors such as genetics, smoking, and stress; or a combination of these causes. Definitive diagnosis is via esophagogastroduodenoscopy.

The incidence of gastric ulcers differs from that of duodenal ulcers. Gastric ulcer disease is about one-fourth as common as duodenal ulcer disease. The pathophysiology of the disorders also varies. Table 34-4 compares the incidence, pathophysiology, and signs and symptoms of the two disorders.

Gastric Ulcer Disease

Gastric ulcers tend to develop in the antral region, adjacent to the acid-secreting mucosa of the body. Although the pathogenesis of gastric ulcer disease is unclear, it is generally thought that the underlying defect is a disruption that increases the gastric mucosal barrier's permeability to hydrogen ions. *H. pylori* is seen in 75% to 85% of patients with gastric ulcers. Gastric acid secretion may be normal or less than normal. A variety of substances can disrupt this barrier. They are summarized in Box 34-2.

Another suggested contributing factor is increased duodenal gastric reflux of bile across an incompetent pyloric sphincter. An increased concentration of bile salts disrupts the gastric mucosa and decreases the electrical potential across the gastric mucosal membrane. This altered electrical potential permits the diffusion of hydrogen ions into the mucosa, where they disrupt permeability and cellular structure. Once the barrier is broken, the damaged submucosal areas exposed to hydrogen ions release histamine, which stimulates an increase in acid and pepsinogen production, causes local vasodilation, and increases capillary permeability. The pepsinogen produces mucosal erosion, resulting in the formation of ulcers. The disrupted mucosa becomes edematous and loses plasma proteins. Destruction of small blood vessels results in bleeding.

Pyloric stenosis has also been given as a possible cause of gastric ulcer formation. With pyloric deformity, gastric emptying is poor, resulting in stasis and antral distention. This distention leads to increased gastrin release and gastric acid production.

Chronic gastritis has also been associated with the development of gastric ulcers. It may precipitate ulcer

PATIENT EDUCATION

Gastroesophageal Reflux Disease

RELATED TO THE OVERALL TREATMENT PLAN/DISEASE PROCESS

☐ Pathophysiology of gastroesophageal reflux and its long-term risks for permanent esophageal damage and cancer of the esophagus

☐ Central role of lifestyle modifications in improving prognosis and keeping the number and cost of required drugs down

☐ Importance of adherence to the treatment regimen

☐ Need for follow-up visits with the primary care provider if the symptoms do not resolve or if they recur

SPECIFIC TO THE DRUG THERAPY

☐ Reason for the drug(s) being given and the anticipated action of the drug(s) on the disease process

☐ Doses and schedules for taking the drug(s)

☐ Possible adverse reactions and what to do when they occur

☐ Coping mechanisms for complex and costly drug regimens

☐ Interaction between lifestyle modifications and these drugs

REASONS FOR TAKING THE DRUG(S)

Patient education about specific drugs is provided in Chapter 20. Specific information related to GERD: drugs used to treat GERD are given to reduce symptoms, heal any esophageal ulcers, reduce the risk for permanent esophageal damage or cancer, and prevent relapse of symptoms. Different drugs have different roles with each of these. The expectations should be clear about what the drugs can and cannot do. Drugs alone will not correct the disorder.

DRUGS AS PART OF THE TOTAL TREATMENT REGIMEN

Lifestyle modification is equally important in disease management. GERD is a chronic condition. Patients with GERD must understand the lifelong nature of the disorder and the need to incorporate the treatment regimen into their everyday lives.

ADHERENCE ISSUES

Any disease process where lifestyle modifications are central to management is prone to problems with adherence. Healthcare providers should be aware of the potential problem of nonadherence, discuss the importance of adherence at each follow-up visit, and assist patients in removing barriers to adherence, such as the complexity and cost of the treatment regimen and the presence of adverse reactions.

Table 34–4 Comparison of Gastric and Duodenal Ulcer Disease

Characteristic	Gastric Ulcer	Duodenal Ulcer
Age at onset	50–70 yr	20–50 yr
Gender	Equal in men and women	More common in men
Cancer risk	Increased	Not increased
Pathophysiology		
Parietal cell mass	Normal or decreased	Increased
Acid production	Normal or decreased	Increased
Serum gastrin	Increased	Normal
Serum pepsinogen	Normal	Increased
Associated gastritis	More common	Usually not present
Helicobacter pylori	Present in 60%–80% of cases	Present in 95%–100% of cases
Clinical manifestations: pain	Located in upper abdomen intermittent	Located in upper abdomen intermittent
	Pain > antacid > relief pattern	Pain > antacid or food > relief pattern
	Food > pain pattern	Nocturnal pain common
Clinical course	Chronic ulcer without pattern of exacerbation and remission	Pattern of exacerbation and remission for years*

*This pattern is significantly affected by eradication of *H. pylori*.

formation by limiting the ability of the mucosa to secrete a protective layer of mucus. Decreased mucosal synthesis of prostaglandin (e.g., NSAIDs) may also create an ulcerogenic environment.

Duodenal Ulcer Disease

Infection with *H. pylori* is the major cause of duodenal ulcers. With the exception of patients taking NSAIDs, 95% to 100% of patients with duodenal ulcer are infected with this organism. It is a spiral-shaped bacterium that lives attached to or just above the gastric mucosa. Once *H. pylori* is acquired, colonization continues for life unless the organism is eliminated by antimicrobial treatment or the usually late-in-life development of atrophic gastritis. Essentially everyone who carries the organism in the gastric mucosal layer has evidence of some tissue reaction (e.g., an inflammatory response and chronic active gastritis), yet most colonized patients remain asymptomatic for life. The strain of *H. pylori* with which an individual is colonized (spiral shape, flagella, and specific ability to attach to Lewis B antigens in persons with type O blood) affects risk for disease.

Once attached to the mucosal layer, *H. pylori* releases toxins, proteases, and phospholipase enzymes that promote inflammation and impair the integrity of the mucosal layer. The inflammatory process includes the release of histamine, which acts the same on the duodenal mucosa and on the gastric mucosa. The end result is ulceration. Eradication of *H. pylori* reduces ulcer recurrence (Lew, 2009).

Diagnosis

Diagnosis of ulcerative disease involves radiographic and endoscopic evaluation of the upper GI tract and testing for *H. pylori* colonization. The American College of Gastroenterology guidelines recommend all patients with peptic ulcers should be tested for *H. pylori* (Chey, Wong, & the Practice Parameters Committee of the American College of Gastroenterology, 2006). A number of tests can be used, including endoscopic testing for cytology and noninvasive tests, including serological testing, urea breath test, stool antigen test, and rapid stool antigen test (Crowe, 2013a).

Invasive diagnostic procedures are determined in consultation with or by referral to a gastroenterologist. Endoscopy is the gold standard for confirming peptic ulcer disease and to rule out gastric cancer (Lew, 2009). For further discussion of the diagnostic process associated with PUD, the reader is referred to management texts. The treatment protocol presented here assumes appropriate diagnosis of PUD.

Pharmacodynamics

Eradication of *H. pylori* is critical to PUD treatment; therefore, all recommended treatment regimens include a combination of a PPI and antimicrobial therapy. Antimicrobial agents used include clarithromycin, tetracycline, amoxicillin, levofloxacin, and metronidazole. They are given in a triple drug regimen or a quadruple drug regimen that includes bismuth subsalicylate. Acid suppression by the PPI in conjunction with the antimicrobial helps alleviate the ulcer-related symptoms, heals gastric mucosal inflammation, and may enhance the efficacy of the antimicrobial agent against *H. pylori* at the mucosal surface. Antimicrobials are discussed in more detail in Chapter 24.

Goals of Treatment

Goals of treatment for PUD are (1) to eradicate *H. pylori*, (2) heal any ulcers, (3) manage or prevent complications such as GI bleeding or the development of gastric carcinoma, (4) prevent relapse, and (5) reduce or eliminate symptoms. Meeting these goals requires both lifestyle modification and drug therapy, but lifestyle modification is less important in PUD than it is in GERD.

Rational Drug Selection

Algorithm

The treatment algorithm outlines the steps in treating peptic ulcers that consist of healing the ulcer and preventing ulcer recurrence through eradication of *H. pylori*. Ulcers that are associated with NSAID use are discussed in Chapter 25.

As with GERD, step 1 involves lifestyle modifications and OTC antacids or histamine$_2$ blockers. Most patients have tried some step 1 interventions before they seek health care. This step alone may be sufficient for patients with mild disease and only occasional symptoms, but this step alone is not likely to heal any ulcers. Progression to step 2 is usually required, especially for duodenal ulcers and for those that are a result of *H. pylori* infection. Figure 34-3 shows the stepped algorithm for peptic ulcer disease. See Table 34-5 for diagnostic tests.

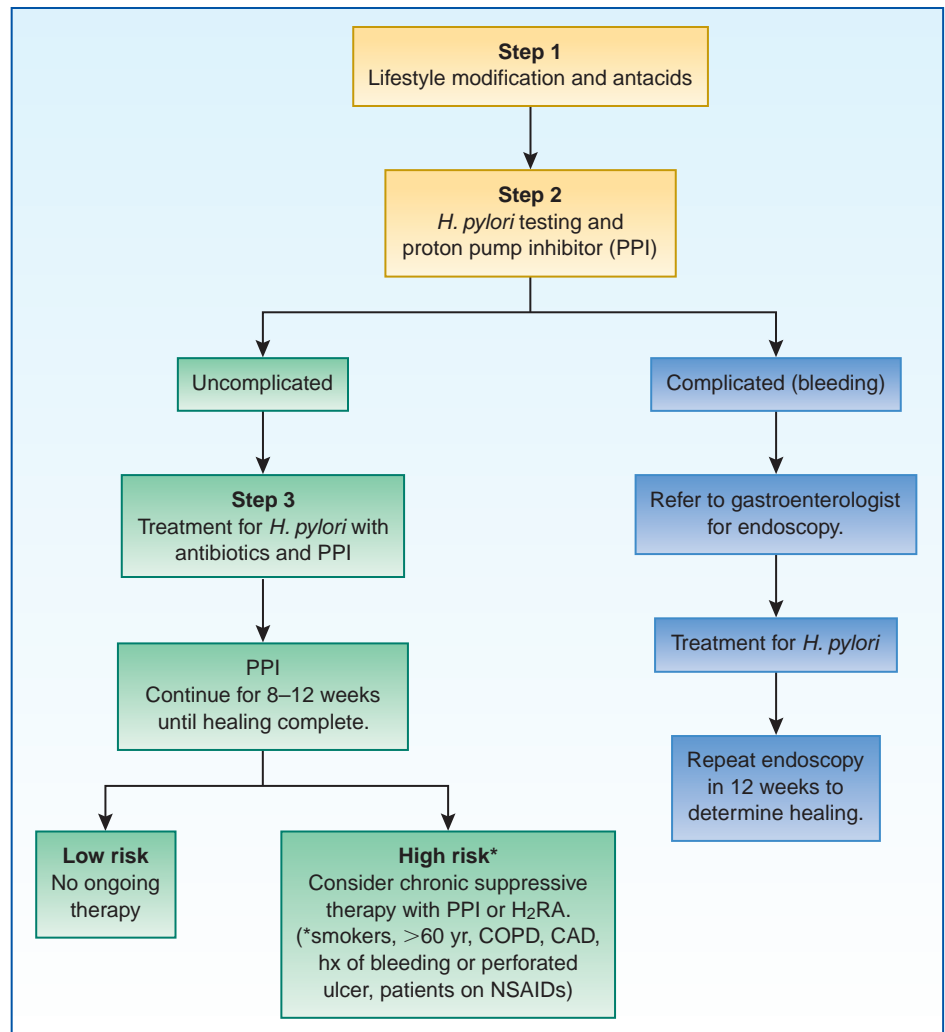
Step 2 for patients with uncomplicated gastric ulcers includes testing and treating for *H. pylori* and acid suppressive therapy with PPIs. Multiple treatment regimens for *H. pylori*


Figure 34–3. Stepped-approach algorithm for peptic ulcer disease.

Table 34–5 Invasive and Noninvasive Diagnostic Tests for *Helicobacter pylori*

Test	Sensitivity	Specificity	Comments
Noninvasive			
Serological ELISA	85%	79%	Detects *H. pylori*; cannot be used to confirm successful cure
Urea breath test	95%–100%	91%–98%	Can be used for screening and confirming cure. PPIs and recent antibiotics can cause false negative.
H. pylori stool antigen test	91%–98%	94%–99%	Can be used for initial diagnosis and test of cure
Invasive			
Rapid urease test	93%–97%%	95%–100%	
Culture of biopsy specimen	70%–80%	100%	
Histological evaluation	>95%	95%–98%	

PPI = protein pump inhibitor.

eradication are available, including combining a PPI and two antibiotics for 14 days (Lew, 2009; Soll, 2011). Maintenance therapy with an antisecretory agent, usually a PPI, at the full healing dose is necessary. Table 34-6 presents the multiple evidence-based treatment regimens.

Ulcers complicated by bleeding require endoscopy for diagnosis of the lesion. Healing should also be documented by endoscopy after 12 weeks of antisecretory therapy (usually PPIs) to document healing. Patients who are taking NSAIDs should be switched to a COX-2 inhibitor to achieve analgesic

Table 34–6 ⊗ **Drug Treatment Protocols for *Helicobacter pylori* Eradication**

	Drug 1	Drug 2	Drug 3	Drug 4	Comments
Triple therapy	Proton pump inhibitor bid	Clarithromycin 500 mg bid or metronidazole 500 mg bid	Amoxicillin 1 g bid	—	Treat for 10–14 d Usual first-line therapy
Triple therapy	Proton pump inhibitor bid	Clarithromycin 500 mg bid	Metronidazole 500 mg bid	—	Treat for 7–14 d Use as first-line therapy in penicillin-allergic patients
Quadruple therapy	Proton pump inhibitor bid *or* Ranitidine 150 mg bid	Metronidazole 250 mg qid	Tetracycline* 500 mg qid	Bismuth sub-salicylate 525 mg qid	Treat for 10–14 d Usually used as second-line therapy in patients who fail first-line therapy
Levofloxacin-based triple therapy	Proton pump inhibitor bid	Levofloxacin 250–500 mg bid	Amoxicillin 1 gm bid		Treat for 10–14 d Second-line or rescue therapy

*Children <8 yr should not take tetracycline. Other treatment regimens with dosage adjustments for children are acceptable. Some come with drugs grouped in packets.
Proton pump inhibitors include esomeprazole 40 mg, lansoprazole 30 mg, omeprazole 20 mg, pantoprazole 40 mg, rabeprazole 20 mg.
Source: Crowe, 2013b; Lew, 2009.

and anti-inflammatory effects similar to NSAIDs but with fewer GI complications (Soll, 2011).

Duodenal and gastric ulcers recur in up to 80% of patients treated with drugs to reduce gastric acid but not treated for eradication of *H. pylori* infection. By comparison, 6% to 15% of patients have recurrent ulcers when their *H. pylori* infection is cured.

Maintenance therapy with an antisecretory agent is not generally required after eradication of *H. pylori.* However, it is prudent to prescribe maintenance therapy for certain high-risk groups: smokers; patients older than 60 years; patients with chronic obstructive pulmonary disease, coronary artery disease, or renal failure; patients with a history of bleeding or perforated ulcer; patients with persistent symptoms; and those who must take NSAIDs or other ulcerogenic drugs.

Patients with gastric or duodenal ulcers who fail to become symptom-free or who develop complications such as GI bleeding while on antisecretory therapy require a referral to a gastroenterologist. Surgery is contemplated for gastric ulcer patients.

Lifestyle Modifications

Evidence is lacking that dietary modifications affect the course of PUD. Frequent small meals and decreased consumption of spices, alcohol, caffeine, and fruit juices have never been demonstrated to affect healing. Dietary changes should be directed at those substances that cause symptoms in each particular patient. An important lifestyle modification is smoking cessation. Smoking both increases the risk for gastric and duodenal ulcers and delays their healing (Soll & Vakil, 2012).

Aspirin and NSAIDs are known to be ulcerogenic. Their use should be discouraged and a high index of suspicion for

NSAID and aspirin use is required because patients do not always report OTC use (Soll & Vakil, 2012).

Drug Therapy

Currently, the FDA approves eight treatment regimens; however, several other combinations have been used successfully. Regimens include triple or quadruple drug therapy with a variety of drugs. The treatment regimens that have the highest rate of success in eradication, the best likelihood of adherence related to number of drugs taken, and adverse effects are presented in Table 34-6. All include a twice-daily dose of a PPI. The most popular antibiotics are clarithromycin (Biaxin) and amoxicillin. Because all these drugs can be taken twice daily, the regimen is simple and has a limited number of drugs.

Selection among the protocols is based on cost, convenience, ability to tolerate the adverse drug reactions of the total regimen, antimicrobial resistance, patient variables, and eradication rates. For each patient, assess the likelihood of adherence and use the most cost-effective but simplest drug regimen that will get the job done.

Adverse Drug Reactions for the Total Regimen

Adverse drug reactions have been reported in up to 70% of patients taking bismuth-based four-drug regimens. Metronidazole-based regimens have increased adverse reactions. Overall, the best regimen for tolerability appears to be a PPI-based three-drug regimen. Happily, these regimens also are highly efficacious.

Antimicrobial Resistance

Concern about antimicrobial resistance has increased, regardless of the disease process for which these drugs are being

used. Chapter 24 discusses resistance to the various antimicrobials. Resistance associated with *H. pylori* eradication has been linked to the length and complexity of the treatment regimen and the tolerability of adverse reactions. Resistance to metronidazole is most common and higher in women (Crowe, 2013b). Resistance to clarithromycin is low (10%), as is resistance to amoxicillin and tetracycline. Acquired resistance occurs in up to two-thirds of treatment failures. Changing drugs and trying a different treatment regimen may be useful in these instances. First- and second-line therapy options are presented in Table 34-6.

Patient Variables

Several patient variables need to be considered. Patients with allergies to any of the drugs in a treatment regimen require a different regimen. Women of childbearing age should use a regimen that does not include tetracycline because of the risk for fetal harm. The same is true for children younger than 8 years because of problems related to discoloration of teeth. Each of the drugs in these regimens has potential drug interactions. Other drugs the patient may be taking must be taken into account.

Given all these parameters, the treatment regimen with good to excellent eradication rates, a low to medium adverse reactions profile, likelihood of adherence based on complexity of the regimen and moderate cost, and limited antimicrobial resistance appears to be clarithromycin plus amoxicillin plus a PPI, all taken twice a day for 10 to 14 days.

Monitoring

Monitoring parameters for each of the drugs in these treatment regimens are presented in Chapters 20 and 24. Documentation of ulcer healing by endoscopy 12 weeks after the end of therapy is the gold standard. Cost considerations suggest reserving it for patients who are at high risk for complications, patients with recurrence, and those who will be on long-term therapy. The urea breath test or stool antigen testing can be used to screen symptomatic patients who are suspected of having recurrent ulcers associated with *H. pylori* infection. Note that serological testing for *H. pylori* may be falsely negative if the patient is on PPIs or recently on antibiotics. Documentation by endoscopy is optional for low-risk patients.

Outcome Evaluation

Figure 34-3 shows the treatment algorithm for PUD. Outcome evaluation targets eradication of *H. pylori* and relief of symptoms. Evaluation also includes the other goals for therapy: healing of lesions, prevention of complications, and prevention of relapse. Relapse rates are high for patients with PUD but can be significantly reduced with appropriate maintenance therapy or eradication of *H. pylori* infection.

Patients with PUD who remain symptom-free without drugs or on maintenance therapy require no more frequent follow-up than their annual physical examination.

PATIENT EDUCATION

Peptic Ulcer Disease

RELATED TO THE OVERALL TREATMENT PLAN/DISEASE PROCESS

☐ Understanding the pathophysiology of ulcer formation and its long-term risks for bleeding and cancer of the stomach

☐ Role of lifestyle modifications in total treatment regimen

☐ Importance of adherence to the treatment regimen, especially in light of antimicrobial resistance

☐ Need for follow-up visits with the primary care provider if the symptoms recur or do not resolve

SPECIFIC TO THE DRUG THERAPY

☐ Reason for the drug(s) being given and the anticipated action of the drug(s) on the disease process

☐ Doses and schedules for taking the drug(s)

☐ Possible adverse reactions and what to do when they occur

☐ Coping mechanisms for complex and costly drug regimens

☐ Interactions between lifestyle modifications and these drugs

REASONS FOR TAKING THE DRUG(S)

Patient education about specific drugs is provided in Chapters 20 and 24. Specific information related to PUD includes the following: drugs used to treat PUD are given to treat *H. pylori,* reduce symptoms, heal any ulcers, reduce the risk for complications, and prevent relapse of symptoms. Different drugs have different roles with each of these.

DRUGS AS PART OF THE TOTAL TREATMENT REGIMEN

Lifestyle modification is important in disease management. PUD is often a chronic condition, requiring lifelong maintenance therapy.

ADHERENCE ISSUES

Any disease process in which lifestyle modifications are required or in which a complex regimen of three or four drugs over a period of weeks is required is likely to have problems with adherence. Health-care providers should be aware of the potential problem of nonadherence, discuss the importance of adherence, and assist patients in removing barriers to adherence, such as the complexity and cost of the treatment regimen and the presence of adverse reactions.

Patients with *H. pylori* infection–associated ulcers that do not respond to the first course of antimicrobial therapy should be evaluated for noncompliance. Ask about missed doses, adverse effects of medications, and completion of the therapy prescribed (Crowe, 2013b; Lew, 2009). Antibiotic resistance may occur. Culture and sensitivity are not routinely used in PUD treatment. A second course of therapy with a different drug

combination for 14 days is recommended (Crowe, 2013b; Lew, 2009). If the patient still has symptoms and eradication fails, referral to a gastroenterologist is appropriate. Other causes, such as Zollinger-Ellison syndrome, may be present.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for the drug being taken, drugs as part of the total treatment regimen, and adherence issues.

HEADACHES

Theresa Mallick-Searle

Headaches are a common presenting complaint in primary care, accounting for 18 million outpatient visits per year in the United States. This makes headaches the seventh-leading chief complaint in ambulatory clinics. More than 80 percent of adult Americans report that they experience recurrent headache, with 35% to 50% labeling their headache severe enough to disrupt their activities of daily living (Marin, 1998; Smith, 1998). Globally, the percentages of the adult population with an active headache disorder are 47% for headache in general, 10% for migraine, up to 70% for tension-type headache in some populations, and 5% for medication-overuse headache (World Health Organization, 2012). These numbers indicate that the disability attributable to tension-type headache is larger worldwide than that due to migraine.

In the United States, 12% of the general population affected, with women affected more frequently than men (Cutrer, Bajwa, & Sabahat, 2014), the cost of direct medical care for migraine is $1.25 to $11 billion, and the cost to American employers is $13 billion annually because of an

estimated 113 million missed workdays and impaired work function (Migraine Research Foundation, 2014). Successful pharmacological management of headache can improve the quality of life for millions of Americans. The Institute for Clinical Systems Improvement (ICSI, 2009) provides guidelines for treatment of multiple types of headaches, while the U.S. Headache Consortium provides evidence-based guidelines for the treatment of migraine (Matcher et al, 2000). These two evidence-based guidelines are used for treatment recommendations in this chapter.

Headaches affect all age groups, from preverbal children to the older patient. When asked, 20% to 40% of school-age children report having had headaches. The onset of migraine usually occurs between the ages of 15 and 25, although younger children may experience migraine. The peak incidence of headache is in young adulthood (25 to 34 years), with the incidence waning as a patient gets older. Onset of headache after age 50 or headaches increasing in frequency or severity should lead to the investigation of underlying neurological disease.

The most common types of headaches can be classified as migraine, tension-type, and chronic daily headache, which may present as a mixed form of tension type and migraine, or chronic migraine. Medication-overuse is also identified as a cause of chronic daily headache. Cluster headaches are uncommon, but severely debilitating. Where still little is known regarding the specific pathophysiology in post-concussive headaches, much research and focus has recently been placed on this underrecognized type of headache. The pharmacological management of common types of headaches is discussed in this chapter. Pathological headaches, caused by space-occupying lesions, alterations in intracranial pressure, or other pathology, are not discussed here, other than to note when the differential should lead to pathology rather than to common headaches. To assist the provider in diagnosing the correct type of headache, it is helpful to use a headache screening questionnaire that addresses four questions adopted by the American Academy of Neurology:

1. How often do you get severe headaches (i.e., without treatment it is difficult to function)?
2. How often do you get other (milder) headaches?
3. How often do you take headache relievers or pain pills?
4. Has there been any recent change in your headaches? (Bajwa & Wootton, 2013).

MIGRAINE

Migraine headaches are a complex multifactorial condition, which may be classified in three categories: migraine with aura (classic migraine), migraine without aura (common migraine), and complicated migraine. Classification of migraine, although important for accurate diagnosis, does not affect the pharmacological management. This chapter discusses acute or abortive therapy and preventive therapy, as well as nonpharmacological therapy for treating migraine.

Pathophysiology

There are several theories regarding the pathogenesis of migraine headache. The vascular theory proposes that the aura preceding migraine is caused by vasoconstriction of intracranial vessels, and vasodilation of the affected vessels results in the typical vascular headache pain that throbs in unison with the pulse. The vascular theory has been disputed because not all migraine sufferers have a pulsatile quality to their headache pain.

Considerable evidence associates migraine with changes in serotonin activity that result in release of vasoactive neurotransmitters (substance P, bradykinin, neurokinin A, and calcitonin gene-related peptides). This produces an inflammatory response around the blood vessels of the dura mater and pia mater and is accompanied by dilation of cerebral blood vessels. Specific excitatory serotonin receptors (5-HT_2), when activated, can lead to migraine. Many of the abortive agents used for migraine appear to stimulate inhibitory serotonin receptors (5-HT_1 and 5-HT_{1D}) or block 5-HT_2 receptors.

There is a strong familial component to migraine, with 20% to 60% of patients reporting a family history of migraine. Migraine is 2 to 3 times more prevalent in women than in men. Women with migraines may have increased headaches around the time of their menstrual periods and if they are taking estrogen-containing medications, such as oral contraceptives. Other known triggers of migraine include alcohol, strong light, noxious odors, extreme fatigue, and certain foods. Table 35-1 lists common triggers that may precipitate a migraine headache in patients prone to migraine.

Goals of Treatment

The overall goal of therapy is to minimize the impact of migraine headaches on patients' quality of life, social functioning, and ability to work. A second goal is prevention of migraine by avoiding each patient's identified triggers and prophylaxis for frequent migraine sufferers. Minimizing adverse effects of pharmacotherapy and avoidance of medication overuse/abuse that can lead to medication-overuse headaches should also be goals of both the provider and the patient.

Rational Drug Selection

Pharmacological management of migraine is divided into two major components: acute or abortive therapy and preventive or prophylactic therapy. Most patients with migraine need only abortive therapy for their headaches. If migraine frequency is greater than twice a month and/or severely debilitating or if abortive agents are ineffective, the health-care provider should consider prescribing daily preventive therapy.

Acute Therapy

Acute or abortive therapy is aimed at reversing, aborting, or reducing pain and accompanying symptoms of an attack that is in progress or is anticipated. Acute therapy for migraines can range from simple over-the-counter (OTC) analgesics to intramuscular (IM) dihydroergotamine, which needs to be

Table 35–1 Common Migraine Triggers

Factor	Triggers
Environmental factors	Noxious smells and fumes Bright light or glare Tobacco smoke
Foods	Caffeine (coffee, tea, caffeine-containing medications or beverages) Nuts, peanut butter, pea pods, lima or navy beans Alcohol (red wine, beer, liquor) Aged cheese Monosodium glutamate (MSG) (in Chinese food, seasoning salt, processed foods, soups) Chocolate (sweets, foods, drinks) Nitrites and nitrates (processed meats, hot dogs) Onions Avocados Dairy products (ice cream, yogurt, cheese, sour cream, milk, cream) Pickled or smoked foods (pickled herring, smoked fish) Citrus fruits, bananas, figs, raisins Aspartame (in many foods and drinks labeled "sugar free") Sulfites Yeast products (in bread, donuts)
Lifestyle	Hunger/fasting Oversleeping Inadequate sleep Stress Lack of exercise Prolonged sitting in an uncomfortable position Extended computer usage
Hormonal	Menses Menopause Oral contraceptives Hormonal replacement therapy
Medications	Nitroglycerin Oral contraceptives Antihypertensives Theophylline Antibiotics (TMP/SMZ, griseofulvin) Histamine$_2$ blockers (cimetidine, ranitidine) Analgesic or ergotamine overuse Indomethacin

TMP/SMZ = trimethoprim/sulfamethoxazole.

administered in a clinic or emergency room setting. Oral (PO) therapy may not be effective in patients with associated nausea or vomiting. The stepwise approach to selecting migraine medications for acute treatment is helpful, based on the severity of the pain and associated symptoms. Figure 35-1 is an algorithm that addresses the steps in acute migraine therapy.

The US Headache Consortium, consisting of the American Academy of Family Physicians (AAFP), American Academy of Neurology (AAN), American Headache Society (AHS), American College of Emergency Physicians (ACEP), American College of Physicians (ACP), American Osteopathic Association (AOA), and the National Headache Foundation (NHF), has evaluated the evidence regarding the clinical effectiveness of pharmacological treatment of acute attacks and their guidelines are used in this chapter (Matcher et al, 2000). Although this section discusses pharmacological treatment, nonpharmacological therapy—specifically applying ice to the head and/or lying down in a darkened room—must accompany the medication. The patient must be advised not to try to "work through" a migraine by just taking medication.

Simple Analgesics

Simple analgesics such as aspirin (ASA) and acetaminophen (APAP) or NSAIDs are the first step in the acute treatment of mild to moderate migraine that is not associated with severe nausea or vomiting. Patients often self-medicate with OTC analgesics, relying on advertising messages to choose a medication. The health-care provider needs to be aware that most patients have already self-medicated to treat their migraines and that they are often seeking care because their treatment is no longer effective. If the provider decides to begin treatment with an OTC product, educating the patient about the rationale for starting with an OTC product will increase compliance.

Clinical experience and population-based studies have demonstrated the effectiveness of OTC analgesics in treating migraine, especially if taken early. The mechanism of action for the various OTC preparations is not completely understood. ASA is thought to have antiprostaglandin and antiplatelet activity that might deliver relief from migraine attack. There is evidence that ASA may also act centrally and has serotoninergic activity. APAP is thought to act centrally and inhibit prostaglandin synthesis. NSAIDs also inhibit prostaglandin synthesis and have a central analgesic mechanism of action. Their anti-inflammatory and antipyretic activity may also contribute to migraine relief. Caffeine is an ingredient in many OTC "headache" preparations (Table 35-2) and plays a role as an analgesic adjuvant when added to ASA or in combination with APAP. The U.S. Food and Drug Administration (FDA) has approved two OTC medications to be labeled specifically for migraine pain: one is a combination of ASA, APAP, and caffeine (Excedrin Migraine), and the other is ibuprofen in a liquid-filled capsule (Advil Migraine).

The dosing of ASA or APAP should be limited to a 1,000 mg dose (10 to 15 mg/kg for children) at the beginning of migraine symptoms or aura, with a maximum of 4,000 mg per day. The U.S. Headache Consortium recommends the combination of acetaminophen plus aspirin plus caffeine (Excedrin Migraine) as a "Group 1 drug with proven pronounced statistical and clinical benefit" (Matcher et al, 2000). APAP has varied results for acute migraine treatment and may not be any better than placebo (Matcher et al, 2000). Medication-overuse headaches are possible if ASA or APAP is used more than 3 days per week.

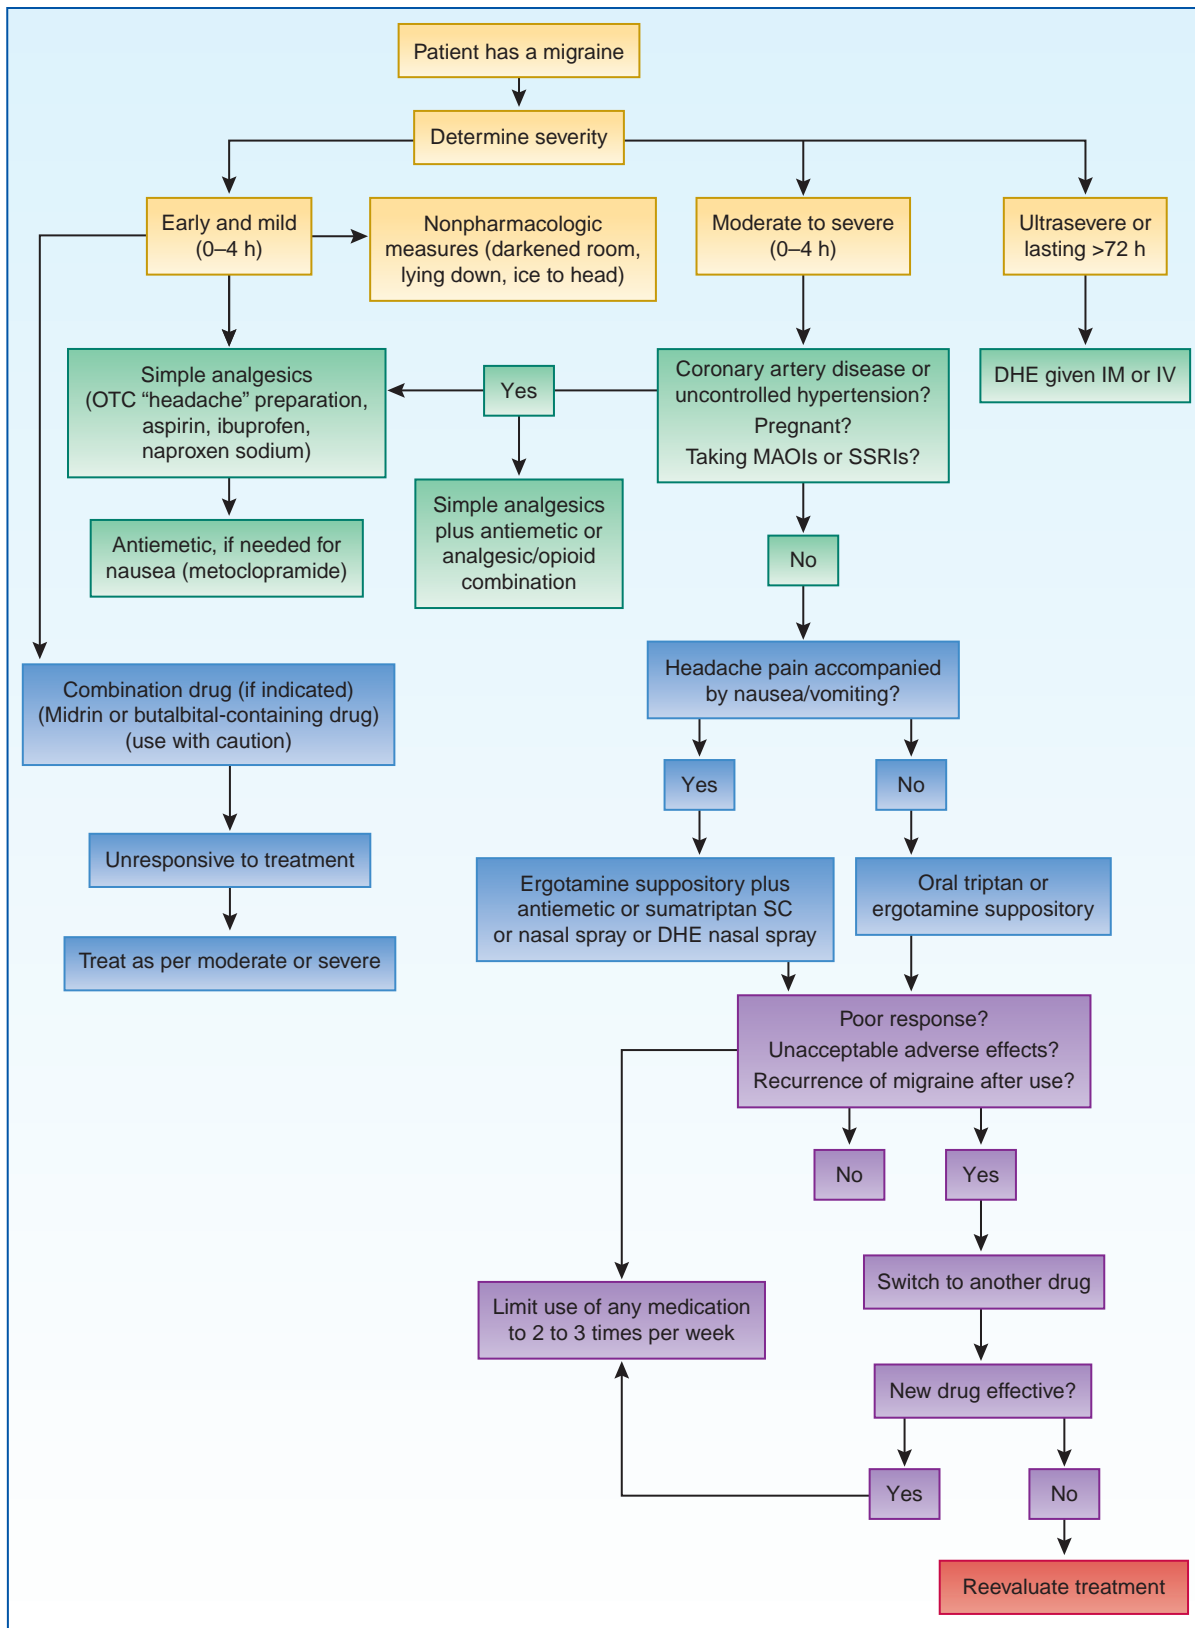
The NSAIDs have been found to diminish the severity and duration of migraine attacks. Although no NSAID has been found to be better than another in clinical trials, there is a variable response to the different agents that differs from patient to patient. Ibuprofen and naproxen are both group 1 drugs with proven clinical efficacy (Matcher et al, 2000). The use of NSAIDs can involve trying multiple medications


Figure 35–1. Treatment algorithm for acute migraine headache.

before an effective agent is found. Naproxen sodium (Anaprox, Aleve) is often a first choice for migraine, as it is quickly absorbed and well tolerated. The initial starting dose of naproxen sodium is 550 mg, followed by 550 mg twice a day

or 275 mg every 6 to 8 hours. The dose of naproxen sodium for children is 10 to 20 mg/kg/d divided in twice-daily dosing. Although the majority of NSAIDs are given PO, in-domethacin (Indocin) is also available in suppository form,

Table 35–2   Drugs Commonly Used: Headaches

Drug	Initial Dose	Maximum Dose	Strengths Available	Rebound Potential	Comments
			Acute Therapy		
Nonnarcotic Analgesics					
Acetaminophen (OTC: Tylenol)	*Adults:* 650–1,000 mg at onset and every 4–6 h *Children:* 10–15 mg/kg/dose	*Adults:* 4,000 mg/day 2–3 d/wk 30 dosages/mo *Children:* 5 doses in 24 h	*Tablets:* 160, 325, 500, 650 mg *Liquid:* 80 mg/0.8 mL; 160 mg/5 mL *Chewable:* 80, 160 mg *Suppositories:* 80, 120, 325, 650 mg	Yes	Safe in pregnancy, lactation, and in most patients Not recommended for first-line therapy except in pregnant patients Risk for drug medication-overuse HA
Aspirin (OTC: Bayer, Bufferin, Ecotrin)	*Adults:* 650–1,000 mg at onset and every 4–6 h *Children:* Not recommended	*Adults:* 4,000 mg/d 2–3 d/wk 30 dosages/mo	*Tablets:* 325, 500, 650, 975 mg *Suppositories:* 300, 600 mg	Yes	Contraindicated in pregnancy (Category D) Avoid use within 1 wk of surgery Risk for medication-overuse HA
Ibuprofen (OTC: Motrin IB, Advil, Nuprin; Rx: Motrin)	*Adults:* 200–800 mg at onset, then every 6 h *Children:* 5–10 mg/kg initially; may repeat every 6–8 h	*Adults:* 2,400 mg/d *Children:* 40 mg/kg/d	*OTC tablets:* 100, 200 mg *Rx tablets:* 400, 600, 800 mg *Suspension:* 100 mg/5 mL *Chewable:* 50, 100 mg	Unlikely	Contraindicated in third trimester of pregnancy; safe during lactation Use with caution in kidney disease, ulcer disease, gastritis
Naproxen (Rx: Naprosyn)	*Adults:* 500 mg at onset, then 250 mg every 6–8 h *Children:* 2.5–5 mg/kg initially and may repeat every 12 h	*Adults:* 1,000 mg/d *Children:* 15 mg/kg/d	*Tablets:* 250, 375, 500 mg *Suspension:* 125 mg/mL	Unlikely	Contraindicated in third trimester of pregnancy; safe during lactation Absorbed more slowly than naproxen sodium Use with caution in kidney disease, ulcer disease, gastritis
Naproxen sodium (OTC: Aleve; Rx: Anaprox)	*Adults:* 825 mg at onset, then 200–550 mg in 3–4 h *Children:* Use suspension form of naproxen	*Adults:* 1,375 mg/d	*OTC tablets:* 200 mg *Rx tablets:* 275, 550 mg	Unlikely	Contraindicated in third trimester of pregnancy; safe during lactation Naproxen sodium absorbed more quickly than naproxen; reaches peak levels in half the time Use with caution in kidney disease, ulcer disease, gastritis
Ketorolac (Rx: Toradol, Sprix nasal spray)	*Adults:* 30–60 mg initially, may repeat 30–60 mg every 6 h *Children:* Not recommended in children <16 yr	*Adults:* 120 mg/d	*Injection:* 15 mg/mL, 30 mg/mL for IM injection *Oral:* 10 mg every 4–6 h; maximum 40 mg daily *Intranasal:* 15.75 mg/spray 1 spray in 1 nostril every 6–8 h.; maximum 4 sprays daily	Unlikely, but frequent use should be avoided	Contraindicated in pregnancy, lactation, kidney disease, ulcer disease, gastritis Use for emergency treatment of severe migraine in patients who cannot use other medications. Do not exceed 5 consecutive days of use.

Table 35–2   Drugs Commonly Used: Headaches—cont'd

Drug	Initial Dose	Maximum Dose	Strengths Available	Rebound Potential	Comments
Diclofenac (diclofenac potassium, Cambia)	*Adults:* 50 mg tid *Children:* Not recommended in children <16 yr.	*Adults:* 150 mg/day	50 mg pwdr pkt to be given on an empty stomach ×1 (Cambia)		Renal and hepatic dosing. Pregnancy (C); lactation is probably safe.
Aspirin/ acetaminophen/ caffeine combination (OTC: Excedrin, Vanquish)	*Adults:* 2 tablets every 6 h	*Adults:* 8 tablets/d, 2 d/wk	Excedrin: APAP 250 mg, ASA 250 mg, caffeine 65 mg Vanquish: APAP 165 mg, ASA 227 mg, caffeine 33 mg	Yes	Same precautions as for ASA and APAP
Tramadol (Rx: Ultram, Ultram ER, Rybix ODT)	Adults: 50–100 mg every 4–6 h 100–300 mg daily for extended dosing Children: Not recommended in children <16 yr	*Adults:* Maximum 400 mg daily			Renal and hepatic dosing. Increased risk of serotonin syndrome when combined with triptans, SSRI, SNRI Pregnancy (C); possibly unsafe in lactation.
Tramadol/ Acetaminophen (Ultracet)	37.5/325 mg every 4–6 h.	Maximum 8 tab/day			
Combination Analgesics					
Butalbital compounds (Rx: Fiorinal, Fioricet, Esgic Plus)	*Adults:* 2 tablets at onset, then 1 tablet every 4–6 h *Children:* Not recommended	*Adults:* 6 tablets per attack 2 d/wk 30 tablets per month Fioricet: One or 2 tablets every 4 hours PRN	Fiorinal: Butalbital 50 mg, ASA 325 mg, caffeine 40 mg Butalbital 50 mg, APAP 325 mg, caffeine 40 mg Esgic Plus: Butalbital 50 mg, APAP 500 mg, caffeine 40 mg	Yes	Same as for ASA and APAP Not for first-line therapy Risk for medication-overuse headache, if taken in greater than recommended dosage or more than 2 d/wk
Isometheptene compound (Rx: Midrin, Isocom)	*Adults:* Migraine: 2 capsules at onset, then 1 capsule every h if needed for relief Tension headache: 1 or 2 capsules at onset, followed by 1 capsule every 4 h *Children:* Not recommended	Migraine: 5 per 12 h, 2 d/wk, 20 per mo Tension headache: 8 per 24 h, 2 d/wk, 20 per mo	Midrin, Isocom: Isometheptene 65 mg, dichloralphenazone 100 mg, APAP 325 mg	Yes	Adverse interaction with MAOIs Contraindicated in uncontrolled hypertension, CAD, PVD Not considered first-line therapy
Narcotic Analgesics					
Codeine-containing compounds (Rx: Tylenol #3, Empirin #3)	*Adults:* 1 or 2 tablets at onset of attack, then 1 every 4–6 h *Children:* Aspirin-containing	*Adults:* 6 tablets per attack, 2 d/wk, 10–15 doses/mo	Tylenol #3: APAP 300 mg with codeine 30 mg APAP with codeine liquid: Codeine 12 mg	Yes and habit-forming Monitor use carefully; if patient is needing more than 15 tablets/mo,	Relatively safe during pregnancy Should not be considered first-line therapy Contraindicated in substance-abuse patients

Table 35–2 Drugs Commonly Used: Headaches—cont'd

Drug	Initial Dose	Maximum Dose	Strengths Available	Rebound Potential	Comments
	preparations contraindicated		and APAP 120 mg/5 mL Empirin #3: ASA 325 mg with codeine 30 mg	reevaluate treatment	Should not be prescribed for chronic daily headache
Meperidine (Rx: Demerol)	*Adults:* Maximum initial dose 150 mg, can repeat 50–100 mg every 3–4 h if needed		*IM injection:* 25 mg/mL, 50 mg/mL, 75 mg/mL, 100 mg/mL	Yes Patients must have someone to drive them home after receiving medication	May be used in pregnancy Use only as "rescue" medication Use sparingly and infrequently when other treatments have been ineffective
Butorphanol (Rx: Stadol NS)	*Adults:* 1 spray to one nostril; may be repeated in 1 h *Children:* Not recommended	*Adults:* 2 sprays (2 mg) per attack, 2 d/wk	Stadol NS: Nasal spray 1 mg/spray	Probably Side effects of orthostasis and sedation	Can be used as a "rescue" medication Effective for nocturnal headaches May be used with caution in pregnancy
Ergot Derivatives					
Ergotamine tablets (Rx: Ergostat, Ergomar)	*Adults:* 1 tablet sublingual at onset of attack; may repeat every 30 min; max 3 tablets per attack *Children:* Not safe in children	*Adults:* 3 tablets/d, 2 d/wk and 10 mg/wk	Sublingual 2 mg tablets	Yes	Contraindicated in pregnancy (Category X) and lactation Contraindicated in CAD and PVD May cause severe nausea and vomiting
Ergotamine and caffeine combination (Rx: Cafergot, Wigraine)	*Adults:* Tablets: 2 tablets at onset, then 1 tablet every 30 min if needed, up to 6 tablets per attack Suppositories: 1/3–1 suppository at onset; may repeat 1 suppository in 1 h, if needed *Children:* Not recommended	*Adults:* 6 tablets or 2 suppositories per attack, 2 d/wk, 10 mg/wk	Cafergot & Wigraine tablets: Ergotamine 1 mg, caffeine 100 mg Cafergot & Wigraine suppositories: Ergotamine 2 mg, caffeine 100 mg	Yes Suppository form better absorbed	Pregnancy Category X; contraindicated in lactation, CAD, PVD May cause nausea and vomiting May premedicate with an antiemetic
Dihydroergotamine (Rx: DHE 45, Migranal)	*Adults:* Injection: 1 mg IV/IM at onset; may repeat 1 mg dose hourly for total maximum of 3 mg IM or 2 mg IV Intranasal: 1 spray each nostril at onset; may repeat in 15 min *Children:* Not recommended	*Adults:* IM: 3 mg/attack IV: 2 mg/attack IM/IV: 6 mg/wk IM home use: 18 doses/mo Intranasal: 6 sprays/ 24 h, 8 sprays/wk	DHE 45 injection; 1 mg/mL Migranal 0.5 mg/spray	Unlikely	Contraindicated in pregnancy, lactation, CAD, PVD, hypertension, and severe renal or hepatic dysfunction. Premedicate with antiemetic: Zofran or metoclopramide for greater effectiveness

Table 35–2   Drugs Commonly Used: Headaches—cont'd

Drug	Initial Dose	Maximum Dose	Strengths Available	Rebound Potential	Comments
Serotonin Receptor Agonists					
Alomotriptan (Axert)	*Adults ≥18 yr:* 6.25 mg or 12.5 mg once. May repeat ×1 after 2 h *Adolescents age 12–17 yr:* 6.25 mg or 12.5 mg in a single dose. May repeat after 2 h *Children:* Not recommended	2 doses/24 h	6.25 mg tablets 12.5 mg tablets	Likely	Contraindicated in pregnancy, ischemic heart disease, CAD, and uncontrolled hypertension None of the triptans can be used within 24 h of ergotamine-containing medications or other triptans. Concurrent use of a triptan or use within 2 wk of MAOIs is contraindicated. All the triptans interact with SSRIs, causing serotonin syndrome. Serious adverse effects rarely reported in adults (stroke, visual loss, and death); have been reported in children after use of SC, oral, and/or nasal sumatriptan. Don't use >4× per mo
Eletriptan (Relpax)	*Adults ≥18 yr:* 20 mg or 40 mg ×1. Reevaluate if no response. May repeat ×1 in 2 h *Children:* Not recommended	Max: 80 mg/d	20 mg tablets 40 mg tablets	Likely	Contraindicated in pregnancy, ischemic heart disease, CAD, and uncontrolled hypertension. None of the triptans can be used within 24 h of ergotamine-containing medications or other triptans. Concurrent use of a triptan or use within 2 wk of MAOIs is contraindicated. All the triptans interact with SSRIs, causing serotonin syndrome. Serious adverse effects rarely reported in adults (stroke, visual loss, and death); have been reported in children after use of SC, oral, and/or nasal sumatriptan. Same as sumatriptan. Don't use >3× per mo
Frovatriptan (Frova)	*Adults ≥18 yr:* 2.5 mg with fluids. May repeat ×1 after 2 h *Children:* Not recommended	Max: 7.5 mg/24 h	2.5 mg tablets	Likely	Longer half-life. Slower onset of action, lower rate of migraine recurrence. Don't use >4× per mo

Table 35–2   Drugs Commonly Used: Headaches—cont'd

Drug	Initial Dose	Maximum Dose	Strengths Available	Rebound Potential	Comments
Sumatriptan (Rx: Imitrex, Sumavel, DosePro (Sumatriptan Injection)	*Adults ≥18 yr:* Oral: 25–100 mg initially; may be repeated every 2 h for up to 24 h SC injection 6 mg; may repeat ×1 in 1 h Intranasal: 5, 10, or 20 mg; may repeat once after 2 h if needed	*Adults:* Oral: 300 mg/d, 4 headaches per mo SC injection: 2 injections/ day, 4 headaches per mo Intranasal: 40 mg/day, 4 headaches per mo 2 tab/24 h	*Tablets:* 25, 50 mg *SC injection:* 6 mg/mL single-dose vial *Nasal spray:* 5 mg/spray, 20 mg/spray	Likely	Contraindicated in pregnancy, ischemic heart disease, CAD, and uncontrolled hypertension. None of the triptans can be used within 24 h of ergotamine-containing medications or other triptans. Concurrent use of a triptan or use within 2 wk of MAOIs is contraindicated. All the triptans interact with SSRIs, causing serotonin syndrome. Serious adverse effects rarely reported in adults (stroke, visual loss, and death); have been reported in children after use of SC, oral, and/or nasal sumatriptan.
Zecuity (sumatriptan iontophoretic transdermal system)	Transdermal: single-dose 6.5 mg *Children <18 yr:*		*Transdermal:* Single-use battery-powered patch 6.5mg/4 h application		
Treximet (sumatriptan and naproxen)	Not recommended 85/500 mg oral, may repeat dosing after 2 h				
Naratriptan (Rx: Amerge)	*Adults:* One 1 mg or 2.5 mg tablet at onset of migraine; may repeat dose in 4 h, if needed *Children 12–17 yr:* Adult doses are used *Children <12 yr:* Safety has not been established	*Adults:* 5 mg/24 h, 4 headaches per mo	*Tablets:* 1 mg, 2.5 mg	Likely	Same contraindications as for sumatriptan Longer half-life than other triptans, less likely to cause medication-overuse headache Interacts with oral contraceptives
Rizatriptan (Rx: Maxalt, Maxalt-MLT)	*Adults (either form):* Take 5–10 mg at onset of migraine; may repeat in 2 h, if needed *Children:* Not recommended in patients <18 yr	*Adults:* 30 mg/24 h, 4 headaches per mo Propranolol patients: use 5 mg dose, up to 3 doses in 24 h	*Maxalt tablets:* 5, 10 mg Maxalt-MLT orally disintegrating tablets: 5, 10 mg	Likely	Same contraindications as for sumatriptan Use with caution in patient concurrently taking propranolol
Zolmitriptan (Rx: Zomig)	*Adults:* 2.5 mg or less initially (may break 2.5 mg tablet in half); repeat if headache returns after 2 h *Children:* Safety not established	*Adults:* 10 mg/24 h, 4 headaches per mo	*Tablets:* 2.5 mg, 5 mg	Likely	Same contraindications as for sumatriptan Use with caution in patients with hepatic dysfunction (<2.5 mg dose) Interacts with oral contraceptives and cimetidine

Continued

Table 35–2 Drugs Commonly Used: Headaches—cont'd

Drug	Initial Dose	Maximum Dose	Strengths Available	Rebound Potential	Comments
Alpha Agonist, Central					
Guanfacine (Rx: Tenex)	*Adults:* 1 mg daily ×12 weeks *Children:* No recommended dosing for migraines		*Tablets:* 1 mg & 2 mg		Centrally acting antihypertensive.
Antiemetics					
Metoclopramide (Rx: Reglan)	*Adults:* 10 mg either orally or IV either before ergotamine derivative or concurrently with analgesic *Children:* Not recommended	*Adults:* 40 mg/d	*Tablets:* 5 mg, 10 mg *Injection:* 5 mg/mL	N/A	Interacts with cimetidine, digoxin, MAOIs, and cyclosporine Safe in pregnancy, Category B
Ondansetron (Zofran, Zofran ODT)	*Adult:* 4–8 mg every 6–8 h *Children ages 4–11:* 4 mg every 4 h *Ages >11* = adult dosing	*Adult:* 24–36 mg daily *Children:* <24 mg daily	*Tablets:* 4 mg & 8 mg *Parenteral:* 4mg/5mL	N/A	Safe in pregnancy (B), lactation is unknown. Prolong cardiac QTc
Promethazine (Phenergan	*Adult:* 12.5–25 mg every 4–6 h *Children:* *>2 yr:* 0.25–1 mg/kg every 4–6 h	*Adult:* 100 mg daily Maximum: 25 mg/dose.	*Tablets/suppository:* 12.5, 25, 50 mg *Parenteral:* (same as oral)	N/A	Use with caution in hepatic impairment.
		Preventive Therapy			
Beta Blockers					
Propranolol (Rx: Inderal, Inderal LA)	*Adults:* Start with 60–80 mg/d, and increase every 3–7 d *Children:* 0.5–1 mg/kg/d divided bid and increased every 3–4 d	*Adults:* 240–320 mg/d (monitor blood pressure [BP] and heart rate [HR]: systolic [BP] should be >100 mm Hg and HR >50 bpm) *Children:* 2–4 mg/kg/d	*Tablets:* 10, 20, 40, 60, 80, 120 mg, 160 mg ER	N/A Pregnancy Category C but safer than some other preventive agents	Contraindicated in CHF, asthma, COPD, PVD, diabetes mellitus, depression, Wolff-Parkinson-White syndrome. Start with a trial of 3 mo; as response improves over time, it needs to be tapered slowly (over a week) if discontinued. Interacts with many drugs, including cimetidine, oral contraceptives, calcium channel blockers.
Timolol (Rx: Blocadren)	*Adults:* Start at 20 mg/d; increase slowly *Children:* Not recommended	*Adults:* 60 mg/d	*Tablets:* 5, 10, 20 mg	N/A	Pregnancy Category C. Contraindications and drug interactions similar to propranolol.

Table 35–2   Drugs Commonly Used: Headaches—cont'd

Drug	Initial Dose	Maximum Dose	Strengths Available	Rebound Potential	Comments
Metoprolol (Rx: Lopressor, Toprol-XL)	*Adults:* Start at 100 mg/d; increase slowly *Children:* Not recommended	*Adults:* 250 mg/d	*Tablets:* 25, 50, 100 mg 200 mg ER	N/A	Pregnancy Category C. Contraindications include bradycardia, second- or third-degree heart block, overt heart failure. Interacts with many drugs, including calcium channel blockers, digoxin, clonidine, and oral contraceptives.
Atenolol (Rx: Tenormin)	*Adults:* 100 mg/d *Children:* Not recommended	*Adults:* 200 mg/d	*Tablets:* 25, 50, 100 mg	N/A	Pregnancy Category D. Contraindications include bradycardia, second- or third-degree heart block, overt heart failure. Interacts with many drugs, including calcium channel blockers, digoxin, clonidine, and oral contraceptives.
Tricyclic Antidepressants					
Amitriptyline (Rx: Elavil)	*Adults:* Start with 10 mg qhs and increase every 2 wk to a total daily dose of 20–50 mg *Children:* Not recommended for children <12 yr	*Adults:* 150 mg/d	*Tablets:* 10, 25, 50, 75, 100 mg	N/A	Contraindicated in patients with narrow-angle glaucoma, urinary retention, pregnancy, breastfeeding, concurrent use of MAOIs (within 14 d of each other), and in suicidal patients.
Nortriptyline (Pamelor)	*Adults:* Start 25–50 mg qhs; increase every 2–3 days. *Children:* Not recommended for headache.	*Adults:* 150 mg/d	*Tablets:* 10, 25, 50, 75 mg	N/A	Do not abruptly stop; wean dosing when discontinuing
Anticonvulsants					
Divalproex (Rx: Depakote, Depakote ER, Depakote Sprinkles)	*Adults:* Initial dose is 125–250 mg bid; may increase 125 mg weekly *Children:* Safety and effectiveness for migraine prevention has not been studied in children <16 yr	*Adults:* 1,000 mg/d	*Tablets:* 125, 250, 500 mg, 500 mg ER, 125 mg DR	N/A	Requires baseline assessment of liver function, platelet count, and bleeding time, as hepatic failure and thrombocytopenia are rare adverse effects Monitor LFTs and CBC every 2 wk ×3 Pregnancy Category D
Topiramate (Topamax)	*Adults:* Start on 25 mg qhs; increase to 25 mg bid in week 2.	*Adults:* 400 mg/d	*Tablets:* 25, 50, 100, 200 mg *Capsules:* 15, 25 mg		Renal dosing adjustment Pregnancy Category D

Table 35–2 Drugs Commonly Used: Headaches—cont'd

Drug	Initial Dose	Maximum Dose	Strengths Available	Rebound Potential	Comments
	During week 3 the dose is increased to 25 mg in the morning and 50 mg at night. In week 4 a dose of 50 mg twice a day. 25 mg bid may be effective in some *Children:* Not recommended for headache				
Oxcarbazepine (Trileptal)	*Adults:* Start 300 mg bid and increase 600 mg/d every week *Children:* Not recommended for headache	*Adults:* 1,200 mg bid	*Tablets:* 150, 300, 600 mg *Solution:* 300 mg/5 mL	N/A	Pregnancy Category C Monitor for hyponatremia, thrombocytopenia, Stevens–Johnson syndrome. Do not abruptly stop; wean off.
Gabapentin (Neurontin, Gralise)	*Adults:* 300 mg bid-tid, increase by 300–600 mg every week. *Children:* Not recommended for headache	*Adults:* 3,600 mg/d	*Tablets:* 100, 300, 400, 600, 800 mg, 600 mg ER *Solution:* 50 mg/mL	N/A	Pregnancy Category C Do not abruptly stop; wean off.
NSAIDs					
Naproxen sodium (OTC: Aleve; Rx: Anaprox)	*Adults:* 550 mg bid	*Adults:* 1,375 mg/d	*TC tablets:* 200 mg *Rx tablets:* 275, 550 mg	Unlikely	Contraindicated in third trimester of pregnancy; safe during lactation Use with caution in kidney disease, ulcer disease, gastritis
Calcium Channel Blockers					
Verapamil (Rx: Calan, Isoptin)	*Adults:* Start with 40 mg bid and slowly increase *Children:* Not recommended	*Adults:* 480 mg/d	*Tablets:* 40, 80, 120, mg	N/A	Contraindicated in pregnancy (Category C), Parkinson's disease, and depression. May be first-line choice in patients with hypertension who cannot take beta blockers.
Serotonin Antagonist					
Methysergide (Rx: Sansert)	*Adults:* Start with 2 mg bid; increase slowly *Children:* Not recommended	*Adults:* 8–14 mg/d	*Tablets:* 2 mg	N/A	Most serious side effect is retroperitoneal fibrosis or related conditions with prolonged therapy. Patient should have a drug-free period of 3–4 wk after every 6 mo of treatment. Contraindicated in pregnancy, CAD, PVD, impaired renal or liver function, and hypertension.

Table 35–2   Drugs Commonly Used: Headaches—cont'd

Drug	Initial Dose	Maximum Dose	Strengths Available	Rebound Potential	Comments
Antispasmodic/Neurotoxin (inhibits acetylcholin release from nerve endings)					
Onabotulinum-toxinA (Rx: Botox)	*Adults:* 155 U injected IM divided in 31 sites every 12 wk. *Children:* Not indicated for headaches		*Injectable units:* 100-unit single dose vial	N/A	Contraindicated in hypersensitivity to the drug. Caution if neuromuscular or facial nerve disorder.
Nutraceuticals Riboflavin Coenzyme Q10 Magnesium Feverfew Butterbur	*Adults:* 400 mg/d 150 mg/d 600 mg/d 100 mg of 0.2% parthenolide/d 50–100 mg bid				

APAP = acetaminophen; ASA = acetylsalicylic acid; CAD = coronary artery disease; CBC = complete blood count; CHF = chronic heart failure; COPD = chronic obstructive pulmonary disease; HA = headache; LFTs = liver function tests; MAOIs = monoamine oxidase inhibitors; N/A = information not available; OTC = over the counter; PVD = peripheral vascular disease; SSRIs = selective serotonin reuptake inhibitors.

which may be helpful if the patient is nauseated or vomiting. Ketorolac (Toradol) is the only NSAID available in an injectable form, which can also be used if the patient is vomiting. Table 35-2 shows the dosing for commonly used NSAIDs.

Midrange Analgesics

Midrange analgesics are commonly prescribed to treat both migraine and tension-type headaches. Combination products that combine either butalbital with ASA or APAP (Fiorinal or Fioricet) or isometheptene with acetaminophen and dichloralphenazone (Midrin) are effective in treating mild to moderate migraine, although the U.S. Headache Consortium guidelines rate these drugs as group 3 drugs, with inconsistent or conflicting clinical efficacy data (Matcher et al, 2000). These products should be used cautiously because medication-overuse headaches can occur if they are taken in greater-than-recommended dosages or more than 2 days per week. Medication-overuse headaches are discussed later in this chapter.

High-Range Analgesics

High-range analgesics include the commonly used opioids, which act centrally to treat the pain of migraine. Although opioids are controversial in the treatment of migraine, there are patients for whom an opioid is the drug of choice. An opioid can be prescribed if the patient is pregnant, if vasoconstrictor medications are contraindicated, or if the migraine is not responsive to ergotamine or serotonin agonists (discussed later). The opioids are group 2 drugs with moderate clinical and statistical benefit (Matcher et al, 2000).

Codeine either alone or in combination with ASA (Aspirin with codeine #3) or APAP (Tylenol with codeine #3) is the opioid most commonly used to treat migraine. The dose of codeine should be 30 to 60 mg, with the lowest effective dose used. Meperidine (Demerol) can be given IM if the patient is unable to take oral medications because of nausea and/or vomiting. The maximum initial dose is 150 mg in an adult, and a dose of 50 to 100 mg can be repeated every 3 to 4 hours. Intranasal butorphanol (Stadol) can be tried in patients who fail nonopioid therapy or who have contraindications to other migraine medications. The dose of one spray in one nostril has a rapid onset (less than 15 minutes) and can be repeated in 1 hour if needed. Adverse effects include orthostasis and sedation. The patient should limit its use to no more than twice a week. Other opioids that are prescribed for migraine include oxycodone and hydrocodone, even though there is little clinical information to support their effectiveness over newer nonnarcotic agents and their use is not supported by the U.S. Headache Consortium. Opioids must be prescribed carefully because of their potential for physical dependence, tolerance, and addiction. Therefore, they should be limited to patients with severe but infrequent headaches or the occasional headache that is unresponsive to nonnarcotic agents.

Ergot Derivatives

Ergot derivatives have been used for many years to treat migraine. Ergotamine and dihydroergotamine (DHE) act as vasoconstrictors that lead to a decline in the amplitude of pulsation in the extracranial arteries and decreased hyperperfusion of the basilar artery area, without decreasing cerebral hemispheric blood flow. Ergotamine controls up to 70% of acute migraine attacks, but its adverse effects of nausea and vomiting and its unpredictable oral absorption limit routine use. Pretreatment with an antiemetic decreases the nausea and vomiting associated with ergotamine use. Ergotamine suppositories (Wigraine, Cafergot) are better absorbed than PO preparations and can be quite effective if administered at the

beginning of migraine symptoms. Misuse of ergotamine may lead to medication-overuse headaches, and use should be limited to two doses, twice a week or less (total weekly dose of 10 mg maximum), up to 12 doses per month. Another caution with ergotamine is that the vasoconstriction can have serious effects on patients with peripheral vascular disease, coronary heart disease, hypertension, and impaired hepatic or renal function. Exceeding recommended amounts of ergotamine can lead to vasospastic adverse effects. Ergotamine derivatives are contraindicated in pregnancy because they can produce prolonged uterine contractions that can result in abortion. Thus, all forms of ergotamine are Pregnancy Category X. Ergotamine is not recommended for children. Most ergotamine preparations are group 3 drugs in the U.S. Headache Consortium guidelines, demonstrating conflicting or inconsistent evidence for their use in acute migraine (Matcher et al, 2000).

>
> **Ergotamine Suppositories**
> Ergotamine suppositories can provide relief if taken at the beginning of a migraine attack. If a patient has not used ergotamine before, instruct the patient to use one-third of a 2 mg suppository initially and repeat in 30 to 60 minutes. Refrigeration makes the suppository easier to slice.

DHE, although chemically similar to ergotamine, does not cause the same peripheral vasoconstrictor effects, making it safer to use and listed as a group 1 drug by the U.S. Headache Consortium (Matcher et al, 2000). It also causes less nausea than ergotamine and does not require pretreatment with an antiemetic. DHE is effective even well into the course of a headache, unlike ergotamine, which must be taken at the beginning of migraine symptoms. DHE can be administered IM (DHE 45) or intranasally (Migranal). DHE has a longer duration of action than does sumatriptan, and so headache recurrence rates are lower. The dosage of DHE 45 is 1 mg (or 1 mL) IM or IV initially and can be repeated at 1-hour intervals to a maximum of 3 mg IM or 2 mg IV. IM DHE can be prescribed for home use if the patient has proper instructions regarding administration. A monthly limit for IM DHE is 18 ampules or 12 headache events. The dose of intranasal DHE is 1 spray (0.5 mg) in each nostril, repeated after 15 minutes, for a dose of 2 mg. Maximum dose is 6 sprays in a 24-hour period and 8 sprays per week. Although intranasal DHE is easier to administer, the patient should be warned that it has a slow onset of action. Precautions for DHE are the same as for ergotamine; it is contraindicated in pregnancy, coronary artery disease, peripheral vascular disease, and hypertension. DHE is not recommended for children.

Serotonin Receptor Agonists

Serotonin receptor agonists act selectively as 5-HT$_1$ receptor agonists, causing vasoconstriction and apparently blocking release of vasoactive substances that lead to migraine.

Sumatriptan (Imitrex, Alsuma, Sumavel Dosepro, Treximet) was the first selective serotonin receptor agonist developed specifically to treat migraine; other agents include almotriptan (Axert), frovatriptan (Frova), naratriptan (Amerge), rizatriptan (Maxalt), and zolmitriptan (Zomig). As they differ slightly in pharmacokinetics and individual response, trial of a different serotonin receptor agonist is warranted if one is not effective.

> ### ⊙ CLINICAL PEARL ⊙
>
> **Triptans**
> It is advisable to administer the first dose of any of the triptans under direct supervision to monitor for unrecognized coronary disease. The patient should receive the first dose in the clinic (or urgent care center) and be monitored for any adverse cardiovascular effects. Sumatriptan is effective in decreasing the severity of headache in 54% to 80% of patients.

It is also effective in relieving the nausea, photophobia, and phonophobia that can accompany migraine. Sumatriptan should be taken after the aura of migraine passes because it has been found to be effective only after the headache symptoms appear. Sumatriptan is available in PO, subcutaneous (SC), and intranasal forms. The dose for PO sumatriptan is 25 to 100 mg initially and may be repeated every 2 hours for up to 24 hours (maximum 300 mg in 24 hours). Although an initial dose of 25 mg should be tried with a patient who has never had sumatriptan, research has shown that an initial dose of 50 to 100 mg is superior in relieving migraine symptoms (Carpay, Schoenen, Ahmad, Kinrade, & Boswell, 2004). Carpay and colleagues studied the efficacy and tolerability of fast-disintegrating, rapid-release sumatriptan and found that 51.1% of patients who received 50 mg of sumatriptan were pain-free after 2 hours, whereas 66.2% of those who received 100 mg were pain-free at 2 hours after dosing. The initial SC dose of sumatriptan is 6 mg, and 82% of patients report relief in 20 minutes. The dose may be repeated in 1 hour if there is no relief, for a maximum of two 6 mg doses in 24 hours. Intranasal sumatriptan has a slower onset than does SC (2 h versus 20 min) and is less effective in relieving headache (62% at 2 h), yet intranasal dosing may be more appealing for children and for patients who fear self-administering injectable medication. After a dose of sumatriptan, up to 40% of headaches recur within 10 to 14 hours, and a second dose may be necessary. Do not repeat the dose of sumatriptan if the patient does not respond to the first dose.

Almotriptan binds with high affinity with 5-HT receptors 1D, 1B, and 1F. Almotriptan is rapidly absorbed from the gastrointentinal (GI) tract with a peak of 1 to 3 hours after administration. Two hours after administration of 6.25 mg of almotriptan, 55% of study subjects reported pain relief from their migraine. When 12.5 mg is administered, 58.5% to 64.9% of subjects reported relief (Ortho-McNeil Neurologics, 2009). Almotriptan has a mean half-life of 3 to 4 hours and is primarily excreted renally. Axert is FDA approved for use in adolescents aged 12 to 17 years.

Frovatriptan is a 5-HT 1B/1D receptor agonist that binds with high affinity to 5-HT$_{1B}$ and 5-HT$_{1D}$ receptors. Frovatriptan peaks in 2 to 4 hours after administration, with food delaying peak by an hour. Bioavailability of frovatriptan is 20% in women and 30% in men. In clinical trials, when 2.5 mg of frovatriptan was administered orally, 37% to 46% of patients had mild or no headache after 2 hours (Endo Pharmaceuticals, 2013). If headache recurs after initial relief, dosing recommendations are that the dose be repeated if it has been at least 2 hours since the last dose. The total daily dose of frovatriptan should not exceed three 2.5 mg tablets per 24 hours.

Naratriptan is similar to sumatriptan in its mechanism of action but differs in its pharmacokinetics. Naratriptan has a higher PO bioavailability (about 70%) and a longer half-life (6 hours) than does sumatriptan. This might lead to a lower rate of headache recurrence, with only 17% to 28% of patients reporting recurrence (Mathew, 1997). These differences may lead the practitioner to choose naratriptan as the first-line triptan. Naratriptan has been studied in adolescents (12 to 17 years), and the reported adverse events do not differ from the adult studies. One factor that may prevent the use of naratriptan is that its half-life and plasma levels are increased with concurrent use of oral contraceptives, and the dose should be lowered.

Rizatriptan, also a 5-HT$_1$ serotonin receptor agonist, has oral bioavailability that is better than sumatriptan (about 45% versus 15%) but not as good as that of naratriptan. Because its half-life is similar to sumatriptan (both 2 to 3 hours), cost and PO absorption may be factors when choosing between rizatriptan and sumatriptan. Rizatriptan is available in PO tablet or PO disintegrating tablet, which may be preferred for some patients with nausea as a major symptom of migraine. One caution with rizatriptan is that plasma levels of rizatriptan are increased significantly when taken with propranolol, and concurrent use should be avoided.

Zolmitriptan has a higher PO bioavailability than do sumatriptan and rizatriptan (60% in females, 38% in males) and a similar half-life. Zolmitriptan is the only triptan that interacts with cimetidine (doubles the half-life and plasma levels of zolmitriptan), and this may be a factor in prescribing. Zolmitriptan's half-life and clearance are also affected by oral contraceptives.

All triptans are contraindicated in patients with coronary artery disease or uncontrolled hypertension because of their potential to constrict coronary artery vessels. The triptans are contraindicated in pregnancy. None of the triptans can be used if ergotamine derivatives have been used in the prior 24 hours because of increased vasospastic reactions; their effects may be additive. The triptans sumatriptan, zolmitriptan, and rizatriptan interact with monoamine oxidase inhibitors (MAOIs) and should not be used concurrently or within 2 weeks of discontinuing the MAOI. All of the triptans interact with selective serotonin reuptake inhibitors (SSRIs), causing serotonin syndrome. Sumatriptan can be used in children, but consultation with a pediatric neurologist is advisable.

Antiemetics

Antiemetics are an integral part of migraine management. Gastric emptying and oral absorption of medications are decreased in migraine patients, especially those patients with nausea and vomiting as a component of their migraine. A dose of metoclopramide (Reglan) is often recommended as part of migraine therapy (ICSI, 2009). Other commonly used antiemetics recommended as adjunct therapy by ICSI (2009) are the phenothiazine antiemetics, perphenazine (Trilafon), prochlorperazine (Compazine), and chlorpromazine (Thorazine).

Preventive Therapy

Preventive therapy should be considered for any patient who experiences severely incapacitating or frequent severe migraines (more than two per month) and patients who cannot tolerate abortive medications because of either chronic illness (coronary artery disease or hypertension) or the adverse effects of abortive medications. Preventive medication is also recommended if the patient is taking abortive medication more than twice a week. The primary goal of preventive therapy is to use the least amount of medication with the fewest side effects to decrease migraine symptoms. If medication overuse is suspected, it must be treated first before starting the patient on preventive therapy; this topic is covered later in this chapter.

Patients must understand that preventive therapy will not completely eliminate migraine and that a 50% reduction in migraine attacks is considered a success. Fewer than 10% of patients become headache-free with preventive therapy. The patient must also be aware that it may take 4 weeks before preventive therapy begins to be effective and that there is an increase in effectiveness for 3 months. It is common for patients to discontinue preventive therapy after only a couple of weeks and label it as ineffective. Education is the key to success for preventive therapy. Another component to preventive therapy is a headache diary that is initiated prior to preventive therapy and then maintained to determine the frequency, severity, and duration of migraine. This tool enables the provider to assess the effectiveness of preventive therapy. Examples of daily, weekly, and monthly headache diaries can be found at the American Headache Society's Web site (http://www.americanheadachesociety.org).

Because preventive therapy cannot completely eliminate migraines, the patient should also have acute or abortive medications to take for migraine. The provider should recognize interactions between preventive and acute therapies and prescribe accordingly (see Table 35-2). The significance of avoiding migraine triggers, which cannot be overlooked in migraine prevention, is discussed later in the chapter.

Beta Blockers

Beta blockers are one of the first-line choices for migraine preventive therapy (ICSI, 2009), with up to a 44% reduction in migraine reported. The mechanism of action in migraine prevention is not clear, but it is thought that beta blockers may affect the central catecholaminergic system and brain

serotonin (5-HT$_2$) receptors. They also block beta receptors in vascular smooth muscle to prevent arterial dilatation. Propranolol (Inderal) and timolol (Blocadren) are the only beta blockers that have been FDA approved for migraine preventive therapy, although nadolol (Corgard), metoprolol (Lopressor), and atenolol (Tenormin) have also been shown to be effective.

Propranolol is typically started at a dose of 60 to 80 mg a day and slowly increased every third or fourth day to a maximum of 240 mg per day in adults. Twice-daily dosing has the highest compliance rate. Individual response varies, and the patient should be monitored closely. A pulse below 50 or a systolic blood pressure below 100 mm Hg in the adult suggests that the maximum dosage has been reached. The dose in children is 0.5 to 1 mg/kg/d, divided into two doses and titrated every 3 to 4 days, to a maximum of 2 to 4 mg/kg/d. Pediatric patients should be monitored closely, and consultation with a pediatric neurologist before initiating and during therapy is advisable. A trial of 3 months in both adult and pediatric patients is necessary because the response improves over time. Treatment should be reassessed every 6 months, and it may be discontinued. Propranolol needs to be tapered slowly (over a week) to prevent drug withdrawal headache. Adverse effects of propranolol include fatigue, lethargy, and depression, and it should not be the first-line drug in depressed patients. It is also not well tolerated by athletes. Propranolol is contraindicated in patients with congestive heart failure, asthma, chronic obstructive pulmonary disease, peripheral vascular disease, diabetes mellitus, or Wolff-Parkinson-White syndrome. Propranolol is Pregnancy Category C, but it is safer than some of the other preventive agents.

If propranolol is not effective or not well tolerated, one of the other beta blockers can be tried; failure to respond to one beta blocker does not predict response to another. If a patient has asthma or other respiratory disorders, metoprolol and atenolol may be used because they are cardioselective (see Table 35-2 for dosing of these agents).

Tricyclic Antidepressants

Tricyclic antidepressants, specifically amitriptyline (Elavil), are effective in reducing the frequency, severity, and duration of migraine attacks. Amitriptyline modulates neurotransmitters and appears to affect the central serotonin receptor function. Its antimigraine effect is unrelated to its antidepressant effect, and the antimigraine effect can often be achieved at lower doses than are required to treat depression. The patient should be started on 10 mg a day taken before bed and increased every 2 weeks to a total daily dose of 20 to 50 mg. Adverse effects that should be monitored include drowsiness (most common), dry mouth, weight gain, constipation, and orthostatic hypotension. Amitriptyline is contraindicated in patients with narrow-angle glaucoma, urinary retention, pregnancy, breastfeeding, and concurrent use of MAOIs. Other tricyclic antidepressants that may be used include nortriptyline (Pamelor, Aventyl), which causes less drowsiness and anticholinergic effect than does amitriptyline.

Antiepileptic Drugs

Antiepileptic drugs (AEDs) are thought to work on migraines in a fashion similar to their effect on seizures. The AEDs are thought to decrease brain excitability by increasing the threshold for activation of the brainstem areas that are thought to be important for initiating migraine (Carmona & Bruera, 2009). The AEDs that are used in migraine include divalproex (valproate), gabapentin, and topiramate (ICSI, 2009).

Divalproex (Depakote) has FDA labeling as a preventive treatment for migraine. Divalproex reduces the number of migraine attacks and also reduces the duration and intensity. It is notably appropriate to use in a patient with coexisting seizure disorder. The initial dose for migraine preventive therapy is 125 to 250 mg twice daily. The dosage can be increased by 125 or 250 mg weekly, to a maximum dose of 1,000 to 1,250 mg per day. Patients who are started on divalproex require baseline assessment of liver function, platelet count, and bleeding time, as hepatic failure and thrombocytopenia are rare adverse effects. Clinical monitoring of symptoms for liver failure or bleeding disorders is more indicative of potential problems than routine laboratory monitoring. Divalproex serum concentrations should be monitored during therapy if poor compliance, toxicity, or drug reactions are suspected. Divalproex is Pregnancy Category D.

Gabapentin has proven efficacy as migraine prophylaxis for some patients and is one of the recommended ICSI migraine prophylaxis drugs (2009). In a controlled clinical trial of gabapentin for migraine prophylaxis, 46.4% of the gabapentin group (2,400 mg/d) had a significant reduction in migraine after 4 weeks of treatment (Neal et al, 2001). Patients should be started on gabapentin 300 mg daily and titrated up to 2,400 mg per day. A suggested titration is 300 mg daily, titrated up to 900 mg daily at the end of week 1, then titrated up to 1,500 mg per day at the end of week 2. During week 3, the dose is increased to 2,100 mg per day and in week 4 the dose increases to 2,400 mg/d (ICSI, 2009; Mathew et al, 2001). Gabapentin is generally well tolerated, although fatigue, somnolence, and weight gain are known adverse effects.

Topiramate (Topamax) has an FDA indication for migraine prophylaxis. It is rapidly absorbed from the GI tract and has a long duration of action. Migraine patients are started on a dose of 25 mg per day and titrated up in 1 week intervals. During week 1, patients take 25 mg before bed, then 25 mg twice a day in week 2. In week 3, patients take 25 mg in the morning and 50 mg in the evening, then 50 mg twice a day. Dosages of 25 mg of topiramate twice daily may be effective (Carmona & Bruera, 2009). Topiramate adverse effects include weight loss, somnolence, fatigue, and kidney stones. The AEDs are described in detail in Chapter 15.

NSAIDS

NSAIDs may also be used for migraine preventive therapy. The most commonly used NSAID is naproxen sodium, dosed at 550 mg twice a day. NSAIDs are particularly effective in treating menstrual migraines if daily dosing is started the week before menses and continued for a week after. In older patients, NSAIDs may pose a higher risk of causing nephrotoxicity or gastrointestinal problems.

Calcium Channel Blockers

Calcium channel blockers are also commonly used for migraine preventive therapy, although their effectiveness has had mixed results and they should not be a first-line choice. Calcium channel blockers are thought to prevent migraine by inhibiting vasospasm of the cerebral arteries and by preventing cerebral hypoxia during migraine attacks. Verapamil (Calan, Isoptin) is the most commonly used for migraine prevention. Nifedipine and diltiazem are not as effective in controlling migraines and probably should not be prescribed for this use. Calcium channel blockers may be the first-line choice for patients with hypertension who cannot take beta blockers. Dosing of verapamil is shown in Table 35-2. Adverse effects include sedation, weight gain, depression, and extrapyramidal symptoms. Calcium channel blockers are contraindicated in pregnancy, Parkinson's disease, and depression.

Methysergide

Methysergide (Sansert) is an ergot derivative that is a 5-HT$_2$ receptor agonist that inhibits or blocks the effects of serotonin. Methysergide is not commonly used because of its potential for adverse effects (reported in 30% to 50% of patients). The most serious adverse effect is retroperitoneal fibrosis or related conditions with prolonged therapy. If methysergide is prescribed, the patient should have a drug-free period of 3 to 4 weeks after every 6 months of treatment. Methysergide is contraindicated in pregnancy. Ergot derivatives should be avoided in patients with coronary artery disease, peripheral vascular disease, impaired renal or liver function, or hypertension.

Botulinum Toxin

In 2010, onabotulinumtoxinA (Botox) was FDA approved for preventive treatment of chronic migraines. Botox is injected in 31 sites divided across seven head and neck muscle areas and may be repeated every 12 weeks.

Nonpharmacological Management of Migraine

Nonpharmacological management of migraine includes a variety of interventions and alternative therapies. The first and most important is migraine trigger identification and avoidance. Alternative therapies, including herbs (feverfew and butterbur), vitamins (riboflavin), and coenzyme Q10, are all commonly used in migraine therapy (Taylor, 2009). Nontraditional health care should be addressed; up to 70% of patients who seek alternative therapy never discuss it with their health-care provider. Lifestyle issues such as stress and work environment can be modified to decrease migraine attacks or make them more manageable.

Identifying Triggers

Identifying and avoiding triggers can significantly decrease migraines. Many patients identify certain foods, odors, or medications that may cause headache. Table 35-1 lists common migraine triggers. Patients need to be encouraged to use their headache diary to determine if something is a trigger. Common foods like chocolate, yogurt, or the food additive aspartame can trigger a migraine, and patients are often not aware that something is provoking their headaches. Smoking cessation and sleep regulation may also prove helpful in headache prevention.

Alternative Therapies

Alternative therapies that may assist in the treatment of migraine vary considerably. MigraLief, a commonly used herbal supplement containing feverfew, riboflavin, magnesium, and other vitamins, is available OTC. A naturopath may prescribe additional herbal medicine to treat migraines. Other alternative therapies that may be beneficial include acupuncture, aromatherapy, chiropractic manipulation, hypnosis, and reflexology. Patients can try massage therapy, relaxation therapy, and yoga, which all appear to reduce the tension and stress that may lead to migraine. The health-care provider should have access to local health education classes that teach yoga and relaxation classes or a local massage therapist for referral. A simple technique of applying ice to the head can often decrease the severity of pain associated with migraine; patients can be encouraged to try this simple technique as an adjunct to or a substitute for their medication.

Biofeedback

Biofeedback techniques are helpful for many patients. Biofeedback is thought to change vascular dilatation. Although the exact mechanism is unclear, some patients do report improvement in their migraine symptoms. Biofeedback is often combined with other relaxation therapies and may give the patient a feeling of control and mastery over the migraine symptoms.

On The Horizon **MIGRAINES**

A number of medications are in the pipeline for treatment of migraines. An inhaled form of dihydroergotamine (Semprana) will be reviewed by the FDA in 2015. Two monoclonal antibody preparations that target calcitonin gene-related peptide (CGRP) are in experimental trials. CGRP is a protein that is thought to trigger migraines. ALD403 (Alder Biopharmaceuticals) and LY2951742 (Lilly) have both demonstrated reduction in migraines compared to placebo. Boehringer Ingelheim Pharmaceuticals' olcegepant, a CGRP antagonist, is undergoing phase II trials in Europe.

Monitoring

Patients with migraine headaches should keep a headache diary, especially when a new treatment is begun or if modifications are made in the therapy. The health-care provider can use the diary to determine if the treatment is decreasing the frequency, duration, or severity of the migraine. The diary can also track adverse side effects of the medication prescribed. Overuse of medication can be determined and an alternative plan developed. Patients should also have their blood pressure monitored for hypertension if they are on a triptan, ergotamine derivative, beta blocker, or calcium channel blocker. Patients on divalproex should have their liver

function and complete blood count (CBC) tested every 2 weeks for a total of 6 weeks.

Outcome Evaluation

The goal of migraine treatment is to minimize the impact of migraine headaches on patients' quality of life, social functioning, and ability to work. It is evaluated by discussing with patients how their migraine is affecting their quality of life and by having them record in their headache diary when their headaches adversely affect their quality of life and ability to work. Modification of the treatment plan multiple times until the optimal treatment is found is important in achieving the goal of minimal impact from migraine on quality of life.

Avoidance of patients' identified migraine triggers often decreases the frequency of headache. It is evaluated by having patients record in their headache diaries any headache associated with a specific trigger. If patients are unable to determine if a specific item is a trigger, an elimination diet may be tried. Patients eliminate one item from the common triggers list for 2 weeks and then reintroduce it into their diet. This process may take weeks or months, but the reward of identifying a trigger is worth the perceived inconvenience.

Before beginning preventive therapy for frequent migraine sufferers, patients must be clear that the final goal is to reduce the frequency of migraine by 50% and that total elimination of migraine is not a realistic goal. Evaluating the success of preventive therapy by use of the headache diary and by demonstrating a decrease in frequency to patients will assist in clarifying the true success of treatment. It is essential to treat patients for an adequate amount of time (2 to 3 months) before a change in treatment.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues (see the Patient Education box).

Patient education is the key to successful migraine treatment. Patient education related to migraine should focus on the following:

1. An understanding of the diagnosis and nature of migraines.
2. The nonpharmacological measures to prevent and treat migraines, such as trigger identification and avoidance and the use of relaxation, massage, or ice to counter pain.
3. Education about the medication that is prescribed. Specifically, expected side effects, adverse side effects, interactions with other medications, and maximum dosages should be explained. Medication overuse should be addressed at the beginning of treatment.
4. The patient as an integral part of the treatment plan. Therapy is less effective if the patient does not keep a headache diary or uses the medication in a way different from how it was prescribed.
5. Realistic expectations of treatment. The patient will probably not be migraine-free, but the goal is to decrease the severity and frequency of migraines. Acute treatment should provide relief within an hour or two, or a change in therapy may be indicated.
6. Caution the patient about using OTC medications to treat the headache unless they are part of the treatment plan.

PATIENT EDUCATION

Headaches

RELATED TO THE OVERALL TREATMENT PLAN/DISEASE PROCESS

☐ Pathophysiology of headache

☐ Role of lifestyle modifications

☐ Importance of adherence to the treatment regimen

☐ Self-monitoring of symptoms and associated symptoms

☐ What to do when symptoms and associated symptoms worsen

☐ Need for regular follow-up visits with the primary care provider

SPECIFIC TO THE DRUG THERAPY

☐ Reason for taking the drug and its anticipated action in the disease process

☐ Doses (including maximum dosage) and schedules for taking the drug

☐ Possible adverse effects and what to do if they occur

☐ Interactions between other treatment modalities and these drugs

☐ Potential for medication-overuse headache

REASONS FOR TAKING THE DRUG(S)

Patient education about specific drugs is provided in the appropriate chapters. Specific reasons for taking the drug(s) should be discussed on an individual basis, depending on the diagnosis and nature of the headache. Medication overuse should also be discussed at the beginning of treatment.

DRUGS AS PART OF THE TOTAL TREATMENT REGIMEN

The total treatment regimen includes pharmacological and nonpharmacological measures, as well as the headache diary. A realistic expectation and goals of the individualized treatment plan should be presented.

ADHERENCE ISSUES

Nonadherence with the treatment regimen may affect functional status. Health-care providers should be aware of the potential problem of nonadherence and discuss the importance of adherence with the patient and family.

Education resources available for both the patient and the provider on the Internet and in print enable better understanding of the pathology and treatment of migraine and other headaches. The patient needs to be directed to reliable information. There are numerous patient-health organizations, pharmaceutical manufacturers, online support groups, and even Web sites that are maintained by private individuals. Box 35-1 provides a short list of the patient-health sites and provider information sites that are considered reliable, comprehensive, and trustworthy and that may be helpful for the health-care provider who cares for patients with headaches.

TENSION-TYPE HEADACHES

Up to 90% of all headaches could be classified as tension-type headaches. At least 15% of patients have experienced their first tension headache by age 10. Tension-type headaches can occur daily and may become persistent and intractable. As with migraine patients, 75% of patients with chronic tension-type headaches are women. Patients may suffer from both tension-type and migraine headaches.

The patient usually describes a bandlike pressure that is a persistent, dull pain. The pain is usually bilateral in location and nonpulsating. The headache may change in intensity and last from 30 minutes to 7 days. Unlike migraine, tension-type headaches are not worsened by physical activity. The patient may have mild nausea or photophobia, but severe nausea, vomiting, and aura are absent. Tension headaches may increase in frequency and severity in times of stress or emotional upheaval. Chronic tension-type headache is diagnosed when the headache is present for more than 15 days per month.

Pathophysiology

The pathology of tension-type headaches is poorly understood. It was thought that muscle contraction was the primary cause of tension headache, and it was previously called muscle contraction headache. The patient may exhibit tenderness of the extracranial soft tissue and of the cervical or masseter muscles. The muscle pain and tenderness in tension headaches may resemble fibromyalgia. Prolonged stress, eyestrain, and sitting for long periods, such as when using a computer, may lead to increased tension headaches. There is little agreement currently about the cause of tension headaches.

Goals of Therapy

The primary goal of tension-type headache treatment is to decrease the frequency and severity of headache and to provide acute relief of headache once it begins. Although total eradication of headaches may not be possible, a combination of relaxation therapy and preventive medication, when necessary, usually decreases the frequency of headache.

Rational Drug Selection

The pharmacological management of tension-type headaches, as with migraine, focuses on acute or abortive treatment and preventive therapy. A key distinction between tension headache and migraine treatment is that tension headaches do not respond to ergotamine derivatives or triptans.

Acute Therapy

Acute therapy in the treatment of tension-type headaches includes a combination of pharmacological and nonpharmacological therapy.

Mild Analgesics

For mild to moderate tension headaches, OTC analgesics are quite effective. ASA, acetaminophen, or one of the NSAIDs (ibuprofen or naproxen), taken at the beginning of a tension headache, can be effective in relieving headache pain. The dosing is the same as for migraine. Patients should be cautioned not to use OTC analgesics for headache more than 2 to 3 times per week because they can cause medication-overuse headache.

BOX 35–1 HEADACHE RESOURCES FOR PATIENTS AND HEALTH-CARE PROVIDERS

American Headache Society

http://www.americanheadachesociety.org

The American Headache Society (AHS) is a professional society of health-care providers dedicated to the study and treatment of headache and face pain. Founded in 1959, AHS brings together physicians and other health-care providers from various fields and specialties to share concepts and developments about headache and related conditions.

American Council for Headache Education

http://www.achenet.org

This site is geared for patients and is connected with the American Headache Society. There is patient information on headaches in general, migraines, and prevention and treatment of headaches, as well as a discussion forum for patients. There are specific sections for children and women.

National Headache Foundation

www.headaches.org

Nonprofit organization dedicated to educating headache sufferers and health-care professionals about headache causes and treatments.

International Headache Society

www.ihs-headache.org

The International Headache Society (IHS) is an international professional organization working with others for the benefit of people affected by headache disorders. The purpose of IHS is to advance headache science, education, and management, and to promote headache awareness worldwide. *Note*: The Web site asks about membership but nonmembers can access all guidelines.

Patients often self-medicate with OTC products prior to seeking care for their headaches, and therefore a history of what the patient has taken for headache relief and in what amounts is necessary. This history assists the health-care provider in determining if the headache has received adequate amounts of analgesic or if the tension headache is complicated by medication-overuse headache.

Combination Medications

Combination medications are commonly prescribed to treat both migraine and tension-type headaches. Products that combine either butalbital with ASA or APAP or isometheptene with APAP and dichloralphenazone are effective in treating tension headache. These products should be used cautiously because medication-overuse headaches can occur if dosages are higher than recommended or if they are taken more than 2 days per week. The provider should distribute a maximum of 30 tablets of either of these medications per month to make sure the patient is not overusing them.

Preventive Therapy

Preventive therapy should be considered if the patient is having more than one to two headaches per week. Used more than twice a week, the medications used for acute tension headache therapy all have the potential for causing medication-overuse headaches. A trial of preventive medication is likely to be helpful and should be considered early in treatment.

Beta Blockers

Beta blockers can be used for prophylactic treatment of tension headache. The dosing and contraindications are the same as for migraine preventive therapy.

Tricyclic Antidepressants

Tricyclic antidepressants are successful in reducing tension headaches both in patients who are depressed and in those who are not. They appear to enhance the endogenous pain-suppressing systems in the brain. Amitriptyline and nortriptyline are used in the same dosages as for migraine (see Table 35-2). Patients with tension-type headaches may also have depression, and dosing for depression may be successful if a lower dose is not effective.

Nonpharmacological Therapy

Nonpharmacological therapy is central in the preventive treatment of tension-type headaches. Stress management, biofeedback, and regular exercise can help to reduce medication use for tension headaches (ICSI, 2009). Topical heat or cold packs should be applied. Massage therapy and relaxation therapy help to relax the muscle tension that can aggravate tension headaches. Alternative therapies such as acupuncture and herbal medicine prescribed by a naturopath may improve headache symptoms. Referral to a psychologist or psychiatrist may assist in identifying and treating underlying anxiety that may be contrib uting to the tension headaches.

Monitoring

Monitoring for effectiveness of acute or preventive medication prescribed for tension headache should be done frequently (every 1 to 2 months) at the beginning of treatment. The patient must keep a headache diary to assist in determining if treatment is successful. Once a patient is stable on an acute or preventive medication, the patient can be seen less frequently. The provider should continue to monitor the use of combination drugs (butalbital and isometheptene compounds) to safeguard against potential medication-overuse headaches developing from overuse.

Outcome Evaluation

Evaluating the success of tension-type headache therapy is achieved by monitoring the patient's headache diary to determine if there is a decrease in the frequency or severity of headaches. If the patient develops new skills, such as stress reduction or relaxation, or begins exercising regularly, these efforts ought to be acknowledged by the health-care provider. As tension-type headaches often last off and on for many years, reevaluation and reworking the treatment regimen may happen multiple times.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment plan, and adherence issues. For general patient education information, see the previous Patient Education section.

Patient education information specific to treating tension-type headaches should focus on the following principles:

1. Patients need to know what tension-type headaches are and how they differ from migraines or pathological headaches.
2. Medication education ensures that the acute or preventive medications are taken appropriately. Prevention of medication overuse should be addressed early in the treatment.
3. Nonpharmacological therapies should be encouraged and the patient given local resources available, such as yoga classes, relaxation tapes, and massage therapists.
4. The importance of the patient's participation by keeping a headache diary needs to be stressed. Because most treatment decisions are based on response to therapy, the headache diary is invaluable to the successful management of headaches.

CHRONIC DAILY HEADACHES

Chronic daily headache is defined as headaches 15 or more days a month for longer than 3 months (Garza & Schwedt, 2014a). Chronic daily headaches (CDH) can be divided into five subtypes: chronic tension-type headache, chronic migraine, hemicrania continua, medication-overuse headache, or

new daily persistent headache. Chronic tension-type headaches have already been addressed. Use of drugs for acute headache treatment more than 9 days a month is associated with increased risk of chronic daily headaches (ICSI, 2009). Medication-overuse is addressed later in this chapter. New persistent daily headache (NPDH) is uncommon, the onset is usually abrupt (patients can often pinpoint the date), and it is usually self-limiting. The cause is thought to be Epstein-Barr virus–induced immune changes. Treatment of NPDH is not discussed in this chapter because little information is available; these patients should be referred to a neurologist for care.

Pathophysiology

The pathology of CDH is often unclear and of mixed origin. There is a clear difference between chronic migraine and hemicrania continua. The boundary between chronic tension-type headache and chronic migraine is less clear and may require a neurology referral for treatment.

The term *chronic migraine* refers to CDH that starts as episodic migraine (less than 15 days a month) that transforms into a chronic pattern of greater than 15 days a month of migraine headache (Garza & Schwedt, 2014b). It was formerly called "transformed migraine." The initial migraines have the pathogenesis of migraine discussed earlier. Chronic migraine is not well understood, but is thought to be related to a combination of atypical pain processing, cortical hyperexcitability, neurologic inflammation, and central sensitization (Garza & Schwedt, 2014b). Risk factors for chronic migraine include female gender, history of head or neck injury, life stress, psychiatric disorders, and comorbid pain disorders (Garza & Schwedt, 2014b).

Hemicrania continua, also known as *chronic paroxysmal hemicrania*, is a rare headache syndrome where the patient, most often a woman, suffers from multiple (10 to 20) and short-lived (less than 20 minutes) episodes of severe unilateral, excruciating pain in the area of the eye, forehead, and temple. Exact pathology is not known but positive emission tomography (PET) scans demonstrate activation of the contralateral posterior hypothalamus and ipsilateral rostral pons during pain episodes (Garza & Schwedt, 2014c). Patients often have autonomic symptoms, including tearing, congestion, eyelid edema, flushing, sweating, or conjunctival injection.

Goals of Treatment

The first goal of treatment for CDH is to break the pattern of daily headache. The patient is then stabilized on prophylactic or preventive therapy.

Rational Drug Selection

Chronic Migraine

In most patients with chronic migraine, the daily headache cycle can be broken by using repeated doses of IV DHE. Approximately 70% to 80% of patients respond to DHE. The patient is given a test dose of 0.33 mL of DHE (1 mg/mL

solution) with 5 mg of metoclopramide or 10 mg of prochlorperazine (Compazine), followed by 0.5 mL of DHE and one of the antinausea medications every 6 hours for 48 to 72 hours. This usually requires inpatient treatment. DHE is contraindicated in coronary and peripheral vascular disease.

Alternatives to DHE include chlorpromazine (Thorazine) and prochlorperazine. If the patient has medication-overuse headache due to misuse of analgesics, ergots, or combination medications, the patient has to be detoxified, which is discussed later in this chapter. Treatment of chronic migraine may require consultation with a neurologist.

Preventive pharmacotherapy can be started after the headache cycle is broken. The patient usually responds to migraine-preventive medications such as propranolol, divalproex, or a tricyclic antidepressant. Amitriptyline is a good choice if the patient is also depressed. The seizure medications topiramate or valproic acid may be used. The patient is on preventive medication until the headache days are reduced by 50%, and then an additional 3 to 4 weeks, for a total of 6 to 12 weeks.

The patient should also receive alternative therapy to treat CDH. Behavioral counseling, biofeedback therapy, relaxation therapy, physical exercise, and acupuncture are all valid alternative therapies for treatment of CDH.

Hemicrania Continua

Hemicrania continua or chronic paroxysmal hemicrania is a rare disorder that responds completely to indomethacin and to nothing else. Indomethacin (Indocin) 75 to 150 mg is given daily; doses up to 200 mg daily may be needed. Referral to a neurologist is recommended.

Monitoring

Monitoring of patients with CDH who are on preventive therapy requires the patient to keep a diary of headache and medication use. Patients' blood pressure should be monitored if they are on a beta blocker, and liver function monitored if on divalproex, as per migraine therapy monitoring. Ongoing monitoring of headache is necessary because 31% may have recurrence of headache in spite of preventive medication.

Outcome Evaluation

Patients with CDH are difficult to treat. Treatment success is determined by how effective it has been in breaking the cycle of daily headaches and how effective the preventive treatment is. The patient's headache diary is key in the evaluation of the success of treatment.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment plan, and adherence issues.

Patient education information specific to treating CDH should focus on the following principles:

1. Education about the nature of the disorder, particularly that it is biological in origin, with neurochemical changes producing the headache.
2. Overuse of analgesics, leading to medication-overuse headache, must be emphasized.
3. The influence of stress, anxiety, depression, and inability to relax should be discussed, and the patient encouraged to use nonpharmacological therapies to decrease headache.

CLUSTER HEADACHES

Cluster headaches are characterized by intense pain lasting for 15 minutes to 2 hours; they occur in "clusters" of several weeks or months, with the headache subsiding for months at a time, often to recur. The patient can experience one to three attacks a day, usually at the same time of day. They occur most frequently at night, awakening the patient from sleep. Men are affected more than women, with onset in their late twenties. The pain of a cluster headache is unique in that it occurs behind or around one eye, with tearing, conjunctival injection, and drooping of the eyelid common symptoms. There may be nasal congestion, facial flushing, and sweating. The pain is so severe that the patient is unable to lie down or sit still, often pacing the floor in pain.

Pathophysiology

There is no clear etiology for cluster headaches. They are most likely a neuronal disorder originating in the hypothalamus. The clockwork-like timing of cluster headaches suggests that the circadian pacemaker or biological "clock" is dysfunctional.

Goals of Treatment

Relieving the pain of an acute cluster headache and decreasing the length of time of the cluster are the goals of cluster headache management.

Rational Drug Therapy

Most patients with cluster headaches require acute and preventive therapy. The acute attacks are severe and last only a short time; therefore, the intervention must be fast-acting. The patient usually requires both acute and preventive medications to manage the headache.

Acute Therapy

Oxygen therapy administered via a 100% nonrebreather mask for 15 to 30 minutes often provides immediate relief of cluster headache (ICSI, 2009; May, 2014b). Sumatriptan, administered SC, or intranasal sumatriptan or zolmitriptan may provide relief of acute cluster headaches (May, 2014b).

Intranasal lidocaine is thought to be effective in treating cluster headache. The patient lies supine, hyperextends the head at 45 degrees, and rotates it 30 degrees to the side of the headache. The lidocaine nasal solution is then dripped into the nostril on the affected side over 30 seconds. The onset is approximately 5 minutes.

Ergotamine derivatives are also effective for acute cluster headaches. Sublingual 2 mg tablets are administered at the beginning of the cluster headache. Ergotamine suppositories or DHE intranasally or IM may also be used (see Table 35-2 for dosing). Ergotamine may also be administered in a 2 mg dose given before bed if nocturnal attacks occur frequently.

Preventive Therapy

Verapamil can prevent cluster headaches in some patients. Calcium channel blockers are thought to prevent cluster headache by inhibiting vasospasm of the cerebral arteries. Dosing of verapamil is given in Table 35-2. Cluster headaches appear to need dosing in the high range to achieve headache reduction.

Divalproex can be effective in preventing cluster headaches. The dosing is the same as for migraine prophylaxis (see Table 35-2).

Lithium appears to have some effect on cluster headaches in some patients, and a trial of lithium is warranted if the patient does not respond to other preventive medications. The dose for cluster headache prevention is 300 mg daily to a maximum of 300 mg 3 times a day. The patient needs careful monitoring for adverse effects, including electrocardiogram (ECG), electrolytes, thyroid function, creatinine, and CBC studies.

Nonpharmacological therapies include avoidance of all alcohol during the clustering of headaches because alcohol often precipitates a headache. Patients often are able to drink alcohol between headache clusters without adverse effects. Tobacco, stress, anger, and vigorous physical activity should be avoided. The patient needs to maintain a normal sleep pattern, if possible. Cluster headaches do not appear to respond to self-care measures such as massage and relaxation.

Monitoring

Cluster headaches can be severely disabling, and the intense pain and loss of sleep can significantly affect the patient's quality of life. The health-care provider needs to monitor the patient for suicidal thoughts during the headache. The headache diary helps to monitor the effectiveness of acute and preventive medications. A patient treated with lithium requires careful monitoring of ECG and chemistries throughout treatment.

Outcome Evaluation

Cluster headaches by definition are self-limiting and will eventually stop, regardless of treatment. The focus of care is to provide measures that shorten or prevent cluster headaches during the cluster. Evaluation of the effectiveness of acute

and preventive therapy is accomplished by self-report with a headache diary. Modifications in pharmacological management of cluster headaches should be based on the headache diary.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment plan, and adherence issues.

Patient education information specific to treating cluster headaches should focus on the following principles:

1. Educating the family about cluster headache, particularly the fact that it is a benign condition, in spite of the severe pain experienced during attacks.
2. Self-management of acute medications. The headache is usually brief, and therefore the patient must be able to self-medicate to provide relief. The pain may be gone by the time the patient can get transportation to a medical clinic.
3. Avoidance of alcohol is crucial during clusters of headaches.

MEDICATION-OVERUSE HEADACHES

Drug-rebound or drug-induced headache was reclassified by the International Headache Society as medication-overuse headache in 2008 (Ferrari, Coccia, & Sternieri, 2008). Medication-overuse headache should be considered in any patient who reports daily use of analgesics or combination medications such as butalbital or ergotamine derivatives or one of the triptans, with medication overuse reported in one-third of patients with chronic daily headaches (Maizels, 2004). Caffeine can also cause withdrawal headache when abruptly discontinued. The headache recurs as the medication wears off, compelling the patient to take another dose of medication, which causes a cycle of medication overuse and rebound. The patient may never have complete relief of pain, leading to a patient concern about serious pathology. A careful history of all the medications, including OTC analgesics that the patient takes on a daily basis, can help to determine if drug rebound is the issue or if a patient has CDH. A thorough history and physical examination with negative findings other than medication use is reassuring to the provider, but not always initially to the patient.

The health-care provider needs to be aware of the clinical features of medication-overuse headaches. According to the International Headache Society diagnostic criteria, the following clinical characteristics are found in medication-overuse headache (Silberstein et al, 2005):

1. Headache presents on more than 15 days/month, fulfilling criteria 3 and 4 below.
2. Regular overuse for more than 3 months of one or more drugs that can be taken for acute and/or symptomatic treatment of headache.
3. The headache has developed or markedly worsened during medication overuse.

4. Headache resolves or reverts to its previous pattern within 2 months after discontinuation of overused medication.

Other symptoms reported may be worsening of headache as analgesia wears off and the slightest physical or mental exertion brings on the headache. An accurate diagnosis is essential because chronic daily headaches and medication-overuse headache have similar presentation (Silberstein et al, 2005).

Pathophysiology

Dependence on either ergotamine or the OTC analgesics is thought to have physical and psychological elements. The overuse of simple analgesics (ASA or APAP), either alone or in combination with butalbital or caffeine, has a high potential for causing medication-overuse headache. Although the exact process is unclear, it is thought to suppress or alter the central pain-control mechanism. Ergotamine causes a clear pharmacological dependence and subsequent withdrawal. When a patient has analgesic-rebound headache, other headache therapies used for acute or preventive therapy may be resistant to treatment. The patient must be detoxified before preventive therapy can be started.

Goals of Therapy

The goal of treating medication-overuse headache is that the patient will no longer be taking daily doses of analgesics or ergotamine and will be stabilized on preventive medication. The goal during the withdrawal period should be minimizing the intensity of the withdrawal headache.

Rational Drug Therapy

Treatment of medication-overuse headache involves (1) withdrawal from offending agents, including caffeine; (2) transition therapy to support the patient during detoxification; and (3) initiation or adjustment of prophylaxis medication (Garza & Schwedt, 2014b; Maizels, 2004;). Anticipating withdrawal from daily or near-daily use of analgesics, butalbital-containing drugs, triptans, or ergotamine can make the patient anxious. The provider needs to adequately prepare the patient prior to the detoxification process, as discussed in the Patient Education section. Preventive therapy can be started when the withdrawal process is started or 2 to 3 weeks before or after the withdrawal process. Preventive therapy for migraine and tension-type headache has already been discussed. The practitioner should consult with a neurologist prior to embarking on detoxification of a patient with medication-overuse headache.

Withdrawal from the simple analgesics, ASA and APAP, or caffeine-containing medications is usually done on an outpatient basis. Naproxen may be used to provide pain relief while the overused medication is withdrawn. Naproxen is dosed at 550 mg twice daily for 2 to 4 weeks or 550 mg twice daily for 1 week then 550 mg daily for a week.

Butalbital-containing drugs (Fiorinal, Fioricet) may need to be tapered slowly because severe problems can develop with abrupt cessation. Serious withdrawal symptoms, such as delirium and seizures, can appear without warning. Butalbital use of less than 8 pills (400 mg) per day can be treated on an outpatient basis. Suggested regimens include Midrin *plus* clonazepam (Klonopin) for 1 week and then taper *or* phenobarbital for 1 week *plus* promethazine (Phenergan) for 1 to 2 weeks. If the patient is using more than eight pills per day, then inpatient drug detoxification is necessary, using IV DHE, metoclopramide, and IV fluids.

Some patients may require inpatient management to get their headache under control. Prevention and astute diagnosis are the roles of the primary care provider in the care of medication-overuse headache. Consultation with a headache specialist is warranted to provide optimal evidence-based care for medication-overuse headache.

Monitoring

Monitoring begins with the provider's regulating the number of doses of acute relief medication the patient is allowed to have each month. If OTC analgesic overuse is suspected, then the provider needs to determine the number of doses the patient is taking in a day or a week. During the withdrawal period, the patient's symptoms need to be monitored. If the patient requires IV medication or fluid intervention, the patient may need to be hospitalized. After the patient has been successfully detoxified from the medication, the provider needs to monitor the effectiveness of the preventive medication in preventing headaches. Effective preventive medication decreases the need for acute therapy. Ongoing assessment of analgesic, triptan, and ergotamine use will determine if the patient is overusing again.

Outcome Evaluation

The successful outcome in medication-overuse headache is a patient who is detoxified from the offending medication and is somewhat headache-free. The patient may still have an occasional headache and need acute or preventive therapy. Monitor for overuse of headache medications and relapse.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment plan, and adherence issues. Patients may have an exacerbation of headache in the first 2 weeks after withdrawal, and it may take 4 to 12 weeks after withdrawal for the patient to show improvement (Maizels, 2004). Educating the patient about what to expect during the withdrawal process will reduce anxiety during the process.

When discussing medication-overuse headache with the patient, the provider must be careful to avoid terms such as *drug abuse*. Patients with medication-overuse headache began with a primary headache disorder and fell into a pattern of overuse, and to label them as "abusers" can be devastating. Before and during the detoxification period, the provider should explain the plan of care and establish a patient's trust. The patient is about to embark on a process that will surely cause moderate to severe headache, a state that the patient has been trying to avoid.

The following principles regarding medication-overuse headache and the withdrawal process need to be discussed with the patient:

1. A clear description of medication-overuse headache and how it develops should be given to the patient.
2. After stopping the medication, the headache will get worse within 24 hours (72 hours for ergotamine) and may last from days to weeks.
3. Patients must be assured that interventions will be taken to make them comfortable and to decrease the severity of headache, including hospitalization, if needed.
4. It may take 1 to 3 months for the patient to have a normal response to acute therapy.

POST-TRAUMATIC (POST-CONCUSSIVE) HEADACHES

The post-traumatic headache syndrome is a common sequelae following injuries to the head or neck. In many patients, particularly those with more severe trauma, headaches may be a problem for months, years, or a lifetime. If the headaches develop within 2 weeks of the event, and persist for more than several months, we would consider this to be the chronic phase of the post-traumatic headache syndrome (Robbins, 2000).

Post-traumatic headache (PTH) is divided into acute and chronic groups whose management and prognosis are clearly different. Although IHS criteria stipulate that PTH should have an onset within 2 weeks of the trauma, it has been observed that a headache linked to the trauma can start later. PTH can be clinically divided into the following groups: migraine-like headache, tension-type-like headache, cluster-like headache, cervicogenic-like headache, and others. Based on these clinical distinctions, therapy can be administered accordingly. However, the distinction is relative and numerous clinical features may be common to all. There seems to be a weak inverse relationship between the severity of the head trauma and the occurrence of a PTH, especially chronic. A holistic approach is not only useful but is necessary for a therapeutic success (Lenaerts & Couch, 2004).

Pathophysiology

The mechanism of post-traumatic headache is poorly understood. Current research is investigating the interplay of biochemical, molecular, and physiological contributors that follow brain injury. Trauma-induced headaches are usually heterogeneous in nature, often including both tension-type pain and intermittent migraine-like attacks. Rebound headaches may develop from overuse of analgesic medications, and the

occurrence of such may complicate significantly the diagnosis of post-traumatic headache. Adequate treatment typically requires both "peripheral" and "central" measures (Lane & Arciniegas, 2002). Other complicating contributing factors to the diagnosis and management of PTH is the presence of post-dural puncture resulting in a chronic "low-flow" dural leak, or the presence of a traumatic brain injury (TBI).

The key pathological sequelae of concussion are glutamate excitotoxicity, inflammation, priming and activation of microglia, blood–brain barrier disruption, axonal damage from mechanical injury and secondary events, calcium dysregulation, and alteration in cerebral blood flow and autoregulation (Neal, Wilson, Hsu, & Powers, 2012).

There are many other symptoms that often accompany the post-traumatic headache syndrome. These tend to be similar in most patients. They include some or all of the following: poor concentration, becoming easily angered, sensitivity to noise or bright lights, depression, dizziness or vertigo, tinnitus, memory problems, fatigue, insomnia, lack of motivation, decreased libido, nervousness or anxiety, irritability, becoming easily frustrated, and decreased ability to comprehend complex issues (Jeter et al, 2012).

Goals of Therapy

Early and aggressive treatment and empathy are essential to the patient's improvement. Prompt recognition and treatment of laceration, peripheral nociceptive sources such as cervical joint displacement, and vascular factors may diminish chronicity. Neuromodulation of pain with prophylactic agents is recommended early. Although it is less necessary for the acute PTH, it will be crucial for the chronic form and should be initiated no later than the 2 months' cut-off time between acute and chronic PTH. Recognition and treatment of psychiatric factors such as depression and anxiety will lessen the risk of chronicity (Lenaerts & Couch, 2004).

Rational Drug Therapy

Medication is the cornerstone of treatment because it is consistently the most effective therapeutic modality to assist with the management of symptoms associated with post-concussive headaches, although no medication has been identified to expedite recovery for TBI. We have available both abortive and/or preventive medication. In the first 3 weeks of the headaches, we usually only utilize abortive medication. If the headaches persist beyond this point, and remain moderate or severe, preventive medicine should be instituted.

Amitriptyline has been widely used for post-traumatic tension-type headaches as well as for the nonspecific symptoms, such as irritability, dizziness, depression, fatigue, and insomnia.

An inpatient program of repetitive intravenous dihydroergotamine and metoclopramide may provide relief of refractory chronic post-traumatic headaches. Greater occipital neuralgia frequently responds to greater occipital nerve block with a local anesthetic, which can also be combined with an injectable corticosteroid. A trial of propranolol or amitriptyline alone or in combination produced a 70% response rate in 21 of 30 adequately treated patients with post-traumatic migraine. Analgesia overuse was a common contributor to post-traumatic headache in 19% to 42% of patients. These patients responded to analgesic withdrawal as favorably as patients whose headaches were not post-traumatic. Patients with post-traumatic paroxysmal hemicrania and hemicrania continua have responded to treatment with indomethacin. (Evans, 2012).

Sleep aids such as melatonin have been used to treat sleep disturbances after concussion. Antidepressants, beta blockers, calcium channel blockers, valproic acid, topiramate, triptans, dihydroergotamine, and gabapentin have all been discussed as potential medical therapies for persistent headaches after concussion (Neal et al, 2012).

In the absence of controlled studies specific to post-concussive syndrome, these data suggest that post-traumatic headaches will likely respond to those treatments used for migraine and tension headache that are used in other settings. Clinicians caring for these patients note that delayed recovery from post-traumatic headaches may be due to inadequately aggressive treatment, analgesia overuse, or comorbidity (Evans, 2012).

Acute or abortive therapy is aimed at reversing, aborting, or reducing pain and accompanying symptoms of an attack that is in progress or is anticipated. The choice of abortive therapy depends upon the type of headache that is being treated. The principle medications for treating post-traumatic migraine, cluster, or tension-type headaches are the same as those outlined in earlier respective sections of this chapter.

Anti-inflammatories are often utilized in the post-traumatic situation where bleeding is not suspected, so as to aid the accompanying cervical or back pain. Muscle relaxants are more helpful than in routine tension headaches, because of cervical muscle spasm. If patients require excessive amounts of abortive medication, we need to consider the use of preventive medication. We do not want to create the rebound headache situation.

Most patients with migraine, and the majority of patients with post-traumatic migraine, simply require abortive medications for their headaches. However, if the migraines are frequent and/or severe, we need to progress to daily preventive therapy. The decision as to when to progress to daily preventive therapy is a difficult one, but most patients with severe post-traumatic migraines also suffer from daily headaches, and they usually benefit from preventive medication (Neal et al, 2012).

Preventive therapy should be considered for any patient who experiences severely incapacitating or frequent severe migraines (more than two per month) and patients who cannot tolerate abortive medications because of either chronic illness (coronary artery disease or hypertension) or the adverse effects of abortive medications. Preventive medication is also recommended if the patient is taking abortive medication more than twice a week. The primary goal of preventive

therapy is to use the least amount of medication with the fewest side effects to decrease migraine symptoms. If medication overuse is suspected, it must be treated first before starting the patient on preventive therapy; this topic is covered earlier in this chapter.

The most commonly employed preventives for the post-traumatic headaches are the antidepressants, particularly amitriptyline (Elavil) or nortriptyline (Pamelor), and the beta blockers. The anti-inflammatories often serve a dual purpose, functioning as both abortives and preventives. The antidepressants that are sedating, particularly amitriptyline, often decrease the daily headaches, migraines, and the associated insomnia. In severe cases, we need to use both a beta blocker and an antidepressant. The selection of preventive medication differs depending upon which headache type is predominant (Neal et al, 2012).

Although the first choices for prevention medication in the post-traumatic situation are usually antidepressants and/or beta blockers, alternative medications may be utilized. Calcium blockers (verapamil) are used for migraines as a first-line therapy. Valproate (Depakote), methysergide (Sansert), and MAO inhibitors (phenelzine) are employed if initial approaches have not been successful. IV DHE, used repetitively in the office or in the hospital, is very useful with severe post-traumatic headaches. Use IV DHE relatively early in the patient's course, often after 1 or 2 months, if the headaches are very severe. Concurrently, daily preventive medication is employed in these patients (Neal et al, 2012).

Monitoring

Clinicians who specialize in the assessment and management of this diagnosis encounter patients with prolonged recovery courses, persistent symptoms, and significant deficits in cognitive functioning. These patients require more involved therapy, which may include additional education, academic accommodations, physical therapy, cognitive rehabilitation, and medication (Meehan, 2011). Monitoring is based on medication choice (see monitoring for migraine, chronic daily headache, medication overuse headache). If OTC supplements are used for "neuroprotection," the prescriber needs to keep abreast of drug-to-supplement interactions.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment plan, and adherence issues. Patients may have an exacerbation of headache in the first 2 weeks after withdrawal, and it may take 4 to 12 weeks after withdrawal for the patient to show improvement (Maizels, 2004). Educating the patient about what to expect during the withdrawal process will reduce anxiety during the process. The following information may be useful in communications with patients (Evans, 2012):

What is post-concussion syndrome?—Post-concussion syndrome is a condition that happens after a mild brain

---

On The Horizon

DRUGS THAT MAY PROVIDE NEUROPROTECTION FOR TBI

Magnesium has demonstrated neuroprotective properties in numerous TBI models. Magnesium has been shown to have many beneficial effects, including noncompetitive NMDA receptor blockade, inhibition of presynaptic excitatory neurotransmitter release, blockade of voltage-gated calcium channels, and reduction in inflammatory cascades (Burd, Breen, Friedman, Cha, & Elovitz, 2010). Unfortunately, the data are lacking in specific and safe recommendations for the use of magnesium in this population. Additional studies should help clarify the clinical utility of magnesium supplementation following TBI (Maas & Murray, 2007).

Progesterone is an agent that appears to provide neuroprotection by multiple mechanisms. After TBI, progesterone has been shown to decrease oxidative stress by reducing membrane lipid peroxidation, reduce BBB disruption, and ameliorate the brain's inflammatory response. A phase III clinical trial, the Progesterone for the Treatment of Traumatic Brain Injury (ProTECT III), is currently underway to further assess the clinical efficacy of progesterone (Vink & Nimmo, 2009).

Erythropoietin has been identified as a neuroprotective agent that appears to ameliorate TBI by multiple avenues. The Erythropoietin in Traumatic Brain Injury (EPO-TBI) trial is currently underway to assess whether erythropoietin can improve neurological outcome in severe TBI patients (Vink & Nimmo, 2009).

Minocycline has been extensively studied in mice and has been shown to be an effective antioxidant and attenuator of the inflammatory sequelae of TBI. The study, A Safety and Feasibility of Minocycline in the Treatment of Traumatic Brain Injury, is currently underway, which will likely lead to additional clinical investigation of this drug (Schouten, 2007).

Cyclosporin is another multifactorial compound that has neuroprotective effects, including improving mitochondrial functioning, blocking free radical production, and inhibiting calcium accumulation. The animal data have been compelling that cyclosporin A (CsA) has therapeutic benefits in TBI models. However, the variability of study designs from the clinical studies has made the outcome data difficult to interpret. The safety of CsA use in TBI has been demonstrated, but additional investigation is needed to clarify the efficacy of the drug (Lulic, Burn, Bae, van Loveren, & Borlongan, 2011).

Numerous other vitamins, minerals, and antioxidant agents are being investigated as potential therapeutic modalities. These include **nicotinamide**, a soluble B-group vitamin. Animal TBI models have demonstrated beneficial effects, including reduced cortical damage, inflammation, and behavioral disruption in animals receiving infusions (Goffus, Anderson, & Hoane, 2010).

Omega-3 essential fatty acids (EFAs) have been shown in experimental TBI models to improve the blood flow, reduce the toxic effects of glutamate, and stabilize membranes. Animal models have shown that specific fatty acids can be supplemented in the diet and provide a protective function for the brain, especially in regard to seizures (Pages et al, 2011).

An antioxidant, *α-lipoic acid*, has also shown neuroprotective effects in an animal model by reducing inflammatory markers, preserving BBB permeability, and reducing brain edema (Toklu et al, 2009). Another agent called *Resveratrol*, which is a polyphenol, also has antioxidant properties and has been shown to improve behavioral outcome in a rat TBI model (Maroon & Bost, 2011). **Zinc protoporphyrin** has also been shown to attenuate brain edema and BBB permeability in an animal model (Vannemreddy et al, 2006).

injury. A "concussion" is another word for a mild brain injury. Common causes of mild brain injuries include:

- Car accidents
- Falling down and other accidents that can happen from daily activities
- Injuries from playing sports such as football, ice hockey, soccer, and boxing
- Injuries that can happen to soldiers during combat. These include injuries from blasts and bullet wounds.

What are the symptoms of post-concussion syndrome?—The symptoms include:

- Headache
- Dizziness
- Feeling very tired
- Feeling irritable or anxious
- Memory problems or problems paying attention
- Problems with sleep
- Being easily bothered by noise

How is post-concussion syndrome treated?—The treatments are different depending on which symptoms a person has. There are medicines that can help with headaches, dizziness, and other problems.

How is headache treated?—There are lots of prescription and nonprescription medicines that can ease the pain of headaches. There are also prescription medicines that can help prevent headaches from happening in the first place. The right medicine for you will depend on what type of headaches you get, how often you get them, and how bad they are.

If you get headaches often, work with your doctor to find a treatment that helps. Do not try to manage frequent headaches on your own with nonprescription pain medicines. Taking nonprescription pain medicines too often can actually cause more headaches later.

HEART FAILURE

Laura Rosenthal

Heart failure (HF) is a major health problem that the American College of Cardiology Foundation (ACCF) and the American Heart Association (AHA) estimate affects more than 5.1 million Americans annually (Yancy et al, 2013). The underlying HF incidence increases with age; the prevalence has increased over the past decade as the U.S. population ages. With the aging population growth, it is expected to increase significantly, especially in the black male population. Despite aggressive investigation into treatment options, the 5-year mortality rate remains 50% within 5 years of diagnosis. Of particular importance in HF management is the design of a treatment program targeted at the patient's underlying pathophysiology. Such a carefully designed program maximizes outcomes and prevents such treatment complications as prerenal azotemia and dehydration. Because multidrug regimens are often necessary, patient education is essential to limit complications, hospitalizations, and hospital readmissions that result from poor adherence to the treatment regimen.

PATHOPHYSIOLOGY

Heart failure is a complex clinical syndrome that can result from any structural or functional cardiac disorder that results in a cardiac output that is inadequate to satisfy the oxygen demands of the body. In HF, several abnormalities occur. Coronary artery disease (CAD) causing myocardial ischemia is the underlying cause in about two-thirds of patients with left ventricular dysfunction. Left ventricular dysfunction (systolic heart failure) begins with injury to the myocardium and is usually a progressive process, even in the absence of additional myocardial insults. The principal mechanism relates to remodeling, which occurs as a homeostatic mechanism to decrease wall stress through increases in wall thickness. The cells generated during remodeling are often abnormal and include a proliferation of connective tissue cells. These cells use energy inefficiently and have little contractile ability. The ultimate result is a change in the structure of the left ventricle in which the chamber dilates, hypertrophies, and becomes more spherical. This process generally precedes the development of symptoms but continues after their appearance and may contribute to the worsening of symptoms despite treatment. One of the advantages of the use of angiotensin-converting enzyme (ACE) inhibitors is their action in reducing remodeling.

As the left ventricle hypertrophies, the sarcomeres of the muscle cells lengthen so that limited numbers of cross-bridges can form and function appropriately and contractile force degenerates. Contractility of heart muscle is a function of the interaction of calcium with the actin-troponin-tropomyosin system. Activator calcium released from the sarcoplasmic

reticulum facilitates the interaction of actin with myosin to create the cross-bridging that produces contraction. The amount of calcium released depends on the amount in stores and the amount that enters the cell during the plateau phase of the action potential. The reduced force at systole causes the ventricles to supply inadequate blood volume to the body and blood pressure (BP) drops, even though the ventricle is very full and overstretched. This triggers counterregulatory mechanisms in the rest of the body, activating the sympathetic nervous system (SNS) and the renin-angiotensin-aldosterone (R-A-A) system (Fig. 36-1). The SNS increases heart rate, tries to increase contractile force, and increases venous tone. A major role of beta blockers in HF treatment relates to reducing the SNS activation. The R-A-A system triggers the retention of sodium and water to increase blood volume and venous return (increased preload). Initially, this brings more venous return to the heart and increases the amount of blood available to the body.

In the long-term, these adaptive mechanisms actually create more failure. The ventricle that is already full and stretched is required to deal with more volume. Diuretics, another cornerstone of pharmacological therapy, assist by reducing increased extracellular fluid volume. The pathology of HF is further compounded by the denial of adequate oxygen as the increased heart rate shortens the diastolic filling time and the coronary arteries have less time to fill. The heart demands more oxygen supply and has less.

Risk factors for HF include hypertension, diabetes mellitus (DM) and metabolic syndrome. (Yancy et al, 2013). Increased systolic and diastolic pressures especially long term, increase the risk and treatment can reduce the risk of developing HF by 50%. Metabolic syndrome, with or without overt DM, now impacts 40% to 50% of the U.S. population over age 40. The coordinated treatment of dyslipidemia, insulin resistance, and hypertension can significantly reduce HF risk.

Types of Heart Failure

Three main forms of HF can occur. Systolic dysfunction typically occurs acutely and often follows a myocardial infarction (MI). Other potential causes include nonischemic cardiomyopathy, generally from use of alcohol, cocaine, chemotherapy and other drugs that depress the myocardium, and conditions that lead to volume overload. The problem is inadequate force generated to eject blood from the ventricles, resulting in decreased cardiac output and ejection fractions of less than 40%. Forty to 60% of patients with HF have this form.

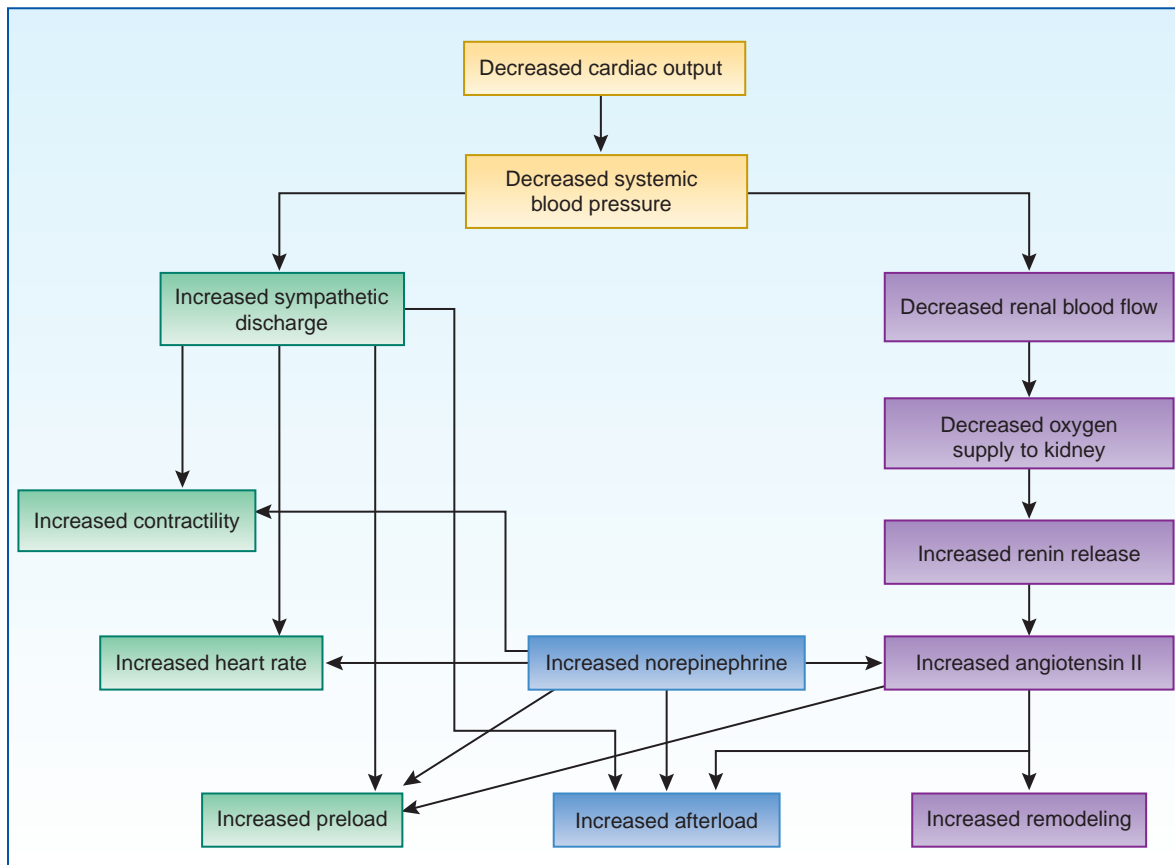
Diastolic dysfunction, also known as heart failure with preserved ejection fraction (HF-pEF), results from inadequate relaxation and loss of muscle fiber elasticity, resulting in a slower filling rate and elevated diastolic pressures. Although cardiac output is reduced, ejection fractions remain within normal limits. Potential causes include valvular dysfunction, hypertrophic and ischemic cardiomyopathy, uncontrolled


Figure 36–1. Compensatory responses in heart failure.

hypertension (HTN), and hypothyroidism. Many of the changes that occur in the cardiovascular system as a result of aging have a greater impact on diastolic function than systolic function. Heart failure with preserved systolic function is primarily a disease of elderly women (greater than 75 years), most of whom have hypertension. Up to 60% of patients with HF have this form; however, the percentage increases with age.

Coronary artery disease (CAD) and atherosclerosis are significant contributing factors for combined systolic-diastolic dysfunction. Framingham data suggest that 76% of patients with HF have hypertension or CAD alone or in combination as the cause. Treatment of these underlying disorders often improves the performance of the heart muscle.

"High-output" failure is a fairly rare form that takes place when the demands of the body are so great that even increased cardiac output is insufficient. Causative factors include hyperthyroidism, anemia, and arteriovenous shunts. Treatment for this form is directed at the underlying pathology and is not discussed here.

Classifications of Heart Failure

The New York Heart Association (NYHA) has classified HF based on the severity of symptoms. This functional classification reflects the amount of activity needed to produce symptoms. It is fairly subjective in nature and treatments used do not differ significantly across the classes. In addition, this system does not deal with patients who are asymptomatic or at high risk for the development of HF. The ACCF/AHA committee (Yancy et al, 2013) sought to develop a staging system that would objectively identify patients throughout the course of their disease and would be linked to treatments that were uniquely appropriate for each stage of their illness. In addition, this classification scheme recognizes that HF, like HTN and CAD, has established risk factors; that evolution of the disorder has asymptomatic as well as symptomatic phases; and that treatment prescribed at each stage can reduce the morbidity and mortality of HF. Table 36-1 compares these two classifications.

Symptoms of Heart Failure

Symptoms have been described as depending on whether the left or the right ventricle is affected. Lung-focused symptoms (often referred to as "congestion") are associated with left-sided failure, and body-focused symptoms, such as edema, are associated with right-sided failure. With the exception of cor pulmonale, which is clearly right-sided in nature, progression of the disease usually involves both ventricles, and the terminology of left-sided versus right-sided failure is less useful clinically. In older adults, the peripheral edema thought to be associated with right-sided HF is actually more often related to venous insufficiency. It should be noted that over 21% of community adults have asymptomatic LV dysfunction. If untreated it results in more than 8% risk of death annually (Redfield et al, 2003).

Peripheral venous disease should be considered as a causative or contributing factor to symptoms in older adults. Regardless of which ventricle is more involved, patients with HF may have a number of symptoms, the most common being breathlessness, fatigue, exercise intolerance, and weight gain secondary to fluid retention. None of these symptoms is specific to HF and several other disorders may present with similar symptoms. Therefore, symptoms alone cannot be relied upon to make the diagnosis, which depends upon good history taking and physical examination, supplemented by diagnostic tests. Diagnostic evaluation will be presented later. The clinical course of the disease depends in large part on the point at which the patient is diagnosed and treatment is started, the appropriate targeting of that treatment, and the underlying pathology.

PHARMACODYNAMICS

Only a small number of HF cases are attributable to specific disorders that can be treated with or improved by surgery. The mainstay of HF therapy is lifestyle management and drug treatment targeted to altering the physiological mechanisms

Table 36–1 **Comparison of Classification Systems for Heart Failure (HF)**

New York Heart Association	American College of Cardiology/ American Heart Association
Class I. No limitations. Ordinary physical activity does not cause fatigue, breathlessness, or palpitation. (Asymptomatic left-ventricular dysfunction is included in this category.)	**Stage A.** Patient at high risk for developing HF but without structural heart disease
Class II. Slight limitations of physical activity. Comfortable at rest, but ordinary physical activity results in fatigue, palpitation, breathlessness, or angina pectoris (symptomatically "mild" HF).	**Stage B.** Patient with a structural disorder of the heart but who has never developed symptoms of HF
Class III. Marked limitations of physical activity. Although patient is comfortable at rest, less than ordinary physical activity will lead to symptoms (symptomatically "moderate" HF).	**Stage C.** Patient with past or current symptoms of HF associated with underlying structural disease
Class IV. Inability to carry on any physical activity without discomfort. Symptoms of congestive HF are present even at rest. With any physical activity, increased discomfort is experienced (symptomatically "severe" HF).	**Stage D.** Patient with end-stage disease who requires specialized treatment strategies such as mechanical circulatory support, continuous inotropic infusions, cardiac transplantation, or hospice care

that create or arise from HF. Four main categories of drugs are used to treat HF, whether it is systolic or diastolic in nature. The four categories of drugs: diuretics, angiotensin-converting enzyme (ACE) inhibitors, cardiac glycosides, and the beta blockers, are listed in Table 36-2.

Diuretics reduce preload by decreasing extracellular fluid volume and can be used to decrease hypertension that increases afterload. ACE inhibitors act on the R-A-A system to decrease preload and afterload. They also affect heart tissue remodeling so that fewer abnormal myocardial cells are

Table 36–2 Drugs Commonly Used: Heart Failure

Drug	Indication	Dosage Form	Initial Dose	Target Dose
Thiazide Diuretics				
Hydrochlorothiazide (Microzide)	Initial therapy for volume overload.	Tablets: 12.5, 25, 50, 100 mg Liquid: 50 mg/5 mL	25 mg daily	50 mg daily
Loop Diuretics				
	Added therapy when resistant to standard therapy or for decompensation			
Furosemide (Lasix) Bumetanide (Bumex) Torsemide (Demadex)	Furosemide is first choice. Torsemide is best when high doses of furosemide are required.	Tablets: 20, 40, 80 mg Injection: 40 mg/5 mL Injection: 0.5, 1, 2 mg Injection: 5, 10, 20, 100 mg	20–40 mg daily or twice daily 0.5–1 mg daily or twice daily 10–20 mg daily	As needed As needed As needed
Angiotensin-Converting Enzyme (ACE) Inhibitors				
Captopril (Capoten) Enalapril (Vasotec) Lisinopril (Zestril) Quinapril (Accupril)	All subsets of patients. Initial therapy or if symptoms not relieved by diuretic. Drug of choice for patients with diabetes.	Tablets: 12.5, 25, 50, 100 mg Tablets: 2.5, 5, 10, 20 mg Tablets: 2.5, 5, 10, 20, 30, 40 mg Tablets: 5, 10, 20, 40 mg	6.25 mg three times a day 2.5 mg twice a day 2.5–5 mg daily 5 mg twice a day	50 mg tid 10 mg bid 20 mg daily 20 mg daily
Angiotensin II Receptor Antagonist				
Losartan (Cozaar) Valsartan (Diovan) Candesartan (Atacand)	Patients intolerant to ACE inhibitors	Tablets: 25, 50, 100 mg Tablets: 40, 80, 160, 320 mg Tablets: 4, 8 mg, 16, 32 mg	12.5–25 mg daily 20–40 mg daily 4–8 mg daily	100 mg daily 160 mg daily 32 mg daily
Digoxin (Lanoxin)	If symptoms unrelieved by ACE inhibitor and diuretic	Tablets: 0.125, 0.25 mg Injection: 0.05 mg/1 mL	0.125 mg daily	As needed
Hydralazine (Apresoline)	With isosorbide dinitrate for intolerance to ACE inhibitor	Tablets: 10, 25, 50, 100 mg Injection: 20mg/mL	37.5 mg 4 times daily	75 mg 4 times daily
Isosorbide dinitrate (Isordil)	With hydralazine for intolerance to ACE inhibitor	Tablets: 5, 10, 20, 30, 40 mg ER Sublingual: 2.5, 5 mg	20 mg 4 times daily	40 mg 4 times daily
Beta Blockers				
Carvedilol (Coreg, Coreg CR) Metoprolol Succinate (Toprol-XL) Bisoprolol (Zebeta)	Patients with diastolic dysfunction or cardiomyopathy in whom reduced heart rate can improve cardiac output	Tablets: 3.125, 6.25, 12.5, 25 mg Extended-release tablets: 10, 20, 40, 80 mg Tablets: 25, 50, 100, 200 mg Tablets: 5, 10 mg	3.125 mg twice a day 12.5-25 mg daily 1.25 mg daily	6.25–25 mg twice daily 200 mg daily 10 mg daily
Aldosterone Antagonists				
Eplerenone (Inspra)	Diastolic HF	Tablets: 25, 50 mg	25 mg daily	50 mg daily
Spironolactone (Aldactone)	Diastolic HF	Tablets: 25, 50, 100 mg	25 mg daily	25 mg daily

generated. Digoxin, a cardiac glycoside, improves myocardial contractility and cardiac output. Beta-adrenergic blockers affect the SNS counterregulatory mechanism of HF. Aldosterone antagonists augment the actions of ACE inhibitors on the R-A-A system.

Three other classes of drugs are used in special circumstances. Nitrates improve systolic and diastolic ventricular function by improving oxygen transport to the myocardium for patients with HF who also have angina. Anticoagulants are used for patients with HF who also have chronic atrial fibrillation. Antiplatelets are used to prevent MI and death in patients with HF who have underlying CAD.

GOALS OF TREATMENT

There are three goals of therapy used to determine treatment options: improvement of symptoms, reduction in morbidity, and reduction in mortality. Specific drug therapies are supported by research documenting their efficacy in attaining one or more of these goals. Physiological goals are to decrease overload (preload and/or afterload), improve contractility, and decrease heart rate. Rational drug selection can be based on these goals, on the mechanism behind the dysfunction, and on the symptom severity of the disease process.

RATIONAL DRUG SELECTION

Guidelines

Although the ACCF/AHA classification system is intended to complement, not replace, the NYHA classification, the ACCF/AHA guidelines will be the main source of recommendations throughout this chapter. It should be noted that these guidelines are not inconsistent with those produced by the National Institute for Health and Clinical Excellence (NICE, 2010), the Veterans Health Administration, Department of Veterans Affairs (2007), the European Society of Cardiology (McMurray et al, 2012), or the Institute for Clinical Systems Improvement (ICSI, 2013). These latter guidelines are used where noted. These clinical practice guidelines describe the management of patients with both left-ventricular (systolic) dysfunction and diastolic dysfunction and include steps in accurate diagnosis, pharmacological and nonpharmacological therapies, counseling, and patient education. Figure 36-2 depicts the stages in the evolution of HF and the recommended therapy at each stage. All recommendations also follow the same evidence-based format of the previous ACCF/AHA guidelines (Yancy et al, 2013), which are:

- Class I. Conditions for which there is evidence for and/or general agreement that the procedure or treatment is useful and effective.
- Class II. Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment.
- Class IIa. The weight of evidence or opinion is in favor of the procedure or treatment.
- Class IIb. Usefulness/efficacy is less well established by evidence or opinion.

- Class III. Conditions for which there is evidence and/or general agreement that the procedure or treatment is not useful/effective and in some cases can be harmful. Class III interventions will be mentioned in this chapter only when they may be harmful and are to be avoided.

Diagnosis of Heart Failure

A complete history and physical examination are always important in the diagnosis of any disorder. This includes history of current or past alcohol use, chemotherapy exposure, illicit drug use, or use of alternative medical therapies. Specific diagnostic tests useful in evaluation of HF include the following:

1. Two-dimensional echocardiograms coupled with Doppler flow studies. This is probably the single most useful diagnostic tool because it facilitates identification of any structural abnormalities. Confirmation by echocardiography of HF diagnosis and/or cardiac dysfunction is mandatory and should be performed shortly after the diagnostic suspicion of HF. Echocardiography is the most practical measurement of ventricular dysfunction and can be used to distinguish between systolic dysfunction and preserved systolic function where the ejection fraction is normal (left-ventricular ejection fraction [LVEF] greater than 45% to 50%) (Heart Failure Society of America [HFSA], 2010; Yancy et al, 2013; Krum, Jelinek, Stewart, Sindone, & Atherton, 2011; McMurray et al, 2012; Scottish Intercollegiate Guidelines Network [SIGN], 2007). These patients generally have HF related to diastolic dysfunction.
2. Chest x-rays may show cephalization of the vascular supply and 12-lead ECGs may show left-ventricular hypertrophy and axis deviation (HFSA, 2010; Krum et al, 2011; SIGN, 2007). Although both provide baseline information, neither alone should form the primary basis for determining the specific cause of HF because they are insensitive and nonspecific.
3. Complete blood count, urinalysis, serum electrolytes (including calcium and magnesium), blood urea nitrogen (BUN), serum creatinine, Hb A1c, liver function studies, fasting lipid profiles, and thyroid-stimulating hormone are useful in determining possible treatable underlying causes of HF and in determining end-organ damage (HFSA, 2010; Krum et al, 2011; SIGN, 2007).
4. The measurement of circulating levels of brain natriuretic peptide (BNP) has been used to identify patients with elevated left-ventricular filling pressures who are likely to exhibit signs and symptoms of HF. The peptide measurement has also been used as an aid in differentiating dyspnea due to HF from dyspnea due to other causes in the emergency setting. Although the assessment of this peptide cannot reliably distinguish patients with systolic from those with diastolic dysfunction, evidence exists supporting its use in both diagnosis and management.

Stage A
At high risk for heart failure but without structural heart disease for symptoms of heart failure

Patients with
- hypertension
- coronary artery disease
- diabetes mellitus

or

Patients
- using cardiotoxins
- with family history of cardiomyopathy

Therapy
- Treat hypertension
- Encourage smoking cessation
- Treat lipid disorders
- Encourage regular exercise
- Discourage alcohol intake, illicit drug use
- ACE inhibition in appropriate patients (see text)

Structural heart disease →

Stage B
Structural heart disease but without symptoms of heart failure

Patients with
- previous MI
- LV systolic dysfunction
- asymptomatic valvular disease

Therapy
- All measures under stage A
- ACE inhibitors in appropriate patients (see text)
- Beta blockers in appropriate patients (see text)

Development of symptoms of heart failure →

Stage C
Structural heart disease with prior or current symptoms of heart failure

Patients with
- known structural heart disease
- shortness of breath and fatigue, reduced exercise tolerance

Therapy
- All measures under stage A
- Drugs for routine use:
  - Diuretics
  - ACE inhibitors
  - Beta blockers
  - Digitalis
- Dietary salt restriction

Refractory symptoms of heart failure at rest →

Stage D
Refractory heart failure requiring specialized interventions

Patients who have marked symptoms at rest despite maximal medical therapy (e.g., those who are recurrently hospitalized or cannot be safely discharged from the hospital without specialized interventions)

Therapy
- All measures under stages A, B, and C
- Mechanical assist devices
- Heart transplantation
- Continuous (not intermittent) IV inotropic infusions for palliation
- Hospice care

Figure 36–2. Stages in the evolution of HF and recommended therapy by stage.

Levels of the peptide have been shown to identify patients at risk for clinical events; therefore NICE (2010) recommends urgent referral to a specialist in all patients with a BNP level above 400 pg/mL. Although recent studies reveal that serum BNP levels have been shown to parallel the clinical severity of HF as assessed by NYHA functional class, their role in monitoring and adjusting drug therapy is less clearly established (Yancy et al, 2013). HFSA (2010) and Krum and colleagues (2011) do not recommend BNP determination for screening in patients without symptoms. They do recommend determination in all symptomatic patients suspected of having HF when the diagnosis is not certain. SIGN (2007) suggests BNP evaluation for widespread use as a screening tool in patients with suspected HF. Because BNP levels tend to fall after commencing therapy for HF, the sensitivity is lower in patients already on treatment, and SIGN does not recommend it for management.

5. Troponin I or T may be tested when the clinical picture suggests an acute coronary syndrome. Elevated troponin levels can also identify a cohort of patients with heart failure who are at higher risk. An initial determination of troponin is suggested by ICSI (2013) for patients presenting to the hospital with acute heart failure to assess for ACS as well as provide guidance regarding risk stratification. An increase in cardiac troponins indicates myocyte necrosis and may identify the patient for whom revascularization should be considered (McMurray et al, 2012).

The ACCF/AHA guidelines list specific recommendations for the evaluation of patients with HF using the class system discussed above. For class I, in addition to the history and physical examination, they recommend assessment of the patient's ability to perform activities of daily living (ADLs), assessment of volume status, and the tests mentioned in the first three sections above. Referral for cardiac catheterization with coronary angiography is recommended for patients with angina who may be candidates for revascularization.

For class IIa, noninvasive imaging, exercise testing, and measurement of ejection fraction are included. Screening for hemochromatosis is also listed, as is measurement of antinuclear antibody, rheumatoid factor, HIV antibodies, urinary vanillylmandelic acid (VMA), and evaluation for obstructive sleep apnea in selected patients.

Treatment Recommendations Based on Stage of Heart Failure

Stage A

Patients with stage A HF are at high risk for developing HF but do not have structural heart disease or symptoms of HF. Initial treatment for HF is focused on reversing underlying pathologies if possible and treating precipitating factors. Lifestyle modification is the first step and includes avoidance of behaviors that may increase the risk for HF, such as smoking, poor diet choices, obesity, sedentary lifestyle, and consuming alcohol or illicit drugs.

Equally important at this stage is control of systolic and diastolic HTN and treatment of lipid disorders in accordance with recommended guidelines found in Chapters 39 and 40. Controlling blood pressure and lipids can reduce the demands on the heart, decrease the risk for or facilitate the treatment of hypertension and CAD, and remove a drug that directly depresses the myocardium. Large, controlled studies have demonstrated that optimal blood pressure control decreases the risk of new HF by approximately 50% (Yancy et al, 2013). For patients with diabetes mellitus, blood glucose levels should be controlled in accordance with current guidelines. Chapter 33 discusses the guidelines for this disorder.

Lifestyle modification (e.g., stopping smoking, not consuming excessive alcohol, cessation of illicit drug use) is appropriate in all stages of HF and is an adjunct to successful drug therapy. The Web site http://www.heartfailurematters.org is an Internet tool provided by the Heart Failure Association of the European Society of Cardiology (ESC) that permits patients, their relatives, and caregivers to obtain useful, practical information in a user-friendly format.

Drug therapy is also instituted in stage A. ACE inhibitors, the cornerstone of therapy for HF in all the guidelines, are recommended for patients with a history of atherosclerotic vascular disease, diabetes mellitus, or HTN and associated cardiovascular risk factors to prevent HF in these high-risk patients. Beta blockers are also recommended for stage A in the ACC/AHA guidelines to control HTN and prevent HF (Yancy et al, 2013).

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors have been shown to improve symptoms, decrease morbidity, and increase life expectancy in all populations (Flather et al, 2000; Garg & Yusef, 1995; Jong, Yusef, Rousseau, & Bangdiwala, 2003; Keyhan, Chen, & Pilote, 2007; Neal, MacMahon, Chapman, & Blood, 2000; Rochon et al, 2004). They affect both preload and afterload through their vasodilating effects, decrease the incidence of remodeling by reducing the local generation and action of angiotensin II in heart muscle (Mancini, 2000), and prevent neurohormonal counterregulatory mechanisms that worsen HF through their action on the R-A-A system.

Patients taking ACE inhibitors show moderate increases in ejection fraction, decreased left-ventricular end-diastolic filling pressures, and improved myocardial energy metabolism. Because they are the only drugs that address all of the pathological mechanisms that produce HF, the ACE inhibitors are appropriate for all subsets of patients unless these patients are pregnant, have bilateral renal artery stenosis, serum potassium levels above 5.5 mEq, or a history of angioedema. They are also useful for preventing the development of HF in patients with ventricular dysfunction but no overt symptoms (stage B). A significant reduction in the development of symptomatic HF and death from any cause has been demonstrated in these patients.

As monotherapy or in combination with beta blockers, ACE inhibitors are superior to all other drugs and drug combinations used to treat heart failure. The NICE (2010) recommends that "all patients with HF due to left ventricular systolic dysfunction should be considered for treatment with an ACE inhibitor" (p. 15) and that such therapy should be started in addition to a beta blocker as first line treatment.

Although ACE inhibitors are most effective with systolic dysfunction, it is often difficult to ascertain if the patient has systolic or diastolic dysfunction at the time of the initial examination. However, 90% of patients with HF have some left-ventricular dysfunction (LVD). ACE inhibitors are the drugs of choice for LVD and create few adverse effects for patients with diastolic dysfunction, even though they are less efficacious with diastolic dysfunction. These drugs are safe to start before it is clear which of the two types of dysfunction exists.

Therapy should be started immediately. There is no need to wait until the disease has progressed. ACE inhibitors are commonly used as primary therapy, with other drugs added if symptoms persist or if volume overload develops at a later time. This is consistent with all of the above guidelines. Start with a low dose to prevent risks of hypotension and hypo - perfusion, especially of the kidneys. Beginning with 6.25 mg captopril (Capoten), the only short-acting ACE inhibitor, permits discontinuance with rapid clearance of the drug should a renal problem occur. Gradually increase ACE inhibitor therapy to improve exercise tolerance and relieve symptoms, while monitoring BP and renal function. BP monitoring is critical not only to assure renal perfusion but also to prevent dizziness and falls. Many patients with heart failure are older adults at high risk for falls with even a limited decrease in cerebral perfusion. Renal function must also be closely watched with BUN, creatinine, and urinalysis. Any deterioration in renal function may require dosage reductions. Because ACE inhibitors alter aldosterone function, potassium levels may rise. Regular monitoring of serum electrolytes is important. Use of potassium-wasting diuretics as concurrent therapy may be helpful. Potassium-sparing diuretics are not used with ACE inhibitors.

Debate continues on the choice of the best ACE inhibitor for long-term therapy, although enalapril is the most studied drug in this class. In randomized, controlled studies, both short-acting and long-acting formulations were equally effective. The long-acting formulations demonstrate some greater risk of prolonged hypotension and impairment of renal function, but only at high doses. However, long-acting forms provide a higher affinity for the ACE receptors and more stable drug levels. They also provide a less complex treatment regimen that is more likely to result in adherence because all ACE inhibitors except captopril have once-daily dosing. The dosing schedule for different ACE inhibitors and the process for changing to a long-acting form is discussed in Chapter 16.

A dry, "tickle" cough occurs in up to 15% of patients and is the leading reason patients give for choosing to discontinue therapy. This adverse effect appears to be related to the action of ACE inhibitors on the bradykinin system. Because they do not affect this system, angiotensin II receptor blockers (ARBs) have actions similar to ACE inhibitors but do not produce the cough. ARBs can be considered an effective substitute for patients who are intolerant of an ACE inhibitor. Valsartan (Diovan) and candesartan (Atacand) are the two ARBs approved for treatment of HF. Although losartan (Cozaar) is not FDA approved for treatment of HF, there seems to be a beneficial class effect (ICSI, 2013). ARBs at higher doses have been shown to reduce mortality risk in HF, and in patients with acute myocardial infarction, valsartan was found to be equally as effective as captopril (Dickstein & Kjekshus, 2002; Konstam et al, 2009; Packer et al, 2001; Pfeffer et al, 2003). Although these are promising findings, current recommendations state that ARBs should be reserved for patients for whom ACE inhibitors are indicated but who are unable to tolerate them; this approach is supported by NICE (2010), as well as the ACCF/AHA (Yancy et al, 2013) and the ESC (McMurray et al, 2012).

Beta Blockers

Unless contraindicated or not tolerated, a beta blocker should be given to all patients with a recent or remote history of MI regardless of ejection fraction or presence of HF (Yancy et al, 2013). These drugs improve ventricular function through their action on the HF counterregulatory mechanisms and have cardioprotective properties.

Other class I recommendations for stage A patients include control of ventricular rate in patients with supraventricular tachyarrhythmias, restoration of normal sinus rhythm, treatment of thyroid disorders, and periodic evaluation for signs and symptoms of HF. Two interesting class III statements are made. Exercise to prevent the development of HF is thought to be ineffective, as is reduction in dietary salt beyond that which is prudent (generally considered to be 2,500 mg/d) for healthy individuals without HTN or fluid retention.

Stage B

Patients with structural heart disease who have not developed symptoms, also known as patients with asymptomatic LV dysfunction (ALVD), are classified as stage B. They include patients without symptoms who have had an MI and those with evidence of left-ventricular dysfunction. These individuals are at high risk for developing HF, but the likelihood of developing it can be diminished by the use of therapies that reduce the risk of additional injury, the process of remodeling, and the progression of left-ventricular dysfunction.

As with stage A, the first drugs of choice are ACE inhibitors for these patients as well. ACE inhibitors are recommended for all patients with cardiac structural abnormalities and low LVEF who have not yet developed HF (Yancy et al, 2013). If the patient has entered the algorithm at stage A, ACE inhibitors should be continued. If they enter the algorithm at stage B, ACE inhibitors should be started. This is the stage, however, where beta blockade is added regardless of the previous HTN medication regimen. Beta blockers are recommended for all patients without a history of MI who have a reduced ejection fraction (less than or equal to 40%) with

no HF symptoms (Yancy et al, 2013; McMurray et al, 2012) and for patients with recent or remote MI regardless of ejection fraction. Beta blockers should be started in conjunction with an ACE inhibitor as soon as possible after diagnosis (McMurray et al, 2012).

Beta blockers are also important for MI prophylaxis for patients who develop HF secondary to an acute MI. Care must be taken in prescribing these drugs because they may precipitate acute decompensation. Patients should be clinically stable (e.g., optimal volume status achieved, lack of dependence on intravenous ionotropic support, no symptomatic bradycardia) prior to starting a beta blocker. Initially, low doses are used, and several months are required to show improvement.

Many large clinical trials (Bonet et al, 2000; Bouzamondo, Hulot, Sanchez, Cucherat, & Lechat, 2001; Brophy, Joseph, & Rouleau, 2001; Hernandez et al, 2009; McMurray et al, 2012; Ong, Ong, & Kow, 2012; Packer et al, 2001; Shibata, Flather, & Wang, 2001; Whorlow & Krum, 2000) have shown that some beta blockers increase life expectancy in patients with HF due to left-ventricular systolic dysfunction compared with placebo. This effect has been seen in patients in all NYHA functional classes of HF (NICE, 2010). The three beta blockers that have the strongest evidence to reduce mortality are bisoprolol, carvedilol, and metoprolol succinate (sustained release formulation) (Yancy et al, 2013). The evidence is strongest for carvedilol (which is actually an alpha$_1$ beta blocker) and modified-release metoprolol. There is little evidence of benefits from other beta blockers.

There is also little evidence to show a clinically significant difference based on selectivity of the beta blocker or on those with or without vasodilating properties. There are no randomized clinical trials of atenolol in patients with HF. The suggestion by the NICE (2010) is that patients who have systolic HF who are not already on a beta blocker should be started on one as first-line treatment along with an ACE inhibitor. Although not specifically mentioned in the guidelines, labetalol (Normodyne) has the same action as carvedilol. Labetalol is not recommended, however, for patients with LVEF less than 45%. Both can also be used safely with digoxin because they do not abolish this drug's inotropic action and in combination with ACE inhibitors to improve left-ventricular function. If patients developed HF while already on a different beta blocker for a concomitant condition such as angina or HTN, the health-care provider has the option to leave them on that drug or change to one of the drugs above. In any case, the "start low and go slow" paradigm should be used with these drugs.

The guidelines also recommend beta blockers for all NYHA classes of HF and mention the same ones named above. The guideline recommends that carvedilol be started at 3.125 mg twice daily and titrated as tolerated up to 25 mg twice daily maximum with 50 mg twice daily maximum for patients weighing more than 85 kg. Metoprolol succinate can be started at 12.5 mg once daily for 2 weeks and doubled upward every 2 weeks as tolerated to a target dose of 200 mg/d. The Veterans Affairs guideline (Veterans Health Administration, Department of Veterans Affairs, 2007) specifies the use of beta blockers related to recent MI and also specifically mentions the drugs above. Beta blockers are also used for a subset of patients with diastolic dysfunction or cardiomyopathies for whom decreased heart rate could improve cardiac output.

All guidelines suggest that treatment with digoxin is not effective in stage B patients who are in sinus rhythm. In addition, the risk for harm is not balanced with any known benefit (Yancy et al, 2013). In the Veterans Affairs guideline (2007), digoxin may be used in stage B when the patient has a rapid ventricular response to atrial fibrillation and there is a need to control the rate. The other guidelines would also support its use under these circumstances. Calcium channel blockers with negative inotropic effects may be harmful in asymptomatic patients with low LVEF. Other interventions that are useful in selected patients are discussed below.

Stage C

Patients with left-ventricular dysfunction with current or prior symptoms of HF are classified as stage C. They are the first stage to have active HF symptoms. The bulk of patients with HF are at this stage. All the class I recommendations for stages A and B are also appropriate here. In addition, moderate sodium restriction (1,500 mg/day) along with daily weight monitoring are indicated to facilitate the most effective use of drugs. Physical activity at this stage should be encouraged, except during periods of acute exacerbations, because restriction of activity promotes physical deconditioning and may contribute to the exercise intolerance common with this stage.

Most patients in this stage will require a combination of three to four types of drugs: ACE inhibitors, beta blockers, cardiac glycosides (digoxin), and a diuretic. The value of these drugs has been established in numerous large-scale clinical trials and the evidence supporting their use is strong. ACE inhibitors and beta blockers have already been discussed. Diuretics and digoxin will be discussed here.

Diuretics

Diuretics are the key of any successful approach to the treatment of heart failure with volume excess (McMurray et al, 2012; Yancy et al, 2013). They should be given until a euvolemic state is achieved and continued to prevent the recurrence of fluid retention. Because of their central role in control of HTN, diuretics may be drugs of choice for earlier stages of HF where the goal is control of HTN. This will be discussed later in the section "Concomitant Diseases." Even if the patient responds favorably to the diuretic, ACE inhibitors and beta blockers should be initiated or continued after euvolemia has been achieved because diuretics cause activation of the R-A-A system and ACE inhibitors and beta blockers have been shown to improve the long-term prognosis of HF.

Diuretics improve symptoms of dyspnea. There is no evidence that they affect morbidity or mortality. Their main function is to reduce preload associated with volume overload. Thiazide diuretics have long been and remain the drugs of choice for patients with HTN. However, for patients with

heart failure, loop diuretics are more effective and have become the preferred diuretic agents for use in most patients with HF. Potassium-sparing diuretics (aldosterone antagonists) are too weak to be of benefit as monotherapy. They can be useful as concurrent therapy with thiazide or loop diuretics to counterbalance the potassium loss common to these latter two groups of drugs.

Two drugs in the aldosterone antagonist class (spironalactone and eplerenone) have shown increased life expectancy and reduced hospitalizations when added to a treatment regimen that included a loop diuretic and an ACE inhibitor (Pitt et al, 2003; Zannad et al, 2011). The ACCF/AHA guideline recommends spironalactone for patients with recurrent class IV symptoms, preserved renal function, and a normal potassium level. The NICE guideline (2010) and Krum and colleagues (2011) also recommend aldosterone antagonists for patients who remain symptomatic despite optimal therapy with beta blockers and ACE inhibitors. The guideline suggests a starting dose of 12.5 mg once daily and seeking advice from a specialist. For eplerenone, the recommended starting dose is 25 mg once daily (Jessup et al, 2009). The doses then may be increased to 50 mg for each of these drugs if needed.

For diastolic HF, spironalactone has a questionable role. The hormone aldosterone contributes to diastolic stiffness by promoting fibrosis. Preliminary studies have shown aldosterone antagonists such as spironalactone reduce systolic and diastolic blood pressures, as well as decrease ventricular remodeling (Pieske, 2012), but there remains conflicting data on whether these agents can improve quality of life and median NYHA class in diastolic HF (Daniel, Wells, Stewart, Moore, & Kitzman, 2009; Pieske, 2012). Two trials are currently underway that further examine the role of the aldosteroneantagonist in diastolic heart failure.

For mild to moderate disease, start therapy with furosemide 40 mg twice daily. Loop diuretics can cause marked diuresis. Before starting them, discontinue any thiazide diuretic currently being used. For loop diuretics, divide the daily dose to prevent great diuresis at one time. If the patient does not respond adequately to the divided dose, try giving the entire daily dose in the morning before increasing the dose. The goal with diuretics is to give the lowest possible dose that achieves the desired effect. Doses should be titrated to increased urine output and promote weight loss of 0.5 to 1 kg daily. Single daily doses are effective, but during times of increased pathology, oral absorption may be compromised, and the IV route or high doses of oral formulations may be needed. Dosing schedules are given in Chapter 16. Monitor weight gain, changes in exercise tolerance, and electrolytes. Diuretic resistance may occur in the presence of decreased renal perfusion or renal stenotic or obstructive pathologies, or with the concurrent administration of NSAIDs. If symptoms seem resistant to the standard doses of the diuretic, check creatinine clearance. Thiazide diuretics cannot be used with creatinine clearances that are lower than 25 mL/min. Loop diuretics can be used with these low creatinine clearances. Patients may also benefit from the addition of metolazone (Zaroxolyn) for its synergistic action on diuresis, but

it is not recommended for chronic daily use because of potential for severe electrolyte shifts.

Although initiation of diuretic therapy is important for patients who have HF with volume overload, it is also important to avoid excessive diuresis, especially for patients who are also on sodium restrictions. Volume depletion can lead to hypotension and prerenal azotemia. For patients concurrently taking ACE inhibitors, renal insufficiency can be induced. Diuretics may be stopped, if necessary, to allow rehydration before restarting an ACE inhibitor. They can be reintroduced after the dose of the ACE inhibitor has been stabilized. ACE inhibitors augment the effectiveness of thiazide and loop diuretics because they decrease glomerular filtration fractions and increase the delivery of solute and water to the distal nephron segments that are responsive to the action of these diuretics.

Long-term use of diuretics can stimulate increased R-A-A activity and sodium retention, which are both counterproductive in treating heart failure. This result is less likely with low doses. In addition to the potential for fluid volume changes, thiazide and loop diuretics present risks for acid–base and electrolyte disturbances that can be proarrhythmic. Monitoring for these problems is discussed in Chapter 16.

The most common electrolyte problem is hypokalemia. Any potassium supplementation must be based on serum levels because not all patients become hypokalemic or require supplementation beyond dietary changes. Potassium supplements must be used cautiously, if at all, for patients concurrently taking ACE inhibitors, which cause elevated potassium. Oral potassium supplements should provide chloride as well to prevent diuretic-induced hypokalemic alkalosis. Hypomagnesemia is also common and may impair potassium repletion. Diuretics also contribute to abnormal glucose and lipid metabolism. Care must be taken and diagnostic tests frequently monitored when diuretics must be used for patients with diabetes or lipid abnormalities.

Cardiac Glycosides

Digitalis was once the only effective drug to treat HF. Its ability to increase contractility by increasing intracellular calcium and inhibiting the sodium-potassium-ATPase pump deals directly with one primary deficit in HF. In addition to its ionotropic effects, digitalis may act as a neurohormonal attenuator. Recent evidence suggests that by inhibiting the sodium-potassium-ATPase in the kidney, digitalis reduces the renal tubular reabsorption of sodium, leading to the suppression of renin secretion from the kidneys. Although digoxin increases the force of contraction and modulates the RAAS, thereby improving functioning and symptoms and reducing hospitalizations, it has little if any effect on mortality. Published data suggest that digoxin does not improve quality of life, symptoms, or mortality rates (Amhed, 2006; Digitalis Investigation Group, 1997; Lader et al, 2003).

The development of ACE inhibitors, combined with the risks of toxicity and multiple drug interactions associated with the cardiac glycosides (CGs), has moved digoxin to a

third-line drug except for selected cases. It is recommended for worsening HF due to left-ventricular dysfunction despite ACE inhibitor, beta blocker, and diuretic therapy. Although beta blockers are first-line therapy for heart failure because they also control HTN and have a role in tachycardia-medicated cardiomyopathy associated with atrial fibrillation, digoxin remains a useful adjunctive drug for HF secondary to atrial fibrillation with a rapid ventricular response because it slows heart rate (McMurray et al, 2012).

Digoxin also remains a consideration for treatment for HF in patients with reduced systolic dysfunction (ejection fraction <40%) while receiving standard therapy with a beta blocker and ACE inhibitor. Digoxin is less beneficial with ejection fractions of more than 40% or in HF secondary to hypertrophic cardiomyopathies. Digoxin is also not useful in HF associated with idiopathic hypertrophic subaortic stenosis, also known as hypertrophic obstructive cardiomyopathy (which it actually worsens), recurrent transient ischemia, or mitral stenosis (unless the patient also has atrial fibrillation). Digoxin can also be problematic when treating older adults and patients with renal insufficiency. Renal function may decrease during heart failure treatment and the drug may not be adequately excreted, allowing it to increase to toxic levels. Digoxin levels should be closely monitored in these patients.

For stable patients, therapy can be started with an oral maintenance dose without resorting to a loading dose. Using a daily dose of 0.25 mg, a therapeutic blood level can be achieved in 5 to 7 days. Check the serum level in 1 week and make any needed adjustments on the basis of clinical response and serum level. Less stable patients require hospitalization for loading doses. Monitor patients on digoxin by following heart rate and rhythm, potassium levels, and renal function. Routine monitoring of serum digoxin levels is generally overdone. Monitoring should occur in addition to clinical judgment rather than as a substitute for it. Chapter 16 has detailed discussion of the reasons for and the process of monitoring associated with the use of digoxin, as well as the process of initiating and maintaining digoxin therapy.

The decision to begin digoxin therapy should not be made lightly. It should be used only when there is clear evidence of chronic systolic dysfunction or one of the disease processes just mentioned. Digitalis toxicity occurs in as many as 25% of patients but is declining in recent years secondary to reduction in overall use as well as dose reductions (Haynes, Heitjan, Kanetsky, & Hennessy, 2008). The mortality rate from this toxicity is usually 4% to 10%, rising as high as 50% with digitalis levels greater than 6 ng/mL.

Patients with mild to moderate heart failure often become asymptomatic on optimal doses of ACE inhibitors and diuretics and do not require digoxin. Digoxin should be added for those patients whose symptoms persist despite optimal doses of these two drugs. For patients already on digoxin, research evidence supports symptom deterioration when it is suddenly withdrawn. For these patients, digoxin should not be withdrawn unless a reversible cause of heart failure has been fully corrected or there is no basis for using the drug in the first place.

Angiotensin II Receptor Blockers

Angiotensin II receptor blockers (ARBs) are recommended as substitutes for ACE inhibitors in patients who are being treated with diuretics, beta blockers, and digoxin and who cannot be given an ACE inhibitor (Jessup et al, 2009; McMurray et al, 2012). The use of these drugs was discussed in earlier guidelines. It should be noted that using an ARB before a beta blocker in patients who are taking an ACE inhibitor is a class III recommendation, meaning it is not effective, and a triple combination of ACE inhibitor, ARB, and beta blocker should be avoided because it may lead to additional undesired side effects.

Calcium Channel Blockers

While the pathology of HF is associated with altered contractility in part associated with calcium movement within the cell, calcium channel blockers (CCBs) are used with considerable caution (Yancy et al, 2013). The NICE (2010) guidelines state that patients should not be routinely treated with calcium channel blockers for HF. These same guidelines do acknowledge that amlodipine, a long-acting dihydropyridine, is not harmful in terms of adverse events and may be considered for treatment of comorbid HTN and/or angina in patients with HF. All other CCBs should be avoided.

Nitrates

Nitrates are effective for a subset of patients whose primary pathology is increased preload. Their use is discussed related to concomitant conditions. They are also accepted therapy in combination with hydralazine when the patient has an intolerance to both an ACE inhibitor and an ARB. Its use in these patients may reduce the risk of death (McMurray et al, 2012). Randomized controlled trials show that isosorbide dinitrate in combination with hydralazine is of significant benefit, reducing both morbidity and mortality, in treatment of heart failure in African American patients on standard therapy with an ACE inhibitor and beta blocker (ICSI, 2013; McMurray et al, 2012; Yancy et al, 2013).

Stage D

Stage D includes patients with refractory end-stage HF. These patients have marked symptoms at rest despite maximal medical therapy. ACE inhibitors and beta blockers are still suggested for treatment of HF in this population, but these patients may only tolerate small doses of medications. Initiation of a beta blocker or ACE inhibitor is contraindicated in patients with a systolic blood pressure less than 80 mm Hg, or who show signs of peripheral hypoperfusion (Yancy et al, 2013). Management of fluid status is also crucial in stage D heart failure. Addition of a second, complementary diuretic to a loop diuretic, as well as strict monitoring of fluid and sodium intake, can assist in the control of fluid retention.

Patients with stage D heart failure may be referred for cardiac transplantation and should be referred to a heart failure program with expertise in the management of refractory HF (Yancy et al, 2013). Routine intermittent infusions

of vasoactive and positive inotropic agents are not recommended for patients with stage D heart failure, although they may be used in the inpatient setting during acute decompensation (Yancy et al, 2013).

Patients With Heart Failure With Preserved Ejection Fraction (HF-pEF)

As many as half of the patient population have heart failure with preserved left ventricular ejection fraction. Unfortunately, there is limited evidence to show the benefit of ACE inhibitors and beta blockers in this population. Three trials using ACE inhibitors and ARBs showed no reduction in morbidity and mortality in patients with HF-pEF. The main underlying causes of HF-pEF include hypertension and CAD. Therefore, treatment in HF-pEF should target these causes. As with all heart failure patients, diuretics should be used in the presence of volume overload to improve symptoms. ACE inhibitors should be considered in patients with diabetes and one additional risk factor or those with symptomatic atherosclerotic cardiovascular disease. Beta blockers should be used in all patients with prior myocardial infarction or atrial fibrillation requiring control of ventricular rate (Yancy et al, 2013).

Cost

The drugs used to treat HF vary in cost from minimal to quite expensive. Diuretics are among the least expensive, but they vary from indapamide (Lozol) ($25 per month) to generic HCTZ ($1.04 per month). HCTZ is the drug of choice for a variety of reasons, and cost certainly also makes it desirable. The ACE inhibitors have become less expensive because several of them are now available as a generic formulation. Because digitalis has been used for so long, it is among the least expensive.

Additional Patient Variables

Concomitant Diseases

Coronary Artery Disease and the Use of Nitrates

The underlying pathology of HF in the presence of CAD relates to poor oxygenation of the myocardium, which results in angina pectoris. Chapter 28 discusses angina and ischemic heart disease. When these disorders occur with or result in HF, nitrates are often added to the treatment regimen for relief of angina symptoms. Nitrates are relatively selective to epicardial vasculature and improve systolic and diastolic ventricular function by increasing coronary blood flow. The mechanism includes both coronary artery vasodilation and improvement of the uptake of oxygen by the myocardial muscle itself. This mechanism is discussed in Chapter 16.

Nitrates are also effective after MI and for those with CAD as the primary cause of their HF. They reduce symptoms and have some effect on mortality when used in the acute setting. Improvement in mortality in primary care has been demonstrated only when isosorbide dinitrate is combined with hydralazine, a peripheral vasodilator. This combination is

usually reserved for patients who are intolerant of ACE inhibitors or for African Americans who remain symptomatic on standard treatment with a beta blocker, ACE inhibitor, and diuretic. Problems with nitrate tolerance require special timing of doses, with nitrate-free intervals daily. Chapter 16 includes discussion of this problem. The dosage of isosorbide dinitrate that produces the most sustained hemodynamic effects and minimizes the development of tolerance appears to be 40 mg every 8 hours. The dosage of hydralazine is up to 800 mg every 8 hours to reduce afterload. NICE (2010) guidelines suggest consultation with a specialist prior to initiation.

Antiplatelet drugs such as aspirin have evidence to support their use in patients with atherosclerotic arterial disease, including CAD. Evidence (Eikelboom, Hirsh, Spencer, Baglin, & Weitz, 2012) supports aspirin's role in reducing the risk of vascular events in these patients. It is recommended by the ACCF/AHA for patients with CAD, although specific evidence for its benefits in patients with HF is lacking (Yancy et al, 2013). The NICE (2010) recommends aspirin 75 to 150 mg once daily for patients with a combination of HF and CAD. Some questions have been raised about the possibility that aspirin may reduce some of the benefits of ACE inhibitors when taken together (Kindsvater, Leclerc, & Ward, 2003; Takkouche, Etminan, Caamano, & Rochon, 2002), but the evidence is not robust. It is worth considering this possibility when prescribing both. If there is true concern for lack of efficacy, alternative antiplatelet drugs, such as clopidogrel (Plavix), may not be affected by concomitant administration of aspirin (CAPRIE, 1996).

Chronic Atrial Fibrillation and the Use of Anticoagulants

Beta blockers have already been discussed as the drug of choice for HF patients who have concomitant atrial fibrillation. Anticoagulants are also helpful in this situation. Randomized control trials have demonstrated that warfarin reduces the risk of stroke in patients with HF and atrial fibrillation (Yancy et al, 2013; McMurray et al, 2012). No such benefit is shown for patients with HF who are in sinus rhythm (Lip & Chung, 2010). It should be noted that in patients with atrial fibrillation, aspirin reduced mortality when compared to lack of treatment. The addition of clopidogrel to aspirin further decreased mortality. Yet, when this combination was compared to warfarin, results showed that clopidogrel used in conjunction with aspirin carried an increased risk of bleeding and there was no evidence of decreased mortality from thrombosis (Hansen et al, 2010).

Diabetes and the Use of ACE Inhibitors

Based on data from the Diabetes Complications Control Trial and more recent trials, the American Diabetes Association recommends the use of ACE inhibitors as the drugs of choice for the treatment of HTN for persons with diabetes, because of their demonstrated effect in reducing diabetic nephropathy. The role of ACE inhibitors in diabetes is discussed in Chapter 33. The same rationale for their use in diabetic patients with HTN holds for patients with HF. The ACCF/AHA

guidelines (Yancy et al, 2013) mention this preference. ARBs may also reduce diabetic nephropathy, but this effect has yet to be demonstrated by longitudinal studies.

Patients with diabetes may experience increased glucose levels with diuretics. Recent evidence shows there may be a relationship between glucose metabolism and hypokalemia caused by thiazide diuretics (Elliott, 2012; Stears et al, 2012). Elevated serum glucose may be prevented with the initiation of potassium supplementation, combination treatment with an ACE inhibitor, or use of potassium-sparing agents (Grossman, Vedecchia, Shamiss, Angeli, & Reboldi, 2011). Thiazide diuretics in low doses are the least likely to cause this adverse response, followed by loop diuretics. ARBs are also acceptable drugs for patients with diabetes because of their limited effects on glucose metabolism, lipid profiles, and renal function.

Providers sometimes avoid the use of beta-adrenergic blockers in patients with diabetes because they have an adverse effect on peripheral blood flow, prolong hypoglycemia, and mask most hypoglycemic symptoms. Recent evidence suggests that these effects may not be as problematic as once thought and therefore beta blockers should not be avoided (Erdmann, 2009). The majority of diabetic patients eventually develop coronary disease, with or without heart failure, and beta blockers are a first-line drug for cardioprotection. Patients with diabetes who need MI prophylaxis and have concurrent heart failure may be placed on low doses of beta blockers and taught to monitor their blood glucose more closely and to recognize diaphoresis as their main indicator of hypoglycemia.

Hypertension and the Early Use of Diuretics

HTN is a common concurrent disorder with heart failure and may contribute to its etiology. Initial therapy for HTN is with diuretics, especially for sodium-sensitive patients such as African Americans, older adults, those who are obese, and those with renal insufficiency. Target blood pressure levels should be <130/<80 if tolerated. The most effective diuretics for both HTN and HF are the thiazides. Loop diuretics are less effective for HTN but have some use, and they are helpful for subsets of patients with stage C HF. ACE inhibitors are drugs of choice for treating HTN in young and Caucasian patients. The dose for treating HTN, however, is double the dose used to treat HF; the lower dose is required for patients who have both disorders.

In patients with low ejection fractions (less than 40%), the vasodilating effects of ACE inhibitors provide adequate perfusion, even with systolic blood pressure (SBP) at or below 90 mm Hg. Because a primary goal for all HF patients, including those in stages A and B, is the control of HTN, drugs that assist with both disorders should have preference in rational drug selection. Chapter 40 discusses in more detail the drugs helpful in treating HTN.

Hyperlipidemia and the Use of Statins

Hyperlipidemia leading to atherosclerotic changes is also a common concurrent disorder that may contribute to the etiology of HF. Treatment of lipid disorders based on the most

current guidelines is a class I recommendation for all HF patients, starting with stage A (Yancy et al, 2013). The newest ACCF/AHA lipid guidelines (2013) recommend the use of HMG-Co-A reductase inhibitors (statins) as first-line therapy when LDL cholesterol-lowering drugs are indicated to achieve treatment goals (Stone et al, 2014). Statins reduce the frequency of ischemic events (Dickstein et al, 2002) and prolong life expectancy in patients with known CAD (Gutierrez, Ramirez, Rundek, & Sacco, 2012). The risk of developing HF is also reduced. The benefits of statins appear to be universal and not restricted by age, although the ESC guideline (McMurray et al, 2012) limits their recommendation to patients with CAD, as two trials revealed lack of evidence that adding a statin to the medication regimen of a patient with normal lipid levels improves HF itself (Kjekshus et al, 2007; Tavazzi et al, 2008). Chapter 39 discusses these recommendations in detail and Chapters 16 and 39 discuss the various statins and rational drug selection among them.

Thiazide diuretics have been associated with elevation in total cholesterol and LDL cholesterol by 5% to 7% (Grossman et al, 2011). This rise is dose-dependent and greater in African Americans. The majority of studies are limited to a span of 3 to 5 years, so long-term effects are unknown, but this problem does not rule them out. ACE inhibitors, ARBs, CCBs, and digoxin do not affect lipid levels and may be used for patients with hyperlipidemia. Beta-adrenergic blockers increase triglycerides transiently and reduce levels of high-density lipids (Bell, Bakris, & McGill, 2009).

Other Comorbidities

Hyperuricemia can be a problem for patients with gout. Diuretics can produce this adverse effect. The least likely to do so are the thiazides, followed by the loop diuretics. This effect may be dose-related. It is recommended that lower doses of thiazides be used if there is concern for hyperuricemia. ACE inhibitors do not affect uric acid levels directly but can influence renal function, which may indirectly affect uric acid metabolism. Digoxin does not affect uric acid metabolism.

Asthma or chronic airway disease may occur with heart failure, especially in older adults. Chronic airway obstruction is the underlying cause of cor pulmonale, right-sided heart failure. Bronchial activity is unchanged by ACE inhibitors. In the 10% to 15% of patients taking these drugs who experience a cough, angiotensin II receptor blockers are an alternative. Alpha-beta-adrenergic blockers and beta-adrenergic blockers should not be avoided in asthma unless the underlying disease is poorly controlled. The use of these drugs is not contraindicated in patients with COPD.

Impaired renal function and electrolyte disturbances also influence drug selection. Because digoxin is excreted essentially unchanged by the kidney, renal impairment suggests cautious use and close monitoring of serum drug levels. Renal impairment is also associated with increased potassium levels, and the administration of potassium-wasting diuretics often results in decreased potassium levels. Both of these situations increase the risk for digitalis toxicity. Patients with a glomerular

filtration rate (GFR) of less than 60 have significantly higher digoxin levels at one month (Shlipak, Smith, Rathore, Massie, & Krumholz, 2004). Dosage adjustments of digoxin are required for patients with decreased renal function, especially older adults. Renal clearance is a factor in the choice of diuretic, as previously discussed. Thiazide and loop diuretics may cause hypokalemia. ACE inhibitors are contraindicated in bilateral renal artery stenosis and should be adjusted for patients with a creatinine clearance less than 30. Careful monitoring of renal function is required with their use.

Age and Gender

Digoxin has a long history of use in infants and children. Thiazides, loop diuretics, ACE inhibitors, and beta blockers are also approved for use with pediatric patients. These drug groups have specific pediatric formulations and dosing schedules.

An initial post hoc analysis of women taking digoxin revealed that digoxin use increased mortality, but a large study cohort of over 20,000 patients with heart failure on digoxin failed to show a gender difference in mortality (The Digitalis Investigation Group, 1997; Flory et al, 2012). Older adults have a higher risk for digitalis toxicity. The indications of toxicity are different in children and older adults than they are in most adults. Digitalis toxicity is discussed in Chapter 16.

HF is the leading cause of death and hospitalization for adults older than 65 years (Hall, Levant, & DeFrances, 2012; Kochanek, Xu, Murphy, Minini, & Kung, 2011) and remains one of the most common Medicare diagnoses-related groups. A large portion of HF risk in this population is attributable to modifiable risk factors. The Health, Aging and Body Composition study (Kalogeropoulos et al, 2009) researched these factors and suggests that racial differences in risk factors and in hospitalization rate need to be considered in prevention and treatment efforts. ACE inhibitors and beta blockers are still the drugs of choice for older adults.

Research that includes older adults often excludes patients with serum creatinine levels above 2.0 because older adults often have elevated serum creatinine levels related to the changes associated with aging, as well as polypharmacy and the presence of multiple comorbidities. Consideration of serum creatinine alone presents some problems. Creatinine clearance may be more accurate in assessing renal function than serum creatinine due to decreased muscle mass in the older adult. The primary reason given in the literature for not reaching goal doses of ACE inhibitors in older adults with HF is renal dysfunction, symptomatic hypotension, cough, and hyperkalemia. There are few clinical trials including older adults with HF on goal doses, but several studies indicate that ACE inhibitors at target doses would benefit the older adult (Chen, Wang, Radford, & Krumholz, 2001; Cleland et al, 2006; Levine, Levine, Bolenbaugh, & Green, 2002; McDonald, 2001).

Pregnancy

ACE inhibitors are contraindicated in pregnancy. Digoxin has been used, but blood levels must be monitored closely to avoid toxicity. Diuretics decrease plasma volume and may decrease plasma placental perfusion. They are used during pregnancy only when benefits clearly outweigh risks. Jaundice and thrombocytopenia have been seen in neonates after diuretic use in the mother. Beta blockers are considered safe in the latter part of pregnancy. A general rule of thumb sometimes proposed is that drugs safe to be used in infants are safe for use in pregnancy, but it is important to remember that consideration must be given to the maternal–fetal drug concentration ratio. Some drugs develop much higher levels of concentration in the fetus than they do in the maternal circulation, and the dose that is therapeutic for the mother may be too high for the neonate. It is best to avoid any drug during pregnancy unless the benefits clearly outweigh the risk to the fetus. Pregnant women with HF are best treated in consultation with a specialist (NICE, 2010).

Drug Combinations

Adherence to any treatment regimen is less likely as the regimen becomes more complex. Drug combinations can increase that complexity. In order to avoid confusion, prevent unintentional medication overdose, and improve adherence, attempts should be made to decrease the number of pills and medications that compose a patient's treatment regimen.

Common combinations include diuretics and ACE inhibitors. When using this combination, withholding or decreasing the dose of the diuretic to permit rehydration prior to initiating the ACE inhibitor reduces the chances of renal dysfunction and hypotension. The diuretic may be reintroduced later. With this combination, monitor BP, potassium, BUN, and creatinine levels, and decrease the diuretic dose if BP falls or prerenal azotemia develops.

Diuretics are also commonly used with digoxin for patients with systolic dysfunction. The diuretics reduce afterload, and digoxin improves contractility. Care must be taken with this combination concerning serum potassium levels, as was previously discussed.

For patients who remain symptomatic on a combination of an ACE inhibitor, beta blocker, and a diuretic, digoxin may be added. With this combination, fluid status and serum potassium levels must be carefully monitored. For patients with persistent dyspnea after optimal doses of diuretics, ACE inhibitors, beta blockers, and digoxin, referral to a specialist is appropriate. The addition of a vasodilator to an ACE inhibitor may relieve symptoms, particularly for patients with hypertension or evidence of severe mitral regurgitation.

For those who cannot tolerate or do not respond to beta blockers, have a heart rate above 70 and an EF below 35%, Ivabradine (Corlanor), a new antianginal medication, was approved to help stablize heart rates and reduce hospitalizations (FDA, 2015).

MONITORING

Monitoring to assess effectiveness in treating the pathology includes a variety of tools. NICE (2010) recommends the following assessments:

1. Functional capacity, chiefly using the NYHA class, specific quality-of-life questionnaires, or a maximal exercise test.

2. Assessment of fluid status, chiefly by physical assessment (e.g., daily weights, jugular venous distention, lung crackles, hepatomegaly, peripheral edema, and orthostatic BP).

3. Assessment of cardiac rhythm, chiefly by clinical examination, but a 12-lead ECG may be used if an arrhythmia is suspected. The ACCF/AHA guidelines specifically state that Holter monitoring is class IIb and could be considered in patients who have a history of MI and are being considered for electrophysiological study to document ventricular tachycardia inducibility (Yancy et al, 2013).

4. Laboratory assessment, including electrolytes and serum creatinine and urea, with special attention to potassium and sodium. Other tests such as thyroid function, hematology, liver function, and level of anticoagulation may be required depending on the medication prescribed and the comorbidity.

Monitoring specific to each drug class is presented in Chapter 16. Serum drug level monitoring is important for digoxin, although it is only recommended routinely in the settings of dose adjustment and suspicion of toxicity. Hypokalemia, which may result from diuretic therapy, enhances sensitivity to the toxic effects of digoxin and is proarrhythmic in all patients with HF. Hypomagnesemia may impair the effectiveness of potassium replacement therapy and should be assessed for patients with refractory hypokalemia. Repeated testing may be useful for patients with a new heart murmur or sudden deterioration even though they are adherent to the treatment regimen.

OUTCOME EVALUATION

A careful history and physical examination should be the mainstay in determining outcomes and directing therapy. The history includes questions about physical functioning, appetite, mental health, sleep disturbances, sexual functioning, cognitive functioning, and ability to perform the usual ADLs, including occupational and social activities. Specific questions are asked about the presence of weight gain, orthopnea, paroxysmal nocturnal dyspnea, edema, and dyspnea on exertion. The patient should report weight increases greater than 2 lb in any single day, increased pulmonary symptoms, and ankle edema. A worsening of any of these parameters requires evaluation of the treatment regimen and may indicate the need to adjust the therapy, especially diuretic dosage.

HF is generally a chronic condition that can be adequately managed in primary care. Consultation or referral to a cardiologist is appropriate when any of the following occurs:

1. Symptoms markedly worsen or the patient becomes excessively hypotensive or experiences syncope.
2. The patient is refractory to standard therapy.
3. There is evidence of renal failure or digitalis toxicity.
4. Adequate support is not present in the home to permit the patient to be treated in that situation.

5. Patients who remain symptomatic on a combination of an ACE inhibitor, a beta blocker, a diuretic, and digoxin should be seen by a cardiologist at least once. Persistent volume overload despite standard pharmacological management may require more aggressive administration of the current diuretic, more potent diuretics via the IV route, or a combination of diuretics. The ICSI (2013) recommends developing a plan for early specialty referral for patients with ischemia or those who are refractory despite optimal medical therapy. Additional testing beyond the usual monitoring may demonstrate evidence of concurrent disorders that may be the source of the resistance to therapy. These disorders may be amenable to other therapies. Surgical intervention may be needed, and hospitalization may be appropriate. Appropriate cardiac consultation should occur during the initial evaluation and at any time that it is felt appropriate (ICSI, 2013).

As with all chronic conditions, lack of adherence to a therapeutic regimen is unfortunately common. Nonadherence with diet and drugs can rapidly and profoundly affect the clinical status of HF patients, and increases in body weight and minor changes in symptoms commonly precede the major clinical episodes that require emergency care or hospitalization. Several factors in the management of heart failure foster this nonadherence. Lifestyle management is central to the treatment regimen for all stages and types of HF, and difficulty in achieving and maintaining lifestyle changes is well documented. Adverse drug reactions and drug costs are also factors. Table 40-9 (Chapter 40) on hypertension details some activities that can improve adherence, and Chapter 6 has additional material to improve positive outcomes.

PATIENT EDUCATION

Patient education should include a discussion of information related to the overall treatment plan as well as lifestyle management and exercise instruction (Davies et al, 2010; Levitan, Wolk, & Mittleman, 2009), information specific to the drug therapy, reasons for the drug being taken, drugs as part of the total treatment regimen, and adherence issues. Unless contraindicated, all patients should also be encouraged to obtain an annual influenza vaccination. Pneumococcal immunization should be provided at diagnosis of HF, if not previously vaccinated. For older adults, if initial vaccination was at 65 years or less, revaccination at 65 years or 5 years after initial immunization, whichever is later, should be done.

Preemptive education for adults based on the Cardiovascular Pooled Risk research projects (Ahmed, 2015) may add up to 13 years of life for patients if they prevent the chronic disease precursors of HF including HTN, DM, and obesity before age 45. Prevention of all of these HF risk factors yields up to an 85% relative risk reduction for women. Men reduce their risk of HF by 73%.

HEART FAILURE

PATIENT EDUCATION

Related to the Overall Treatment Plan and Disease Process

☐ Pathophysiology of heart failure, its prognosis, and its long-term effects on other organs of the body besides the heart

☐ Role of lifestyle modifications, including dietary and activity modifications, in improving prognosis and keeping the number and cost of required drugs down

☐ Importance of adherence to the treatment regimen

☐ Self-monitoring of symptoms of worsening failure, including daily weights

☐ What to do when symptoms worsen

☐ Need for regular follow-up visits with the primary care provider

Specific to the Drug Therapy

☐ Reason for the drug being given and its anticipated action in the disease process

☐ Doses and schedules for taking the drug

☐ Possible adverse effects and what to do if they occur

☐ Coping mechanisms for complex and costly drug regimens

☐ Interactions between other treatment modalities and these drugs

Reasons for Taking the Drug(s)

Patient education about specific drugs is provided in Chapter 16. Specifically for HF, additional information includes the following: These drugs are given to reduce mortality, reduce symptoms, and improve functional status. Some drugs do all of these **(ACE inhibitors)**; most do only one. The expectations should be clear about what the drugs can and cannot do. HF is a chronic condition that rarely occurs in a short period of time, and it is not likely to be corrected in a short period of time, if at all. Patients with HF must understand the seriousness of this diagnosis, including the 5-year mortality rate of 50% and the potential need for surgeries such as heart transplantation. All of this must be done while maintaining hope and emphasizing that a good quality of life is possible.

Drugs as Part of the Total Treatment Regimen

The total treatment regimen includes sodium restriction and avoidance of excessive fluid intake. **Diuretics** reduce fluid volume and may interact with dietary restrictions, resulting in orthostatic hypotension. Care should be taken not to reduce fluid volume too quickly, which exacerbates the problem of decreased cardiac output and may lead to hypotension or renal insufficiency. Patients should report symptoms of fluid volume deficit. They should be told to rise slowly from a supine to a standing position to permit the body to redistribute body fluids. Sodium restriction may lead some patients to seek salt substitutes that have a potassium salt as part of their contents. For patients taking **ACE inhibitors**, this can result in excessively high potassium levels. Such salt substitutes should be avoided. Nonsalt herbal seasoning is more appropriate.

Regular aerobic exercise such as walking or cycling may improve functional status and decrease symptoms. Regular, gradually increased exercise may lead to enough improvement, in some cases, to reduce the drugs needed. Timing of exercise with the peak action of drugs is important. Patients are often able to predict the timing of voiding after taking a diuretic or times when other drugs are more likely to produce dizziness. Exercise timing should take these into consideration.

Adherence Issues

Nonadherence with the treatment regimen in HF may reduce life expectancy and certainly affects functional status. Health-care providers should be aware of the potential problem of nonadherence, discuss the importance of adherence at each follow-up visit, and assist patients in removing barriers to adherence (e.g., cost, adverse effects, or complexity of the regimen).

HUMAN IMMUNODEFICIENCY VIRUS DISEASE AND ACQUIRED IMMUNODEFICIENCY SYNDROME

James Raper • Gina Dobbs

Now in the third decade of treating patients with HIV infection, we can celebrate our many successes. In a short time, we have transitioned a terminal illness into a manageable chronic disease. Since the discovery of human immunodeficiency virus (HIV) in 1981, we have learned a great deal about HIV-associated epidemiology, natural history, pathogenesis, therapy, and immunological host response. However, HIV disease and its sequel, acquired immunodeficiency syndrome (AIDS), remain a global health problem of unprecedented dimensions. Since the beginning of the epidemic, more than 60 million people have been infected with the HIV virus, and approximately 30 million people have died of AIDS. In 2010, there were an estimated 34 million people living with HIV, 2.7 million new infections, and 1.8 million AIDS-related deaths (World Health Organization, 2012). On a global scale, the HIV epidemic has stabilized, although with unacceptably high levels of new HIV infections and AIDS deaths. Globally, an estimated 34 million people were living with HIV in 2011. The annual number of new HIV infections declined from an estimated 3.0 million in 2001 to 2.5 million in 2011. Overall, 1.7 million people died due to AIDS in 2011, compared with an estimated 1.7 million in 2001.

While the percentage of people living with HIV has stabilized since 2000, the overall number of people living with HIV has steadily increased as new infections occur each year, HIV treatments extend life, and new infections still outnumber AIDS deaths. Women account for more than half of the cases of HIV worldwide, and nearly 60% of HIV infections in sub-Saharan

Africa. Over the past 15 years, the proportion of women with HIV has remained stable globally but has increased in many regions. Young people aged 15 to 24 years account for an estimated 45% of new HIV infections worldwide. An estimated 330,000 children younger than 15 years became infected with HIV in 2011. Globally, the number of children younger than 15 years living with HIV increased from 1.6 million in 2001 to 3.3 million in 2011. More than two-thirds (60%), 23.5 million, live in sub-Saharan Africa (AMFAR, 2012). In the United States and dependent areas, the cumulative estimated number of diagnoses of AIDS through 2010 was 1,163,575 (Centers for Disease Control and Prevention [CDC], 2010). The cumulative estimated number of deaths of persons with AIDS in the United States and dependent areas in 2009 was 641,976, including 614,394 adults and adolescents and 4,986 children under age 13 years (CDC, 2010).

Thanks to increasingly effective antiretroviral therapy (ART), the natural history of HIV disease has been favorably altered. A developing list of potent medications, used in combination therapy, has slowed the progression of HIV disease and has dramatically reduced the death rates for people living with HIV. In 2009, the most recent estimates, there were 1,291,739 persons (1,257,942 adults and adolescents and 3,491 children under age 13 years) living with HIV/AIDS in the United States and six dependent U.S. areas (CDC, 2010).

PATHOPHYSIOLOGY

HIV induces defects in host cell–mediated and humoral responses, making the person susceptible to opportunistic infections and certain neoplasms. It is essential to understand the complex pathogenesis of HIV in order to appreciate the impact of HIV on the immune system and the development of interventions to prevent viral replication and advance immunological recovery.

AIDS is a clinical syndrome characterized by progressive immune system suppression, resulting in the development of opportunistic diseases. It is caused by chronic HIV infection. The first reported cases were described in 1981, the causative agent of AIDS was identified as HIV in late 1983, a serological test for HIV infection was available in 1985, and the first therapy was licensed in 1987 (Bennett, 2003). HIV is a member of a family of viruses known as retroviruses, so named because they are able to create DNA copies of their RNA genome, thus reversing (retro) the usual flow of genetic information. HIV is a lentivirus, a type of virus that characteristically produces diseases with a long incubation period leading to cancer, severe immune suppression, or both. The basic pathology in AIDS is a loss of CD4-positive T lymphocytes, cells critical to maintaining cell-mediated immune function. This damage results in progressively severe immune dysfunction.

HIV-1

The retrovirus HIV can be divided into two serotypes, HIV-1 and HIV-2; HIV-1 is predominantly responsible for HIV infection worldwide. Retroviruses are RNA-containing viruses

that require the formation of proviral DNA within the host to complete their life cycle and infect other cells (Colagreco, 2003). The HIV-1 virus, like other retroviruses, is covered by a lipid bilayer derived from host-cell membranes. Viral glycoproteins are incorporated into the bilayer, as well as host adhesion molecules that may be involved in attachment to target cells (Kilby & Eron, 2003). The early characterization of HIV-1 centered on the CD4 T lymphocytes as the primary target of the HIV virus, the helper cells that are responsible for cell-mediated immune reaction (Ansari & Etzel, 2000; Kilby & Eron, 2003). The infectivity of HIV requires the surface glycoprotein (gp120) and the transmembrane glycoprotein subunit (gp41) of gp160, a viral precursor protein that binds to the CD4 receptor. The presence of a chemokine coreceptor, CCR5, also is required for cell entry (Colagreco, 2003).

Following uncoating, the viral RNA is transcribed by the reverse transcriptase enzyme into proviral DNA. The integrase enzyme then integrates the proviral DNA into the host nucleus. The integrated viral genes may remain inactive or become transcribed back into genomic RNA and messenger RNA, which are then translated into viral proteins. Late stages of viral processing involve cleavage of viral proteins by the protease enzyme into new HIV particles, followed by assembly and the release of new infectious virions to infect other cells (Colagreco, 2003).

Viral replication is a dynamic process, involving continuous rounds of de novo virus infection and replication in infected host cells with rapid turnover of both free virus and virus-producing cells (Kilby & Eron, 2003). One billion to 10 billion virions are produced daily. One of the difficulties in eradicating the virus is the existence of an HIV reservoir of latently infected memory CD4 T cells carrying integrated provirus. Those reservoirs of replication-competent virus can persist in resting CD4 T cells of patients that are receiving ART. Low-level, ongoing replication of HIV may occur despite suppression of the HIV virus with potent combination ART (Kilby & Eron, 2003). To date, complete restoration of immune function has not been possible with ART, although partial restoration of pathogen-specific immunity to recall antigens is possible. ART can increase the number of circulating CD4 T cells, which is associated with prolonged survival and a diminished rate of common opportunistic infections.

Following initial HIV infection, immediate widespread dissemination of the virus to other lymphatic systems and organs occurs (Ansari & Etzel, 2000). Infectivity is high during primary infection, with high plasma viremia detected in blood and the presence of virus in sexual organs and secretions. During acute infection, the immunological host response involves potent, cytotoxic CD8 T lymphocytes, which limits viral replication and reduces symptomology as plasma viremia declines. In adults, a new steady-state plasma HIV RNA "viral set point" is established approximately 6 months or longer after the initial infection that can remain stable for months or years before progression to AIDS. The time course of progression to AIDS varies in adults, with average

durations of 10 to 11 years reported in the absence of anti-retroviral therapy (Ansari & Etzel, 2000).

HIV-2

Although HIV-1 is found around the world, the prevalence of HIV-2 is highest in West Africa. HIV-2 is a zoonosis disease believed to have first infected humans as early as the 1940s by jumping from sooty mangabeys to humans as a result of bush meat hunting and slaughtering. HIV-2 has a lower transmission rate and a less pathogenic course. HIV-2 is common in the following countries: Angola, Benin, Burkina Faso, Cape Verde, Cote d'Ivoire (Ivory Coast), Gambia, Ghana, Guinea, Guinea-Bissau, Liberia, Mali, Mauritania, Mozambique, Niger, Nigeria, Sao Tome, Senegal, Sierra Leone, and Togo.

Transmission

Three principal means of HIV transmission have been identified: blood, sexual contact, and mother-to-child (vertical) transmission (Kirton, 2003). The frequency of transmission is influenced by the amount of infectious virus present in the body fluid and the extent of contact an individual has with body fluids.

HPTN 052 was a clinical trial of 1,763 HIV serodiscordant couples that examined the extent to which antiretroviral therapy (ART) can, when taken by HIV-infected people, decrease their infectivity and thereby reduce the chance that they will pass HIV on to their heterosexual partners. The results of the study were so compelling that the study's Data and Safety Monitoring Board (DSMB) asked the research team to share the results with all study participants and offer ART to the control group before the study ended (Matassa, 2011).

Stages—Natural History of HIV

The natural history of HIV disease progresses through several stages. After viral transmission, a symptomatic primary HIV infection, often called acute retroviral syndrome, occurs in 50% to 90% of the people infected. The onset of symptoms is usually 2 to 4 weeks following infection, but the incubation may be as long as several months in rare cases. Typically, a flulike viral syndrome develops, with fever, lymphadenopathy, pharyngitis, rash, and myalgias or arthralgias (Freeman & Winland-Brown, 2001). Diarrhea, headaches, and nausea and vomiting are also common. Early detection of acute HIV infection provides an opportunity to follow patients prospectively soon after infection and thereby reduce disease progression and incidence of opportunistic infections. Because patients with a recent diagnosis of HIV are more likely to reduce risk behaviors if they are linked to primary HIV care than if they are not receiving care, early detection may also be a critical component of preventing further transmission, a significant public health initiative.

At this stage, serological tests are not helpful because seroconversion to a positive HIV antibody test usually occurs at 4 to 12 weeks after exposure and infection. When acute HIV infection is suspected, an HIV serological screening test should be performed in conjunction with a plasma HIV RNA test (viral load). The plasma RNA test should be performed even if the serologic screening test is negative; a fourth-generation HIV antigen/antibody combination test is the preferred serologic screening test if available. The detection of HIV RNA or antigen in the absence of HIV antibody should be considered a preliminary positive result. HIV RNA testing from a new specimen should be repeated immediately to confirm the presence of HIV RNA. In order to exclude a false-positive result, both serological and RNA testing should be repeated when low-level quantitative results (<5,000 copies/mL) from an HIV RNA assay are reported in the absence of serological evidence of HIV infection.

Generally, 95% or more of patients seroconvert within 6 months after HIV transmission. The period from infection to 6 months following HIV transmission is known as early HIV disease. At around 6 months after infection, HIV establishes a "set point," representing a stable balance between immune suppression of the virus and ongoing viral replication. In any individual patient, this steady-state set point seems to be relatively stable over a period of years in the absence of ART. One possible effect of early therapy is to alter this set point to a level associated with longer survival.

The next stage is asymptomatic infection. During this period, the patient is clinically asymptomatic and generally has no abnormal findings on physical examination except enlarged lymph nodes (Freeman & Winland-Brown, 2001). Symptomatic HIV infection is marked by the development of common infections and other conditions that are more severe and persistent in the presence of HIV infections but by themselves do not define AIDS. Examples of the conditions include thrush, oral hairy leukoplakia, peripheral neuropathy, cervical dysplasia, constitutional symptoms, and recurrent herpes zoster. Advanced HIV disease is the development of AIDS as defined by the 1993 CDC case definition (CDC, 1992). This definition includes a list of conditions indicative of severe immunosuppression, as well as the inclusion of all patients with a CD4 count below 200 cells/mm^3.

Viral Structure and Genetic Material

HIV particles appear spherical and their genetic material is enclosed in a special protein shell known as a capsis. HIV also has an outer layer known as an envelope, which is picked up from the host cell membrane as HIV buds out of the cell. Projecting out from the envelope are numerous spikes or knobs that originate from the virus. Each spike consists of three or four molecules of a protein called gp120, which is linked to another protein called gp41; together, the proteins are called gp41. The knobs bind to receptors on cells of the immune system that carry a marker known as the CD4 molecule.

HIV Life Cycle

There are seven steps in the HIV replication cycle (Fig. 37-1) (NIAID, 2013).
Figure 37–1. HIV replication cycle. Courtesy: National Institute of Allergy and Infectious Diseases (NIAID, 2013).

Fusion and Entry

HIV can replicate only inside human cells. The process typically begins when a virus particle bumps into a cell that carries on its surface a special protein called CD4. The spikes on the surface of the virus particle stick to the CD4 and allow the viral envelope to fuse with the cell membrane (Step 1). The contents of the HIV particle (reverse transcriptase, integrase, and other viral proteins) are then released into the cell, leaving the envelope behind (Step 2).

Reverse Transcription and Integration

Once inside the cell, the HIV enzyme reverse transcriptase converts the viral RNA into DNA (Step 3), which is compatible with human genetic material. This DNA is transported to the cell's nucleus, where it is spliced into the human DNA by the HIV enzyme integrase (Step 4). Once integrated, the HIV DNA is known as provirus.

Transcription and Translation

HIV provirus may lie dormant within a cell for a long time. But when the cell becomes activated, it treats HIV genes in much the same way as human genes. First, using human enzymes, it converts them into messenger RNA. Then the messenger RNA is transported outside the nucleus, and is used as a blueprint for producing new HIV proteins and enzymes (Step 5).

Assembly, Budding, and Maturation

Among the strands of messenger RNA produced by the cell are complete copies of HIV genetic material. These gather together with newly made HIV proteins and enzymes to form new viral particles, which are then released from the cell (Step 6). The enzyme protease plays a vital role at this stage of the HIV life cycle by chopping up long strands of protein into smaller pieces, which are used to construct mature viral cores.

The newly matured HIV particles are ready to infect another cell and begin the replication process all over again (Step 7). In this way the virus quickly spreads through the human body. And once a person is infected, that person can pass HIV on to others in bodily fluids.

GOALS OF TREATMENT

The goals of treatment with ART medication are listed in Box 37-1. The most important goals are to (1) reduce HIV-associated morbidity and prolong the duration and quality of survival, (2) restore and preserve immunological function, (3) achieve maximal and durable suppression of plasma HIV viral load, (4) and prevent HIV transmission.

These goals are achieved by reducing HIV-related morbidity and mortality, improving quality of life, and restoring and preserving immunological function in persons infected with HIV (Moyle et al, 2008).

Unfortunately, complete eradication of HIV infection is not possible with the available antiretroviral medications because latently infected CD4 T cells that are established during the earliest stages of acute HIV infection (Chun et al, 1998) persist with a long half-life in spite of prolonged suppression of HIV plasma viremia (Chun et al, 1997; Finzi et al, 1997, 1999; Wong et al, 1997).

Providers who follow approved treatment guidelines and strategies recognize substantial reductions in HIV-related morbidity and mortality (Mocroft et al, 1998; Mofenson et al, 1999; Palella et al, 1998; Delaney et al, 1998; Vittinghoff et al, 1999) and reduced vertical transmission from infected mother to infant (Garcia et al, 1999). Higher HIV plasma viral loads are associated with more rapid disease progression (Mellors et al, 1996), whereas other factors, such as heightened T-cell activation with cellular turnover and expression of immune activation markers, probably contribute as well to clinical disease progression and the rate of CD4 T-cell decline (Rodriguez et al, 2006).

The goal of maximal viral suppression with initial ART may be difficult in some patients who have preexisting medication resistance. Unfortunately, about one of every six new HIV cases diagnosed in 2007 involved virus with ARV drug-resistance mutations (CDC, 2010). To be successful, ART regimens need to contain at least two, and preferably three, active medicines from multiple medication classes. If maximal initial suppression below the level

of HIV detection (less than 50 copies/mL) is not achieved or is lost, it is important to change medication regimens to include at least two active medicines to achieve the maximal suppression goal. If it is not possible to achieve the HIV RNA less than 50 copies/mL goal in a clinically and immunologically stable patient, a time period of persistent detectable viremia may be acceptable while waiting for the availability of new medicine.

In general, viral load reduction to less than 50 copies/mL in most treatment-naïve patients occurs within the first 12 to 24 weeks of therapy. Predictors of virological success are presented in Box 37-2. Virological suppression is always observed. Viral suppression rates in clinical practice may be lower than the 80% to 90% seen in clinical trials. However, the use of current, easier-to-take, coformulated, and potent ART regimens probably decreases the differences in outcomes between clinical trials and clinical practice (Moore, Keruly, Gebo, & Lucas, 2005). To achieve treatment goals, clinicians and patients must work together to define priorities, investigate options, and mutually determine the best treatment plan.

BOX 37–2 PREDICTORS OF ART VIROLOGICAL SUCCESS

- High-level patient adherence to ART regimen
- High potency of antiretroviral medication regimen
- Higher baseline CD4 T-cell count
- Low baseline HIV plasma viral RNA level
- Rapid (i.e., equal to or greater than 1 $\log_{10}$ in 1 to 4 mo) reduction of viral RNA level in response to ART

Rationale for ART Medication Selection

The clinical management of HIV is complex. Practical strategies must be identified so that virological suppression can be attained with therapy plans that patients can adhere to consistently. The treatment of HIV disease is a dynamic, rapidly changing arena, as newer drugs are developed and different combinations evaluated. Selecting the initial combination ART regimen is extremely important. Today, there are more than 22 U.S. Food and Drug Administration (FDA) approved antiretroviral medicines from six mechanistic classes from which to design combination ART regimens. HIV medications are always used in combination to reduce the amount of HIV in the blood (plasma viral load) by helping to block or "inhibit" certain steps during the HIV replication process.

Principles of Therapy

The U.S. Public Health Service has identified certain principles of therapy of HIV infection (CDC, 1998; Panel on Antiretroviral Guidelines for Adults and Adolescent, 2012). First, ongoing HIV replication leads to immune system damage

---

BOX 37–1 HIV TREATMENT GOALS

- Improve quality of life
- Obtain maximal and durable suppression of HIV
- Prevent vertical HIV transmission
- Prolong survival
- Reduce HIV-related morbidity
- Reduce transmissibility of HIV
- Restore and preserve immunological function

and progression to AIDS. HIV infection is always harmful, and long-term survival free of clinically significant immune dysfunction is unusual. The extent of HIV replication and its rate of CD4 T-cell destruction are indicated by plasma HIV RNA levels. The extent of HIV-induced immune damage that has already occurred is indicated by the CD4 T-cell counts. Therefore, plasma HIV RNA and CD4 T-cell levels must be regularly measured (every 3 to 6 months) to determine the risk for disease progression in an HIV-infected person and to identify when to initiate or modify antiretroviral treatment regimens (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2012). Treatment decisions should be individualized based on the risk of disease progression as indicated by plasma HIV RNA levels and CD4 measurements. The goal of therapy should be the maximum achievable suppression of HIV replication. The use of potent combination ART to suppress HIV replication to below the levels of detection of sensitive viral-load assays limits the potential for selection of ART-resistant HIV variants.

The most effective way to achieve sustained suppression of HIV replication is the concomitant initiation of combinations of effective anti-HIV medications that are not cross-resistant with ART agents. Because there is a finite number of available and effective ART drugs and cross resistance between specific drugs has been shown, it is critical that every ART drug used in combination therapy be used according to optimal schedules and dosages.

These dosing principles should be applied to HIV-infected children, adolescents, and adults. However, the treatment of HIV-infected children involves unique pharmacological, virological, and immunological considerations (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2012). Women should receive optimal ART even if they are pregnant. In fact, ART of the pregnant woman with zidovudine alone or with standard three-drug combinations has dramatically reduced the rates of vertical transmission from mother to child (Perinatal HIV Guidelines Working Group, 2009). Treatment of acute HIV infection should be considered optional at this time (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2012).

INITIATING ART MEDICATIONS

The most current recommendations (Panel on Antiretroviral Guidelines for Adults and Adolescents, 2012) suggest ART for all HIV-infected individuals. The strength of the recommendations depends on stage of the disease. Randomized controlled trials provide definitive evidence supporting the benefit of ART in patients with CD4 counts <350 cells/mm³. Since results from multiple observational cohort studies demonstrate benefits of ART in reducing AIDS- and non-AIDS–associated morbidity and mortality in patients with CD4 counts ranging from 350 to 500 cells/mm³, the recommendation is for ART for patients with CD4 (CD4 count <350 cells/mm³).

The recommendation to initiate therapy at CD4 count >500 cells/mm³ is based on growing awareness that untreated HIV infection or uncontrolled viremia may be associated with development of many non-AIDS–defining diseases, including cardiovascular disease (CVD), kidney disease, liver disease, neurological complications, and malignancy; availability of ART regimens that are more effective, more convenient, and better tolerated than earlier ART combinations no longer widely used; and evidence from one observational cohort study that showed survival benefit in patients who started ART when their CD4 counts were >500 cells/mm³.

Regardless of CD4 count, initiation of ART is strongly recommended for individuals with the following conditions:

- History of an AIDS-defining illness
- HIV/hepatitis B virus (HBV) co-infection
- HIV-associated nephropathy (HIVAN)
- Pregnancy
- Effective ART also has been shown to prevent transmission of HIV from an infected individual to a sexual partner; therefore, ART should be offered to patients who are at risk of transmitting HIV to sexual partners

However, the potential benefits of early intervention must be weighed against the risks of early therapy. One major factor is nonadherence for patients who are not yet ready to commit to a complex drug regimen and potential adverse effects that may decrease their quality of life. Therefore, the clinician and the patient need to have an in-depth discussion of the potential toxicities and the complexities of the ART regimen. Box 37-3 presents these risks and benefits.

Patients initiating antiretroviral therapy should be willing and able to commit to lifelong treatment and should understand the benefits and risks of therapy and the importance of adherence. Patients may choose to postpone therapy, and providers may elect to defer therapy, based on clinical and/or psychosocial factors on a case-by-case basis.

The recommended treatment for HIV infection is a combination of three or more medications from two different classes (Table 37-1). The six different mechanistic classes or "families" of HIV antiretroviral medications include nucleoside reverse transcriptase inhibitors (NRTIs), also called "nukes"; nonnucleoside reverse transcriptase inhibitors (NNRTIs), also called "nonnukes"; protease inhibitors (PIs); fusion inhibitors (FIs), also called "entry inhibitors"; integrase strand transfer inhibitors (INSTIs); and CCR5 antagonists. Each class of HIV medications inhibits HIV replication in a different way. The primary difference among the classes is the stage of the HIV life cycle that the medications target.

The main mechanism of action of NRTIs is the inhibition of replication of retroviruses, including HIV, by interfering with viral RNA-directed DNA polymerase (reverse transcriptase). NNRTIs also inhibit replication of HIV by acting as a specific, noncompetitive, reverse transcriptase inhibitor and by disrupting the catalytic site of the enzyme. PIs are selective and competitive inhibitors of HIV protease. PIs play an essential role in preventing cleavage of protein precursors essential for HIV maturation, infection of new cells, and replication. FIs work by blocking an important step in the process of HIV entry into CD4 cells known as fusion. By blocking fusion, FIs may prevent HIV from entering and infecting CD4 cells. Integrase inhibitors (IIs) work by blocking

BOX 37–3   POTENTIAL BENEFITS AND RISKS OF ART

Potential Benefits of Early Therapy

- Maintenance of a higher CD4 T-cell count and prevention of potentially irreversible damage to the immune system
- Decreased risk for HIV-associated complications that can sometimes occur at CD4 counts more than 350 cells/μL, including tuberculosis, non-Hodgkin lymphoma, Kaposi's sarcoma, peripheral neuropathy, HPV-associated malignancies, and HIV-associated cognitive impairment
- Decreased risk of nonopportunistic medical conditions, including cardiovascular disease, renal disease, liver disease, and non–AIDS associated malignancies and infections
- Decreased risk of HIV transmission to others, which will have positive public health implications

Potential Risks of Early Therapy

- Treatment-related side effects and toxicities
- Viral resistance to medications because of incomplete viral suppression, resulting in loss of future treatment options
- Less time for the patient to learn about HIV and its treatment and less time to prepare for the need for adherence to ART
- Increased total time exposed to medication, with greater chance of treatment fatigue
- Premature use of ART before the development of more effective, less toxic, and/or better studied combinations of antiretroviral medications
- Transmission of medication-resistant virus in patients who do not maintain full viral suppression

Table 37–1   ART Medications and Treatment Strategies, Naïve Patients

- 2 NRTIs + 1 drug from one of the following classes; NNRTI, PI (preferably boosted with ritonavir), INSTI, or a CCR5 antagonist.

Preferred regimens are those with optimal and durable efficacy, favorable tolerability and toxicity profile, and ease of use.
The preferred regimens for nonpregnant patients are arranged by order of FDA approval of components other than nucleosides, thus, by duration of clinical experience.

	Comments
NNRTI-Based Regimen	Efavirenz should not be used during the first trimester of pregnancy or in women trying to conceive or not using effective and consistent contraception.
• Efavirenz/emtricitabine/tenofovir	
PI-Based Regimens (in alphabetical order)	Tenofovir should be used with caution in patients with renal insufficiency.
• Atazanavir/r + emtricitabine/tenofovir	Atazanavir/r should not be used in patients who require >20 mg omeprazole equivalent/day.
• Darunavir/r (once daily) + emtricitabine/tenofovir	
INSTI-Based Regimen	
• Raltegravir + tenofovir/emtricitabine	
Preferred Regimen† for Pregnant Women	
• Lopinavir/r (twice daily) + zidovudine/lamivudine	

Alternative regimens are those that are effective and tolerable but have potential disadvantages compared with preferred regimens. An alternative regimen may be the preferred regimen for some patients.

	Comments
NNRTI-Based Regimens (in alphabetical order)	• Rilpivirine should be used with caution in patients with pretreament HIV RNA >100,000 copies/mL.
• Efavirenz + (abacavir or zidovudine)/lamivudine	• Use of PPIs with rilpivirine is contraindicated.
• Rilpivirine + emtricitabine + tenofovir	Abacavir:
• Rilpivirine + abacavir + lamivudine	• Should not be used in patients who test positive for HLA B*5701.
PI-Based Regimens (in alphabetical order)	• Use with caution in patients with high risk of cardiovascular disease or with pretreatment HIV-RNA >100,000 copies/mL.
• Atazanavir/r + abacavir /lamivudine	Once-daily lopinavir/r is not recommended in pregnant women.
• Daranavir/r + abacavir /lamivudine	
• Fosamprenavir/r (once or twice daily) + either abacavir/lamivudine or tenofovir/emtricitabine	
• Lopinavir/r (once or twice daily) + either abacavir/lamivudine or tenofovir/emtricitabine	
INSTI-Based Regimen	
• Raltegravir + abacavir /lamivudine	

Acceptable regimens are those that may be selected for some patients but are less satisfactory than preferred or alternative regimens.

	Comments
NNRTI-Based Regimen	Nevirapine should not be used in patients with moderate to severe hepatic impairment (Child-Pugh B or C).
• Efavirenz + zidovudine/lamivudine	Nevirapine should not be used in women with pre-ART CD4 count >250 cells/mm³ or in men with pre-ART CD4 count >400 cells/mm³.
• Nevirapine + (emtricitabine/tenofovir or zidovudine/lamivudine)	
• Nevirapine + abacavir/lamivudine	Use nevirapine and abacavir together with caution. Both can cause hypersensitivity syndrome reactions within the first few weeks after initiation.
• Rilpivirine + zidovudine/lamivudine	

Continued

Table 37–1 ART Medications and Treatment Strategies, Naïve Patients—cont'd

PI-Based Regimen • Atazanavir + (abacavir or zidovudine)/+ lamivudine • Atazanavir/r + zidovudine/lamivudine • Daranavir/r + zidovudine/lamivudine • Fosamprenavir/r + zidovudine/lamivudine • Lopinavir/r + zidovudine/lamivudine **INSTI-Based Regimen** • Raltegravir + zidovudine/lamivudine **CCR5 Antagonist-Based Regimens** • Maraviroc + zidovudine/lamivudine • Maraviroc + (emtricitabine/tenofovir or zidovudine/lamivudine)	Zidovudine can cause bone marrow suppression, lipoatrophy, and rarely lactic acidosis with hepatic steatosis. Lopinavir/r (twice daily) + zidovudine/lamivudine is the preferred regimen for use during pregnancy. Atazanavir/r is generally referred over unboosted atazanavir. Unboosted atazanavir may be used when ritonavir boosting is not possible. Perform tropism testing **before** initiation of maraviroc. Maraviroc may be considered in patients who have only CCR5-tropic virus.

*Lamivudine may substitute for emtricitabine or vice versa.

†For more detailed recommendations on antiretroviral use in an HIV-infected pregnant woman, refer to "Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States," at http://aidsinfo.nih.gov/guidelines

FIs = fusion inhibitors; INSTIs = integrase strand transfer inhibitor; NNRTIs = nonnucleoside reverse transcriptase inhibitors; NRTIs = nucleoside reverse transcriptase inhibitors; PI = protease inhibitors.

the integrase enzyme that HIV needs to make more virus. CCR5 antagonists work by blocking a molecule called CCR5 that is found on the surface of CD4 cells so HIV cannot enter.

The most extensively studied combination ART regimens for treatment-naïve patients include either (1) one NNRTI with two NRTIs or (2) one PI (with or without ritonavir boosting) with two NRTIs. The potent inhibitory effect of ritonavir on metabolism of the cytochrome P450 (CYP450) 3A4 isoenzyme allows the addition of low-dose ritonavir to other PIs (except nelfinavir) as a pharmacokinetic booster to increase medication levels and prolong plasma half-lives of the active PIs. This "boosting" allows for reduced dosing frequency and/or pill burden, which may improve overall adherence to the ART regimen. The increased trough concentration (C_{min}) may improve the antiretroviral activity of the active PIs, which can be beneficial when the patient harbors HIV-resistant strains to PIs (Dragsted et al, 2003, 2005; Shulman et al, 2002). The potential for increased risk of hyperlipidemia and drug–drug interactions is the major drawback associated with ritonavir boosting.

Both NNRTI- and PI-based regimens result in suppression of HIV RNA levels and CD4 T-cell increases in a large majority of patients (Gallant et al, 2004; Gulick et al, 2006; Riddler et al, 2006; Squires et al, 2004; Staszewski et al, 1999). A list of several preferred and alternative ART regimens is available from which to choose (see Table 37-1). ART regimens vary in efficacy, pill burden, and potential side effects. A patient-specific individualized regimen that maximizes adherence may be more successful in achieving full viral suppression. Many patient-specific characteristics are considered in the selection of an ART regimen. These characteristics include the following:

• Comorbid conditions (e.g., cardiovascular disease, chemical dependency, liver disease, psychiatric disease, pregnancy, renal diseases, or tuberculosis)
• Convenience (e.g., pill burden, dosing frequency, and food and fluid considerations)
• Gender and pretreatment CD4 T-cell count if considering nevirapine

• Genotypic drug resistance testing
• HLA B*5701 testing if considering abacavir
• Patient adherence potential
• Potential adverse drug effects
• Potential drug interactions with other medications
• Pregnancy potential

Medications Used to Treat HIV

There are currently six different mechanistic classes or "families" of HIV antiretroviral medications that include nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), fusion inhibitors (FIs), integrase strand transfer inhibitor (INSTIs), and CCR5 antagonists. The characteristics of FDA-approved ART medications are presented in Table 37-2 and the mechanistic classes are discussed in the following section.

Reverse Transcriptase Inhibitors

Reverse transcriptase inhibitors come in several forms. We will discuss nucleoside and nucleotide inhibitors in this section and nonnucleoside reverse transcriptase inhibitors in the following section. Nucleoside and nucleotide analogue reverse transcriptase inhibitors (NRTIs and NtRTIs) are a class of antiretroviral medicines that inhibit the activity of reverse transcriptase, a viral DNA polymerase enzyme that retroviruses need to reproduce. This class of antiviral medicine was the first to be used to treat HIV and remains a backbone for most ART regimens. Available HIV NRTIs include abacavir, didanosine, emtricitabine, lamivudine, stavudine, and zidovudine. The only HIV NtRTI is tenofovir.

Nucleoside Reverse Transcriptase Inhibitors

In order for NRTIs to work, they must undergo chemical changes (phosphorylation) to become active in the body. Nucleotide analogues bypass this step. Thus, NtRTIs are already chemically activated. When HIV infects a cell, reverse

Table 37–2 Antiretroviral Agent Characteristics

Drug Name	Form	Usual Adult Dose	Food Effects	Renal Failure Dosing			Liver Failure Dosing	Toxicity
				CrCl 30–59 mL/min	CrCl 10–29 mL/min	CrCl <10 or Dialysis		
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)								
Abacavir (Ziagen)	300 mg tab; (see also: Trizivir); 20 mg/mL po soln	300 mg bid	No effect	Standard			Usual	Hypersensitivity: fever, rash, GI sx, dyspnea[3,6]
Combivir	Zidovudine 300 mg + lamivudine 150 mg (tab)	1 bid	No effect	Fixed formulation not recommended			Usual	Zidovudine side effects[3]
Didanosine (Videx EC)[1]	125, 200, 250, and 400 mg EC caps[2]	— EC caps with Tenofovir; >60 kg 400 mg qd / 250 mg qd; <60 kg 250 mg/d / 200 mg/d	½ hr before or 2 hr after meal Separate dosing of ATV, TPV/r	>60 kg 200 mg/d; <60 kg 125 mg/d	>60 kg 125 mg/d; <60 kg 100 mg/d	>60 kg 125 mg/d; <60 kg 75 mg/d[5]	Usual	Pancreatitis, peripheral neuropathy, GI intolerance[3]
Emtricitabine (Emtriva)	200 mg cap	200 mg qd	No effect	200 mg q72h		200 mg q96h	Usual	Minimal[3] HBV flare[10]
Lamivudine (Epivir)	150, 300 mg tab (see also: combivir & trizivir); 10 mg/mL po soln	150 mg bid or 300 mg qd	No effect	150 mg ×1 then 100 mg/d		150 mg ×1 then 25–50 mg/kg/d	Usual	Minimal[3] HBV flare[10]
Epzicom	Lamivudine 300 mg + abacavir 600 mg	1 qd	No effect	Fixed formulation not recommended in renal failure			Usual	Abacavir hypersensitivity HBV flare[10]
Stavudine (Zerit)[1]	15, 20, 30, 40 mg cap; 1 mg/mL po soln	Wt >60 kg: 40 mg bid; Wt <60 kg: 30 mg bid	No effect	>60 kg 20 mg q12h; <60 kg 15mg q12h	>60 kg 20 mg q24h; <60 kg 15 mg q24h	>60 kg 20 mg q24h; <60 kg 20 mg q24h[5]	Usual	Peripheral neuropathy, pancreatitis, lipoatrophy, ascending paresis (rare)[3]
Tenofovir (Viread)	300 mg tab (see also: truvada)	300 mg qd	Take with meal	300 mg q48h	300 mg 2 d/wk	300 mg q7d[5]	Usual	Minimal. Renal toxicity (rare)[3] HBV flare[10]

Table 37–2 Antiretroviral Agent Characteristics—cont'd

Drug Name	Form	Usual Adult Dose	Food Effects	Renal Failure Dosing			Liver Failure Dosing	Toxicity
				CrCl 30–59 mL/min	CrCl 10–29mL/min	CrCl <10 or Dialysis		
Trizivir (TZV)	Zidovudine 300 mg + lamivudine 150 mg + abacavir 300 mg (tab)	1 bid	No effect	Fixed formulation not recommended in renal failure			Usual	Hyper-sensitivity-reaction (abacavir), bone marrow suppression (z), GI Intolerance (zidovudine)[3] HBV flare[10]
Truvada	Tenofovir 300 mg + emtricitabine 200 mg	1 qd	No effect	Fixed formulation not recommended in renal failure			Usual	Minimal. Renal toxicity, HBV flare[10]
Zidovudine (Retrovir)	100 cap, 300 mg tab; (see also: combivir & trizivir) 10 mg/mL IV soln 10 mg/mL po soln	300 mg bid 200 mg tid	No effect	300 mg bid	300 mg qd	100 mg tid	Usual	Peripheral neuropathy, stomatitis[3]
Protease Inhibitors (PIs)								
Atazanavir (Reyataz)	100, 150, and 200 mg capsules	400 mg qd; ATV 300 mg/retonavir 100 mg qd. Boosting is often preferred and is required if ATV is combined with tenofovir or EFV	Take with food. Avoid concurrent buffered ddI, antacids.	Standard			CPS 7–9: 300 mg qd CPS >9: Avoid	Benign increase in indirect bilirubin, GI intolerance, transaminitis, prolongation of QTc (caution with conduction defects or drugs that do this)[9]
Fosamprenavir[2] (Lexiva)	700 mg tabs	1,400 mg bid or 700 mg/retonavir 100 mg bid or 1,400 mg/retonavir 200 mg qd	No effect	Standard			CPS 5–8: 700 mg bid CPS >9: Avoid	Rash, GI intolerance, transaminitis, headache, hepatitis[9]

Drug	Formulations	Dosage	Food			Toxicity
Indinavir (Crixivan)	200, 333, 400 mg caps	800 mg q8h; separate buffered didanosine ≥1 hr IDV 400 mg/retonavir 400 mg bid or [4] IDV 800 mg/retonavir 100–200 mg bid [4]	1 hr before or 2 hr after meal unless with retonavir	Standard	600 mg q8h	GI intolerance nephrolithiasis, transaminitis, benign increase in indirect bilirubin[9]
Lopinavir/ Ritonavir (Kaletra)	200/50 mg tabs; LPV 80 mg + retonavir 20 mg/mL po soln[2]	400 mg LPV + 100 mg retonavir (2 tabs) bid soln: 5 mL bid	No effect	Standard	7	Transaminitis, GI intolerance (esp. diarrhea), asthenia[9]
Nelfinavir (Viracept)	250, 625 mg tabs; 50 mg/g powder	1,250 mg bid or 750 mg tid	Take with high-fat meal	Standard	7	GI intolerance, diarrhea, transaminitis[9]
Ritonavir (Norvir)	100 mg caps, 600 mg/ 7.5 mL po soln	600 mg q12h[4]; separate didanosine ≥2 h	Food improves GI tolerance	Standard	7	GI intolerance, paresthesia, transaminitis, taste perversion[9]
Saquinavir[2] (Invirase)	200 mg caps, 500 mg tabs	SQV 1,000 mg bid + retonavir 100 bid[2] SQV 2,000 mg qd + retonavir 100 mg qd[2]	Take within 2 hr of meal	Standard	7	GI intolerance, transaminitis[9]
Tipranavir (Aptivus)	250 mg caps	500 mg bid with retonavir 200 mg bid	Take TPV and retonavir with food	Standard	CPS B or C: Avoid	Hepatotoxicity - monitor ALT, skin rash, GI intolerance, multiple drug interactions
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)						
Delavirdine (Rescriptor)	100, 200 mg tabs	400 mg tid	No effect	Standard	7	Rash
Efavirenz [8] (Sustiva)	50, 100, 200 mg caps, 600 mg tabs	600 mg hs	Avoid high-fat meal	Standard	7	CNS ×2–3 wk, rash, hepatitis, false + cannibinoid test
Nevirapine (Viramune)	200 mg tabs 50 mg/5 mL po susp	200 mg qd ×14 d, then 200 mg bid	No effect	Standard	Standard; give post-dialysis	Avoid	Rash, hepatitis; hepatic necrosis esp women with CD4 >250 in first 6 wk

Table 37–2 **Antiretroviral Agent Characteristics—cont'd**

Drug Name	Form	Usual Adult Dose	Food Effects	Renal Failure Dosing			Liver Failure Dosing	Toxicity
				CrCl 30–59 mL/min	CrCl 10–29mL/min	CrCl <10 or Dialysis		
Rilpivirin (Edurant)	50 mg tabs	50 mg/d	Take with a meal of ~ 400 kcal (13 g of fat. Avoid PPIs.					Rash and psychiatric disorders
Fusion Inhibitors								
Enfuvirtide (Fuzeon, T-20)	90 mg single-use vials to be reconstituted with 1.1 mL H₂0	90 mg (1 mL) SQ q12h into upper arm, anterior or abdomen (rotate sites)	N/A	Standard			Usual dose	Site reactions
CCR5 Antagonists								
Maraviroc (Selzentry)	150 & 300 mg tabs	300 mg bid with all NRTIs; nevirapine, timpranavir; enfuvirtide 150 mg bid CYP3A inhibitors (with or without a strong CYP3A inducer); protease inhibitors (other than tipranavir); delavirdine 600 mg bid CYP3A inducer (if used without a strong CYP3A inhibitor [see above]): CYP3A inducer (if used without a strong CYP3A inhibitor [see above]): efavirenz; etravirine	N/A	Standard	Not recommended	Not recommended	Monitored closely for adverse events	Rash and hepatotoxicity
Integrase Strand Transfer Inhibitors								
Raltegravir (Isentress)	400 mg tabs	400 mg bid	N/A	Standard			Monitor for toxicity	Rash & insomnia

[1] The combination of didanosine and stavudine "should be used in pregnant women only when the potential benefit clearly outweighs the potential risk." Efavirenz should be avoided in first trimester of pregnancy and used with caution in women with reproductive potential. Avoid APV liquid in pregnancy.

[2] The following are no longer available: buffered didanosine, lopinovir/r 133/33 mg cap, amprenavir, or fortovase.

[3] Class adverse reaction: lactic acidosis with steatosis. Most common with stavudine, ddI, and zidovudine.

[4] Various dosing recommendations when using dual PI, PI plus NRTI, or dual PI plus NNRTI.

[5] Give post-dialysis

CPS = Child Pugh Score

[6] Registry for hypersensitivity: 1-800-270-0425.

[7] More frequent monitoring required. Drug change or dose change could be considered on a case-by-case basis noting the risk of resistance with underdosing.

[8] Efavirenz should be avoided in first trimester of pregnancy and used with caution in women with reproductive potential. Avoid APV liquid in pregnancy.

[9] Class adverse effects include lipodystrophy with hyperglycemia, fat redistribution, hyperlipidemia, and possible increased bleeding with hemophilia. ATV does not cause hyperlipidemia. All PIs may cause elevated transaminases.

[10] Lamivudine, emtricitabine, and tenofovir; risk of flare of chronic HBV if discontinued.

Adapted from "Tools for Grantees: A Pocket Guide to Adult HIV/AIDS Treatment February 2006 edition" (HRSA, 2006).

transcriptase copies the HIV single-stranded RNA genome into a double-stranded HIV DNA. The HIV DNA is then integrated into the host chromosomal DNA, which allows host cellular processes such as transcription and translation (supra) to reproduce HIV. NRTIs/NtRTIs block the function of reverse transcriptase and prevent completion of synthesis of the double-stranded HIV DNA, thereby preventing HIV from reproducing. Whereas NRTIs/NtRTIs are analogues of the naturally occurring deoxynucleotides needed to synthesize the viral DNA, their mode of action is to compete with the natural deoxynucleotides for incorporation into the growing viral DNA chain. However, unlike the natural deoxynucleotides substrates, NRTIs/NtRTIs lack a 3′-hydroxyl group on the deoxyribose moiety. Thus, following incorporation of an NRTI/NtRTI, the next incoming deoxynucleotide cannot form the next 5′-3′ phosphodiester bond needed to extend the DNA chain. So, when an NRTI/NtRTI is incorporated, viral DNA synthesis is prevented, a process known as chain termination. All NRTIs/NtRTIs are competitive substrate inhibitors.

Most NRITs/NtRTIs are eliminated via the kidneys so as to require renal adjustment when creatinine clearance is less than 50 mL/minute. Abacavir is eliminated by a complex mechanism in the liver. Therefore, it does not require renal function adjustment. However, the half-life of abacavir is increased in mild hepatic impairment and must be dose-adjusted for Child-Pugh class A and it is contraindicated for classes B and C. Common side effects of the NRTI/NtRTI class include anemia, bone marrow suppression, flatulence, headache, myopathy, nausea, rash, renal issues, and vomiting.

Symptomatic and life-threatening lactic acidosis may occur with NRTIs. Lactic acidosis occurs more commonly in patients with hepatomegaly and hepatic steatosis. Abacavir is contraindicated in HLA B*5701 positive patients. Genetic screening for B*5701 effectively predicts the high probability of abacavir-associated hypersensitivity reaction, a multisystem syndrome that produces a constellation of symptoms that may include rash, fever, respiratory symptoms, or gastrointestinal symptoms. Abacavir-associated hypersensitive reaction can be fatal if abacavir is continued or is rechallenged. Didanosine and stavudine are associated with peripheral neuropathy and pancreatitis. Tenofovir is associated with a variety of side effects, including decreased bone mineral density; increased biochemical markers of bone metabolism; acute renal failure; acute tubular necrosis; decreased urine volume; Fanconi syndrome; renal impairment; increased creatinine; interstitial nephritis (including acute cases); nephritis; nephrogenic diabetes insipidus; new onset or worsening renal, proximal renal tubulopathy, renal failure, and renal insufficiency.

NRTI/NtRTIs are sometimes prescribed in fixed-dose (fd) combination formulations with other NRTI/NtRTIs and other antiretrovirals agents to decrease pill burden and simplify ART regimens. Emtricitabine, lamivudine, and tenofovir are also active against hepatitis B virus.

Nonnucleoside Reverse Transcriptase Inhibitors

Nonnucleoside reverse transcriptase inhibitors (NNRTIs), also known as nonnucleosides or nonnukes, attach themselves to reverse transcriptase and prevent the enzyme from converting RNA to DNA. As a result, HIV's genetic material cannot be incorporated into the healthy genetic material of the cell, which prevents the cell from producing new virus. The pharmacokinetics of NNRTIs are complex. Although possessing a common mechanism of action, the approved NNRTIs—delavirdine, efavirenz, etravirine, nevirapine, and rilpivirine—differ in structural and pharmacokinetic characteristics. Each undergoes biotransformation by the CYPP450 enzyme system. This makes them prone to clinically significant drug interactions when combined with other ARTs. NNRTIs interact with other concurrent medications and complementary/alternative medicines, acting as either inducers or inhibitors of drug-metabolizing CYP450 enzymes. These drug interactions become an important consideration in clinical use when designing combination regimens, as recommended by current guidelines. Common side effects of the NNRTI class include: difficulty sleeping, dizziness, drowsiness, fatigue, headache, liver problems (which can be severe and life-threatening), nausea, vomiting, diarrhea, rash (which can be severe), and vivid dreams.

Protease Inhibitors

Protease inhibitors (PIs) are a class of medications used to treat or prevent viral infection such as HIV and hepatitis C. HIV-PIs prevent viral replication by inhibiting the enzyme activity of HIV-1 protease in the CD4 cell that cleaves nascent proteins for final assembly of new virions. All PIs have a similar mechanism of action and do not depend on intracellular conversion to be active in the host cell. Available PIs include atazanavir, fosamprenavir, indinavir, lopinavir/ritonavir, nelfinavir, ritonavir, saquinavir, and tipranavir. Like NNRTIs, PIs are metabolized by CYP450 enzymes. This makes PIs subject to drug interactions with other medicines that use the CYP450 pathway. Ritonavir is a very potent CYP450 inhibitor of other PIs (except nelfinavir) and therefore is commonly paired in low doses to pharmacokinetically intensify the half-life of other PIs in a prescribing practice known as ritonavir boosting. Drug interactions with boosted and nonboosted PIs must be considered when devising an effective, well-tolerated ART regimen. PIs are eliminated in the feces and do not require renal dosing adjustment. Common side effects of the PI class include: bleeding problems, diarrhea, gastrointestinal disturbance, hyperglycemia, hyperlipidemia, lipodystrophy, and liver problems that can be severe.

Integrase Strand Transfer Inhibitors

Integrase strand transfer inhibitors (INSTIs) prevent insertion of HIV DNA into the human DNA genome, thereby blocking the ability of HIV to replicate. Integrase is an enzyme that allows HIV genetic material to integrate into the DNA of human CD4 cells, making it possible for the infected cell to make new copies of HIV. By interfering with integrase, INSTIs prevent HIV genetic material from integrating into the CD4 cell, thus stopping viral replication. The stage in

which HIV genetic material is integrated into human DNA is not fully understood. For that reason, developing an effective integrase inhibitor was not easy and many INSTIs failed very early in clinical trials.

However, raltegravir (2007) and cobicistat-boosted elvitegravir (2012) were approved by the FDA. They act at the final phase of integration when the viral strand is transferred into the host cell. Integrase inhibitors should be used with caution when administered with strong inducers of uridine diphosphate glucuronosyltransferase (UGT1A1), including rifampin. These inducers of UGT1A1 may reduce plasma concentrations of raltegravir. Similar to rifampin, ritonavir-boosted tipranavir reduces plasma concentrations of raltegravir. The most common side effects related to raltegravir are creatinine kinase elevations, diarrhea, headache, myopathy, nausea, pyrexia, and rhabdomyolysis. The most common side effects of elvitegravier include nausea and diarrhea, upper respiratory tract infections and bronchitis, back and joint pain, and urinary tract infections; cobicistat is associated with gastrointestinal side effects, including nausea, vomiting, and diarrhea. Cobicistat may also exacerbate kidney impairment in some people.

CCR5 Antagonists

CCR5 antagonists selectively bind to the human chemokine receptor CCR5 present on the cell membrane, preventing the interaction of HIV-1 gp120 and CCR5, which is necessary for CCR5-tropic HIV-1 to enter cells. Maraviroc is only one CCR5 antagonist licensed by the FDA. CXCR4-tropic and dual-tropic HIV-1 entry are not inhibited by maraviroc. Maraviroc is a selective, slowly reversible, small molecule. It is a substrate of CYP3A and Pgp; therefore, its pharmacokinetics are modulated by inhibitors and inducers of these enzymes/transporters. The CYP3A/Pgp inhibitors ketoconazole, lopinavir/ritonavir, ritonavir, darunavir/ritonavir, saquinavir/ritonavir, and atazanavir ± ritonavir all increase the C_{max} and the area under the curve (AUC) of maraviroc. The CYP3A inducers rifampin, etravirine, and efavirenz decreased the C_{max} and AUC of maraviroc. The most common adverse events reported with maraviroc are cough, dizziness, pyrexia, rash, and upper respiratory tract infections. Additional adverse events include diarrhea, edema, esophageal candidiasis, influenza, parasomnias, rhinitis, sleep disorders, and urinary abnormalities.

Fusion Inhibitors

Fusion inhibitors work by attaching themselves to proteins on the surface of CD4 cells or proteins on the surface of HIV and thereby prevent fusion of HIV-1 with CD4 cells. Enfuvirtide, the only FDA-approved entry inhibitor that targets the gp120 or gp41 proteins on HIV's surface, was licensed in 2003. By binding to the first heptad-repeat (HR1) in the gp41 subunit of the viral envelope glycoprotein and preventing the conformational changes required for the fusion of viral and cellular membranes, enfuvirtide interferes with the entry of HIV-1 into cells by inhibiting fusion of viral and cellular membranes. Enfuvirtide is not an inhibitor of CYP450 enzymes. Coadministration of enfuvirtide and other drugs that are inducers or inhibitors of CYP450 is not expected to alter the pharmacokinetics of enfuvirtide. Common side effects of enfuvirtide include skin itchiness, swelling, and pain at the site of the injection (injection site reactions). Other side effects may include dizziness, fatigue, insomnia, and numbness in feet or legs.

COST CONSIDERATIONS

HIV medicines are very expensive. Medication costs vary widely, depending on the choice of medications; the complexity of the ART regimen; where medications are purchased, neighborhood pharmacy versus mail order; and who is doing the purchasing, government versus individual. For most patients, private insurance providers, Medicare, state Medicaid, drug assistance programs, state AIDS Drug Assistance Programs (ADAPs), or community resources pay most of the cost. Patient co-payments also vary widely by individual prescription insurance plan. Many pharmaceutical manufacturers of HIV drugs have implemented co-pay programs to provide financial assistance to patients who qualify financially and medically. Although HIV medications are very costly, not taking them can be even more costly (Chen et al, 2006). Table 37-3 provides some indication of the expense involved in the treatment of HIV.

AIDS Drug Assistance Program

The national AIDS Drug Assistance Program (ADAP) is a major source of medications for the treatment of HIV disease. The program is funded through Part B of the Ryan White HIV/AIDS Treatment Modernization Act (formerly known as the Ryan White Comprehensive AIDS Resources Emergency [CARE] Act), which provides grants to states and territories. Program funds may also be used to purchase health insurance for eligible clients and for services that enhance access to, adherence to, and monitoring of drug treatments. Grants are awarded to all 50 states, the District of Columbia, Puerto Rico, Guam, the U.S. Virgin Islands, and the Pacific jurisdictions. Congress mandates funds that must be used for the ADAP, an important distinction because other part B spending decisions are made locally.

Patient Assistance Programs

Over 250 pharmaceutical companies operate Patient Assistance Programs to assist the uninsured who cannot afford their medicine, including HIV medications. However, very few people know about these important programs and those that do often find that applying for them is a confusing and prohibitive process. It is very easy to learn how to advocate for financially challenged patients. There is a common HIV Patient Assistance Program application available at the federal Health Resources and Services Administration HIV/AIDS Programs Web site (http://hab.hrsa.gov/patientassistance).

Table 37–3   **Brand-Name Antiretroviral Medications, Usual Adult Dosing, and Monthly Average Wholesale (AWP) Price by Mechanistic Class**

Generic Name	Brand Name	Usual Adult Dose	AWP	RTV AWP Price*	Total
Nucleoside and Nucleotide Reverse Transcriptase Inhibitors (N/NTRTIs)					
Abacavir (ABC)	Generic	300 mg bid or 600 mg daily	$603		$615
Abacavir/lamivudine (ABC/3TC)	Epzicom	600/300 mg daily	$1,170		$1,073
Abacavir/lamivudine/ zidovudine (ABA/AZT/3TC)	Trizivir	300/150/300 mg bid	$1,840		$1,608
Didanosine (ddI)	Generic	400 mg EC daily if >60 kg or 250 mg EC daily if <60 kg	$236 $236		$425 $272
Emtricitabine (FTC)	Emtriva	200 mg daily	$544		$437
Emtricitabine/ tenofovir (FTC/TDF)	Truvada	200/300 mg daily	$1,467		$1,118
Lamivudine (3TC)	Generic	150 mg bid or 300 mg daily	$430		$458
Lamivudine/zidovudine (ZDV/3TC)	Generic	300/150 mg bid	$931		$993
Stavudine (d4T)	Generic	40 mg bid if >60 kg or 30 mg bid if <60 kg	$411 $403		$456 $448
Tenofovir (TDF)	Viread	300 mg daily	$942		$772
Zidovudine (ZDV)	Retrovir	300 mg bid	$360		$535
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)					
Efavirenz (EFV)	Sustiva	600 mg daily at bedtime	$785		$785
Etravirine (ETV)	Intelence	200 mg bid with a meal	$978		$978
Nevirapine (NVP)	Viramune	200 mg bid; dose if initiated at 200 mg daily for 14 d to reduce rash risk	$650		$650
	Viramune XR	400 mg daily	$708		$708
Rilpivirin (RPV)	Edurant	50 mg daily	$804		$804
Protease Inhibitors (PIs)					
Atazanavir (ATV)	Reyataz	400 mg daily (2 caps daily) or 300 mg daily + 100 mg RTV daily	$1,222 $1,165	$308	$1,222 $1,473
Darunavir (DRV)	Prezista	600 mg bid + 100 mg RTV bid	$1,230	$616	$1,846
		800 mg daily + ritonavir 100 mg daily	$1,102	$616	$1,846
Fosamprenavir (FPV)	Lexiva	1,400 mg daily + 100 mg ritonavir daily or 1,400 mg bid	$994 $1,988	$308	$1,302 $1,988
Indinavir (IDV)	Crixivan	800 mg q8h or 800 mg bid + 100–200 mg ritonavir bid	$548 $548	$616	$548 $1,164
Lopinavir/ritonavir (LPVr)	Kaletra	400/100 mg bid (2 tabs bid)	$871		$871
Nelfinavir (NFV)	Viracept	1,250 mg bid (2 bid)	$965		$965
Ritonavir (RTV)§	Norvir	100 mg daily 200 mg daily	$308 $616		$308 $616
Saquinavir mesylate (SQV)	Invirase	1,000 mg bid + RTV 100 mg	$1,121	$616	$1,737
Tipranavir (TPV)	Aptivus	500 mg bid with RTV 200 mg bid	$1,415	$1,242	$2,657

Table 37–3 Brand-Name Antiretroviral Medications, Usual Adult Dosing, and Monthly Average Wholesale (AWP) Price by Mechanistic Class—cont'd

Generic Name	Brand Name	Usual Adult Dose	AWP	RTV AWP Price*	Total
Fusion Inhibitors (FIs)					
Enfuviritide (T-20)	Fuzeon	90 mg by subcutaneous injection bid	$3,248		$3,248
CCR5 Antagonists					
Maraviroc (MVC)	Selzentry	300 mg bid	$1,260		$1,260
Integrase Strand Transfer Inhibitors (INSTIs)					
Raltegravir (RAL)	Isentress	400 mg bid	$1,228		$1,228
Fixed-Dose Tablets From More Than One Class					
Emtricitabine‡/ rilpivirine/tenofovir	Complera	200/50/300 mg once daily	$2,323		$2,323
Efavirenz/emtricitabine/ tenofovir	Atripla	600/200/300 mg once at hs	$2,253		$2,253
Elvitegravir/Cobicistat†/ Emtricitabine/Tenofovir	Stribild	150/150/200/ 300 mg once daily	$2,810		$2,810

§RTV (Norvir) coadministration as a "boosting-agent" that is required to achieve therapeutic drug levels and thereby adds to the ART cost.

‡ Elvitegravir is only available in the fixed-dose preparation, Stribild.

†Cobicistat is not active against HIV. It works by inhibiting an enzyme called CYP3A4 that is responsible for breaking down (or metabolism) of certain medications, including several HIV drugs. This helps boost the effectiveness of these drugs, while allowing fewer pills or doses on a daily basis.

MEDICATION RESISTANCE

Antiretroviral medication resistance occurs when HIV replicates while the patient is taking ART. The replication may be the result of poor patient adherence to the ART regimen or possible drug–drug or drug–food interactions, abnormal absorption, distribution, metabolism, or excretion of the medicine, resulting in HIV replication and genetic mutational changes. The first sign of HIV resistance to ART is the presence of detectible plasma viral RNA on two separate viral load measurements. Various assays are used to determine the nature of HIV medication resistance. The most commonly used resistance assays are phenotypic and genotypic assays.

Phenotype assays are used to measure sensitivity to various antiretroviral agents. The assay reports HIV sensitivity in terms of a ratio above the normal or wild-type IC_{50}. In other words, it is the half-maximal (50%) inhibitory concentration (IC) of a medicine (50% IC, or IC_{50}). This information allows a provider to determine the relative extent of resistance. Genotype assays are used to identify the presence of specific resistance mutations of the HIV genes known to be associated with resistance to specific antiretroviral agents (Table 37-4).

Genotype testing identifies viral mutations on the reverse transcriptase (RT), protease (PR), envelope, and integrase genes. Notation of the specific mutations is standardized by identifying the first letter of the usual amino acid, the location on the gene (number), followed by the first letter of the amino acid change related to the mutation. For example, the M184V mutation conveys that on the 184 position of the RT enzyme, the methionine amino acid residue was replaced with a valine amino acid residue. This is one of the most commonly associated cytosine analogue-resistant mutations to confer high-level resistance to medications such as emtricitabine and lamivudine. Other RT gene mutations, such as M41L, D67N, K70R, L210W, T215Y/F, and K219O/E, are more commonly known as thymidine analogue mutations, or TAMs. The presence of these mutations affects all NRTIs. K65R reduces viral sensitivity to abacavir, didanosine, emtricitabine, lamivudine, and tenofovir while increasing sensitivity to zidovudine (Grant et al, 2010). K103N, a major RT mutation, renders cross-resistance to efavirenz and nevirapine.

PR gene mutations are classified as critical and secondary. When present, PR mutations render HIV resistant to various PI agents. As the number of mutations emerges, HIV develops increasingly high-grade resistance whereby mutation can prevent the PI from binding to the catalytic site of action, allowing the normal gag-pol protein to be cleaved and form new virus. Like some RT mutations, some PR mutations confer broad, PI class cross-resistance to multiple medicines. L90M and I50L are two examples of very significant critical PR cross-resistance mutations.

Medication resistance to most PIs requires multiple mutations in the HIV protease and seldom develops following early virological failure, especially when ritonavir boosting is used. However, medication resistance to efavirenz or nevirapine is conferred by a single mutation in reverse transcriptase and develops rapidly following virological failure (Hirsch et al, 2003).

Table 37–4 Resistance Mutations to Antiretroviral Medicine

Antiretroviral Medicine	Codon Mutation	
Mutation in reverse transcriptase gene associated with resistance to NRTIs (nucleoside reverse transcriptase inhibitors)		
Multi-NRTI Resistance: 69 Insertion Complex (affects all NRTIs)		
	M41L, A62V, 69, K70R, L210W, T215Y/F, K219O/E	
Multi-NRTI Resistance: 151 Insertion Complex (affects all NRTIs)		
	A62V, V75I, F77L, F116Y, Q151M	
Multi-NRTI Resistance: Thymidine Analogue-Associated Mutations (TAMS; affects all NRTIs)		
	M41L, D67N, K70R, L210W, T215Y/F, K219O/E	
Abacavir (ABC)	K65R, L74V, Y115F, M184V	
Didanosine (ddI)	K65R, L74V	
Emtricitabine (FTC)	K65R, M184V	
Lamivudine (3TC)	K65R, M184V	
Stavudine (d4T)	M41L, K65R, D67N, K70R, L210W, T215Y/F, K219Q/E	
Tenofovir (TDF)	K65R, K70E	
Zidovudine (ZDV)	M41L, D67N, K60R, L210W, T215Y/F, K219Q/E	
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)		
Efavirenz (EFV)	L100I, K101P, K103N/S, V106M, V108I, Y181C/I, Y188L, G190S/A, P225H	
Etravirine (ETV)	V90I, A98G, L100I, K101E/H/P,V106I, E138A/G/K/Q,V179D/F/T, Y181C/I/V, G190S/A, M230L	
Nevirapine (NVP)	L100I, K101P, K103N/S, V106A/M, V108I, Y181C/I, Y188C/LH, G190S/A	
Rilpivirine (RPV)	L100I, K101P, K103N/S, V106A/M, V108I, Y181C/I, Y188C/L/H, G190S/A	

Mutation in the Protease Gene Associated With Resistance to Protease Inhibitors (PIs)		
PIs	*Critical*	*Secondary*
Atazanavir (ATV)	I50L, I84V, N88S	L10I/F/V/C, G16E, K20R/M/I/T/V, L24I, V32I, L33I/F/V, E34Q, M36I/L/V, M46I/L, G48V, F53L/Y, I54L/V/M/T/A, D60E, I62V, I64L/M/V, A71V/I/T/L, G73C/S/T/A, V82A/T/F/I, I85V, L90M, I93L/M

Lopinavir/Ritonavir (LPVr)	V32I, I47V/A, L76V, V82A/F/T/S	L10F/I/R/V, K20M/R, L24I, V32I, L33F, M46I/L, I47V/A, I50V, F53L, I54V/L/A/M/T/S, L63P, A71V/T, G73S, L76V, V82A/F/T/S, I84V, L90M
Nelfinavir (NFV)	D30N, L90M	L10F/I, D30N, M36I, M46I/L, A71V/T, V77I, V82A/F/T/S, I84V, N88D/S L90M
Saquinavir (SQV)	G48V, L90M	L10I/R/V, L24I, G48V, I54V/L, I62V, A71V/T, G73S, V77I, V82A/F/T/S, I84V, L90M,
Tipranavir (TPV)	I47V, Q58E, T74P, V82L/T, I84V	L10V, L33F, M36I/L/V, K43T, M46L, I47V, I54A/M/V, Q58E, H69K/R, T74P, V82L/T, N83D, I84V, L89I/M/V

Mutations in the Envelope Gene Associated With Resistance to Fusion Inhibitors (FIs) and CCR5 Antagonists		
Enfuviritide (T-20)	G36D/S, I37V, V38A/M/E, Q39R, Q40H, N42T, N43D	
Maraviroc (MVC)	Activity limited to CCR5 virus only. CXCR4-CCR5 mixed and CXCR4 viruses do not respond.	
Mutations in the Integrase Gene Associated With Resistance to Integrase Inhibitors (IIs)		
Raltegravir (RAL)	E92Q, Y143R/H/C, Q148H/K/R, N155H	

Adapted from Johnson et al, 2011.

Pretreatment

About one of every six new HIV cases diagnosed in 2007 involved virus with ARV drug-resistance mutations (CDC, 2010). The presence of transmitted medication-resistant viruses, particularly those with nonnucleoside reverse transcriptase inhibitor (NNRTI) mutations, may be responsible for not achieving the treatment goal of HIV suppression of less than 50 copies/mL (Wheeler, Mahle, & Bodnar, 2007). Therefore, pretreatment HIV genotypic resistance testing should be considered in selecting the best ART regimen.

Although covered by most insurance providers, resistance assays are expensive. Clinicians should be familiar with the important considerations and limitations associated with HIV resistance testing (Box 37-4) and be able to explain these to the patient. It is critical that, whenever possible, collection of blood for resistance testing should be performed when the patient is taking ART or within 4 weeks of stopping antiretroviral medicine. Resistance testing is not recommended when viral load (VL) is less than 1,000 copies/mL.

Virological Failure

Virological failure, defined as the failure to achieve or maintain suppression of viral replication to less than 50 copies/mL, may be categorized as either (1) incomplete virological response (as when two consecutive HIV RNAs are greater than 400 copies/mL after 24 wk or when HIV RNA is greater than 50 copies/mL by 48 wk in a treatment-naïve patient who is initiating ART), or (2) virological rebound (when HIV RNA is repeatedly detected at greater than 50 copies/mL after virological suppression). Baseline HIV RNA affects the time course of suppression. Some patients take longer than others to suppress HIV RNA levels. The timing, pattern, and/or slope of HIV RNA decrease may predict ultimate virological response (Weverling et al, 1998).

Unfortunately, there is no consensus on the optimal time to change ART when virological failure occurs. The more aggressive approach is to change the medication regimen for any repeated detectable viremia after suppression to less than 50 copies/mL in a patient taking ART. Again, an assessment of adherence is essential. Other approaches for when to change ART allow for detectable viremia up to an arbitrary level (e.g., 1,000 to 5,000 copies/mL when resistance testing can more easily be performed). However, ongoing viral replication in the presence of ART promotes the selection of drug-resistance mutations (Barbour et al, 2002) and may limit future ART options. Isolated episodes of viremia ("blips," e.g., single levels of 51 to 1,000 copies/mL) may simply represent laboratory variation (Nettles et al, 2005) and are not usually associated with subsequent virological failure. Rebound to higher viral load levels or more frequent episodes of viremia increase the risk of failure (Greub et al, 2002).

Causes of ART Failure

Although ART is highly successful, it is not without failure. Many factors are associated with an increased risk of ART treatment failure (Box 37-5). Suboptimal adherence and toxicity

---

BOX 37–4   HIV DRUG RESISTANCE TESTING: EIGHT IMPORTANT CONSIDERATIONS AND LIMITATIONS

1. Biological cutoffs are based on normal distribution of susceptibility to drug for wild-type strain from treatment-naïve patients.
2. Clinical cutoffs are based on data from clinical trials or cohort studies to determine change in susceptibility that results in reduced virological response.
3. Clinical phenotypic cutoff values include diminished versus no response; partial activity may be useful when treatment options are limited. Analysis complicated by prior drug exposure and activity of other drugs in salvage regimen.
4. Consider phenotyping over genotyping when treatment history is complex and/or significant resistance is expected.
5. May detect resistance only in species that make up more than 10% to 20% of viral population.
6. Measures susceptibility to individual medicines, not medication combinations.
7. Phenotypic resistance reported as fold change in IC_{50} for the test strain versus reference wild-type strain.
8. Testing should be performed on therapy whenever possible or within 4 weeks of stopping antiretroviral medicines and is not recommended when VL is less than 1,000 copies/mL.

BOX 37–5   FACTORS ASSOCIATED WITH ART FAILURE

Patient factors at baseline:
- AIDS diagnosis
- Comorbid conditions (e.g., affective mental health disorders and active substance use)
- Earlier calendar year of starting ART when less-potent regimens or more poorly tolerated antiretroviral medicines were used
- Higher pretreatment HIV RNA level (regimen-specific)
- Lower pretreatment or nadir CD4 T-cell count
- Pretreatment drug-resistant virus
- Prior ART failure, with development of drug resistance or cross-resistance
- ART adverse effects and toxicity
- Nonadherence to ART and medical appointments
- Suboptimal pharmacokinetics caused by variable absorption, metabolism, and/or penetration into HIV reservoirs, food or fasting requirements, adverse drug–drug interactions with concomitant medications and foods
- Suboptimal potency of the ART regimen
- Unknown causes

may account for 28% to 40% of treatment failures and regimen discontinuations (D'Arminio Monforte et al, 2000). Multiple risk factors for treatment failure can occur simultaneously. Factors not associated with treatment failure include gender, pregnancy, and history of past substance use.

When ART failure occurs, determining the cause(s) is essential. Candid conversation with the patient and his or her family member(s) coupled with investigation of pharmacy records allows the clinician to explore the various risk factors for ART failure. In assessing ART failure, it is important to identify as many contributing factors as possible. Careful identification of the reasons for failure allows the clinician to address patient needs more effectively and reduces the potential for subsequent ART failure.

Other circumstances should be considered when assessing for virological failure and planning for optimal patient outcomes. In some patients with extensive prior treatment and drug resistance (e.g., when new ART that contains at least two fully active agents cannot be identified), viral suppression below 50 copies/mL is difficult to achieve. When maximal virological suppression cannot be achieved, the goals are to preserve immunological function and to prevent clinical progression. Even partial virological suppression of HIV RNA greater than $0.5 \log_{10}$ copies/mL from baseline is associated with clinical benefits (Murray, Elashoff, Iacono-Connors, Cvetkovich, & Struble, 1999). However, these marginal benefits must be balanced with the ongoing risk for accumulating additional resistance mutations. It is reasonable to maintain a patient on the same regimen, rather than changing the regimen, depending on the stage of HIV disease.

DISCONTINUATION OR INTERRUPTION OF ANTIRETROVIRAL MEDICATIONS

Discontinuation or interruption of ART is associated with HIV viral rebound, immune decompensation, and clinical progression. Similarly, discontinuation of ART regimens containing emtricitabine, lamivudine, or tenofovir in patients with hepatitis B co-infection may experience an exacerbation of hepatitis on ART discontinuation (Bessesen, Ives, Condreay, Lawrence, & Sherman, 1999). Nonetheless, unplanned interruption of ART may become necessary for a number of reasons. Concurrent illness, severe drug toxicity, surgery that precludes oral therapy, and antiretroviral medication nonavailability are some of the common reasons patients discontinue ART. Potential risks and benefits of interruption vary according to a number of factors, including the clinical and immunological status of the patient, the reason for the interruption, the type and duration of the interruption, and the presence or absence of resis - tant HIV at the time of interruption.

Monitoring

Although ART prolongs life and improves quality of life by suppressing HIV replication and decreasing symptoms of uncontrolled HIV, ART is potentially harmful if not periodically monitored. Monitoring is multidimensional in the care of an HIV-infected patient. In addition to monitoring the effectiveness of ART, it is a standard of care to monitor the following:

- Adherence to medications and medical visits
- Affective mental health problems
- Alterations in metabolism of lipids and glucose
- Cardiovascular risk
- Hepatitis B and C co-infection
- High-risk behaviors
- Immunization status
- Renal and hepatic function
- Sexually transmitted infections
- Somatic signs and symptoms
- Tobacco, alcohol, and substance use

Plasma HIV RNA by PCR or "viral load" measures the effectiveness of ART to control viral replication. Sequential measurement of the CD4 count is performed to determine the degree of immune system reconstitution. When available, a viral load test is performed shortly after ART is started. If the treatment is working effectively, the viral load will drop to below the level of detection—less than 50 copies/mL. Ideally, this occurs within 24 weeks of initiating ART, but for some patients it can take 6 months. Viral load tests are performed every few months. As there can be some variability in viral load test results, they are monitored over a period of time. An increase in viral load may be followed by a fall in CD4 count and a greater risk of developing opportunistic infections. If viral load is increasing, it is important to determine the cause. Causes for loss of virological control are usually related to impaired medication adherence, drug interactions, altered medication absorption, and development of drug resistance.

OUTCOME EVALUATION

The patient-lived experience of HIV disease and the medications used to treat it are uniquely individual. Patients present to care at various stages of the disease, frequently challenged by multiple life circumstances that complicate the treatment plan. These challenges include, among others, active substance abuse, chronic pain, comorbid medical conditions, domestic violence, lack of child care, lack of health insurance, lack of transportation, mental illness, nonadherence to ART and provider visits, opportunistic infection(s), pregnancy, sexual abuse, stigma, unstable living conditions, and victimization. These challenges require a multidisciplinary team to optimize patient outcomes. Owing to complex social and medical problems, optimal patient outcomes are difficult to achieve. Thus, it is critical to formulate attainable treatment plans that are appropriately adapted to the individual patient and his or her living situation. A variety of personal and system barriers can potentially diminish patient resolve and confidence in lifelong treatment with ART. Positive predictors of success entail adherence to ART and routine surveillance for effectiveness of therapy and its potentially harmful events.

Although the path to treatment success is arduous without access to specialty HIV health care and modern ART, and drug toxicities and resistance continue to be formidable challengers, effective, well-tolerated therapies coupled with a pipeline of

On The Horizon — FIVE DRUGS FOR THE FUTURE

New HIV-drug development continues.

- **GS-7340** (tenofovir alafenamide, TAF), a new oral pro-drug, was well tolerated and had better antiviral activity at lower doses than tenofovir disoproxil fumarate (Viread, TDF) in early studies. Reportedly, in 38 people over 10 days, 25 mg of GS-7340 outperformed 300 mg of the currently approved tenofovir formulation. Along with fewer side effects, GS-7340 showed higher potency, which could mean longer and better viral suppression over time.

- **Dolutegravir** (GSK-572) is an investigational integrase inhibitor, but it has distinguished itself from the two approved integrase inhibitors, raltegravir (Isentress) and elvitegravir. Dolutegravir has a long half-life of 15 hours, indicating it can be taken once a day. It does not require pharmacokinetic boosting. Although resistance can occur, dolutegravir shows activity against raltegravir- and elvitegraivr-resistant viral strains. The drug may be coformulated in a once-daily pill with abacavir and lamivudine.

- **S/GSK-1265744 (744)**, an integrase inhibitor similar to dolutegravir, shows high potency and an exceedingly long half-life. Orally at once-daily doses of 30 mg, patients showed a median 2.6 log reduction in viral load. Interestingly, when using nanotechnology to formulate 744 to be injected subcutaneously or intramuscularly, a single dose showed a half-life between 21 and 50 days. After a single dose, patients had detectable levels of 744 up to 48 weeks after injection. Like dolutegravir, 744 seems to have a high barrier to drug resistance. 744 showed activity against raltegravir- and elvitegraivr-resistant viral strains. In terms of safety, there were some injection-site reactions and nodules associated with subcutaneous dosing. But conceivably, 744 could be taken as infrequently as every 3 months for treatment, or even as PrEP (pre-exposure prophylaxis).

- **Cenicriviroc (CVC),** an investigational CCR5 antagonist, not only antagonize CCR5 binding, it also antagonizes CCR2 binding. CCR2 is a receptor that sits on the surface of macrophages and may be involved in inflammation. CVC showed potent antiretroviral activity. Cenicriviroc has been found to be well absorbed and within the expected therapeutic range of potency. Further studies will assess the safety, efficacy, and effect of CCR2 inhibition on inflammatory biomarkers.

- **Albuvirtide** is a fusion inhibitor like enfuvirtide that offers a lot of activity against HIV but requires twice-daily injections. Albuvirtide, on the other hand, is an investigational fusion inhibitor that when given intravenously has a long average half-life of 11 days, warranting weekly dosing. Albuvirtide has a similar design to enfuvirtide. It is a peptide that is an analogue of gp41, one of the envelope proteins on HIV's surface, and thereby blocks HIV through CD4 membrane fusion. In very early studies, Albuvirtide was generally well tolerated, with no injection-site reactions and no serious adverse events.

evolving new medications herald a bright future for those chronically infected with HIV. HIV clinicians have immediate Internet access to current comprehensive treatment guidelines from the U.S. Department of Health and Human Services (DHHS) and the International AIDS Society—USA (IAS-USA).

CONCLUSION

Medical care for HIV-infected persons has grown increasingly complex and is beyond the scope of this chapter. However, a multiplicity of available resources exists to assist clinicians in providing high-quality care to their HIV-infected patients. The U.S. Department of Health and Human Services AIDSinfo Web site (http://www.aidsinfo.nih.gov/) is a dependable source of up-to-date information for the following:

- Fact sheets on HIV/AIDS-related drug interactions
- HIV treatment guidelines
- Locating resources on HIV/AIDS-related topics
- Preventive and therapeutic HIV vaccine research
- Research studies on investigational drugs, vaccines, and other new or existing treatments for HIV/AIDS

The Health Resources and Services Administration (HRSA) also provides multiple HIV medical care performance measures at ftp://ftp.hrsa.gov/hab/habGrp1PMs08.pdf. These performance measures can be used to help establish and measure the quality of HIV care being rendered. The performance measures include the following:

- ART adherence assessment and counseling
- ART for pregnant women
- Cervical cancer screening
- Frequency of CD4 measurement
- Hepatitis B vaccination
- Hepatitis C screening
- HIV risk counseling
- Lipid screening
- Medical evaluation visits
- Oral examination
- PCP prophylaxis
- Prescription of ART
- Syphilis screening
- TB screening

The following recommendations and treatment guidelines from the Centers for Disease Control and Prevention are also available at www.cdc.gov/hiv/resources/guidelines/index.htm:

- *A Guide to Primary Care for People With HIV/AIDS*
- *A Guide to the Clinical Care of Women With HIV*
- *Adults and Adolescent Treatment Guidelines*
- *Appendix: Recommendations to Help Patients Avoid Exposure to or Infection From Opportunistic Pathogens*
- *Co-Infection Guidelines*
- *Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents*
- *Interim Guidance—HIV-Infected Adults and Adolescents: Considerations for Clinicians Regarding Swine-Origin Influenza A (H1N1) Virus*

- *MMWR: Guidelines for the Prevention and Treatment of Opportunistic Infections Among HIV-Exposed and HIV-Infected Children*
- *Pediatric Treatment Guidelines*
- *Perinatal Guidelines*
- *Sexually Transmitted Diseases Treatment Guidelines*
- *Tuberculosis Treatment Guidelines*

HIV DISEASE

PATIENT EDUCATION

Related to the Overall Treatment Plan/Disease Process

☐ After diagnosis, patients need to be educated regarding what it means to be HIV positive (they are infected with the HIV virus) versus what AIDS is (their immune system has been affected and they are at risk for life-threatening infections).

☐ Patients need education regarding the chronicity of HIV treatment. The clinician may make an analogy of HIV disease to diabetes; diabetics need insulin for the rest of their life and patients with HIV disease must take their medications daily for the rest of their lives.

☐ HIV-infected patients need to be vaccinated with the recommended adult vaccines, including an annual **influenza vaccine**.

☐ Symptoms of opportunistic infections should be discussed so that patients receive early treatment.

Specific to the Drug Therapy

☐ Highly active antiretroviral therapy (HAART) is a combination of medications and all should be taken together as prescribed to decrease viral load.

☐ Adherence to HAART is critical to prevent the development of drug resistance.

Reasons for Taking the Drug(s)

☐ Prevention of serious complications from AIDS.

☐ Prevention of transmission of infection to the uninfected (public health issue).

Drugs as Part of the Total Treatment Regimen

☐ Importance of seeking treatment when symptoms appear.

☐ Patients need routine preventive care, including lipid monitoring, cardiovascular health screening, cervical cancer screening, STI screening, and immunizations.

Adherence Issues

☐ Importance of following the HAART treatment regimen instructions to prevent resistance and to keep viral loads low.

☐ Importance of contacting the health-care provider if side effects or rash appears.

☐ The potential for drug interactions.

HORMONE REPLACEMENT THERAPY AND OSTEOPOROSIS

Marylou V. Robinson

HORMONE REPLACEMENT THERAPY

Hormone replacement therapy (HRT) may be instituted any time there is loss of the body's ability to produce estrogen and progestin. This would include surgical removal of the ovaries as well as menopause. The term ERT is used to differentiate estrogen-only replacement therapy. General recommendations from the American Academy of Obstetricians and Gynecologists (ACOG), the American Society of Reproductive Medicine, the National Association of Nurse Practitioners in Women's Health, the North American Menopause Society, and the U.S. Preventative Services Task Force (USPSTF), along with the U.S. Food and Drug Administration (FDA), support the use of ERT/HRT for the treatment of moderate to severe menopausal symptoms.

The use of ERT/HRT to treat and prevent other chronic illness, with the exception of osteoporosis, is no longer encouraged (USPSTF, 2013). Consideration of alternative osteoporosis treatments for women who are not also experiencing menopausal symptoms must be made. Current use guidelines for ERT/HRT propose utilizing the lowest dose of hormones for the shortest duration possible to help increase the quality of life and decrease the sometimes dramatically disruptive symptoms of menopause. The Woman's Health Initiative (WHI) results and subsequent guidelines indicate that replacement therapy for up to 5 years is reasonably safe (Writing Group for the Women's Health Initiative [WHI] Investigators, 2002).

The WHI, which was started in 1991 and planned a longitudinal study of participants over 15 years, took the broadest look at all the purported health benefits of HRT and ERT. The HRT arm of the study was stopped in 2002 due to a negative risk-to-benefit ratio showing an increased incidence of heart disease, stroke, thromboembolic events, and breast cancer among women taking HRT agents of conjugated estrogen (Premarin) and medroxyprogesterone. The ERT arm was also stopped early in 2004 because of increased risk of stroke in women taking estrogen only. Age-cohort analysis of the WHI data suggests that the timing of initiation of ERT/HRT may play a role in coronary heart disease (CHD) risks. Women who initiate ERT/HRT at the time of menopause appear to be at less risk to develop CHD related to ERT/HRT use. Experts suggest that lower doses of hormones may be adequate to control the symptoms of menopause and not significantly raise the risk of CHD. See Box 38-1.

Pathophysiology

Between the ages of 42 and 56, most women experience a decline in ovarian hormone function, with the resultant natural cessation of menses. At menarche, the ovary starts production of three steroids: estrogen, progestin, and androgen. These three steroids have a dramatic effect on the brain, hypothalamus, pituitary, and the ovary itself. Sex hormones play an important role in the dynamic process of the formation and remodeling of neuronal circuits and neurotransmitters. The target organs of ovarian steroids are the uterine epithelium, the uterine tubes, the breasts, and the vagina. However, these hormones also play other important roles in the body.

In young women, the predominant hormone produced is 17β estradiol, the most biologically active estrogen. After menopause, there is more estrone, a derivative of estradiol. Adipose tissues have a major role in how much estrone is produced; hence the observed difference in menopausal symptoms can vary in thin versus obese women. Estriol is the least active and shortest-acting estrogen.

There are two major estrogen receptors, α and β. The alpha receptors are more plentiful in the breast, endometrium, and ovary. The beta receptors are found in bone, lung, and kidney and in many supporting tissues all around the body. Estrogen is not a reproductive-only active hormone. Its widespread impact creates the multisystem symptoms of menopause when levels naturally drop at the time of the climacteric.

Physiological Effects of Estrogen

Effects of estrogen on the reproductive system include maturation of reproductive organs; development of secondary sexual characteristics; regulation of menstrual cycle; and endometrial regeneration postmenstruation. Estrogen also affects closure of long bones after the pubertal growth spurt; maintains bone density by decreasing rate of bone resorption through antagonizing the effects of parathyroid hormone (PTH); maintains normal structure of skin and blood vessels through its actions on the endothelial cells in the arterial walls, including the induction of nitric oxide to facilitate vasodilation and oxygen uptake by cells; alters plasma lipids (increased high-density lipoprotein [HDL], slight reduction in low-density lipoprotein [LDL], reduced total cholesterol, increased triglycerides) through its action in the liver; reduces motility of the bowel through its modulation of sympathetic nervous system control over smooth muscle; alters production and activity of selected proteins resulting in higher levels of thyroxine-binding globulin, sex-hormone binding globulin, transferrin, and renin substrate; enhances coagula -bility of blood by increasing the production of fibrinogen; and facilitates loss of intravascular fluid into extracellular space by its action on the renin-angiotensin-aldosterone cycle (retention of sodium and water by the kidney) resulting in edema and decreased extracellular fluid (ECF) volume. In the brain, estrogen maintains stability of the thermoregulatory center. Decline in this function results in acute activation of the sympathetic nervous system and vasomotor instability, causing hot flashes.

Knowledge of the actions of estrogen on areas of the body beyond the reproductive organs combined with the epidemiological evidence of increased incidence of cardiac and related disorders postmenopause leads to the assumption that the lack of endogenous estrogen might be a major contributing factor to this increased incidence. From that conclusion, it was logical to assume that the administration of exogenous estrogen would prevent this problem. Subsequent randomized controlled trials (RCTs) found some flaws in this assumption and even found that use of replacement hormones increased the cardiovascular risk among women. The Heart and Estrogen/Progestin Replacement Study (HERS) studies found that neither ERT nor HRT increased nor decreased the incidence of CHD. The WHI study was halted early due to findings of a statistically significant increased incidence of CHD, stroke, thromboembolic events, and breast cancer in women taking HRT, and an increased incidence of stroke in women taking ERT. These results challenged the traditional use of ERT and HRT and raised significant clinical questions in the pharmacological management of postmenopausal women. As a result, the use of ERT and HRT to prevent cardiovascular disease is no longer recommended (USPSTF, 2013).

The concerns that having a hysterectomy, even without adding ERT/HRT afterward, could increase CHD appear to have been put partially to rest. The surgical menopause of having one or both ovaries removed has been tracked over 11 years in the SWAN study (Mathews, Gibson, El Khoudray, & Thurston, 2013). No additional heart disease risk, after a short rise after surgery, has come to light. Women over the age of 65 were not enrolled in this analysis. With the risk of CHD being highest after 65, transfer of these findings cannot be made to this overall higher-risk group.

From the PEPI (Post-menopausal Estrogen/Progestin Interventions) study through the WHI, studies looking at bone density and estrogen use consistently support the role of estrogen in the prevention of bone loss. Even relatively low doses of estrogen appear to have a beneficial effect on bone. The use of estrogen to prevent osteoporosis is discussed in detail below.

Physiological Effects of Progestin

Effects of progestin on the reproductive organs include thickening of the endometrium and increasing its complexity in preparation for pregnancy; thickening of cervical mucus; thinning the vaginal mucosa; and relaxation of smooth muscles of the uterus and fallopian tubes. During pregnancy, progestin maintains the thickened endometrium, relaxes myometrial muscles, thickens the myometrium for labor, is responsible for placental development, and prevents lactation until the fetus is born. In the absence of pregnancy, the reduced production of estrogen and progestin by the corpus luteum results in the shedding of the endometrium to produce menstruation. Progestin is also responsible for alveolobular development of the secretory apparatus of the breast. It also has actions outside the reproductive system. It stimulates lipoprotein activity and seems to favor fat deposition; increases basal insulin levels and insulin response to glucose; promotes glycogen storage in the liver; promotes ketogenesis; competes with aldosterone in the renal tubule to decrease Na+ resorption; increases body

temperature; and increases ventilatory response to CO_2, resulting in a measurable decrease in $PaCO_2$. The latter occurs only during pregnancy.

Thickening of the endometrium related to estrogen stimulation is thought to increase the risk for endometrial cancer, and studies have supported a direct correlation between ERT use and an increased incidence of endometrial cancer (Thorneycroft, 2004). To prevent this occurrence, progestins have been added to HRT as a way to oppose the effects of estrogen on the endometrium and prevent endometrial hyperplasia. Topical progesterone creams and gels, however, do not reach the serum levels required to provide this protection (Pattimakiel &Thacker, 2011). The endometrial estrogen-related cancer risk is also correlated with estrogen dose and length of exposure. Thin women appear to be at greater risk (Brinton & Felix, 2013). These data, combined with the results of the HRT arm of the WHI, have raised concerns about whether the traditional combination estrogen-progestin therapy in a continuous mode is appropriate and are leading factors that contributed to the recommendations to use the lowest dose for the shortest duration possible, and limit treatment to less than 5 years.

Physiological Effects of Androgens

In the female, small amounts of androgens are produced in the ovary and the adrenal gland. Some are precursors to estrogen (androstenedione), serving as an alternate route to estrogen production. At puberty, androgens contribute to the skeletal growth spurt and growth of pubic and axillary hair, activate sebaceous glands (acne), and play a role in libido. Administration of exogenous androgens during menopause is often related to the role they play in skeletal growth and libido.

Menopausal Changes in Hormones

Perimenopause is the transitional period between reproductive and nonreproductive years. During this time approximately 90% of women experience extreme variability in frequency and quality of menstrual flow (McCance & Huether, 2014). Commonly, women experience a short cycle with a shortened follicular phase, ovulation, and insufficient luteal phase; followed by a long cycle with an extended follicular phase, anovulation, and high estradiol levels in the premenstrual phase; followed by a short follicular phase and an anovulation cycle. Perimenopausal cycles are correlated with elevated and irregular follicle-stimulating hormone (FSH), decreased inhibin, normal luteinizing hormone (LH), and slightly elevated estradiol levels. All of these are associated with reduced follicular genesis. The perimenopausal period may last for up to 10 years in some women, during which time hormone levels continue to fluctuate.

Menopause is a period of time in which no menses occur for 12 consecutive months when estrogen and progestin are low, despite FSH and LH levels that are increased due to lost ovary function. If left intact, the postmenopausal ovary continues to produce androgens. These androgens, as well as those from the adrenal gland, are then converted in fatty tissues into less potent estrogens: estrone and estriol. This peripheral

conversion of androgens may vary greatly. This variation in peripheral conversion contributes to the spectrum of menopausal symptoms encountered in practice—some women pass through menopause with limited symptoms, whereas others experience severe vasomotor and vaginal symptoms.

These altered levels of hormones result in the symptoms common to the perimenopausal and postmenopausal period. Vasomotor symptoms, which typically begin during the perimenopausal transition, are actually caused by rapid changes in estrogen levels rather than low levels and tend to abate gradually over time for postmenopausal women. ERT/HRT are effective treatments for these symptoms, and data still support the use of both of these replacement therapies for this indication. Breast tissue involutes, yielding a moderate decrease in mammary tissue during perimenopause, and there is significant reduction in glandular breast tissue with an associated increase in fat deposits and connective tissue. Administration of exogenous estrogen (ERT) and HRT is associated with increased risk for breast cancer; however, the data regarding the relative risk of breast cancer among ERT/HRT users have been inconsistent. For women at increased risk of breast cancer, ERT/HRT is contraindicated. The immediate drop in breast cancer incidence following the WHI report has not been sustained, making some experts doubt the true nature of the breast cancer and estrogen risk (Shapiro, Farmer, Stevenson, Burger, & Mueck, 2012).

The urogenital tract also undergoes changes, but this tends to occur later than the vasomotor symptoms. The uterus atrophies and decreases in size. The vagina narrows, shortens, and loses some of its elasticity. Vaginal walls lose their ability to lubricate quickly. Intercourse may become painful. The vaginal pH increases, contributing to a higher incidence of vaginitis. The vaginal epithelium also atrophies, resulting in vaginal irritation, burning, itching, white discharge, and vaginal bleeding. Dyspareunia also results. Urethral tone declines and is associated with an increased risk for urinary frequency, urgency, and incontinence. Topical estrogen has been effective in helping to relieve these symptoms.

Other postmenopausal changes also occur outside the reproductive system. Bone mineral density is reduced, cardiovascular disorders increase, and the risk for various cancers increases. Some of these increased risks can be associated with normal aging, which makes it difficult to directly correlate them with loss of female hormones. In the past, ERT and HRT have been used in an attempt to prevent these disorders. However, large-scale studies have questioned the efficacy and safety of some of these uses.

After the WHI study, the pendulum has swung back and forth on the issue of whether to recommend ERT/HRT. A consensus statement made by the American Society for Reproductive Medicine, the Asia Pacific Menopause Federation, the Endocrine Society, the European Menopause and Andropause Society, the International Menopause Society, the International Osteoporosis Foundation, and the North American Menopause Society (NAMS) all agree that HRT should be used as the best solution for symptomatic menopause. The dose used should be the lowest possible to

achieve a reduction of symptoms for individuals. One size does not fit all (NAMS, 2012).

Pharmacodynamics

Estrogens

Estrogen occurs naturally in the body in three forms: estradiol, estrone, and estriol. Estradiol (17β-estradiol) is the most potent and plentiful and is principally produced by the ovaries. The ovaries also produce estrone. Androgens are converted to estrone in ovarian and peripheral adipose tissue. Estriol is the principle metabolite of estrone and estradiol. Most all of the estrogens prescribed for ERT are estradiol, although there are formulations of estrone as well as combinations of estradiol and estrone.

Estradiol formulations are available as conjugated equine estrogen, which is marketed as Premarin, and as esterified estrogen (Menest). Both are taken orally. Premarin 0.625 mg, the most commonly prescribed dose, was the estrogen used in the WHI. Estradiol is also available in oral, injectable/depo, transdermal, and topical formulations (see Chapter 22). Oral drugs are subject to extensive metabolizing through the liver; this may explain some of their effects on lipids and coagulation factors. In contrast, the topical and transdermal formulations are not subject to first-pass metabolism and so have fewer associated changes in coagulation and changes in lipids. Transdermal meds are considered safer.

Estrone formulations include synthetic conjugated estrogen-A (Cenestin) and synthetic conjugated estrogen-B (Enjuvia). Both of these forms derive their estrogen from plant sources but are still manufactured in a laboratory. Plant-derived estrogens have not been shown to have reduced adverse effects over other estrogen sources.

A complexity of hormone therapy is that each of these chemicals has different interactions with the estrogen receptors in the body. Frustratingly, how likely a drug is to bind to a receptor is not correlated with how "potent" it is in creating a therapeutic change. High-affinity drugs with large amounts of 17β-estradiol can have the same impact as a low dose of a medication with low receptor affinity given over a longer time period. This creates many moving parts hard for nonspecialists to grasp, thereby they tend to prescribe a few medications and "hope for the best." Dissatisfied patients have migrated toward having an individualized dosing regimen provided to them using bioidentical and/or compounded substances.

Progestogens

Medroxyprogesterone (MPA) is the primary exogenous progestin prescribed, either alone or in combination with estrogens. It is a synthetic hormone manufactured and branded as Provera. It was the drug used in combination with estrogen (Prempro) in the WHI. Norethindrone (Aygestin) is another frequently used progestin. Their actions are similar to those of the body's own hormone. Two plant-derived "natural" hormones have FDA approval: micronized progesterone (Prometrium), which is taken orally, and Prochieve (also sold under the brand name Crinone), which is a bioadhesive vaginal gel. Use of the latter for hormone replacement is off-label; it has been approved for use in infertility and secondary amenorrhea. Like synthetic progestins, these "bioidentical" hormones are manufactured in the laboratory, so they are synthetic too.

Prescribers are cautioned not to interchange the name progesterone with progestin. MPA was the progesterone used in Prempro, which became the focus of the WHI warning and subsequent aversion to HRT. The other forms of progestogens have less severe chemical and biological impacts on risks such as cancer and inflammatory changes. MPA has a much higher level of bioavailability. Hence, research underway is trying to clarify if the strong warnings about MPA should also extend to the rest of the drug class. This is complex because the various progestogens differ in the way they interact with the receptors. This variance is the basis for the belief that there will be different breast cancer and cardiovascular endpoints; however, that evidence does not yet exist. What is understood, is that progesterone delivered topically does not generate enough antiproliferative impact on an intact uterus to prevent estrogen-induced hyperplasia (Pattimakiel & Thacker, 2011).

It should be noted that the FDA reserves the term *bioidentical* to substances made in compounding pharmacies. Unfortunately, the literature does not adhere to this definition. The more recent issues of quality and lack of standardization of compounding pharmacies makes use of these medication sources something that requires caution. Compounding has a real benefit for creating doses of ERT/HRT for women who are allergic to peanuts and other tree nuts; the micronized FDA forms of progesterone uses a peanut oil base.

All FDA-approved medications require notification to consumers about potential risky side effects. The compounding pharmacies are not required to do so. Because there are no lengthy precautionary handouts, women can get the impression they are somehow safer than the FDA drugs. This is inherently false, because many of the compounding recipes use the exact same ingredients as found in the formulary drugs, including the medications of concern in the WHI. Unlike the WHI medications, the other formulations of estrone, estradiol, and nonconjugated estrogens and other progestins have not been placed under the same level of scrutiny. The lack of longitudinal research cannot be falsely assumed to mean they have less risk (Flies, Ko, & Pruthi, 2011). Determination of less risk cannot be based on shorter-term observational studies. Likewise, there is no reason to believe these drugs offer higher risk. Prescribers are cautioned to counsel patients that we do not know the risk profile.

The American Society of Reproductive Medicine and ACOG have doubts that there are any real benefits from using these products and believe there are some risks associated with quality and purity issues. There are no known head-to-head studies. The major menopause societies do not recommend their use. Off-label use of medications brings inherent legal risk as well. The addition of substances such as DHEA, thyroid hormone, and androgens creates a more complex interaction with a women's physiology that has not been evaluated in controlled studies.

Goals of Treatment

The aim of ERT and HRT is to provide relief from symptoms associated with menopause. Under this general umbrella, the goals are to:

- Prevent or reduce vasomotor symptoms
- Prevent or reduce vaginal atrophy associated with estrogen decline
- Reduce the risk for osteoporosis
- Ensure that the benefits of ERT/HRT outweigh the risk associated with treatment by providing comprehensive pretreatment evaluation of contraindications and risk, and assisting women in making informed decisions about therapy

Treatment of menopausal symptoms and reduction of postmenopausal bone loss with hormone therapy, by prescription medications or herb supplements, have risks that require careful selection and screening of patients. Each woman should be assessed for the presence and severity of vasomotor and vaginal symptoms and screened for contraindications to therapy and predisposing diseases/risks that would increase the likelihood of an adverse event(s). Patient education requires comprehensive discussion of the current risk and benefits of therapy, the current indications for therapy (as these indications are evolving), review of practice recommendations regarding lowest effective dose for the shortest duration of time, and requirements for interval screening and follow-up while on therapy. Clinicians should be prepared to discuss details of the research findings heralded in the media as well as critically appraise an individual's risk for adverse events. A full review of the range of treatment options available, including the option for herbal therapies and the option not to engage in therapy, is critical in the management of women in the perimenopausal to postmenopausal years. The use of ERT/HRT is an intensely personal, emotional decision for many women since the release of the WHI findings. It is no longer acceptable to automatically put all perimenopausal and postmenopausal women on essentially the same drug at essentially the same dose. Individualizing treatment options around patient preference, risk/benefit profiles, and research findings will continue to shape clinical practice.

Clinicians need to assist patients in making rational decisions about the use of medication therapy in menopause. To assist both the prescriber and the patient in making informed choices, the following questions should be considered: What are the personal benefits of using ERT or HRT? How severe are the symptoms—and what are the key symptoms that need to be treated? What are the risks specific to this individual patient's situation? What health history, lifestyle, or family genetic factors could influence the safety of ERT/HRT therapy? Does the patient wish to investigate pharmaceutical options at this time? What alternative options—such as sleep aids, bisphosphonates, antidepressants, herbal preparations, or lifestyle changes—would be appropriate alternatives to ERT/HRT?

For women who elect to use ERT/HRT, annual risks, benefit assessments, and quality-of-life issues need to be considered each year when prescriptions are renewed for perimenopausal and postmenopausal hormonal therapy. In addition, nonpharmacological behaviors such as weight loss, smoking cessation, reduced alcohol intake, regular exercise, and healthy dietary habits need to be encouraged at all office visits.

Rational Drug Selection

General consensus recommendations from the leading national organizations of clinicians who care for women, along with those of the U.S. Preventative Services Task Force and the FDA, were presented earlier in this chapter. The consensus supports the use of ERT/HRT for the treatment of moderate to severe menopausal symptoms using the lowest dose of hormones for the shortest duration possible.

In general, the following recommendations concerning HRT or ERT can be made:

1. Use the lowest dose that relieves the symptoms for the shortest time frame. The optimal time frame appears to be up to 5 years.
2. Individualize the choice of drug and dose based on the woman's risk profile.
3. Monitor women at least annually for changes in risk profile, development of adverse effects, and continued need for therapy.
4. Only start HRT at the time of menopause onset. A disproportionate number of adverse effects in the WHI occurred in women who were postmenopause several years when HRT was initiated and/or restarted.

Historically, ERT/HRT had been used to treat conditions other than symptomatic management of menopausal symptoms. Prescribers should understand that outdated information might still be found in older references and Web sites and be able to counter the requests for supplements other than those currently approved. The nonvasomotor and nonvaginal historical reasons for initiating ERT/HRT are briefly outlined below.

Cardiac Disease Prevention

Because women have traditionally been regarded as "protected" from cholesterol and CV events compared to men, ERT and HRT were promoted to extend this "protection" beyond menopause. Evidence demonstrates the opposite: ERT/HRT should not be used to prevent CHD and care should be used in prescribing it to women who have cardiac risk factors (see below).

Osteoporosis Prevention

HRT and ERT have both consistently demonstrated a decreased risk for osteoporosis and hip fracture. Estrogen-containing therapies continue to be indicated for the prevention and treatment of osteoporosis in postmenopausal women with menopausal symptoms and risk for bone loss. HRT is not used solely for the prevention or treatment of osteoporosis. In women without concurrent vasomotor menopausal symptoms, therapy should be undertaken with other osteoporosis agents

because of the risks associated with hormonal treatments and the excellent track record of these agents in sustaining bone density. Osteoporosis and its treatment are discussed later in this chapter. Hormones and osteoporosis agents can be used together for severe cases.

Cognitive Performance, Sleep Disturbance, and Skin Changes

Data on the effects of HRT or ERT on cognitive changes associated with Alzheimer's disease, on insomnia, and on skin changes such as wrinkles are inconsistent. The Women's Health Initiative Memory Study (WHIMS), a substudy of WHI (Chlebowski et al, 2003) reported an increased risk of developing probable dementia in postmenopausal women 65 years of age or older during 5.2 years of treatment with daily conjugated estrogen 0.625 mg alone and during 4 years of treatment with daily conjugated estrogen 0.625 mg combined with MPA 2.5 mg, relative to placebo. It is unknown whether this finding applies to younger postmenopausal women. The "protection" against an aging brain is not supported.

Relief of Perimenopausal and Postmenopausal Symptoms

Relief of menopausal symptoms can be dramatic after the initiation of hormonal therapy. The benefits of short-term hormone use may very well outweigh the small risk over a short time. Women may report feeling more in control of their bodily functions, exhibit improved emotional stability, and reestablish sleep patterns. Dyspareunia and vaginal irritation due to vaginal atrophy improve. Urogenital tissue response to estrogen treatment often relieves urinary urgency. A small percentage of women using ERT/HRT report headaches, fluid retention, breast tenderness, and erratic menses.

The various formulations of estrogen are discussed in Chapter 22. For women who have no objections to estrogens from animal sources, conjugated equine estrogen (Premarin) is available in doses from 0.3 mg to 1.25 mg. Suppression of hot flashes has been shown to be best at 0.625 mg, followed by 0.45 mg and 0.3 mg/d (Liu, 2004). Vasomotor symptoms begin to decrease by week 2 of therapy and reach maximal effect by week 8 of therapy. Dosage increases should not occur, however, until at least a 6 to 8 week interval to give the drug time to reach maximal effect at the dose.

When initiating therapy for any age group, begin with low doses (0.3 mg) every other day for 2 months. Next, increase the estrogens to daily use for another 2 months. Progestin must be included in the treatment regimens above if the patient has a uterus. If symptoms such as bleeding or breast pain do not occur, increase the estrogen to 0.625 mg daily if vasomotor symptoms or vaginal atrophy have not resolved. Some women may need only the lower estrogen dosages as long as they have adequate diets.

Micronized estradiol (Estrace, Gynodiol) is the only bioidentical estrogen-alone product available in pill form. It is available in 0.5 mg to 2 mg. Suppression is found at 1 mg and 2 mg doses. The typical regimen is 1 mg taken daily. The lower dose (0.5 mg) has been used for osteoporosis prevention and is less useful for vasomotor symptom relief. Because of the risks associated with hormone therapy, alternative agents should be considered if osteoporosis is the primary goal of therapy.

For women who prefer estrogens derived from plant sources, estrone-based drugs are available. Conjugated-synthetic estrogen-A (Cenestin) is available in doses from 0.3 mg to 1.25 mg. Patients should be started with Cenestin 0.45 mg daily. Subsequent dosage adjustment may be made based on the individual patient response. This dose should be reassessed periodically by the health-care provider. The lowest effective dose of Cenestin for the treatment of moderate to severe vasomotor symptoms has not been determined. The majority (77%) of women randomized to Cenestin required a total daily dose of 1.25 mg to relieve vasomotor symptoms, whereas the remaining 23% required 0.625 mg or less. By week 8, the vasomotor symptoms were significantly decreased. Conjugated-synthetic estrogen-B (Enjuvia) is available in doses of 0.625 mg to 1.25 mg, with the lower dose producing relief in many women. Estropipate (Ogen, Ortho-EST) is also derived from plant sources and available in 0.75 mg to 6 mg tablets. Following the rule to use the lowest dose to control symptoms, the dosing regimen should start at 0.75 mg.

Several ERT/HRT formulations are available in transdermal delivery systems for the indication of managing vasomotor and urogenital menopausal symptoms. The major advantage of this formulation is its once- or twice-weekly application. A very positive advantage is that topical agents avoid the "first-pass effect," which dramatically decreases the negative effects of generating bad lipid profiles. A potential disadvantage is the incidence of skin irritation (20% to 40%) in users of a patch delivery system. Menostar is a transdermal patch that delivers a very low dose (0.014 mg) of estradiol. It is indicated only for osteoporosis prevention in women without a uterus or in combination with a progestin periodically (every 6 to 12 months) during therapy to prevent endometrial hyperplasia.

Complementary and Alternative Therapies

Phytoestrogens and herbal therapies abound for relief of peri- and postmenopausal symptoms. There is a high level of use of complementary and alternative medicine (CAM) therapies across ethnicities and cultures. The data supporting these treatments for symptom relief are discussed in detail in the chapter on herbals and alternative medicine. Prescribers are directed to the NIH CAM Web site for the most accurate and evidence-based recommendations. Of note, the polyphenols in green tea, already recognized for their antioxidant effects, may be an active ingredient explaining why women who drink green tea appear to have a slower progression of postmenopausal bone loss (Shen, Yeh, Cao, Chyu, & Wang, 2012). This is not certain evidence.

Phytoestrogens

Phytoestrogens are plant compounds that are functionally or structurally related to endogenous estrogens and their active metabolites. They may be agonistic, partially agonistic, or antagonistic with estrogen receptors. Isoflavones are phytoestrogens

that are found largely in soy and red clover. Supplemental soy is of no benefit over placebo, especially in the anticipated bone health or suppression of vasoactive effects (Amato et al, 2013). Studies have been inconsistent in demonstrating efficacy of red clover–based products in improving hot flashes and other menopausal symptoms. Black cohosh, gingko biloba, and evening primrose oil have shown no increased efficacy in treating hot flashes in placebo-controlled trials. Most bioidentical estrogens are derived from soy. The FDA warns that these products are not regulated, and cautions that women who are consuming amounts sufficient to achieve effective symptom relief from a phytoestrogen may also experience significant estrogenic stimulation of the endometrium and breast and be at similar risk for adverse events as are those women who use pharmaceutical agents.

Botanicals/Herbals

Plants are used therapeutically in the form of herbs, oils, pills, teas, and tinctures. They may be classified as dietary supplements. The herbal preparations approved for treatment of menopausal symptoms by the German Commission E include black cohosh root and chaste tree fruit. Liu and colleagues (2001) evaluated eight botanicals for estrogenic activity. They found that red clover, hops, and chasteberry had significant binding affinities with estrogen receptors. Dong quai and licorice had weak binding. Asian ginseng, North American ginseng, and black cohosh displayed no binding to estrogen receptors. Langer (2005) reported that black cohosh failed to relieve vasomotor symptoms. This finding was replicated by the National Center for Complementary and Alternative Medicine at the National Institutes of Health; black cohosh failed to show that it reduces the frequency and severity of hot flashes and night sweats in menopausal and perimenopausal participants. Chasteberry contains hormone-like substances with antiandrogenic effects. It also has significant binding affinities for both estrogen-receptor alpha and estrogen-receptor beta. Studies regarding the efficacy of chasteberry have shown symptom reduction; however, questions regarding study design limit the ability to draw clinical conclusions.

For further information on these herbal remedies, the reader is referred to Chapter 10, the German Commission E, and the National Center for Complementary and Alternative Medicine.

Nonhormonal Medications

Several nonhormonal medications have demonstrated benefit in reducing menopausal symptoms. Selective serotonin reuptake inhibitors (SSRIs) (discussed in Chap. 29) and clonidine (Chap. 14) have mixed reported relief of vasomotor symptoms and sleep disturbance. The GLOW study demonstrated the increased fracture risk with SSRI medications after 5 years of use (Aldachi, 2013). The serotonin-norepinephrine reuptake inhibitors (SNRI) have more evidence to support a reduction in the impact on vasomotor symptoms but without a statistically significant actual reduction in intensity. Gabapentin holds promise as a true hot flash reduction medication (Hall, Frey, & Soares, 2011). The North American Menopause Society has published a comprehensive review of alternative treatments for vasomotor symptoms.

Prevention and Management of Vulvovaginal Atrophy and Dryness

In addition to the vasomotor symptoms associated with menopause, the decline in estrogen causes the vaginal mucosa and vulvar skin to become thin and atrophic. The result is discomfort, itching, dyspareunia, and increased cases of vaginitis. Low-dose (0.3 to 0.625 mg) oral ERT with estrogen from both plant and animal sources has been shown to decrease vaginal pH, thus reducing vaginal infections. Estrogen also thickens and revascularizes the vaginal epithelium, increases the number of superficial cells, and reverses vaginal atrophy (Liu, 2004).

Vaginal application of estrogen also produces these positive effects, and improvement in symptoms can be seen in as few as 2 weeks of treatment. Low-dose vaginal estrogens (in ring or cream form) have a less stimulating effect on the endometrial tissue and, therefore, have a reduced risk for endometrial hyperplasia compared to the oral forms. Estrace is a bioidentical vaginal cream approved for the treatment of vaginal and urinary symptoms. The usual doses for all the creams include nightly application at first, followed by a 2 to 3 times a week regimen if symptoms are controlled. Topical application using vaginal rings and vaginal tablets may be preferred to creams in some patients because of the ease of use and a perception that these options are less "messy" than the creams. The Estradiol ring (Femring) is inserted and changed only every 90 days. The total amount of estrogen to which the body is exposed is less with the topical formulations, which may be a consideration for women who have risk factor concerns with ERT.

Studies reported by Thorneycroft (2004) found no evidence of increased risk of CHD, breast cancer, or endometrial cancer with the use of vaginal ERT. There was a slight increase in endometrial hyperplasia with higher doses, so it might be prudent to periodically withdraw patients treated with vaginal ERT, which includes estradiol tablets more than 10 micrograms twice a week, an estradiol ring more than 7.5 micrograms, and estradiol creams more than 0.5 g per week. Any bleeding must be worked up. There are no long-term studies of use without progestin supplementation. An alternative is to use micronized progesterone 200 mg for 12 days a month, which will be followed by a withdrawal bleed. The lower risk of endometrial hyperplasia with vaginal products does not eliminate the need to consult with oncology for women who have had breast cancer or other estrogen-positive cancers.

A new drug, ospemifene (Osphena) has the FDA indication to also assist in vaginal issues, specifically dyspareunia (FDA, 2013). The mechanism of action is as both an estrogen agonist *and* antagonist, dependent on the tissues it is impacting. It is an alternative when estrogen-based medications are not tolerated, patients prefer not to use a "messy" cream, or the medications are considered to be risky in the presence of localized lesions that could be precancerous. Ospemifene has a Black-Box Warning that it might thicken uterine linings, which would predispose the patient to endometrial cancer, a risk not associated with low-dose topical estrogen medications. The drug was not studied in combination with progestins because

the original developers considered it more akin to a SERM type of medication. It is also linked to a risk of thromboembolization. Therefore, the FDA has required all estrogen Black-Box Warnings be placed on this drug. Preclinical studies assumed an antagonistic effect on breast tissue and an agonist effect on bone (like a SERM), but there is no clinical trial evidence to support or deny this.

Reduced Risk for Colon Cancer

Colorectal cancer is the third most common cancer in women in the United States and the third most common cause of cancer death in women (Thorneycroft, 2004). Since this cancer is also associated with aging, it clearly is a cancer to be considered with menopause. Reduction in colon and rectal cancers are correlated with both postmenopausal ERT and HRT use and the doses that help with vasomotor symptoms also provide that benefit. The decrease appears to be approximately 40% and the WHI showed a statistically significant reduction. Women with a family/genetic history of colon cancer would benefit from this therapy. These drugs are not indicated for this sole indication.

Increased Risk for Breast Cancer

Data regarding the effects of HRT and ERT on breast cancer are inconsistent and controversial (Shapiro et al, 2012). The WHI evidence suggests that a progestin receptor may be involved in invasive breast cancer; the arm of the study with just estrogen supplements did not have the same breast cancer incidence of the estrogen plus progestin arm of the study (Chlebowski et al, 2003, 2013). No evidence exists that ERT or HRT directly initiates a neoplastic process, but they may be promoters, increasing the rate of division of neoplastic cells. Based on all the available data, it seems prudent to carefully monitor all women on ERT/HRT for breast cancer through annual office evaluation and mammography.

The use of ERT/HRT is contraindicated in women with a history of breast or gynecological cancers and those with first-degree family members with breast cancer. Duration and timing of therapy also seems to be a factor in breast cancer risk. If HRT is started at the very beginning of menopause, breast cancer risk is higher in part due to the continued levels of natural hormone in addition to the drugs (Chlebowski et al, 2013). Women with extended use, especially therapy continued beyond 7 years, are at increased risk.

Advocates of bioidentical hormones have claimed that this cancer risk is not associated with the use of medications other than conjugated estrogens and medroxyprogesterone. The FDA, leading menopause societies, cancer centers, and endocrine specialties do not endorse this claim, stating that it is not backed by evidence (Flies et al, 2011; Stunkel et al, 2012). There have been no head-to-head studies; nor have there been longitudinal studies of women on these selections of medications to lend evidence to the claims. However, the FDA does list bioidentical approved medications that are widely used by many. The different physiological impacts of progestins on the body are cited as creating better quality of life and less cardiovascular risk by proponents of these newer medications that were not included in the WHI research that halted much of the HRT therapies taken by women (Holtorf, 2009).

Increased Risk for Endometrial Cancer

There is a clear and consistent increased risk for endometrial cancer in women with a uterus who are treated with unopposed ERT. To help decrease this risk, progestin has been added to hormone treatment options for women with an intact uterus to help prevent endometrial hyperplasia and cancer. The use of unopposed estrogen in a woman with a uterus is contraindicated. Further discussion occurs in the progestin section below.

Risk for CHD

The first indications that early assumptions about ERT/HRT and improved cardiovascular health might not be true happened years before the WHI. The PEPI study, conducted in 1995 (Writing Group of the PEPI Trial, 1996), started to question this initial hypothesis of a level of "protection" with supplements. Although the drugs tested (estrogen alone, estrogen with MPA, and estrogen with micronized progestin) increased HDL, lowered LDL, and fibrinogen levels and had no adverse effect on blood pressure, these apparently positive CHD risk factors did not translate into decreased CHD events. The ERA (Estrogen Replacement and Atherosclerosis) studies (Herrington et al, 2000; Hodis et al, 2003) contributed to the same conclusion. HERS was the first large randomized trial that looked at reduction in mortality by using menopausal estrogens. Women with CHD had higher adverse events and incidence of death during therapy. Women without cardiovascular disease showed modest benefit but not until the fourth and fifth years of therapy. The definitive study was the WHI, which stopped the HRT arm of its study earlier than planned based on an increased risk for CHD versus possible benefits of HRT. The ERT arm, which included women who did not have a uterus, failed to show statistically significant benefits in prevention of CHD. It is worth noting that the ERT arm of the study was subsequently halted early because of increased incidence of stroke.

The age and years of postmenopause in the WHI study have raised the possibility that the adverse cardiovascular findings may be related to the length of time that the normal hormone balance had been interrupted prior to initiation of hormone therapy and the vascular capacity to respond. Meta-analysis of age-adjusted cohorts and other studies suggest that the risk of CHD might be substantially less in women who initiate ERT/HRT early in perimenopause and menopause (Langer, 2005). Progestin has been shown to block estrogen receptors, which might interfere with nitric oxide production in the endothelial cells and diminish the beneficial effects of estrogen. Questions remain as to the reasons that HRT is associated with increased risk over ERT alone. These questions need to be answered by further research.

It is important to note that oral estrogens are associated with increased levels of C-reactive protein (CRP), a factor associated with increased CHD risk in women (Mosca, Barret-Connor, & Kass Wenger, 2011). Importantly, there is no increased risk of heart attack and stroke with transdermal and intravaginal preparations.

Increased Stroke and Thromboembolic Event Risk

Increased risk for thromboembolic events has been a long-standing concern related to hormone replacement, whether estrogen alone or in combination with progestins. The WHI found significantly increased risk for stroke in post-menopausal women for both ERT and HRT. For HRT the risk was apparent in each decade of age, but for ERT the risk appeared to emerge after age 60 (Langer, 2005). The risk for venous thromboembolic disease, including pulmonary embolism, was doubled in women in the HRT arm, with no difference based on age. There was a nonsignificant increase by about one-third with ERT alone (Anderson et al, 2003, 2004). The risk of a thromboembolic event is greatest in the first year after initiating therapy.

Progestin Therapy

Progestin therapy alone is used for contraception in younger women with menorrhagia. It is also used in the perimenopausal and postmenopausal period in combination with estrogen to prevent endometrial hyperplasia that increases the risk for endometrial cancer. It is not 100% protective. Endometrial biopsy results from the HOPE trial (Liu, 2004) indicate that there was a 3.17% incidence of hyperplasia in the 0.3 mg (Premarin) group versus 27.27% hyperplasia in the 0.625 mg group at 2 years.

Different types of progestogens not only have differing effects on the endometrium, they also have differing effects on estrogen-associated benefits to lipids. Norethindrone acetate has been shown to reverse these benefits on HDL cholesterol while still offering effective endometrial protection. MPA and micronized progestin do not attenuate the effects of estrogen on lipid levels. Norgestimate improves HDL to a level intermediate between MPA and micronized progestin, while also providing good endometrial protection (Langer, 2005).

Combination Therapy with Estrogen and Progestins

Although HRT is as effective as ERT in preventing the uncomfortable symptoms sometimes associated with menopause, reducing the risk of colon cancer, and reducing the risk for osteoporosis and hip fracture, it is not more effective in these areas. The risks associated with HRT are discussed in the ERT section above. Given the studies that indicate a role in increased risk for CHD, it is prudent to avoid HRT, especially in women with CHD risk factors. For this reason, the only specific indication discussed for combination therapy will be the prevention of endometrial hyperplasia and cancer in a menopausal woman with an intact uterus.

Decreased Risk for Endometrial Cancer

Combinations of estrogen and progestin are used when the uterus is intact. Research has consistently demonstrated the risk for endometrial cancer in direct correlation with unopposed ERT in women who have an intact uterus (Brinton & Felix, 2013; Thorneycroft, 2004). The risk also increases substantially the longer the ERT is used and persists for 5 or more years after ERT has been discontinued. Although this effect appears to be dose-related, with higher hyperplasia associated with higher estrogen doses, the risk remains for all dose levels of ERT. To prevent this increased incidence of hyperplasia and cancer, progestin, which reduces the buildup of endometrial tissue, is added to the treatment regimen.

There are several combination therapies for use in menopause. The following regimens have been prescribed and all provide effective prevention of endometrial cancer:

1. Estrogen (0.625 mg) plus medroxyprogesterone acetate (MPA) 2.5 mg daily (Prempro)
2. Estrogen (0.625 mg) plus micronized progesterone 100 mg daily
3. Estrogen (0.625 mg) daily plus MPA 10 mg for 10 to 12 days
4. Estrogen (0.625 mg) daily plus MPA 5 mg for 14 days (Premphase)
5. Estrogen (0.625 mg) daily plus micronized progesterone 200 mg for 12 days (PEPI)
6. Estrogen (0.625 mg) for days 1 to 25 plus MPA days 16 to 25 (the first regimen used, which has the disadvantage of more hot flashes)
7. Estrogen (0.625 mg) plus progestin Monday through Friday (may experience more hot flashes)

Continuous Versus Cyclical (Sequential) Patterns

The most common reason women give for discontinuing HRT is irregular and unpredictable vaginal bleeding. Continuous regimens (1 and 2 above) eliminate monthly withdrawal bleeding, but they are associated with a higher rate of breakthrough bleeding, especially during the first 6 months of therapy. This is most likely to occur in women who have recently become postmenopausal because endogenous production of estrogen is more labile from cycle to cycle in these women. Currently available data suggest that the best profile for a positive risk/benefit ratio for all indications for ERT/HRT accrue when therapy is started near the time of menopause onset. This unwanted side effect may create a problem for many women.

To deal with breakthrough bleeding issues, cyclical or sequential therapy was introduced. These regimens (3 through 7 above) are preferred until endogenous hormone production stabilizes, typically 2 to 3 years after menopause. Differences in potency of various progestins result in differences in rates of bleeding. The PEPI study tested MPA and micronized progestin side by side and found that the micronized progestin was associated with less bleeding during the first 6 months than either the continuous or cyclical MPA (Lindenfeld & Langer, 2002). With any formulation of progestin, breakthrough bleeding decreases substantially after the first 6 months and both drugs produced effective protection from endometrial cancer.

Brinton and Felix (2013) have uncovered a pattern of endometrial cancer risk correlated with how progestins are taken. Continuous-dose patterns appear to confer lesser risk compared to women who did not take any progestin. Interestingly, heavier women had the lowest risk with dosing more than 25 days a month. Women on cyclic dosing for less than 10 days monthly had the highest risk of cancer. There has yet to be a response concerning the safety of intermittent dosing.

Testosterone Therapy

When traditional HRT/ERT is not successful in suppressing hot flashes (only a 28% reduction typically in the WHI) and improving sex drive, estrogen in combination with testosterone has been used empirically. Peripheral conversion of androgens may augment ERT and reduce hot flashes. Masculinizing adverse effects such as lower voice and increased facial and body hair can occur when testosterone is used alone. These adverse effects may not regress after testosterone is withdrawn. Traditionally, testosterone has been used topically (2%) in Aquaphor or petrolatum for vulvar "dystrophies." See the chapters concerning women's health drugs for other treatments for vulvovaginitis.

Available formulations are the following:

1. Esterified estrogen 0.625 mg plus testosterone 1.25 mg
2. Esterified estrogen 1.25 mg plus testosterone 2.5 mg (this higher estrogen is used in post-oophorectomy patients under 49 years of age)
3. Conjugated estrogens 0.625 mg plus testosterone 5 mg
4. Conjugated estrogens 1.25 mg plus testosterone 10 mg

Figure 38-1 presents a treatment algorithm for HRT/ERT.

Monitoring

Women taking hormonal therapy for menopausal symptoms have similar adverse effects and precautions no matter what the estrogen source and the route of administration. Annual complete history, physical examination, and mammogram are needed to evaluate for changes in risk profiles that may indicate a need to alter treatments and screen for early adverse effects of therapy. Liver function tests need to be done at baseline, along with a lipid profile, and repeated annually if abnormal. Authorities agree that all postmenopausal bleeding requires uterine biopsy. Laboratory monitoring of the precise estradiol level (E2) needed to bring vasomotor symptoms under control is not yet available. The available laboratory tests to measure estradiol vary widely and are deemed not reliable to measure the true level of hormone with any replicable accuracy (Rosner, Hankison, Sluss, Vesper, & Wierman, 2013). Importantly, many prescribers of compounded ERT/HRT use a saliva test to monitor how much of each hormone is needed and make dosage changes based on these lab values. The prescriber is directed to the laboratory literature that considers this form of hormone-level testing to be extremely unreliable. Variance in hormone levels in saliva can vary in just a few hours, with diet and even time of day. Collection methods are fraught with unreliable results; replication of values is poor at best (Flies, Ko, & Pruthi, 2011). The FDA does not endorse its use. Symptom endpoints are the things to monitor, not levels of hormones.

Outcome Evaluation

Women may present for treatment complaining of heavy menses. When the bleeding problem is serious enough to cause a drop of 2 g of hemoglobin within one menstrual cycle, management usually requires specialty care. The patient may need a dilation and curettage. It is not uncommon for fibroids and hyperplasia to cause this degree of bleeding. Both conditions will require referral and surgery.

Postmenopausal bleeding—that is, bleeding of any degree after 12 or more months of amenorrhea—needs an evaluation that includes history, physical, pelvic examination, mammogram, pelvic ultrasound, and endometrial biopsy. Laboratory tests are necessary to rule out bleeding disorders and endocrine disease. Biopsy uncovers endometrial cancers.

Frequently, older women present with symptoms of urinary incontinence or chronic bladder infections. If there is blood in the urine (even as few as 8 to 10 RBCs per high-powered field) and the culture is negative, the patient will need a urological evaluation. Because older women who have not been on ERT/HRT have cervical atrophy, performing an endometrial biopsy in the office is too painful. If all of the work-up demonstrates no disease, then local topical therapy is within the primary care scope to support urethral and vaginal tissue health.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues. Media attention to the WHI has led to some misinformation about ERT/HRT. Patients may present to the clinic very fearful about beginning this therapy or wondering if they should stop therapy, even when they have been on such therapy for years without incident. Providers need to inform patients that hormonal therapy has a role postmenopause, but that role is limited and therapy should be undertaken based on symptoms and risk assessment. (See Patient Education box on page 1114.)

OSTEOPOROSIS

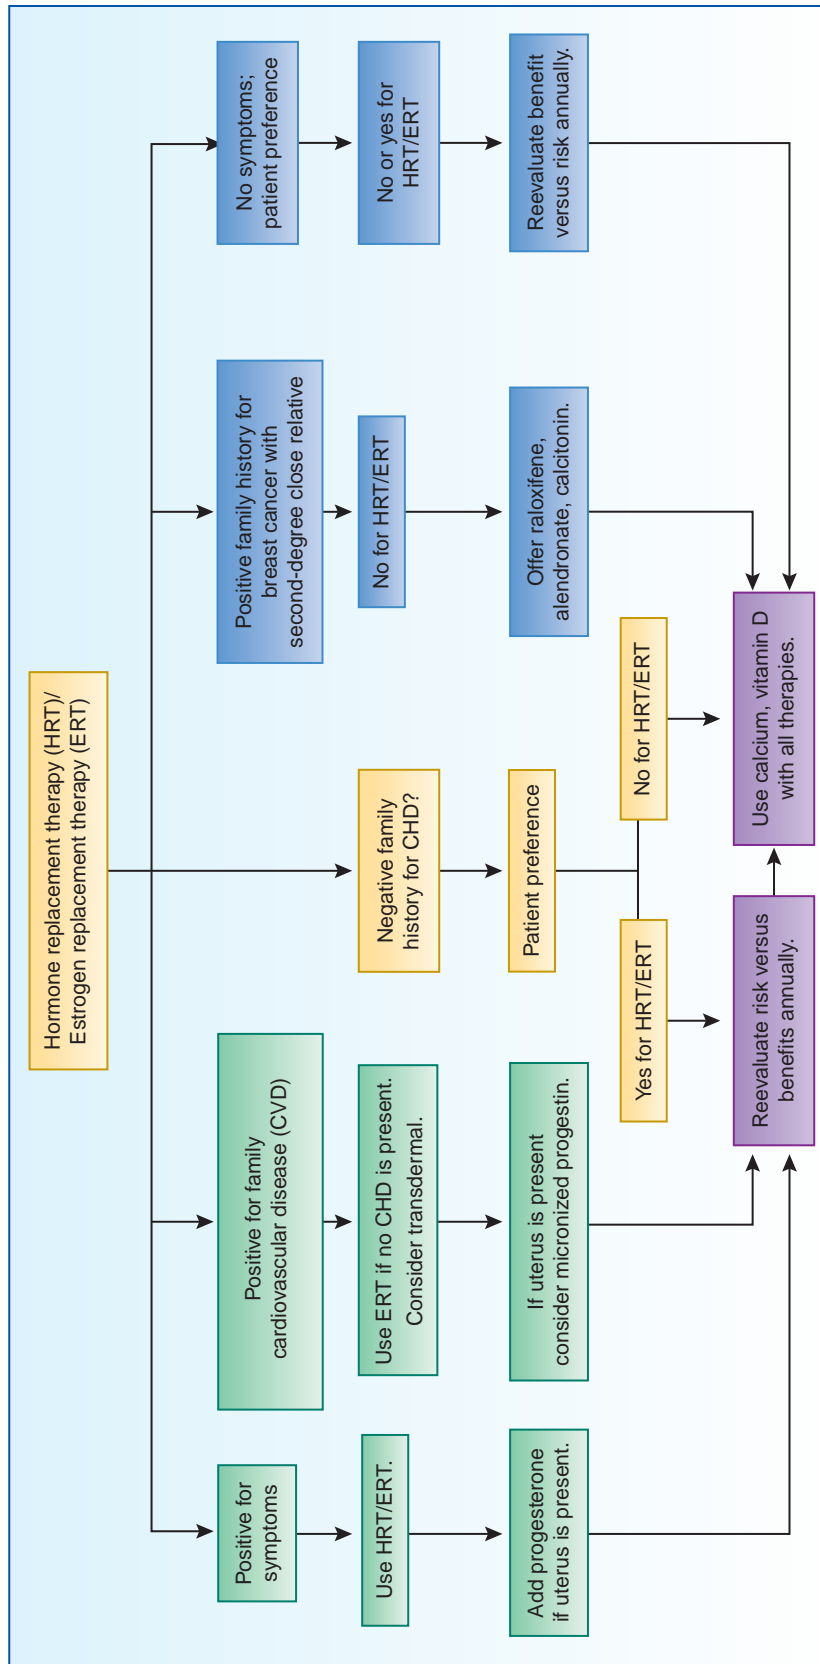
Osteoporosis is a worldwide phenomenon. A white woman older than 50 years has more than a 40% chance of having such a fracture during the rest of her life (International Osteoporosis Federation [IOF], 2012). The lifetime risk for men and nonwhite women is less, but it is still substantial and rising in groups such as Hispanic women. Osteoporosis is the most important underlying cause of these fractures, especially in older adults. Using the World Health Organization's definition, there are roughly 10 million Americans older than 50 years with osteoporosis and an additional 34 million with low bone mass (osteopenia) of the hip, which puts them at risk for osteoporosis, fractures, and the complications associated with them. As the life expectancy of women reaches the mid-80s, osteopenia in perimenopausal women does not bode well for bone health of many seniors, especially among white and Asian women in industrial societies (IOF, 2012; National Institute of Arthritis and Musculoskeletal and Skin Diseases [NIAMSD], 2010b). By age 65, at least 6% of men have dual-energy x-ray absorptiometry-determined osteoporosis (Qaseem et al, 2008).


Figure 38–1. Treatment algorithm: Hormone replacement therapy/estrogen replacement therapy.

HORMONE REPLACEMENT THERAPY

Related to the Overall Treatment Plan/Disease Process

☐ Pathophysiology of the changes that take place in the female physiology at menopause that make a woman vulnerable to atrophy of the genital organs, vasomotor instability, and emotional lability, and when lower estrogen levels cause undesirable lipid patterns

☐ Role of lifestyle modifications and the various treatment protocols and medications available

☐ Importance of adherence to the treatment regimen

☐ Need for regular follow-up visits with the primary care provider, including annual screening tests such as mammography

Specific to the Drug Therapy

☐ Reasons for the drug's being given

☐ Doses and schedules for taking the drug

☐ Possible adverse effects and what to do if they occur, especially if uterine bleeding occurs

☐ Interactions between other treatment modalities and these drugs

Reasons for Taking the Drug(s)

Additional information includes the following: Quality-of-life issues such as relief of hot flashes; target organ atrophy prevention; treatment of osteoporosis; prevention of early heart disease, which may be more successful, especially in families who have a hereditary tendency for cardiac disease; and the preliminary data on retention of cognition, which seems promising.

Drugs as Part of the Total Treatment Regimen

The total treatment regimen includes the following: therapy with alternative herbs and healthier lifestyle, which may relieve symptoms but have not proved to bestow reduced morbidity, as has drug therapy; hormonal therapy is indicated for vaginal atrophy and bladder outlet syndrome; and referral to an appropriate specialist to provide the appropriate care when adverse effects occur as a result of estrogen therapy.

Adherence Issues

Nonadherence to the treatment regimen may be a result of various causes. Concerns about the WHI results should be discussed with correction of any inaccurate interpretations of media messages. Nonadherence due to the possible risk of cancer should be discussed, and the absolute risk of cancer rather than relative risk of cancer should be calculated annually. The possibility of minor discomforts, such as breast tenderness, bloating, fluid retention, and the need for follow-up visits, should be discussed prior to therapy. If irregular or unexpected bleeding occurs, patients should be advised to contact their health-care provider for modifications to the treatment regimen rather than stop therapy on their own.

The direct costs of caring for patients who have osteoporotic fractures are estimated to range up to $20 billion each year and that does not take into consideration the indirect costs in lost productivity and wages for the patient and family. With over 75% of fragility fractures actually occurring after age 65 (Bischoff-Ferrari et al, 2012), the personal and medical costs skyrocket. The risk of death from complications associated with a hip fracture approaches 25% within the first year of the incident; this is increased for those with chronic disease. Over 50% of hip fracture patients have lifelong mobility issues, with 25% requiring admission to long-term care (NAMS, 2012).

Real improvements in bone health can be made through assessment of risk factors, preventive strategies, accurate early diagnosis of osteoporosis, and effective treatment. This section will focus on drugs used for prevention and treatment of osteoporosis with special emphasis on their use in women who are postmenopausal. There is no reliable method of determining when menses will stop; however, research is underway: the "SWAN" study that is making progress in narrowing the prediction to around 2 years with around 85% sensitivity and 77 % specificity. Having a target date can improve therapies directed at the first years of menopause when bone loss is at its height (Greendale, Ishii, Huang, & Karlamangia, 2013). Knowing this needs to be tempered with the understanding that widespread screening is probably not cost-effective. Screening should be limited to men over 70 years of age, women over age 65, and younger women if their 10-year fracture risks are equal to or greater than a 65-year-old without risks (USPSTF, 2011).

Pathophysiology

Normal Bone Physiology

The bony skeleton is created by a process that changes throughout a person's lifetime. The underlying process is *remodeling,* which occurs in three phases. Phase 1 (activation) occurs when a stimulus (e.g., hormone, drug, vitamin, or physical stressor) activates the bone cell precursors in a localized

area of bone to form osteoclasts. In phase 2 (resorption), the osteoclasts excavate (resorb) bone, leaving behind a cavity that follows the longitudinal axis of the haversian system in compact bone and parallels the trabeculae in spongy bone. Phase 3 (formation) then results in the laying down of new bone by osteoblasts lining the walls of the cavity. Successive layers of bone are laid down until the cavity is filled. The entire process takes about 3 to 4 months.

In order for this process to work, osteoblasts and osteoclasts must communicate with each other. A protein called osteoprotegrin (OPG) may be the key in this conversation. OPG binds to OPG-ligand, preventing the action of osteoclasts and stimulating the action of osteoblasts. The balance between OPG and OPG-ligand appears to control bone resorption and growth. The development of drugs to affect the balance between these two may help in the future to treat disease associated with bone loss.

During childhood and adolescence, the process is one of modeling, which allows for the formation of new bone at one site and the removal of older bone from another site within the same bone. This process allows bones to increase in size and to shift in space. Later in life, the process becomes one of remodeling when existing bone is resorbed and replaced without an increase in the total amount of bone. This process occurs throughout life and becomes dominant by the time the bone reaches peak mass, typically in one's early 20s. Most of the adult skeleton is replaced about every 10 years.

Peak bone mass is determined largely by genetic factors. Other factors that contribute to bone health include diet, endocrine status, and physical activity. A number of diseases and certain drugs and toxic agents can cause or contribute to development of bone loss including chronic use of thyroid supplements, glucocorticoids, proton pump inhibitors and SSRI medications (Table 38-1).

The growth of bone, its response to mechanical stressors, and its role in storage of minerals is dependent on the proper functioning of circulating hormones that respond to changes in serum calcium and phosphorus levels. If calcium or phosphorus levels are low, parathyroid hormone (PTH) stimulates osteoclasts to resorb bone, and calcium and phosphorus are released into the bloodstream. PTH also stimulates the intestines to absorb more calcium and the kidneys to activate more vitamin D to facilitate this absorption. The kidney is also stimulated to reabsorb calcium back into the bloodstream. Disease processes in any of these organ systems can produce osteoporosis. Estrogens also play a role in bone remodeling by reducing the bone-resorbing action of PTH. The reduction in estrogen found with menopause is a significant factor in the increased risk for osteoporosis seen in postmenopausal women.

Table 38–1 **Medical Conditions and Drugs That Increase the Risk for Development of Osteoporosis**

Medical Conditions		
AIDS/HIV	Hemophilia	Parathyroid tumor
Amyloidosis	Inflammatory bowel disease	Pernicious anemia
Ankylosing spondylitis	Type 1 diabetes mellitus	Rheumatoid arthritis
COPD	Lymphoma and leukemia	Severe liver disease
Congenital porphyria	Malabsorption syndromes	Sprue
Cushing's syndrome	Mastocytosis	Stroke (CVA)
Eating disorders	Multiple myeloma	Thalassemia
Gastrectomy	Multiple sclerosis	Thyrotoxicosis
Hemochromatosis	Hyperparathyroidism	Hypogonadism
Drugs		
Aluminum and *excess use of antacids*	Gonadotropin-release hormones	Progesterone (long acting)
Anticonvulsants (phenobarbital; phenytoin; carbamazepine)	Immunosuppressants like cyclosporine and tracroloimis	*Aggressive treatment of hypothyroidism with thyroxine*
Cytotoxic drugs like chemotherapy and methotrexate	Lithium	Tamoxifen and aromatase inhibitors
Glucocorticosteroids equivalent to 5 mg of prednisone or greater for at least 3 months	Long-term heparin use	Total parenteral nutrition
Warfarin use for >1 year	*Selective serotonin reuptake inhibitors*	*Proton pump inhibitors used >1 year*
ACTH	*Gonadatropin-releasing hormone agonists*	

COPD = chronic obstructive pulmonary disease; CVA = cerebrovascular accident.

Bone Loss (Osteoporosis)

Bone loss occurs when the balance between osteoclastic activity and osteoblastic activity is altered. Figure 38-2 shows the changes within cancellous bone as a consequence of bone loss. Osteoporosis is a generalized metabolic disease characterized by decreased bone mass as a result of this imbalance. The World Health Organization definition of osteoporosis is having a bone density 2.5 standard deviations below the average adult peak bone mass. The bone that remains is histologically and biochemically normal, but there is not enough of it to maintain skeletal integrity and mechanical support. The disease can be generalized, involving major portions of the axial skeleton, or regional, involving one segment of the appendicular skeleton. Both spongy and compact bone are lost, but the spongy bone loss exceeds the compact bone loss (McCance & Huether, 2014). The end result is fractures—vertebral, hip, and wrist fractures are the most common.

There are several well-known risk factors for osteoporosis, such as family history, slight build, fair complexion (Scandinavian), age, diets low in calcium and vitamin D, and minimal sun exposure. Table 38-2 shows these and other risk factors including those for fractures secondary to osteoporosis. There are also a wide variety of diseases and certain drugs and toxic agents that can cause or contribute to development of osteoporosis. Factors associated with increased risk for osteoporosis in men (NIH, 2011) include (but are not limited to) the following:

- Being older than 70 years of age
- Glucocorticoid use of 5 mg or greater for 3 months or longer
- Anticonvulsants including phenobarbital, phenytoin, and carbamazapine
- Long-term proton pump inhibitor use for more than 1 year
- Body weight less than 70 kg or weight loss more than 10% compared with usual young adult or adult weight in recent years
- Heavy tobacco use or consuming more than 14 drinks of alcohol per week
- Sedentary lifestyle
- Deficits in vitamin D or calcium intake

Normal   Osteoporotic
Figure 38–2. Micrographs of normal and osteoporotic bone.

Table 38–2   **Risk Factors for Osteoporosis and Resultant Fractures**

Risk Factors for Osteoporosis

- Thin, small-boned frame
- Estrogen deficiency <45 yr
- Advanced age (62 in women, >70 in men)
- Diet low in calcium and vitamin D
- White and Asian ancestry (African American and Hispanic women are at lower but significant risk)
- Cigarette smoking
- Alcohol intake >2 drinks per day
- Limited physical activity/sedentary lifestyle

Risk Factors for Fracture Secondary to Osteoporosis

- Personal history of fracture as an adult
- History of fragility fracture in a first-degree relative
- Low body weight (57.7 kg for women, 70 kg for men)
- *Weight loss of >10% in recent years*
- *Height loss of 1.5 in.*
- Use of oral corticosteroid therapy for >3 mo
- Hormone deprivation therapy used for >1 year as treatment for prostate cancer
- Impaired vision
- Dementia
- Recent falls

Source: Adapted from *Osteoporosis and Asian American Women, Osteoporosis and African American Women,* and *Osteoporosis and Hispanic Women* (all from NIAMSD documents, 2010); Qaseem et al, 2008; and University of Texas, 2008.

- Prostate cancer therapy
- Undiagnosed low testosterone

Osteoporosis is typically not diagnosed in men until a fracture occurs because there is no set screening triggers as there are for women (USPSTF, 2011). As in women, small stature and being of the white race are risks. The antihormone therapies for prostate cancer are akin to the increased risk of bone loss with the antihormone therapies used for women with breast, ovarian, and uterine cancers.

For women, the same is true with the following exceptions or additions: the age is greater than 62, the body weight is less than 57.7 kg or body mass index (BMI) less than 21 kg/m2, and there is a history of hip fracture in a parent or a personal history of fracture after menopause (Qaseem et al, 2008). These and other risk factors are shown in Table 38-2.

Ethnic Differences

The bone density of various ethnic groups varies as does their risk for osteoporosis. The National Institute of Arthritis and Musculoskeletal and Skin Diseases (2010a, b, c) published some data about these differences. Tools are available to assess osteopenia and osteoporosis risk at http://www.shef.ac.uk/FRAX.

African American Women

Although African American women tend to have higher bone mineral density than white women throughout life, they are still at significant risk for osteoporosis (NIAMSD, 2010a).

The misperception that it does not occur in this population can delay prevention and treatment. As African American women age, their risk for hip fracture doubles approximately every 7 years and they are more likely to die from the hip fracture than are white women. Diseases prevalent in this population, such as sickle cell disease and lupus, can increase the risk for developing osteoporosis. Most African American women consume 50% less calcium than the Recommended Dietary Allowance (RDA), placing them at risk related to poor calcium intake. This is compounded by the fact that 75% of all African Americans are lactose intolerant, so they avoid milk and other dairy products that are excellent sources of calcium.

Asian Women

Studies show that Asians share many of the risk factors that apply to white women and are at high risk for developing osteoporosis. Compared to white women, Asian women tend to consume less calcium, in part because 90% of Asians are lactose intolerant. Although they generally have lower hip fracture rates than do white women, the prevalence of vertebral fracture is as high (NIAMSD, 2011b).

Hispanic Women

The prevalence of osteoporosis in Hispanic women is similar to that of white women. Ten percent of Hispanic women 50 years and older are estimated to have osteoporosis, and 49% are estimated to have bone mass that is low, but not low enough for a diagnosis of osteoporosis (NIAMSD, 2010c). The incidence of hip fracture in this population is on the rise. In addition, this population also consumes less calcium, probably also related to lactose intolerance. Finally, Hispanic women are twice as likely to develop diabetes as are white women, which may increase their risk for bone loss.

Pharmacodynamics

The results of the Women's Health Initiative called into question the use of estrogen for the sole indication of osteoporosis prevention and treatment due to the risks for cardiovascular adverse responses. Estrogens prevent osteoporosis by reducing the bone-resorbing action of PTH. Estrogen receptors have been found in bone, which validates the hypothesis that estrogen may have direct effects on bone remodeling.

Raloxifene (Evista) is a selective estrogen receptor modulator (SERM) approved for preventing and treating postmenopausal osteoporosis, as a well as prevention of estrogen-receptor-positive (ER positive) breast cancer. Because it selectively activates certain estrogen pathways in bone and has antiestrogen effects on the uterus and breast, raloxifene reduces the resorption of bone with less risk for cardiovascular effects. Most of the effect is on reduction of vertebral fractures by 34%; other site fracture reduction is insignificant.

This drug also has positive effects on lipid metabolism by decreasing total and LDL cholesterol levels. It does not affect other lipid fractions. SERMs are associated with hot flashes because they do not impact natural estrogen-level variations (Zhang, Simondsen, & Kelesar, 2012). Some early menopausal women discontinue therapy because of this adverse effect. There is some risk of postmenopausal uterine cancer development over time. SERMS also contribute to thromboembolic events. The other SERM class medications do not have the same degree of bone density effect as raloxifene.

Bisphosphonates also reduce bone resorption by adhering tightly to bone and inhibiting osteoclastic activity. Although no drug is free of adverse effects, bisphosphonate adverse effects are largely gastrointestinal (GI) in nature and not associated with the same life-threatening consequences seen with estrogen. The exception is the risk atrial fibrillation risk even in those without prior cardiovascular disease. This is more common in the IV formulations (Sharma et al, 2013). Bisphosphonates are listed by all guidelines as first-line therapy. Bisphosphonates are discussed in more detail in Chapter 21. In extreme cases they can be used in combo with SERMs.

Natural calcitonin balances parathyroid hormone by shutting down osteoclastic activity and increasing osteoblastic activity in the presence of hypercalcemia. Low serum calcium levels increase the secretion of endogenous calcitonin, with a resulting small decrease in serum calcium. All previously marketed calcitonin drugs were pulled off the market due to cancer-associated risks.

Teriparatide (Forteo) is a synthetic PTH derived from recombinant DNA technology. Its bone actions are identical to that of human PTH. Unlike other drugs used to treat osteoporosis in which the action is to prevent bone breakdown, this drug acts to stimulate bone formation. In once-daily doses, it does this through preferential stimulation of osteoblastic activity over osteoclastic activity. Most of its anabolic effects occur within the first 6 months of therapy. This drug is only recommended for postmenopausal women who are at high risk for fracture and to increase bone mass in men with primary or hypogonadal osteoporosis who are at high risk for fracture and cannot use other bone medications. It is taken only for 2 years. It can cause orthostatic hypotension within 4 hours of the dose and hypercalcemia. Of note, it has an increased risk for osteosarcoma development that must be closely monitored. It cannot be taken by patients with Paget's disease, those who have had external beam or implanted skeletal radiation or a history of bone metastasis.

Denusomab (Prolia), a human antibody against the tumor necrosis factor RANKL, inhibits osteoclast survival and function. Its use is typically reserved for those who do not respond to bisphosphonate therapy or for cancer patients with bone metastasis. It can be injected twice yearly with a significant (69%) reduction of new vertebral fracture and the very positive reduction (40%) of hip fractures. This newer and very expensive medication is under scrutiny for reports of osteonecrosis of the jaw, increases in sepsis, and unanticipated deaths at levels higher than the bisphosphonates.

Calcium and vitamin D are also critical to bone formation and are generally recommended as complementary agents in the prevention and treatment of osteoporosis. However, the

U.S. Preventive Services Task Force has not found evidence that higher doses of vitamin D over 400 IU and 1 g of calcium lessens fracture risk in patients without a documented vitamin D deficiency (Nestle & Nesheim, 2013). This appears to counter the meta-analysis done by Bischoff-Ferrari and associates (2012), which linked high doses of vitamin D (800 IU) to fracture prevention in older people. The USPSTF states many of the studies were of questionable methodology, leaving the recommendations to be unreliable.

Of the 600 to 1,000 mg of calcium consumed daily, only 100 to 250 mg are absorbed from the gut. In the steady state, renal excretion of calcium and phosphate balances intestinal absorption. The movement of calcium and phosphate across the intestinal lining is closely regulated. Intestinal diseases can disrupt this balance. Hormonal regulation of calcium, mentioned earlier, greatly affects calcium metabolism. Ions such as sodium and fluoride also have an impact on calcium balance. Inadequate vitamin D can produce a decrease in calcium absorption from the intestine and an increase in parathyroid hormone, both of which may lead to bone loss and fractures. Serum levels of vitamin D for optimal bone health are 30 to 100 ng/mL. Deficiency occurs when the amount is less than 20 ng/mL. Drugs taken for other diseases, such as thiazides for hypertension, also affect calcium metabolism. Patients with low levels should be supplemented, but those at normal levels do not have additional benefits with higher doses (Nestle & Nesheim, 2013). Vitamin D supplements come in two active forms: D25-dihydroxy and D1,25-dihydroxy. The latter is the more biologically active. The D3 is formed in the skin or comes in supplements and is converted to D25-dihydoxy in the liver. D2 is a plant-synthesized vitamin that is absorbed from the diet or a supplement and is changed into D1, 25-dihydroxy in the kidney.

It is known that calcium supplementation without vitamin D does not reduce fracture rates (Nestle & Nesheim, 2013). Calcium supplements can also increase the incidence of kidney stones. In addition, there is concern that excess serum calcium deposits into soft, vascular plaque, which makes the plaque less able to regress in the face of statin therapy. These adverse issues should be tempered with the knowledge that taking calcium cuts overall mortality in women compared with women who do not take the supplements (Langsetmo et al, 2013).

Goals of Treatment

The ideal goal of treatment for osteoporosis is that the pharmacological therapy be inexpensive, safe, and effective. Nonpharmacological therapy (and prevention) includes an appropriate exercise program. The best treatment for osteoporosis is prevention. Developing a healthy lifestyle while building bone mass is the most cost-effective strategy. Excessive dieting and exercise or fad diets that are deficient in essential nutrients contribute to reduced bone mass.

Prevention of osteoporosis includes a low-impact aerobic exercise program; however, excessive exercise is not good because stress fractures may result. For treatment of osteoporosis,

weight-bearing activity such as brisk walking (20 min, 3 to 4 times/wk) is ideal. Resistance training (lifting weights or using strength-training machines) is a slow process, so programs should start low and work up over a period of months.

Of new importance is keeping belly fat down to a minimum. Not only is this a cardiac risk factor, but abdominal obesity is now recognized as contributing to less than ideal bone mass (Cohen, 2013). The myth that carrying extra weight strengthens bones has been overturned. The purported mechanical stress for bone growth is probably eliminated by the circulating cytokines and decreased insulin-like growth factors, which results in boss loss. This visceral adiposity is a negative factor for bone health. Additional support for this newly recognized risk factor is a study that measured decreased structural bone health using a new in vivo tool that measures microscopic cracks (Farr et al, 2014). Diabetic women with normal DEXA scans were found to have significant loss of bone strength and quality. This OsteoProbe tool, however, is not in wide use.

Rational Drug Selection

Estrogen Therapy

There is a direct correlation between rate of bone loss in menopausal women and estradiol levels. Bone resorption has also been shown to be highest in the first postmenopausal year. Women in the immediate postmenopausal years are the ones who are most in need of protection from osteoporosis (Greendale et al, 2013).

A head-to-head trial comparing the effects of alendronate alone, conjugated equine estrogen alone, and a combination of the two, found that while both the alendronate and estrogen alone significantly increased bone mineral density (BMD), the combination was better than either alone for bone health (Greenspan et al, 2002); however, the risks of hormone therapy overshadow the added benefit, so it is not used except in extreme cases. This study also looked at stopping therapy after 2 years by switching women who had been on the drugs to placebo. Those on alendronate alone who were switched to placebo had no change in BMD. However, the women initially on estrogen who were switched to placebo had a significant decrease in BMD, almost to baseline levels, within 1 year. The same results are expected in women who react to the WHI study data and stop taking estrogen.

Even though the WHI raised concerns about the risk for coronary events, stroke, pulmonary emboli, and breast cancer in women who took a combination of estrogen and progesterone, it is important to note that the number of hip and vertebral fractures was lower at a statistically significant rate for women taking the combination and for women taking estrogen alone. The addition of progestin to estrogen therapy did not produce a significant difference in BMD. The findings from the WHI have led women's health specialists, the USPSTF, and the FDA to recommend that estrogen products not be considered first-line therapy for the prevention and treatment of osteoporosis unless a woman is also experiencing

vasomotor or vaginal atrophy menopausal symptoms. When ERT alone is chosen, low-dose therapy has been shown to produce a positive effect on BMD, even though the dose-related response is less. Lower doses also produce less risk for endometrial hyperplasia in women with an intact uterus; however, unopposed oral estrogen in these women is contraindicated.

Balancing these risks and the availability of other drugs to prevent and treat osteoporosis should be discussed with women, who can then make an informed decision about whether or not to use estrogen. Prescribing information is presented earlier in this chapter. Long-term efficacy of taking estrogen in lower doses for prevention of osteoporosis remains unknown at this time.

Calcium Therapy

A major goal of the use of calcium and vitamin D is increased bone health. Bone buildup is largely complete by the time one is a young adult. To assure a sufficient degree of bone density in adulthood, active promotion of adequate levels of calcium and vitamin D should begin with children and adolescents.

Most guidelines suggest supplementation with calcium and vitamin D both for prevention of osteoporosis and as part of the treatment protocol, especially if screening suggests vitamin D deficiency. Supplementation with vitamin D to an acceptable level of greater than 30 ng/mL before initiating bisphosphonate therapy is recommended.

The wholesale use of calcium and vitamin D supplements for the community-dwelling postmenopausal woman is no longer endorsed by the USPSTF (2013). The evidence only supports use being limited to institutionalized elders over 65 or those who have demonstrated a fragility fracture. The use of vitamin D is still endorsed as a falls risk preventative; hence, those with a prior fracture, high falls risk, and with demonstrated deficiencies are the only patients now being encouraged to take these supplements. The long-term, automatic use of calcium and vitamin D supplementation has not reduced the risk of fractures in those in the community without fracture histories (Nestle & Nesheim, 2013).

When indicated, calcium is the least expensive drug used in osteoporosis therapy. Generic calcium carbonate (Tums) costs pennies a day and contains the most elemental calcium per dose. It should be taken with food to enhance absorption because acid is needed for maximal absorption. Calcium citrate contains less elemental calcium but is better absorbed and may be preferred by patients with reduced gastric acid production (e.g., older adults) or high gastric pH such as those on proton pump inhibitors or histamine2 (H2) blockers because it does not require acid for absorption (NIAMSD, 2011). Calcium formulations should be taken with vitamin D to improve the uptake of the calcium.

For those with osteoporosis risk and osteopenia, dietary sources are encouraged. The typical American diet provides 600 to 1,000 mg calcium daily. The best calcium sources are dairy products and certain vegetables such as broccoli. Whole milk is not recommended for infants after 12 months of age, but yogurt and cheese can be introduced in the infant diet

after 6 months of age (Office of Dietary Supplements, 2013). Yogurt has more than 400 mg per 8-oz serving and broccoli has 150 mg. The average absorption of calcium from dietary sources is only 10% to 12%. Vitamin D is necessary for optimal absorption. Table 38-3 shows the recommended dietary calcium intake in the United States by age. This includes the maximum recommended dosing; overintake is potentially harmful. What remains unclear is the dosing for obese patients. It is understood that Vitamin D absorption is reduced up to 40% (Dihaliwal, Mikhail, Feurerman, & Aloia, 2014), but dosing recommendations specific to the population were not found.

Calcium supplementation is economical. Table 38-4 presents information on available calcium preparations. When increased demand after menopause exceeds the typical dietary intake (1,200 mg), calcium alone as a supplement is not enough to prevent or treat osteoporosis. Patients need

Table 38–3 Recommendations for Adequate Dietary Calcium Intake in the United States

Age	Calcium Intake (mg/d)	Upper Intake Levels (mg)
0–6 months	200	1,000
7–12 months	260	1,500
1–3 years	700	2,500
4–8 years	1000	2,500
9–18 years	1300	3,000
19–50 years	1,000 for men 1200 for women	2,500
50 to >70 years	1,200	2,000

Based on the Office of Dietary Supplements (NIH, 2013). Verified with USPSTF 2013 guidelines.

Table 38–4 Calcium Preparations

Drug	Active Calcium	How Supplied
Calcium acetate	25%	1,000 mg tabs (250 mg calcium)
Calcium carbonate	40%	650 mg tablets (260 mg calcium)
Calcium citrate	21%	950 and 2,376 mg in tablets (200 and 500 mg calcium)
Calcium gluconate	9.3%	500, 650, 975 mg and 1 g tablets (45 mg calcium)
Calcium lactate	13%	325 and 650 mg tablets (42.5 mg and 84.5 mg calcium)
Tricalcium phosphate	39%	1,565.2 mg tablets (600 mg calcium)

Source: Wolters Kluwer Health, 2011, *Drug facts and comparisons*. St. Louis, MO: Wolters Kluwer Health, Inc.

pharmacotherapy, used in conjunction with vitamin D, exercise, and avoidance of certain lifestyle behaviors.

If patients complain of constipation with calcium in combination with carbonate, other formulations need to be substituted. The presence of milk allergy and lactose intolerance can also greatly affect the amount of calcium in the diet and make supplementation mandatory.

Calcium is always ingested in combination with other ions. Depending on which ion, the dose may need to be given away from mealtimes to avoid reduced absorption. Most calcium supplements in combination are only 40% to 50% active, so the practitioner needs to calculate the number of tablets depending on the size of tablet. A 600 mg Tums tablet has 240 mg of active calcium, and five Tums tablets fulfill the requirements for a postmenopausal woman.

Bisphosphonate Therapy

Indications

Primary and Secondary Prevention

NICE (2011a) recommends alendronate (Fosamax) for *primary prevention* in women over 70 years who have an independent risk factor for fracture and for women over 75 years with more than two risk factors. This drug is recommended by NICE (2011b), USPSTF (2011), and the Canadian Consensus Conference for women who are over 65 years and who are confirmed to have osteoporosis (Reid et al, 2009). This drug has also been studied in men, as has risedronate. Ibandronate (Boniva) is recommended as second-line therapy in *primary prevention* for postmenopausal women over 65 years of age with prior vertebral fractures. The American College of Physicians (Qaseem et al, 2008) also recommends that providers consider drug therapy for men and women who are at risk for developing osteoporosis but does not specifically state which drugs to use. The NICE (2011b) guidelines also discuss *secondary prevention*. They recommend the same drugs in the same order for this purpose but limit this recommendation to postmenopausal women who have osteoporosis and have sustained a clinically apparent osteoporotic fragility fracture.

There may be positive outcomes for hip replacement patients who start bisphosphonates after implant surgery. There is a correlation between duration and adherence to bisphosphonate therapy and a 59% reduction in the risk for the need for revision surgery. This positive impact was not found for patients who had already been on bisphosphonates (Prieto-Alhambras et al, 2014).

Patients may present with osteopenia, a precursor to osteoporosis. If the patient has other risk factors for osteoporosis and is found to be osteopenic (bone density of 1 to 2.5 standard deviations below the average adult peak bone mass), treatment with a bisphosphonate may be indicated for prevention of osteoporosis; however, there are doubts whether this is the best choice for those without prior fracture. Osteopenia is not a disease state (Kanis et al, 2013). The debate whether osteopenia should be treated has moved toward an individualized risk-to-benefit ratio discussion that must be undertaken between patient and provider.

Adverse Effects

The adverse effects of bisphosphonate and other bone agent therapies are covered in more detail in Chapter 21. The important risk-to-benefit ratio discussion must include the very, very low rate of osteonecrosis of the jaw and the rare subtrochanteric femoral fractures. Atrial fibrillation development is linked with zoledronic acid use. The media has broadcast these issues with the implication that most patients are at risk. The reality is that the benefit and protection from avoidance of a hip fracture dramatically overshadows the low risks (Black et al, 2010; Rizzoli et al, 2011).

Suggestions are being made that a "drug holiday" should be scheduled after a period of 3 to 5 years of bisphosphonate use (McClung, 2013). The binding of the medication with the bone is long-term; therefore, it is probably still effective over the next 3 to 5 years. Considering the small potential of adverse events, arranging a temporary cessation of drug use over 2 years is being touted as keeping the good qualities of mortality reduction and continuing to support bone health. Those on long-term steroid therapy are probably not good candidates for a drug holiday (McClure et al, 2013).

Treatment of Postmenopausal Women

Among the bisphosphonates, alendronate (Fosamax), risedronate (Actonel), ibandronate (Boniva), and zoledronic acid (Zometa) are all approved for preventing and treating postmenopausal osteoporosis. Studies have been done in large numbers of postmenopausal women with low bone mineral density in varying lengths of time from 2 to 10 years. In each study, the number of symptomatic fractures was reduced. Risedronate was helpful for women who had demonstrated osteoporosis. Ibandronate studied in osteoporotic women or those at high risk showed a reduced rate of vertebral fractures, whereas alendronate, risedronate and zoledronic acid have demonstrated the ability to reduce both hip and vertebral fractures. Zoledronic acid is selected when prior oral bisphosphonate use has not retarded bone loss on scans or when oral agents are not well tolerated.

Dosage schedules vary among guidelines but generally have lower doses for prevention and higher ones for osteoporosis treatment. Patients with a history of GI bleeding, peptic ulcer disease, and gastroesophageal reflux disease (GERD) are not good candidates for bisphosphonates because of the esophageal irritation common with this drug class.

Treatment of Men

Treatment for men who are age 70 or older and who are diagnosed with osteoporosis or have a high risk for hip fracture is similar to that of women. Alendronate is the drug recommended as first-line therapy. In the event of bisphosphonate intolerance, men do not have the option of using estrogen or anti-estrogen therapy.

Treatment of Men and Women Taking Corticosteroid Therapy

Both alendronate and risedronate are approved for use by men and women with glucocorticoid-induced osteoporosis (Watts et al, 2010) as first-line therapy (*Drug Facts and*

Comparisons, 2009; ICSI, 2011). The corticosteroid dose mentioned is equivalent to 5 mg/d of prednisone for a duration of 3 or more months. Chapter 21 provides more information on these drugs, including their dosing.

Cost Versus Dosing Schedule

Because the cost is approximately the same for all oral drugs that have gone generic, the convenience of once-monthly dosing may favor ibandronate. Obviously, the required infusion center costs associated with the zoledronic acid places it in a much higher cost tier. The cost and convenience of bisphosphonates should also be compared with much lower costs for estrogen and estrogen-progestin therapies (as appropriate). ERT/HRT dosing is typically daily.

Adequate supplementation with calcium and vitamin D is necessary before initiating therapy, and some newer formulations have either vitamin D or calcium included. No dosage adjustment is necessary as long as renal function remains between 35 and 60 mL/minute. Creatinine levels must be checked prior to any zoledronic acid infusion.

Reports that generic bisphosphonates, especially alendronate, are causing more GI side effects than the branded version have surfaced (Kanis et al, 2012). If true, that means more patients will be nonadherent to the plan. Substitution with the brand-name drug will increase costs; however, so will the costs of avoidable fractures if the patient refuses therapy.

Selective Estrogen Receptor Modulators

Raloxifene

Raloxifene (Evista) is a selective estrogen receptor modulator (SERM) approved to treat osteoporosis. Postmenopausal women with established osteoporosis had a statistically significant reduction in vertebral fractures when taking 60 mg to 120 mg of raloxifene at the 3-year mark, but at 8 years this difference disappeared. There was, however, a marked reduction in the incidence of invasive breast cancer in women taking this drug for the same period.

Though considered an alternative to tamoxifen as a breast cancer antagonist, raloxifene is not as powerful as the other SERM drugs for that indication. Postmenopausal women taking raloxifene versus placebo had a lower risk for cardiovascular events, most likely secondary to lowered serum LDL. It is indicated for prevention and treatment of osteoporosis in women who do not want to use or are unable to take estrogen therapy. It shares with estrogen the precaution to avoid use in women who have previously had a deep vein thrombus or embolism. SERMs only block estrogen binding, but free serum estrogen remains in the system (Zhang et al, 2012); therefore, they cannot comfortably be taken by pre- or perimenopausal women due to the presence of higher levels of natural estrogen and subsequent intolerable hot flashes.

Guidelines do not recommend raloxifene for *primary prevention* of osteoporotic fragility fracture in postmenopausal women but do list it as a second-line drug for secondary therapy. It is also second-line therapy for women without thrombotic risk who are at increased risk for breast cancer.

Bazedoxifene and others

Bazedoxifene in combination with a conjugated equine estrogen (Duavee) is a SERM plus estrogen combination marketed primarily for dyspareunia treatment. The SERM component of bazedoxifene is protective for the uterus from the estrogen component. It has positive bone health and reduction of menopausal hot flash characteristics as well. Most SERMS have vertebral bone improvement indications; Duavee has shown improvement in hip density. The FDA has indicated it be used for bone health for postmenopausal women with significant risk of bone loss. It carries all the contraindications and risks of any other estrogen-containing medication.

Raloxifene appears to work better in younger patients; bazedoxifene appears to work better as the risk for more fractures increases. These findings are not established until there is longer term use of bazedoxifene.

Adverse Reactions

When compared with estrogen and progesterone, raloxifene's adverse reactions were in the areas of more hot flashes, genital and urinary infection, and chest pain. HRT, by contrast, demonstrated more vaginal bleeding, breast pain, and flatulence. Bazedoxifene plus estrogen carries similar side effects of both of these drug classes.

A previous history of venous thromboembolic events such as deep vein thrombosis, pulmonary embolism, and retinal artery embolism is a contraindication for use of SERMs. Patients with multiple risk factors for osteoporosis should receive BDM assessments to evaluate their need for this drug.

Patients need to be warned that these drugs should be discontinued 72 hours prior to prolonged bedrest and to avoid inactivity while traveling by car or plane. Women need to know that raloxifene medication will not stop hot flashes; in fact, it could trigger hot flashes at the beginning of therapy.

Cost and Dosing Schedule

The dose of raloxifene is 60 mg daily without regard to meals. The cost for a 1-month supply is about the same as for bisphosphonates but over twice the cost of estrogen. It must be taken daily. Bazedoxifen plus estrogen is also a daily medication which comes in 0.45 mg/20 mg and 0.625 mg/20 mg doses. As a brand name drug the cost is higher than most generics. Concurrent supplements of calcium and vitamin D daily are still needed with all SERM medications.

Human Parathyroid Hormone

Teriparatide (Forteo) is the only drug in this class and has limited indications. It is reserved for women at high risk of fracture, including those with very low bone mineral density with a previous vertebral fracture and who are unable to take a bisphosphonate or have had an unsatisfactory response to other therapies. It should be used only after evaluation by a specialist. A prospective, placebo-controlled trial in a large number of women with postmenopausal osteoporosis whose

average age was 70 years found a statistically significant decrease in the incidence of vertebral fracture. The doses used in this study were 20 mcg to 40 mcg once daily for 21 months. The safety and efficacy of this injectable drug have not been evaluated beyond 2 years of treatment. It is very costly and has some possible cancer-causing long-term effects. With its very limited indications, it is a third-line drug in treating osteoporosis.

Combination Therapy

Additive effects on bone mineral density tests have been found with alendronate plus raloxifene combinations and in estrogen plus bazedoxifene (Duavee); however, evidence that this will reduce fractures at a higher level is still not established. There is some concern that this combination of two different reabsorptive agents could suppress bone turnover to the point that fracture might actually be increased. This concern is echoed when a bisphosphonate is followed by a PTH medication or denosumab (Kanis et al, 2013). Early studies imply that SERM therapy after PTH analogue may increase the benefit gained from the original analogue impact (Kanis et al, 2013). Teriparatide and bisphosphonates did not have added value. The combination of teriparatide and denosumab after 1 year of therapy had much more positive impact than each used separately (Tsai et al, 2013). This is especially encouraging due to the increase in the femoral neck and hip density. However, the suspicion that bone formation is suppressed as evidenced by newer biomarkers of bone turnover has the experts withholding full endorsement of this therapy (Tsai et al, 2013).

Comparisons

Estrogen is effective in preventing fractures but has cardiovascular and cancer risks. Most SERMs are also effective in preventing fractures, have less cardiovascular risk, and actually reduce the risk for breast cancer, unless mixed with estrogen. They still carry the thromboembolic risks. All require daily dosing. Bisphosphonates are effective in preventing fractures and have once-weekly or once-monthly dosing. They do not have breast cancer reduction characteristics. Bisphosphonates are listed as first-line therapy for osteoporosis in all the guidelines. Estrogen and SERMs are secondary medications for osteoporosis. Synthetic PTH meds have specific indications and carry cost issues and possible cancer risks. Calcium, especially when combined with vitamin D, is central to prevention of osteoporosis and the resultant fractures. They are inexpensive and should be used even if other drugs are chosen. Vitamin D alone is ineffective for osteoporosis treatment or risk reduction (Aloia et al, 2013) Finally, low-impact weight-bearing exercise is critical to prevention of osteoporosis. It should be noted that tamoxifen is a SERM, but contributes to bone loss in premenopausal women. Table 38-5 shows comparison of fracture reduction by class. Figure 38-3 depicts an algorithm for the prevention of osteoporosis in patients without the disease, and Figure 38-4 presents a treatment algorithm for osteoporosis.

Table 38–5 Fracture Risk Reduction Comparisons

	Vertebral Fracture Reduction	Non-Vertebral Reduction
Bisphosphonates		
Alendronate	48%	50% spine and hip
Ibandronate	50%	29.9%
Risendronate	36%	41%–49%
Zoledronic acid	70&	41% hip
Anabolic Hormone		
Teriparatide	65%	53%
Estrogenic Hormone		
Estrogen		34% combined hip and vertebral
Rank Ligand Inhibitors		
Denosumab	68%	
Selective Estrogen Receptor Modulators		
Raloxifen	30%–55%	
Estrogen plus Bazedoxifene	1.5%	1.21%

Based on information from Wright (2011) and manufacturer resources.

Monitoring

Before beginning treatment for osteoporosis, rule out common treatable disorders that can also cause low bone density. These include hyperparathyroidism, vitamin D deficiency, hyperthyroidism, and renal disease. Tests for these disorders are serum calcium and albumin, 25-hydroxy vitamin D, TSH, and serum creatinine levels, respectively. Serum creatinine levels are drawn prior to initiating therapy.

Measurement of bone mineral density is the most accurate predictor of fracture risk and efficacy of these drugs. Each 10% change below peak bone mass is associated with a doubling of the fracture risk for patients with osteoporosis. Dual-energy x-ray absorptiometry (DEXA) is the gold standard by which bone mineral density and therapy are monitored, but a quantitative computed tomography (QCT) can be used. Initial evaluation with these scans can also suggest when a disease process other than aging is the probable cause of the bone loss (Table 38-6).

Once therapy has been established, DEXA is repeated 1 to 2 years later to determine progress. Only the dual-energy DEXA can be used to monitor progression after therapy is initiated. How often to repeat DEXA at later dates is controversial (Rosen & Drezner, 2013). According to the American Association of Clinical Endocrinologists (AACE) (Watts, et al, 2010), DEXA should be used for the following:

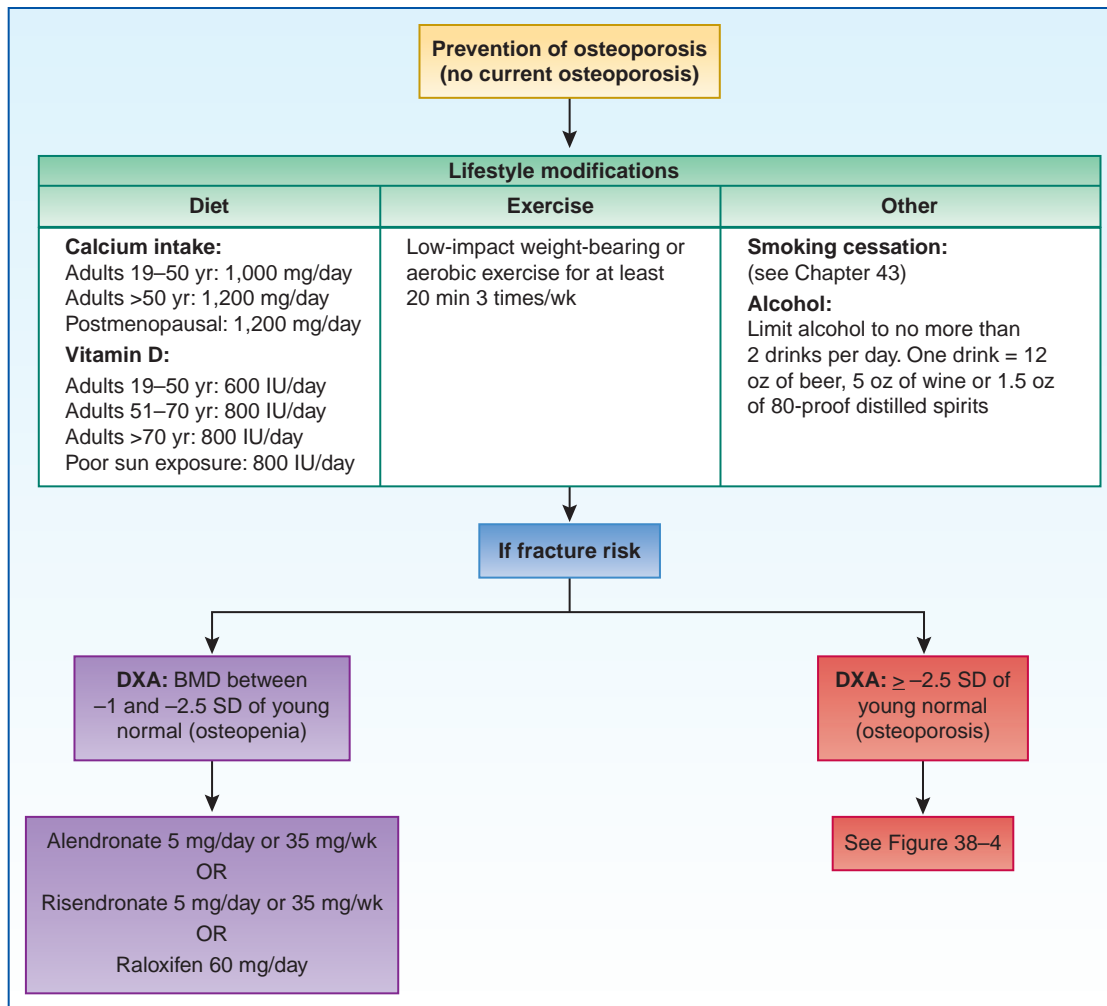
1. Women who are estrogen-deficient, to make decisions about therapy


Figure 38–3. Prevention of osteoporosis in patients without the disease.

2. Women who have vertebral abnormalities or osteopenia detected on x-ray, to confirm the diagnosis
3. Patients who are being treated for osteoporosis, to monitor for treatment efficacy
4. Patients receiving long-term glucocorticoid therapy, to guide therapy to preserve bone mass
5. Patients with asymptomatic primary hyperthyroidism or other diseases associated with high risk for osteoporosis, to make therapy decisions.
6. All women 40 years and older who have sustained a fracture
7. All women older than 65 years

ICSI (2011) adds the following risk factors:

1. Body weight less than 127 lb or BMI less than or equal to 20
2. Current smoker
3. Surgical menopause before 40 years
4. On hormone replacement for more than 10 to 15 years
5. Premenopausal women with amenorrhea for more than 1 year
6. Anyone with severe loss of mobility (unable to ambulate outside one's dwelling without a wheelchair) for more than 1 year

Table 38-5 lists methods for bone density measurements. The use of heel scans sometimes found in health fairs and shopping malls can give a false sense of security; the heel is one of the densest bones in the body and requires quite a bit of skeletal bone loss elsewhere before it typically becomes less dense. A "good" heel scan can create an impression of sound bone health, when the opposite is true. Imaging studies of the chest, extremities, and spine can easily uncover occult bone density issues even when obtained for nonbone health reasons.

Estrogen

Estrogen requires the same monitoring when prescribed for osteoporosis as it does when it is used for ERT/HRT. Obtain annual renal function tests on all patients older than 65 years and on those with potentially reduced renal function, such as patients with diabetes.

Calcium

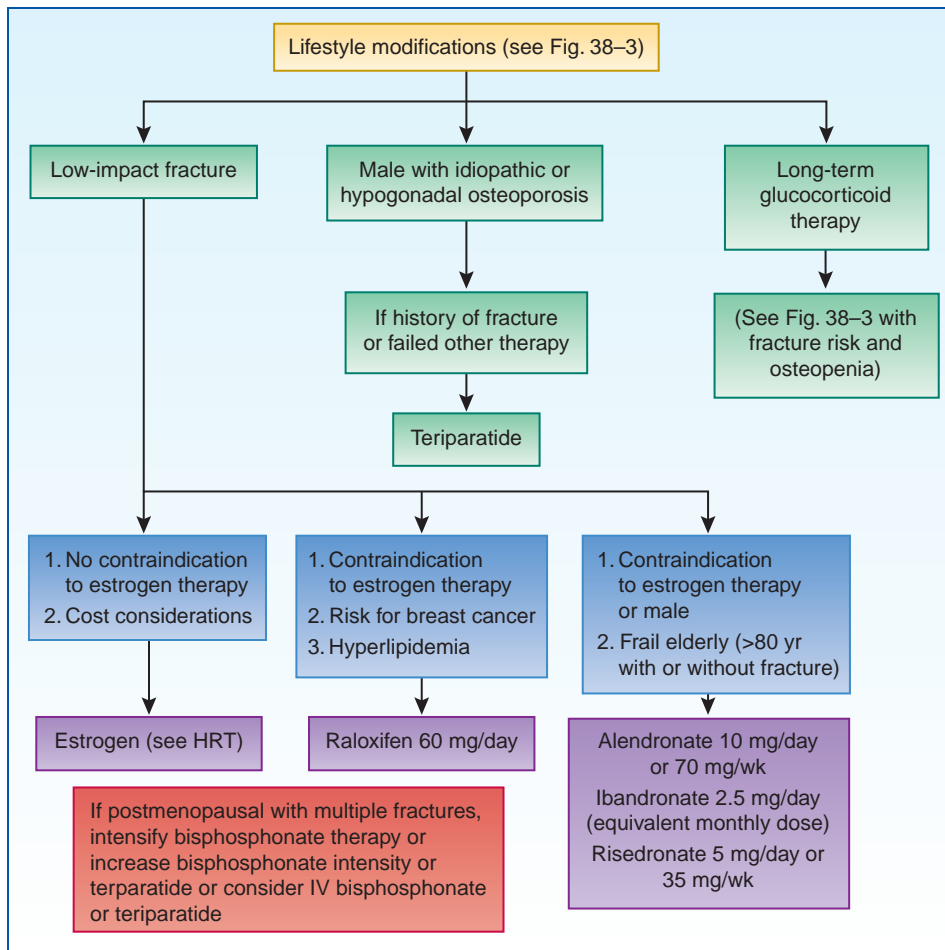
The use of calcium alone for supplementation rarely needs blood test follow-up, but treatment of conditions with vitamin D and high-dose calcium can induce high levels in serum and then in the kidneys.


Figure 38–6. Treatment algorithm: Osteoporosis. (Adapted from *Osteoporosis and African American Women; Osteoporosis and Asian American Women; Osteoporosis and Hispanic Women* [all from NIAMS documents, 2005]; and National Osteoporosis Foundation, 2004, *Physician's Guide.*)

Bisphosphonates

Monitoring of bisphosphonates is aimed at electrolyte measurement, renal function, and GI symptoms of patients older than 65 years, and of those with multiple medical conditions.

Dosage alterations or contraindications to using specific bisphosphonates occur with serum creatinine levels above 2.5 mg/dL or creatinine clearance less than 30 mL/min. Because bisphosphonates inhibit intestinal calcium transport, careful monitoring of serum calcium should be done during therapy. Phosphate, magnesium, and potassium should also be monitored because these electrolytes may be altered by bisphosphonate administration.

SERMs

Evaluation of therapy with SERM therapy can be done every 2 years with DEXA, but beneficial effects may be demonstrated as early as 1 year after therapy. Other monitoring is similar to that of estrogen.

Outcome Evaluation

Osteoporosis is expected to begin 2 to 5 years after menopause in women not using ERT/HRT. Assess patients who have had fractures, unusual bone pain, high-risk physical characteristics, or a history of systemic cortisone use. The

Table 38–6 Common Methods for Bone Density Measurements

Test	Sites Measured	Comments
Dual energy x-ray absorptiometry (DEXA)	Spine, hip, total body	Limitations: misdiagnoses low bone mass in patients with arthritis, spinal deformity, or prior spinal surgery
Peripheral dual energy x-ray absorptiometry (P-DEXA)	Wrist, finger, heel	Limitations: older adults who tend to have arthritis in these sites (see above). Omits several areas (vertebra and hip) that are common sites of osteoporosis in this age group. Cannot be used to measure progress of therapy.
Quantitative computed tomography (QCT)	Spine and hip	Good with spinal issues. Limitations: machine must be recalibrated between uses; higher radiation
Ultrasound	Heel, tibia, finger	Limitations: new, younger, no x-ray

advanced practice nurse can begin this evaluation with a history and physical examination, laboratory tests, and imaging studies. If any of these tests or imaging studies indicates acute bone pathology, referral for specialty care is indicated.

Patients who have other medical conditions and multiple medications to manage are candidates for consultation or referral. Consider referral if more than one consultation is made with the specialist over medication choices. After therapy is established and the patient is not having adverse drug effects, most primary care providers handle routine monitoring.

OSTEOPOROSIS

PATIENT EDUCATION

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues. Patients who have taken teriparatide should take advantage of the voluntary patient registry to help track the rare occurrence of osteosarcoma.

Related to the Overall Treatment Plan/Disease Process

☐ Pathophysiology of the dynamic relationship between the osteoclasts and osteoblasts in the process of bone metabolism to help the patient understand how the lack of estrogen begins a cascade of events ending with the increased risk of osteoporosis in the early years after cessation of menses. For men, discussion of the role of other factors is important.

☐ The role of excessive intake of alcohol, nicotine, and caffeine and low intake of calcium and vitamin D as modifiable risks for osteoporosis and how nondrug treatments such as diets high in calcium and vitamin D, exercise, and avoidance of the high-risk lifestyles can help to prevent osteoporosis.

☐ An understanding of how knowledge of family history, ethnicity, and genetic characteristics helps to identify patients with nonmodifiable risk factors for osteoporosis.

☐ Importance of adherence to the treatment regimen

☐ Importance of supplementing the diet with additional calcium (up to 1,500 mg) and vitamin D (800 mg) to the osteoporosis therapy

☐ Self-monitoring of symptoms

☐ What to do when symptoms worsen

☐ Need for regular follow-up visits with the primary care provider and for screening tests such as BMDs every 2 years.

Specific to the Drug Therapy

☐ Reason for the drug(s) to be taken and anticipated action in the disease process

☐ Doses and schedules for taking the drug(s)

☐ Possible adverse effects and what to do if they occur

☐ Interactions between other treatment modalities and these drugs

Reasons for Taking the Drug(s)

Patient education specifically for osteoporosis should include the following: that prevention of osteoporosis is more successful than having to treat it later, especially in those who have a hereditary tendency for bone loss disease; treatment of fractures is far more expensive than drug therapy; and postmenopausal fractures are associated with early loss of independent living and reduced life expectancy.

Drugs as Part of the Total Treatment Regimen

The total treatment regimen includes lifestyle modification: healthy diet, dietary supplements, and exercise. However, these lifestyle modifications may not be enough, especially in older patients. Some form of drug therapy is usually necessary. A variety of therapies are available, and selection of estrogen versus nonestrogen therapy is possible with the same results for prevention and treatment of spine, hip, and wrist fractures associated with osteoporosis.

Adherence Issues

Adherence issues include the following:

☐ Media reports about disease and drug therapies have an increasing impact on patients and primary care practices.

☐ Membership in health maintenance organizations may affect the choice of drugs patients will receive.

☐ Patients' fears or issues about drug therapy may not be based on facts.

☐ Drug therapy educational handouts should be available to patients and their families.

☐ Monitoring appointments are problematic if patients are homebound or transportation is difficult.

HYPERLIPIDEMIA

Marylou V. Robinson

Cardiovascular diseases (CVD) are the major cause of death in the United States. Almost 500,000 people die each year from heart attacks, most commonly related to coronary artery disease (CAD). The care focus is expanding beyond just CAD or coronary heart disease (CHD) to include CVD issues of peripheral vascular disease and strokes as equally important endpoints for evaluating therapeutic effect. One-third of the American population is considered to be at high risk for CVD. The perfect storm of an obesity epidemic, uncontrolled hypertension, metabolic syndromes, and rampant consumption of nutritionally risky diets combined with high stress and lack of regular exercise are all components of the problem. This chapter focuses upon the major contributor of cholesterol to the pathological picture.

Atherosclerosis is characterized by deposits of cholesterol and lipoproteins in artery walls. Three major classes of lipoproteins are found in the serum of fasting individuals: low-density lipoproteins (LDL), high-density lipoproteins (HDL), and very-low-density lipoproteins (VLDL). Guidelines for identifying risk for CAD and CVD have traditionally focused on serum cholesterol levels above 200 mg/dL, fasting triglceride TG levels above 150 mg/dL, and LDL levels above 100 mg/dL. The newest guidelines place a stronger emphasis upon individual risk factors with lifestyle and pharmacological therapies individualized to reduce that risk. In the classic Framingham studies, a 10% decrease in serum cholesterol level was associated with a 2% decrease in the incidence of CVD morbidity and mortality. Other studies have confirmed, in men and women who were initially free of CHD, a direct relationship between levels of LDL cholesterol and the rate of new-onset CHD. Early trials with HMG-CoA reductase inhibitors (statins) indicated that a 1% decrease in LDL cholesterol reduces the risk of CVD by about 1% (National Cholesterol Education Program [NCEP], 2001). However, these studies and risk tools were not reflective of the true American population because they did not include African Americans and women. Frequently, healthier cohorts of individuals were enrolled in longitudinal studies to monitor the onset of CVD risks in the population. The current guidelines attempt to be more inclusive of the average population.

The management of hyperlipidemia presented is based on the 2013 guidelines of the American College of Cardiology and the American Heart Association but also reflects the anticipated therapeutic shifts that will evolve from developing perspectives over time and the publication of the JNC-8 and Obesity guidelines (JNC-8, 2014; Stone et al, 2013). Chapters 14 and l6 provide specific information on the drugs used.

PATHOPHYSIOLOGY

Serum fat and cholesterol are carried in the circulation in complexes of lipids and proteins called lipoproteins. Fat is transported as TG and phospholipids, and cholesterol is

transported in free and esterified forms. Most of the cholesterol in plasma is carried in LDLs. High concentrations of LDLs are associated with an increased risk of CVD. Serum lipoproteins are formed via two pathways: dietary, or exogenous, and liver synthesis, or endogenous.

Exogenous Pathway

After a meal, fat and cholesterol are absorbed by the intestinal cells, esterified into TG and cholesterol, and then packaged into chylomicrons, which are transported via the lymphatic system to the thoracic duct where they enter the venous circulation. Activated endothelial lipoprotein lipase then hydrolyzes the TG into free fatty acids and glycerol, which are removed from the circulation for use by fat and muscle cells. Surface cholesterol is transferred to HDLs. The chylomicrons shrink during this process and become remnants that are removed from the circulation by apolipoprotein (apo) E after it binds to a liver receptor. Antihyperlipidemic pharmacotherapy focuses on the pathway in which fats are absorbed, transported, and metabolized. Medications that affect the absorption of fat and cholesterol in the intestine are classified as bile acid-binding resins, and medications that increase lipolysis of TG are classified as fibric acid derivatives. Lifestyle modifications also affect the absorption, transport, and metabolism of fats through this pathway.

Endogenous Pathway

VLDLs are synthesized and secreted by the liver into the circulation and contain TG and some cholesterol. VLDL is hydrolyzed to free fatty acids and glycerol by lipoprotein lipase in the capillary endothelium. Fat and muscle cells absorb the fatty acid and glycerol. About 50% of the VLDL remnants are taken up by apo B and E receptors in the liver, and the other 50% stays in the circulation and becomes intermediate-density lipoproteins (IDLs). IDLs are then enriched with cholesterol by hepatic triglyceride lipase to become LDLs, which carry about 75% of the circulating cholesterol. LDLs circulate for 2 to 3 days and are removed for use by all types of tissue.

LDL receptors in the liver are downregulated by the presence of LDL; therefore, one mechanism for lowering LDLs is pharmacotherapy that increases the number of LDL receptors in the liver (bile acid-binding resins, statins). Drugs that inhibit VLDL synthesis in the liver (niacin, fibric acid derivatives) also reduce LDLs via the endogenous pathway.

On The Horizon

Drugs in the pipeline are seeking to interfere with the synthesis of PCSK9 (proprotein convertase subtilisin/kexin type 9) in the liver. This liver protein is part of the natural synthesis of cholesterol in the body. If blocked with a targeted RNA particle, cholesterol levels drop (Fitzgerald et al, 2013).

Atherogenesis

There are four main types of lipoproteins: VLDLs, IDLs, LDLs, and HDLs. The lipoproteins that contain apo B100 have been identified as the vehicles that facilitate transport of cholesterol into the arterial wall, leading to atherogenesis. LDLs, which make up 60% to 70% of the total serum cholesterol, are the major culprit in this inflammatory-mediated process. LDL levels are increased in individuals who consume large amounts of saturated fats and/or cholesterol, who have defects in the hepatic LDL receptor (familial hypercholesterolemia), or who have a polygenic form of increased LDLs. The relationship of elevated LDL cholesterol to the development of CVD is a multistep process beginning relatively early in life (McCrindle, Kwiterovich, McBride, Daniels, & Kavey, 2012; National Heart, Lung, and Blood Institute [NHLB], 2011).

When serum LDL levels exceed a threshold of 100 mg/dL, they cross the arterial wall and become embedded in the arterial lumen. In the arterial lumen, LDLs undergo oxidation, are taken up by macrophages, and form a plaque known as a fatty streak. The severity is related to the degree of inflammatory changes and metabolites to include Lipoprotein-Associated Phospholipase A2(Lp PLA $_2$). Atherosclerotic plaques are made up of foam cells, which are transformed macrophages and smooth muscle cells filled with cholesterol. Glycation of lipoproteins in poorly controlled diabetes also contributes to foam cell generation. Arterial hypertension accelerates this process. HDL suppresses the foam cell production, resulting in an anti-inflammatory response. The role of HDL may have less significance than previously believed, with the exception of when it increases after baseline values were very low (Vogel, 2013); but more evidence is needed to move away from all efforts to raise serum HDL levels.

The second step of atherogenesis involves the formation of scar tissue over the fatty plaque in the arterial wall. This formation is called a fibrous plaque. Over time, fibrous plaques become unstable and are prone to rupture, causing potentially life-threatening luminal thromboses. Plaque rupture or erosion is responsible for most acute coronary events (e.g., myocardial infarction, unstable angina, and coronary death). Elevated LDL cholesterol provides fatty substrate for plaque formation, and the larger the plaque, the more unstable it will be.

HDLs, which make up 20% to 30% of total serum cholesterol, function as acceptors of free cholesterol as it passively diffuses from cells. This reverse transport is the mechanism by which cholesterol may be removed from atherosclerotic plaques. Figure 39-1 shows the relationship of lipid metabolism to atherosclerotic plaque formation. Apo A-I and A-II are the major apos in HDL. The level of apos and HDLs are proposed to be inversely related to CVD risk. As serum HDL and apo levels increase, it is believed atherogenesis decreases.

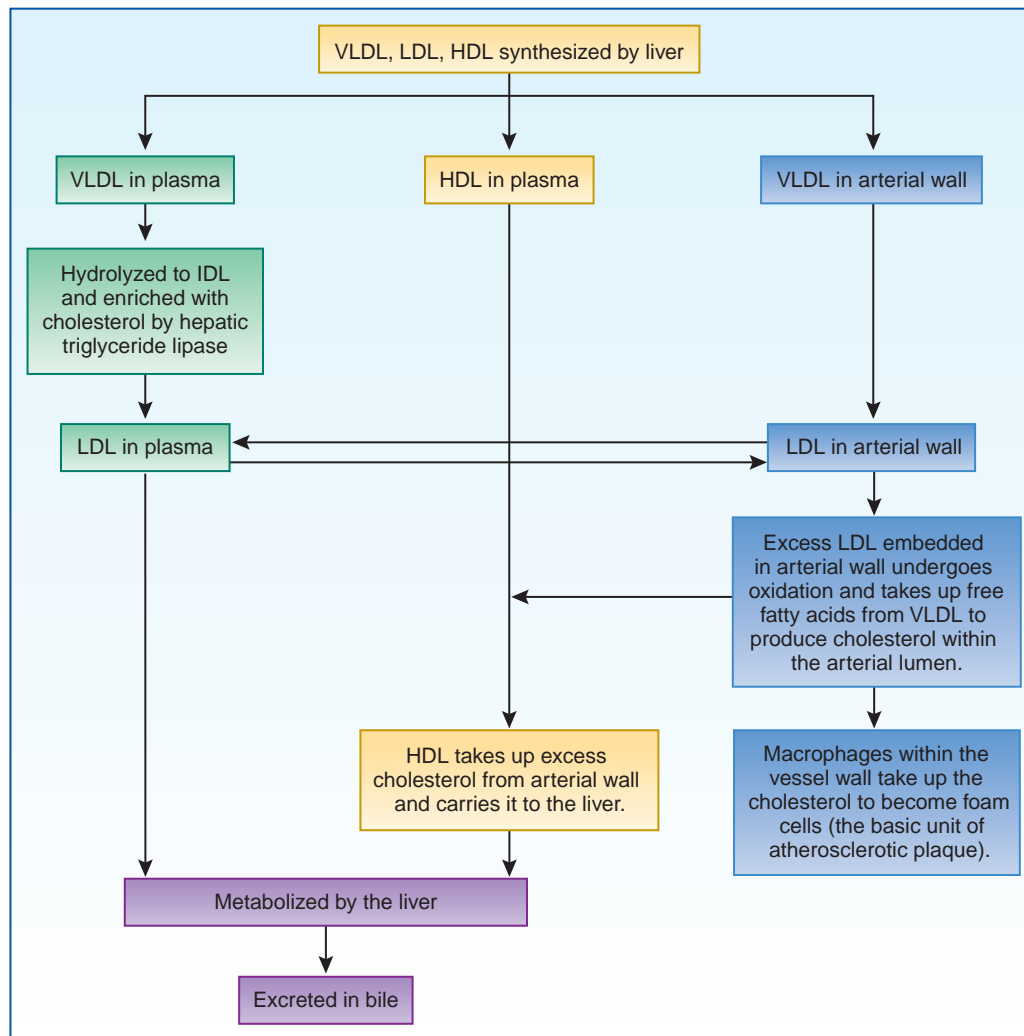
Although LDLs are the lipoprotein toward which therapy has been traditionally directed, some experts believe the ratio of total cholesterol to HDL to be a more powerful predictor of atherosclerotic CVD risk. Strong epidemiological evidence links low levels of HDL cholesterol to increased coronary


Figure 39–1. Relationship of lipid metabolism to atherosclerotic plaque formation. Excess LDL embedded in the arterial wall undergoes oxidation and takes up free fatty acids from VLDL to produce cholesterol within the arterial lumen. If the excess cholesterol is not taken up by HDL and carried to the liver, macrophages within the vessel wall create atherosclerotic plaque from this excess cholesterol.

morbidity and mortality, and low levels are consistently shown to be an independent risk factor for CVD. However, high values do not confer the reduction in risk once hoped for (Vogel, 2013). Factors that contribute to low HDL are shown in Table 39-1. Each of these factors has been a target of therapy, but results have not been stellar. Drugs that may raise HDL levels include nicotinic acid (niacin), fibrates, and statins. There are drugs in development that specifically target increasing HDL levels, but they have not had major successes yet in preliminary clinical trials.

To make the divisions of "good and bad" more complex, newer research has determined that HDL can "go bad" and become dysfunctional if oxidized by myeloperoxidase. This would reverse the typical "cleansing" function of HDL; it would instead harden and become part of a dangerous arthroma (Huang et al, 2014). Because the HDL testing cannot yet discriminate between "good " versus "bad" forms of the HDL, no therapeutic decisions or options are available at this time.

Table 39–1   Factors That Contribute to Low HDL Cholesterol Levels

Cigarette smoking
Drugs: beta blockers, anabolic steroids, progestational agents
Elevated serum triglycerides
Genetic factors (approximately 50% of cases)
Overweight and obesity (probably most important)
Physical inactivity
Type 2 diabetes mellitus
Very high carbohydrate intake (>60% of total energy intake)

Source: Adapted from the *Third Report of the Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol in Adults,* 2001. Rockville, MD: National Institutes of Health, National Heart, Lung, and Blood Institute.

VDDL Levels

VLDLs are triglyceride-rich lipoproteins that contain 10% to 15% of the total serum cholesterol. The major apos of VLDL are apo B100; apo C I, II, and III; and apo E. VLDLs

are produced by the liver and are precursors of LDL. Some forms of VLDL, particularly VLDL remnants, appear to promote atherosclerosis similarly to LDL. VLDL + LDL cholesterol is called non-HDL cholesterol. The non-HDL number can be calculated by taking the total cholesterol (TC) and subtracting the HDL. Non-HDL cholesterol includes all lipoproteins that contain apo B and is now considered to be a two times better predictor of CV events than LDL (Davidson et al, 2011). Individuals with high TG (200 to 499 mg/dL) , also present as having most of their cholesterol in these small VLDL remnants.

Understanding the role of inflammatory markers, especially C-reactive protein (CRP), has shifted the emphasis away from primarily treating LDL (Davidson et al, 2011). The JUPITER trial demonstrated that the inflammatory markers are more important for outcomes. The antioxidant properties of statin medications may turn out to be at least equally effective as their antilipid effects. This evidence prompted the Food and Drug Administration (FDA) to approve statin use (specifically, Crestor) in individuals without CVD with increased CRP levels over 2 mg/L and one other risk factor like HTN, strong family history, or smoking habits (FDA, 2010). Even cardiac events are more closely related to non-HDL-C than are LDL and apo B levels (Boekholdt et al, 2012). This is especially true in diabetics. This newer emphasis on non-LDL risk prediction is now formally incorporated into individual risk guidelines (Ansell, 2012). Lipid experts claim the non-HDL levels will become a more potent predictor of risk than the LDL (Boekholdt et al, 2012). This would be a shift in who gets treatment. Using 2001 guidelines, someone with a normal LDL but high non-HDL would not be treated; in the 2013 guidelines, they would be treated after consideration of all other cardiovascular risk factors.

Elevated TG is also recognized as an independent risk factor for CVD. TGs are closely linked with metabolic syndrome and diabetes. TG levels greater than 150 mg/dL should be treated once the LDL interventions are undertaken. If the initial medications do not subsequently reduce TG, then pharmacotherapy to directly address TGs must be considered to handle this other non-HDL risk. If TGs are over 150 mg/dL, the measurement of LDL is less accurate, making therapeutic judgments more complex. Isolated TG elevations cannot be treated with statins alone; they should be treated with fibrates, niacin, or omega-3s (Berglund et al, 2012).

GOALS OF TREATMENT

The therapeutic goal for the management of hyperlipidemia is to reduce morbidity and mortality from CVD by reducing atherogenesis. Research suggests that at least a 30% to 40% decrease in LDL levels needs to be achieved to reach this goal (Grundy et al, 2004). Because LDL cholesterol levels below 100 mg/dL throughout life are associated with very low risk for CVD, they were traditionally termed "optimal"; however, several major clinical trials published since the ATP III guidelines have indicated that an LDL goal of lower than 70 mg/dL may be a reasonable therapeutic option for patients when CVD risk is high to very high. Current guidelines do not focus on a particular numeric endpoint with one size fitting all. The key is reduction of risk. This is partially due to the fact that when statins reduce the level of LDL, the athrogenic apo B particles are not lowered to the same extent (Davidson et al, 2011).

The target of very low serum levels is contentious. Very low LDL has been implicated as a cause of depression, anxiety, and memory loss. Serum levels of LDLs may have an effect on neurological serotonin levels. These concerns were primarily based on case reports with naturally occurring extra-low LDL levels, not drug-induced states (Zhang et al, 2005). The FDA issued a safety warning in 2012 about these rare cases; however, a review of 57 studies found no evidence to support the claim of memory impairment over the long term (Richardson et al 2013). Cancer risks with low serum LDL levels have been shown to be the same with either high or low lipid levels (Yang et al, 2008) . Because the level of adverse events associated with the treatment of hyperlipidemia has not been established, the reporting of any CV event is important. One more recently reported is the low, but potential, risk of developing new-onset diabetes with statins. This is more common in individuals already at high borderline metabolic risk when taking rosuvastin and a less obvious trend with the less efficacious pravastatin (Navarese et al, 2013). This recent meta-analysis and a 2012 FDA warning have yet to alter therapeutic initiatives because the risk of significant CV issues from cholesterol is significantly higher than the risk of developing DM.

Lipid reduction also decreases the primary risk of non-hemorrhagic stroke and is also effective in secondary prevention of subsequent ischemic strokes (Elkind, 2013). Each 39 mg reduction of LDL decreases the relative risk of stroke by 21%. This is why strokes have been added as a hard-stop endpoint for calculating cardiovascular risk.

Atherogenesis occurs even when serum LDL cholesterol levels are 100 to 129 mg/dL, especially with higher inflammatory markers (Davidson et al, 2011). Atherogenesis proceeds at a significant rate when LDL levels are 130 to 159 mg/dL; such levels are termed "borderline high." Markedly accelerated atherogenesis occurs at levels of 160 to 189 mg/dL (high) and over 190 mg/dL (very high). Davidson and associates (2011) rank CRP levels of 1.0 to 3.0 mg/L as conferring intermediate risk and high risk at greater than 3.0 mg/L, even without links to high LDL.

Confirmed by log-linear data, a clear increased risk of CVD exists in populations who have higher serum LDL levels (NCEP, 2001). Unfortunately, an independent relationship between LDL reduction and actual percentage of risk reduction is unclear. Data that specify how much a reduction in serum level LDLs decreases how much risk of CVD are not available. The reports of relative risk reduction are extrapolations from the data, not actual endpoints. Early clinical benefits of statin therapy are now recognized to be lipid-independent! This is likely related to the reduction of vessel endothelial inflammation (pleiotrophy) of this drug class.

Atherosclerosis can be identified on gross pathological examination of coronary arteries in adolescence and early adulthood (McCrindle et al, 2012; NHLB, 2011). The cholesterol level in young adulthood predicts the development of CVD later in life. Prospective studies with long-term follow-up have found that elevated serum cholesterol and more rapid changes in BMI in the teenage years (Attard, Herring, Howards, & Gordon-Larsen, 2013) and early adulthood predicted an increased incidence of CVD in middle age. Traditional clinical intervention with LDL-lowering therapy in adult patients with advanced coronary atherosclerosis results in a short-term risk reduction aiming to stabilize plaque and prevent acute coronary syndromes. In contrast, LDL-lowering earlier in life slows atherosclerotic plaque development, the foundation for unstable plaque. This provides a rationale for long-term lowering of serum LDL cholesterol using both public health and clinical approaches (see Children and Adolescents section below).

A 20 year longitudinal study supports a "legacy" effect after just 5 years of statin therapy (Packard, 2014). A cohort of men aged 45 to 64 were given statin therapy and matched with patients who were not started on medications. There was a reduction of 31% in the incidence of non-fatal MI and deaths from CVD in the statin group. Another 10 year study of a subset of the Framingham cohort age 35 to 55 years old without prior CVD demonstrated a 39% of increased CVD even with only slightly elevated cholesterol levels (Navar-Boggan et al, 2015). Their original risk was less than 4.4% and grew to a 16.5% risk in 10 years. Both of these studies underscore early, aggressive therapy has real outcomes.

Though raising HDL levels has been postulated to be a goal, the evidence is not there to make it the primary goal. When LDL levels drop, HDL frequently rises. The positive impact is more likely to be the lowering of LDL, not a direct impact of raising HDL. Even a meta-analysis of genetic studies monitoring cohorts of the population that have higher rates of naturally occurring HDL does not translate into significant MI risk reduction (Voight et al, 2012).

RATIONAL DRUG SELECTION

Hyperlipidemia presents a problem in therapeutic management because patients are usually asymptomatic until damage to the cardiovascular system occurs. Central aspects of treatment are lifestyle modifications, especially dietary, which include the reduction of elements that are often perceived as "making food taste good." Finally, patients often want a prescription for a drug that will "cure" the problem, which currently is not a realistic treatment option. The drugs that are prescribed for hyperlipidemia are added to the therapeutic plan after lifestyle management has failed because the medications available can potentially produce serious adverse events. For effective management of hyperlipidemia, the treatment protocol must be palatable and low cost and have the fewest possible side effects. The factors to consider before developing a treatment plan are the presence or the absence of CVD, any associated risk factors, specific patient variables

and desires, patient interest, plus a realistic consideration of a cost–benefit ratio.

The level of individual risk has become a cornerstone of the new guidelines. The following sections blend the new guidelines with the decades of evidence of all risk factors for the prescriber to consider when selecting medications. The higher the CV risk, the more aggressive the statin treatment recommendations in the new guidelines. Any risk prediction over 7.5% is now earmarked as needing a discussion about whether to start statin therapy (Goff et al, 2013). The guidelines are not intended to be static and absolute, but only to serve as the stepping-stone for individualized decision making.

Risk Stratification

Multiple patient variables based on risk profiles are considered in setting individual goals for lipoprotein levels. The guidelines highlighting a 7.5% risk level are not meant to be absolute standards for starting medications, but only a trigger point for consideration of personal risks. These risks fall into modifiable and nonmodifiable categories. The modifiable risk factors such as diet, smoking behavior, and exercise are targets of therapy through lifestyle modifications. Nonmodifiable risk factors include age, gender, race, and family history. Both categories of risk factors are part of the calculation of overall risk for CVD. Table 39-2 presents the major risk factors for CVD exclusive of the serum LDL.

Five factors are considered contributory to low risk and negative risk for CVD: not smoking, normal BP, normal weight, normal glucose metabolism, and low cholesterol levels. Public education programs of the 1980s and 1990s contributed to measurable decreases in cardiac disease rates in the United States. This progress is waning with the advent of the obesity epidemic; the only positive trend is that a lower percentage of the population smokes than did in the 1970s (Ford, Li, Zhao, Peason, & Capewell, 2009). Currently, only 7.5% of patients are able to achieve the five low-risk factors, a percentage that has dropped from the 10.5% of adults studied in 1994 (Ford et al, 2009). In addition to encouraging patients not to smoke, advanced practice nurses need to place emphasis on helping patients achieve optimal weight, BP, and glucose metabolism and to exercise. The reported positive trend of having lower levels of lipids across the population must be tempered with the understanding that levels have been successfully reduced in higher-risk patients by the wide use of statins (Carroll, Kit, Lacher, Shero, & Mussolino, 2012). Unfortunately, the reported reduction of exercise in youth will skew that trend toward reversal. The good news of pediatric cancer survival rates has also created a new risk group of early onset cardiovascular disease patients. There is a 9% decrease in arterial health in the survivors (Steinberger et al, 2012).

A gradient potential of CVD risk has been delineated in the literature over the past decade. CVD risk equivalents include diabetes, metabolic syndrome, symptomatic carotid artery disease, peripheral arterial disease with an ankle/brachial index less than 0.9, abdominal aortic aneurysm, and

Table 39–2 **Major Risk Factors for Coronary Heart Disease (CHD) (Exclusive of LDL Cholesterol)**

Risk Factor	Positive Risk	Negative Risk
Age	Male: ≥45	Male: <45
	Female: ≥55	Female: <55
Family history	Premature CHD (MI or sudden death before 55 yr in father or other male first-degree relative or before 65 yr in mother or female first-degree relative)	No family history of CHD
Cigarette smoking	Current smoking (any cigarette smoking in past month)	Nonsmoker
Hypertension	BP ≥140/90 mm Hg or on antihypertensive medication	Normotensive
HDL cholesterol	HDL ≤40 mg/dL	HDL ≥60 mg/dL
Diabetes mellitus	Presence, especially if poorly controlled	Absence

BP = blood pressure; HDL = high-density lipoprotein; MI = myocardial infarction.

Source: Adapted from the *Third Report of the Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol in Adults,* 2001. Rockville, MD: National Institutes of Health, National Heart, Lung, and Blood Institute.

a 10-year risk of myocardial infarction/coronary heart disease (MI/CHD) death. The newly developed Pooled Cardiovascular Risk Calculator (http://myamericanheart.org/cvriskcalculator) does not take all of these risks into consideration, which has created rebuttals to its full adoption. Some experts believe that the 2013 guidelines recommend treatment for too many people. Approximately 45 million more Americans are now being considered as at risk for CVD and within the guideline-recommended parameters for use of statins. Some experts say this is without merit (Ridker & Cook, 2013). Others believe there is significant overestimation of risk up to 154% (DeFillippis et al, 2015). The guideline authors counter these arguments with an emphasis upon an individualized personal risk evaluation with discussions of the risks between patient and provider. They insist this goes beyond making provider-centric decisions based on lipid values or only on calculated scores. They also suggest that most of these patients were undertreated by prior guidelines because primary prevention of the first CV is the best goal. The guideline authors have also provided a list of factors that require future consideration for guideline revision that include some of the major objections to the 2013 publication (Table 39-3).

The biggest area of contention is the recommendation for treatment for individuals with mild disease. The newly selected 7.5% risk of CVD over the next 10 years is a major change from the 10% to 20% risk considerations of the Framingham score era. There are experts who are concerned that the risk of statin adverse events may outweigh any future benefit in this group. Abramson, in the *British Medical Journal* (2013), calculates that 140 individuals in this category must take a statin to prevent one heart attack. He goes on to state 1 out of every 5 of those patients might encounter an adverse effect. So the informed discussion must consider that numeric in order that the decision to treat be based on actual statistical evidence. The guidelines provide a list of risk factors that might trigger statin use in this population during those therapy decisions (see Table 39-4).

The REGARDS study (Reasons for Geographic and Racial Differences in Stroke) (Muntner et al, 2014) has provided a positive endorsement of the new risk calculator. This

Table 39–3 **Factors to Be Considered in Future Guidelines**

1. Specifics on TG therapy
2. The non-HDL impact on decision making
3. LDL particle marker roles in diagnosis and treatment
4. Role of imaging study results in treatment decisions
5. Refining the optimal time frame and age for initiating therapy
6. Determining statin impact of specific subgroups like CKD and HF patients
7. Evaluation of longitudinal adverse effect impacts of medications
8. Inclusion of subgroups of patients typically excluded or underrepresented in RCTs (e.g., HIV, transplant patients, ethnic populations)
9. Impact of genetic testing and pharmacogenetic implications

prospective population-based study went beyond stroke outcomes to also include CHD and nonfatal MI. The actual occurrence of adverse outcomes in patients in the lowest risk category were "spot on" with the predicted risk calculated from the new guidelines; interestingly, the highest risks appeared to be overestimated. This was attributed to the fact that over 40% of the highest-risk cohort were started on statins and thereby reduced the incidence of bad outcomes (Muntner et al, 2014).

CVD tends to cluster in families. A positive family history of clinical CVD or sudden death in first-degree male relatives before age 55 or first-degree female relatives before age 65 is an important risk factor. The family history should include relatives with the presence or absence of high cholesterol levels, nonlipid risk factors, and the age of onset of each risk factor. This information provides data to assess for inherited lipoprotein disorders.

Ethnicity is also now a recognized risk factor for CHD. For the first time, there are recommended treatment algorithms for lipid management based on race and gender differences in risk factors (Stone et al, 2013). Genetic constitution may result in the need for special attention to certain portions of the treatment algorithm. These features are discussed under specific variables below. Dietary considerations are also of concern (Nettleton, Polak, Tracy, Burke, & Jacobs, 2009).

High Risk: CVD or CV Risk Equivalent

Patients at high risk are those with clinical evidence of CVD or with CV risk equivalents. The literature suggests that having coronary disease substantially increases future risk of another coronary event; this risk increases even more in the presence of elevated cholesterol levels. In women with existing CVD, the rates of new coronary events are similar to those of men. In older adults, new events occur with higher frequency than in younger adults with similar cardiac histories. The authors of the 2013 guidelines consider anyone over the age of 62 as having high risk simply on age alone (Goff et al, 2013). The benefits of lipid lowering in patients with established CVD have been repeatedly demonstrated in clinical studies. Patients without CVD but who have angina, claudication, stroke, TIA, electrocardiogram (ECG) abnormalities, or previous coronary revascularization procedures (Knatterud et al, 2000) have similar risk rates to those of patients who have existing CVD. These softer endpoints, however, are not included in the first edition of the Pooled Cardiovascular Risk tool. Only the endpoint risks for the first "hard" cardiovascular event within the next 10 years are included in the 2013 guidelines. The rationale is that treatment will be targeted toward the individuals most likely to benefit from cholesterol reduction. The hard-stop events include nonfatal myocardial infarction, cardiovascular associated death, or a stroke.

Coronary calcium scores are sometimes considered in various discussions of risk. It has been assumed that the more dense form may be more dangerous. The presence of calcium in the deposits indicates long-term presence, with the higher degree of calcification (the CAC score) being assumed to be hazardous. This has come under scrutiny recently (Criqui et al, 2014). It is becoming understood that the volume of the plaque, not the density, may be more predictive of CV events. Prescribers are referred to the newest evidence published on the CAC scoring systems recommendations.

Of note in the 2013 guidelines is a recommendation *not* to use statins in advanced heart failure patients. It is recognized that this disease state is a frequent comorbidity with lipid disorders; however, there is no evidence that statins impact mortality in this population (Goff et al, 2013; Stone et al, 2013). Any benefit is in early disease when lipid reduction might be helpful; once heart failure is advanced, these drugs have limited to no benefit.

Patients with diabetes are included in this high-risk category, but the presence of diabetes is considered a CV equivalent, not a hard ASCVD event. The absolute risk for first major coronary events for patients with type 2 diabetes approximates that for nondiabetic patients with clinical CVD (Haffner, Lehto, Ronnemaa, Pyorala, & Laasko, 1998; Malmberg et al, 2002). The benefit of lowering LDL cholesterol in patients with type 2 diabetes is well supported. Type 2 diabetics are in this high-risk category because they have an increased MI case fatality rate. In one study, death occurred in 45% of men with diabetes and 35% of women with diabetes, compared to 38% for men and 25% for women without diabetes (Miettinen et al, 1998). In an effort to forestall a high risk of CV events in DM patients over age 40, the newest Canadian guidelines urge use of statins, even if patients have no other risk factors (CDA, 2013). The American Diabetes Association 2015 standards recommend moderate statin doses for patients without overt CVD and high doses for those with established disease (ADA, 2015).

Some authors are concerned that the presence of prediabetes is not directly addressed in the 2013 American guidelines. Others are concerned that specific CRP levels are not strongly emphasized (Ridker & Cook, 2013). The guideline authors counter that any new scoring system will be imperfect, just as the old system was. When considering that the 10-year risk of 7.5% to 10% is still an imperfect process, only a few individuals will actually have a cardiac event and others may have had it prevented, but there is no way to measure that effect.

The cost effectiveness of treating the high-risk groups was established even when drug therapy involved expensive brand names. With the advent of most medications in generic formulations, there is no longer any viable argument against more aggressive therapy based on cost. LDL-lowering drug therapy is also cost-effective for primary prevention in patients with CVD risk equivalents.

Lower Risk: Zero or One Risk Factor

It should be noted that the lower-risk group still has cardiac event risk, although the risk is lower than in groups deemed to have high risk. Data from multiple research trials support that lowering LDL cholesterol is important even for those without CVD. Given that clinical trial participants were likely to be healthier than the general population and that event

rates likely will increase as the patient ages, an event rate of 20% per decade presents a minimum estimate of absolute annual risk for those with moderately elevated cholesterol levels.

Patients traditionally considered at low risk for CVD are those with LDL cholesterol levels below 100 mg/dL, HDL cholesterol levels above 60 mg/dL, a total cholesterol-to-HDL ratio below 4.5, VLDL cholesterol levels of 50 to 100 mg/dL, or fasting TG of 150 to 200 mg/dL, no clinical evidence of CVD, and fewer than two risk factors (Brugsts et al, 2009). These optimal numbers reflect zero risk factors but do not provide a true "zero risk" for anyone. It should be remembered that this serum level is only one factor in risk assessment and that a more holistic picture of personal risk needs to be addressed when considering whether pharmacy interventions are indicated. Statin therapy is typically not used in this population.

Asymptomatic patients now have a separate guideline (Brugsts et al, 2009; Greenland et al, 2010) that addresses the cost-effectiveness of using testing to uncover occult disease. History taking, calculating risk scores, and standard lipid testing are approved. CRP testing is not approved for screening women under 60 or men under 50 in this category. Going beyond those basics—including liproprotein measurements, echocardiography, stress testing, and CT angiography for calcium deposit evaluation—is not recommended. If DM is a comorbidity, the recommendations accelerate the screening to include these things on an individual basis.

Treatment Algorithms

Lifestyle Modifications

Lifestyle modifications are the core of treatment for hyperlipidemia. Most cholesterol experts advocate a two-pronged approach for reducing CVD risk: the population approach and the clinical approach. The focus of the population approach includes working with the media so that information from healthcare providers is valued and considered credible. A public health success story of a 58% decrease in trans-fat consumption over the past decade is credited to this effort (Carroll et al, 2012; Doell, Folmer, Lee, Honigfort, & Carberry, 2012). Current legislation to ban all trans-fat in American food products will continue this trend. Further population-based foci includes promoting U.S. Dietary Guidelines using pamphlets/handouts; promoting regular physical activity, up to 30 minutes on most days of the week; ensuring that weight, height, and waist circumference are measured at least annually; providing access to body mass index (BMI) tables in the waiting and exam rooms; ensuring that all adults 20 years and older have their blood cholesterol measured and their results explained; ensuring that all adults have their BP measured and their results explained in keeping with current HTN guidelines; making antismoking literature available; and asking all patients about their smoking habits at every office visit.

Clinical approaches have similar foci as the population-based approach but are directed at specific patients. Clinicians should promote targeted changes in individual lifestyle to produce significant reductions in a patient's risk. These include promoting regular physical activity based on the patient's cardiac status, age, and other factors; teaching about weight management, including 10% weight-loss goals for patients who are overweight (Mente, deKoning, Shannon, & Anand, 2009); following the "treating tobacco use and dependence" guideline (U.S. Department of Health and Human Services, 2000); and promoting the Therapeutic Lifestyle Changes (TLC) during follow-up visits.

The general aim of dietary therapy is to lower cholesterol levels while still maintaining a nutritionally adequate eating pattern. Research has demonstrated that the benefits of eating a heart-healthy and blood-glucose-reducing diet extends across all ethnic groups (Nettleton et al, 2009). It is now understood also be a major factor affecting secondary prevention and is considered a near equivalent to drug therapy (Naci & Ioannidis, 2013). Essential components of the TLC diet are the following:

- Avoidance of heavily saturated fats
- Plant stanols/sterols 2 g/d; plant sterols block cholesterol absorption
- Increased viscous (soluble) fiber to 10 to 25 g/d; viscous fibers increase bile-acid losses
- Total calories adjusted to maintain desirable body weight and prevent weight gain

One group of authors notes that a combination of plant sterols and viscous fiber "is the dietary equivalent of combining a bile acid-binding resin and a statin" (Jenkins, Kendall, & Marchie, 2005).

Patients might elect to follow a high-protein Atkins-style diet to have a greater initial weight loss; however, proteins can be heavy in fats and increase the cortisol hormones that increase CRP, a hallmark of dyslipidemia (Ebbeling et al, 2012). Providers should caution not to exclude only one type of food group; balance is required. There are no "bad foods." For years, eggs were demonized as the major source of dietary cholesterol. Newer research indicates eating eggs might increase CVD risk but primarily in those patients who are already diabetic (Rong et al, 2013). This was a restricted-scope review, but it gives insight into overturning a one-size-fits-all myth about cholesterol sources. Education should show that not all calories are "created equal," in terms of health impacts; however, there is no longer an emphasis on low vs. high glycemic index foods.

Alcohol ingestion is also related to CVD. Observational studies consistently show a J-shaped relationship between alcohol consumption and total mortality. Case-control, cohort, and ecological studies indicate lower risk for CVD at low-to-moderate alcohol intake. A moderate amount of alcohol is no more than 1 ounce of ethanol (e.g., 24 oz beer, 10 oz wine, or 2 oz whiskey) for men. Women and lighter-weight men should consume no more than half this amount. There are purported cardiovascular benefits related to rational alcohol intake in men older than 45 years and women older than 55 years. The beneficial mechanism associated with moderate alcohol use is unknown but may be related to an increase in HDL cholesterol and apo A1 and modest improvement in hemostatic factors (NCEP, 2001).

The dangers of overconsumption of alcohol are well known. Patients with levels of alcohol consumption in excess of a moderate amount present with adverse effects that include HTN, arrhythmia, and myocardial dysfunction. Alcohol excess also promotes pancreatitis and liver dysfunction. Because up to 10% of adults in the United States misuse alcohol, care should be taken about advice given related to alcohol intake, with disadvantages clearly delineated.

Dietary sodium, potassium, and calcium are also not mentioned in the macronutrient recommendations. Recommendations about these minerals are found in Chapter 9. Counter to popular belief, multivitamin intake does not alter CHD risk patterns except in those with nutritional deficits (Fortmann, Burda, Senger, Lin, & Whitlock, 2013).

Lifestyle modifications take time and are part of the treatment regimen whether the patient is being treated with medications or not. Modifications involve active assistance from the health-care team. Figure 39-2 shows the steps in achieving therapeutic lifestyle changes. Even though treating to LDL goal is no longer the standard, if the LDL cholesterol levels have not been lowered after 3 months of TLC, the decision must be revisited as to whether to consider adding drug therapy. Many patients with hyperlipidemia also have HTN. The 2013 lipid guideline supports the new JNC-8 recommendations (2014).

Drug Therapy

The new guidelines identify four groups most recommended to receive statin therapy. These are outlined in Table 39-5.

These are groups deemed most likely to benefit because they typically have higher risk equivalents. Dependent upon degree of risk, a low to high intensity of treatment is recommended (Table 39-6).

CVD and CV Risk Equivalents

For patients with CVD and CV risk equivalents, the type and intensity of LDL-lowering drug therapy is determined by the baseline LDL level plus the entire holistic consideration of personal risks. The 2013 recommendations for high and low statin therapy are based on how much of a lipid-lowering effect is desired and also how fast it should be reduced. Those requiring more than a 50% reduction in lipids are started on a high-dose and high-intensity statin; the moderate level is suggested for those needing a 30% to 50% reduction; and lower doses are expected to gain less than a 30% reduction in LDL (Stone et al, 2013). Figure 39-3 shows the therapeutic approach for this group of patients.

Because novice prescribers desire more specifics in helping them grasp how to evaluate and treat lipid levels, the old ATP III levels are included in Table 39-7 and Table 39-8 as basic reference points and the therapeutic algorithms are referenced in Figures 39-4, 39-5, and 39-6. It is *imperative* that a treatment to a numeric goal orientation *not* be adopted, nor is the inclusion in this text meant to suggest that it be adopted.

Persons with baseline LDL cholesterol at or above 130 mg/dL generally will require LDL-lowering drugs to

achieve LDL cholesterol levels below 100 mg/dL, so drug therapy (usually with a statin) is initiated simultaneously with TLC. Newest guidelines still recommend that the LDL cholesterol for high-risk patients be under 100 mg /dL in the most extreme cases. Though the use of drugs for this population may be central to their therapy, in cases where the patient has metabolic syndrome, dietary therapy is intensified early in the program, with an increased effort to lose excess weight and increase physical activity. If the patient also has elevated TG, a lipid-lowering agent that focuses on that abnormality may be considered. Table 39-9 outlines the classification of TG level, which did not change with the 2013 lipid guidelines.

Zero or One Risk Factor

Individuals in the group with zero or one risk factor usually have a 10 year CV risk of less than 10%. The traditional goal for this patient group is LDL cholesterol levels lower than 160 mg/dL to reduce long-term risk for CVD; the new goal is a progressive reduction toward that level. TLC is initiated and continued for 3 months. After 6 weeks, the LDL panel is redrawn and dietary enhancers of LDL lowering (e.g., plant stanols/sterols and viscous fiber) are increased if needed. After 3 months, another LDL panel is drawn. If LDL cholesterol has lowered, TLC therapy is continued. For LDL cholesterol of 160 to 189 mg/dL, drug therapy is optional. The presence of influential factors such as smoking, poorly controlled HTN, or very low HDL, suggests the risks are not low and drug therapy should be initiated. If the LDL cholesterol remains above 190 mg/dL despite TLC therapy, drug therapy

* Therapeutic options include intensifying LDL-lowering dietary or drug therapies, emphasizing weight reduction and increased physical activity, adding drugs to lower triglycerides, and intensifying control of other risk factors (ATP III).

Table 39–8 **ATP III Low-Density Lipoprotein Goals (reference only)**

LDL Cholesterol Patient Category	Goal (mg/dL)
Coronary heart disease (CHD) or CHD risk equivalent	<100
Multiple (two or more) risk factors	<130
Fewer than two risk factors	<160

LDL cholesterol goal for multiple-risk-factor patients with a 10 year risk higher than 20% is less than 100 mg/dL.

Source: Adapted from the *Third Report of the Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol in Adults,* 2001. Rockville, MD: National Institutes of Health, National Heart, Lung, and Blood Institute.

is the more likely treatment option. Some patients may present with very high LDL cholesterol levels (e.g., greater than 220 mg/dL). These individuals usually have a genetic form of hyperlipidemia that cannot be treated adequately with TLC alone.

Drug Therapy

The choice of the pharmacotherapy is heavily weighted toward statins but can also be based on the specific elevated lipoprotein involved. There is a strong trend away from the non-statin lowering medications without specific indications. Detailed discussion of each drug class is provided in Chapter 16.

1. Statins allow most high-risk patients to attain lowered serum LDL levels. Patients treated with a statin may also see a modest decrease in serum TG and an increase in serum HDL. Long-term studies have shown statins to be generally safe and effective. Most compendiums list LDL-lowering agents according to their impact on serum LDL levels. From greatest to lowest impact on serum LDL, the drugs are ranked as follows: rosuvastatin, atorvastatin, simvastatin, lovastatin, pravastin, and fluvastatin. The newest statin, pitiva - statin, has an LDL-lowering effect that falls within the list's midrange.

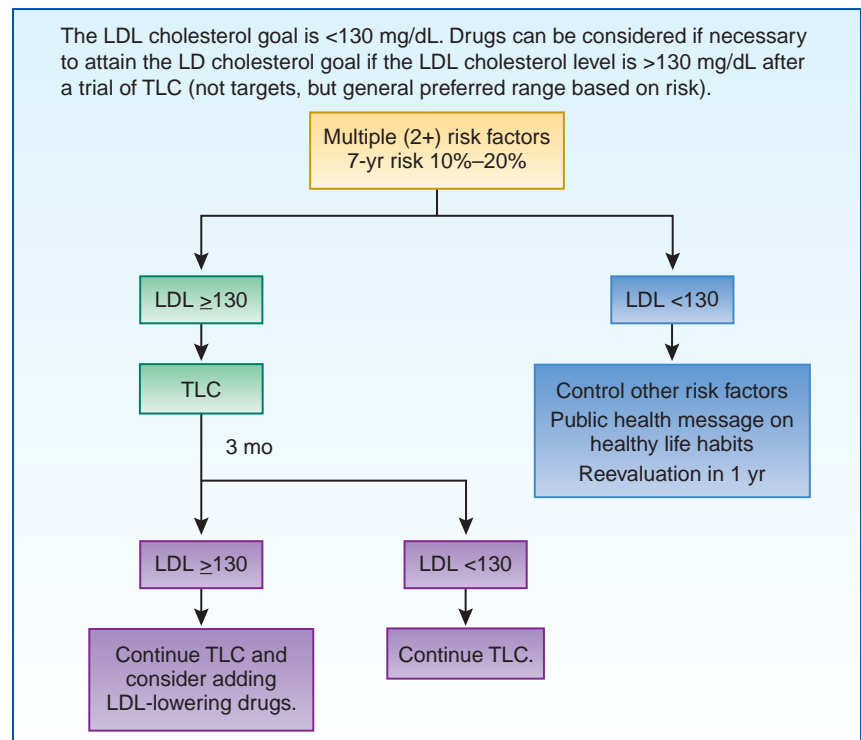
In many trials, fewer than half of patients with CVD were able to achieve the desired serum LDL cholesterol goal of 100 mg/dL on standard doses of statins (Sacks, et al, 2000). These patients may require relatively high doses of statins (Cannon, 2005; Nissen et al, 2004) if it


Figure 39–4. Traditional approaches for patients with multiple risk factors and 10 year CHD risk 10% to 20%.

The LDL cholesterol goal is <130 mg/dL. Drug therapy can be considered if LDL cholesterol is >160 mg/dL after a trial of TLC (not targets, but desired range based on risk).

≥500	Very high

Source: Adapted from the *Third Report of the Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol in Adults,* 2001. Rockville, MD: National Institutes of Health, National Heart, Lung, and Blood Institute.

is determined that pursuing this goal has an increased personal benefit that outweighs the risk of adverse lipid therapy events.

If patient response to a prescribed agent is not adequate after 3 months, the patient should have the statin dosage increased, be switched to a different agent , or be considered for combination drug therapy. A 2009 systematic review comparing combination therapies to maximum doses of single agents (Sharma et al, 2009) reported very weak evidence that combination therapies offer anything additional regarding mortality and MI and CVA survival. Medications used in combination therapy all have individually established data confirming that they are helpful in cholesterol reduction. The STELLAR trial results on monotherapy tempered the expectation that massive changes in cholesterol levels would result as dosages of drugs were increased. Typically, only a 6% reduction in TC is expected when the dosage of a statin is increased (Jones et al, 2003). Monotherapy does not always address all sources of dyslipidemia. It should be remembered that increasing the dose also increases the risk of adverse events.

2. Nicotinic acid (niacin) was always touted as effective in lowering total cholesterol and triglyceride levels and raising HDL levels. More recent studies that fail to support CV endpoint improvements such as stroke and MI have contributed to a moving away from its use in lipid management (MERCK, 2012; Vogel, 2013). In addition, difficult-to-tolerate side effects such as nausea and flushing have contributed to this trend. However, others believe that with selective low dosing when combining a niacin product with a bile acid-binding resin, patients can lower VLDL and LDL and reduce the side effects of the niacin. Slow-release nicotinic acid (Niaspan) has been studied as another way to reduce the side effects of niacin while still getting therapeutic blood levels of nicotinic acid as well as combining it with premedication of aspirin, but this has not proven to be clinically useful. Nicotinic acid is best for treating patients who have elevated total cholesterol and TG and low HDL levels who cannot tolerate statins. Because nicotinic acid is a vitamin and sold over the counter (OTC), the U.S. Food and Drug Administration (FDA) has issued a

statement on using OTC products as a substitute for prescribed cholesterol-lowering drugs, including nicotinic acid. The FDA concluded that the nature of hypercholesterolemia and its potential sequelae are such that OTC use of these drugs is not a safe and effective means for treating this condition in lieu of prescription treatment.

3. Bile acid-binding resins have a strong record of efficacy and safety and are most useful for patients with moderately elevated LDL levels and a low CVD risk profile who are unable to reduce their LDL by TLC alone. Many young adult men and premenopausal women fit the profile appropriate for treatment. Bile acid-binding resins are often used as monotherapy for women who are pregnant or may become pregnant. Patients with combined familial hyperlipidemia who find nicotinic acid products not tolerable may benefit from a combination treatment that includes a bile acid-binding resin plus niacin plus statin.

4. Fibric-acid derivatives are effective triglyceride-lowering drugs that may modestly lower LDL and raise HDL for some patients. Because these drugs usually do not produce substantial reductions in LDL cholesterol, they are not appropriate for effective lowering of LDL levels as a primary LDL-lowering agent. They can be valuable in combination with a statin for patients with very high triglyceride levels, for diabetic patients with elevated TG and good renal function, and for patients with familial dysbetalipoproteinemia. Prudent monitoring and caution is used for increased risk of myopathies and hypoglycemia. Fibric-acid derivatives do have a significant GI side effect profile.

5. Drug combinations are commonly used for patients with more than one lipoprotein abnormality. For patients with elevated LDL and TG below 200 mg/dL, the main goal of treatment is to lower LDL levels first as hypertriglyceridemia does not carry the same risk for CVD as elevated LDL cholesterol levels. Combination therapy can be achieved by ordering two separate agents or by ordering more convenient, but more expensive, single-dosage formulations. Hard CV endpoint benefits are not evident in the literature (Sharma et al, 2009); however, quality of life effects and reduction of lipids are evident.

Combinations of statins with low-dose nicotinic acid have been used for patients at high risk for CVD; however, combining the powerful LDL-lowering action of the statins with the postulated triglyceride-lowering and HDL-raising properties of nicotinic acid did not achieve the major vascular event reduction in the AIM HIGH Study (MERCK, 2012). The HPS2-THRIVE study's poor preliminary results, however, triggered MERCK to pull its niacin-based drug off the market (MERCK). Neither study design included patients with severely low HDL levels, so future analysis may provide insight as to whether niacin has a niche population impact. It should be noted that niacin did

increase HDL during these studies but is now considered to have more adverse risk than positive effect except in severe lipid disorders. The niacin in the HPS2-THRIVE study was mixed with an antiflushing agent previously untested in combination with niacin in a major trial, which may have been the issue with achieving endpoints.

The FDA has approved the orphan drugs mipomersen (FDA, 2013) and lomitapide (FDA, 2012b) for treatment of severe forms of familial hyperlipidemia. Mipomersen is a weekly injection associated with a 24% reduction in LDL. Lomitapride is an oral medication in a new class of drugs that inhibits bowel enzymes that help manufacture cholesterol in the liver. It lowered LDL by 47% in a small trial. Both drugs are used as adjuvant therapy with statins plus low-dose niacin as the most efficacious and practical combination for the treatment of combined familial hyperlipidemia.

The combination of statins and fibrates carries an increased risk of myopathy. Treatment with this combination should be undertaken carefully with frequent patient monitoring for symptoms of myopathy. Any reported myopathy symptoms should be followed up with creatinine kinase (CK) testing. The agent should be discontinued if the CK is greater than 10 times the upper limit of normal. The combo does decrease lipid levels; however, the hard endpoints of CV mortality do not improve when compared to just statins alone (ACCORD, 2010).

6. Alternative treatments have a role in managing elevated lipids; however, the Physicians Health Study has shown daily vitamin and supplement therapy does not reduce CV events in "healthy male adults" (Sesso et al., 2012). Omega-3 fatty acids have a place in treating very high triglyceride levels (greater than 500 mg/dL) in adult patients. Omega-3 fatty acid treatment results in HDL levels that are clinically unaffected and LDL levels that may actually rise. Many lipid experts have moved away from recommending their use after a meta-analysis did not find any primary, nor secondary, benefit in CVD (or cancer) prevention (Rizos, Nitzani, Bika, Kostapanos, & Elisaf, 2012). However, they did not find any harm in using them.

Omacor is a prescription formulation that is a more concentrated (840 mg) and quality-controlled source of both the eicosapentanoic acid (EPA) and docosahexaenoic acids (DHA) than those found in OTC supplements (avg 200 to 500 mg). Omacor has the same "fish burp" side effect as its OTC counterparts but may be more tolerable to patients because of its twice-a-day dosing schedule. Concerns about mercury content that surround OTC fish oil products are lessened because Omacor is a regulated drug and not a nutritional product.

There are omega-3 carboxylic acids now approved for cases of high trigylcerides that do not respond to primary interventions. The EVOLVE study (Epanova for Lowering Very High Triglycerides) gained approval in a subclass of omega-3 medications that have both EPA and DHA components. The full picture of pancreatitis risk and cardiovascular outcomes is still unknown. This medication joins icosapant ethyl (Vascepa), approved in 2012, for the same severe lipid disorder. Due to the complexity of the pathophysiology underlying resistant triglyceride levels, it is recommended to prescribe these medications in consultation with a lipid specialist.

> Red yeast rice, an alternative therapy for hyperlipidema appears to mimic statin medications. The FDA has issued warnings about some formulations of this product that contain the prescription drug lovastatin. Manufacturers claim the yeast growing on their product is the naturally occurring chemical on which lovastatin is based. The unregulated production and packaging of these products makes them unsuitable as a substitute for prescription drug therapy, especially in the era of options that include less expensive generic drug formulations. The omega-3 found in flax and nuts (ALA) does not lower TG, but has other healthy fiber benefits.

Additional Patient Variables

Children and Adolescents

Atherosclerosis can begin in childhood (McCrindle et al, 2012; NHLB, 2011). Up to 25% of children and adolescents have cholesterol levels above 200 mg/dL. Most cases of elevated cholesterol are related to the same environmental factors that result in adult hyperlipidemia. Genetic disorders of lipid metabolism occur in 0.% to 1% of the population. Children with such disorders often have total cholesterol levels 1.5 to 3 times higher than normal. Approximately 80% of these children will experience symptomatic CVD at an age younger than 20 years.

There is controversy about when and whether to screen children for lipid issues (Newman, Pletcher, & Hulley, 2012). The diagnostic rate is thankfully low, but the value to children previously undiagnosed with familial disorders is significant (McCrindle et al, 2012). Limiting screening only to those with known family history does not reflect the reality that many pediatric medical histories do not include an in-depth family medical history or the history is unknown. Testing of children with cutaneous xanthomas is highly suggested. The European Atherosclerosis Society has published newly understood prevalence of familial disorders at levels much greater than previously appreciated (Cuchel et al, 2014). This has increased the testing of more first-degree relatives of known cases.

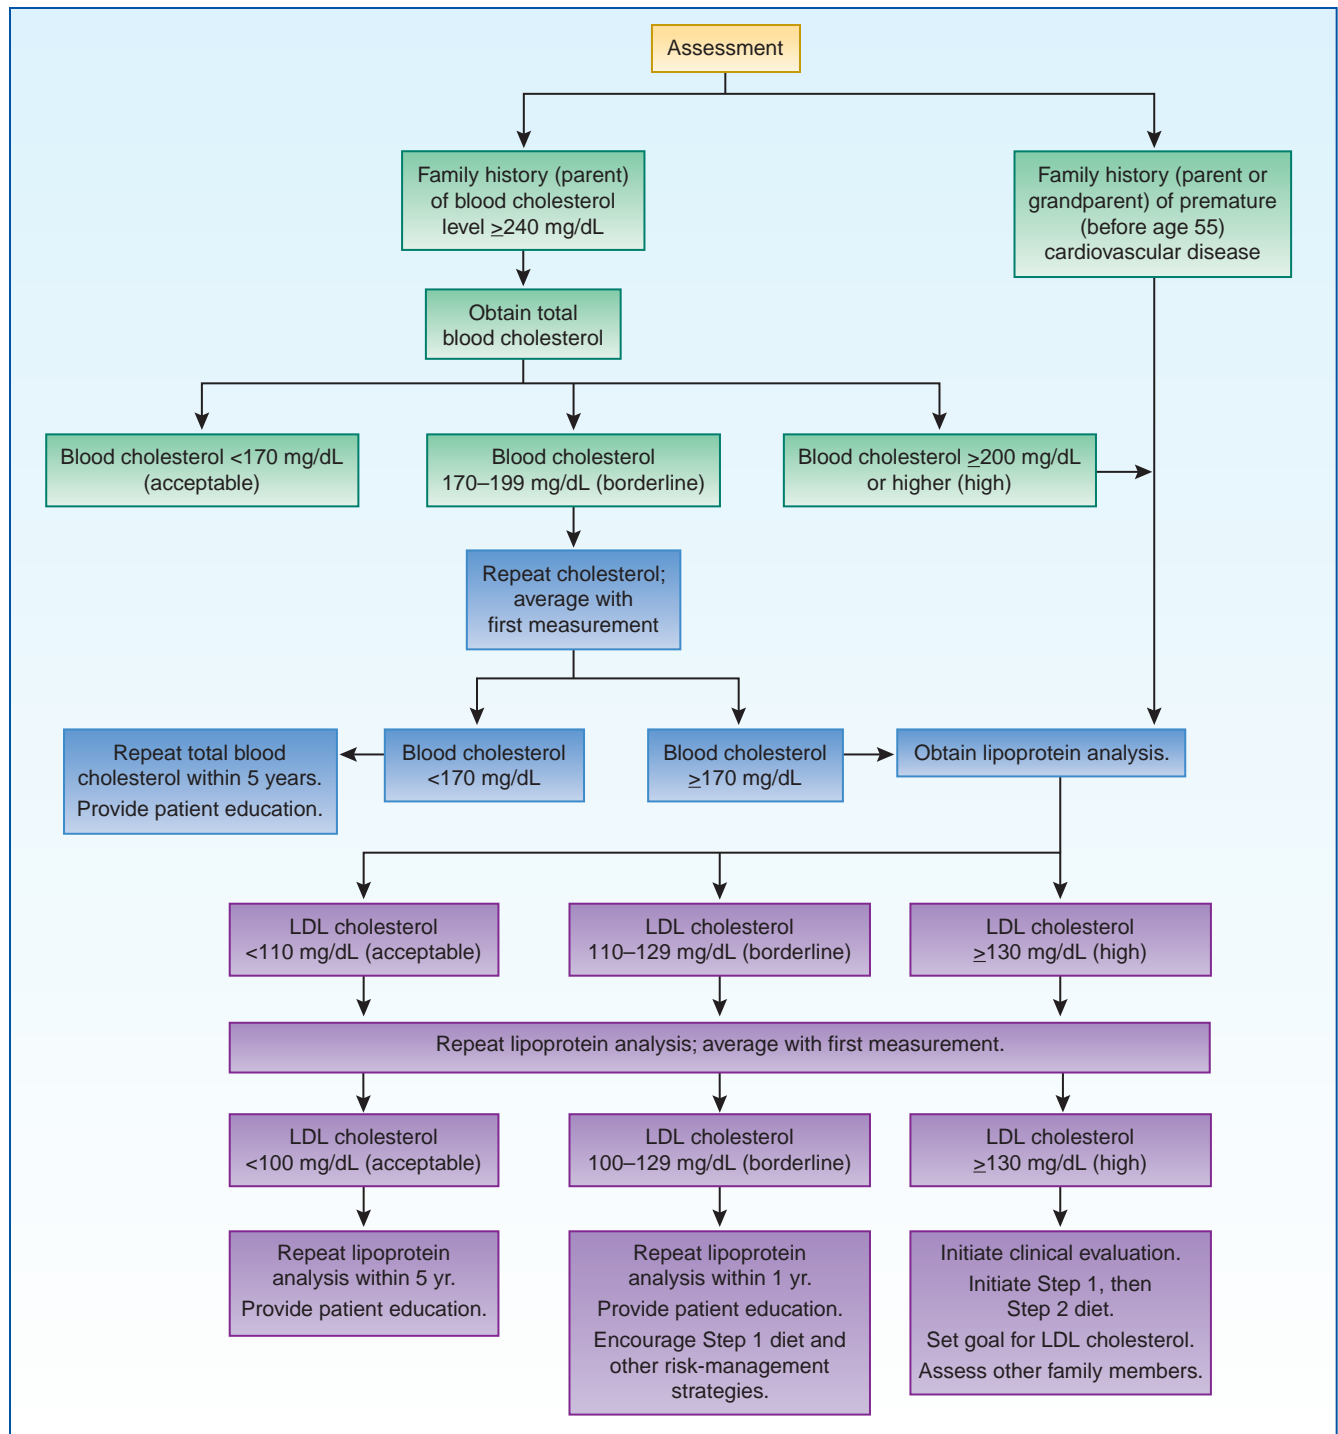
Optimal cholesterol levels in children are lower than in adults because longer duration of elevated lipid levels theoretically translates into longer-term opportunity for vascular wall changes (NHLB, 2011). Total cholesterol should be below 170 mg/dL (LDL less than 100 mg/dL). Borderline cholesterol levels are 170 to 199 mg/dL, and high cholesterol levels are 200 mg/dL or above. LDL greater than or equal to 130 mg/dL is considered hyperlipidemia in children (NHLB, 2011). Figure 39-7 shows the treatment algorithm for children.


Figure 39–7. Management of blood cholesterol in children.

In children, as with adults, the goal is primary prevention. Lifestyle modifications mirror the TLC for adults. In infants, the diet should include breastfeeding and late introduction of solid foods. The use of whole milk until age 1 to provide required fatty acids for neurological development is still recommended; however, children should be switched to 2% milk and transitioned to skim milk by age 2 (Daniels & Greer, 2008). Framingham or newer pooled risk scores do not exist for children; the scores start at age 20 years. Unlike the adult risk probabilities over the next 10 years as the determinant

for therapy, the pediatric risk includes more of a lifetime risk perspective with the intent to prevent early onset CVD. For children, family histories become key, and children with male parents, grandparents, uncles, or siblings having premature CVD (angina, MI, stroke or sudden cardiac death before age 55) o r with female relatives with histories before age 65 are considered to have increased risk.

Reduction in CVD risk factors, such as passive smoking, sedentary lifestyle, and excessive weight, and appropriate management of hypertension, obesity, and diabetes are all

essential in childhood dyslipidemias, just as they are for adults. Attention to individual smoking habits should be implemented by age 10. TLC changes should be initiated as a first line of treatment and maintained for at least a 6 month trial, before pharmacotherapy is considered, except in cases of distinct high risk.

High-risk children include those with type 1 diabetes, chronic renal disease, and cancer and transplant survivors, and those who have documented coronary vessel issues post-Kawasaki disease or familial dyslipidemia syndromes. A new emphasis is now placed on obese children who develop type 2 diabetes, as they may exhibit characteristics of metabolic syndrome.

The population approach for therapy includes attention to school lunch programs and alerting parents and children to the dangers of junk food. Providers can take strong stands on increasing emphasis on physical activities during school. Individual focus prevention should include encouragement of after-school engagement in active-motion events, including sports, dance, and general play for at least 60 minutes a day (Gidding et al, 2009). Parents should place limits on sedentary entertainment such as TV and computer games.

When drug therapy is considered, consultation with a pediatrician experienced in lipid disorders is advised; for children less than 10 years of age, drug therapy should be managed by specialists. Medications are suggested for LDL levels greater than or equal to 190 mg/dL without CV risk factors; LDL greater than or equal to 160 with one personal risk or strong family risk; and LDL greater than or equal to 130 mg/dL and two high-risk factors (NHLD, 2011). Among the available antihyperlipidemics, nicotinic acid has a history of established safety in children younger than 18 years. Statins are useful in children with heterozygous or homozygous familial hyperlipidemia with LDLs greater than 500 mg/dL. Long-term use has not revealed any adverse impact on development, but the population taking medications is very limited. Positive impact on carotid intima media thickness mirrors that found in adults.

Very few children should have to take medications after TLC interventions are implemented. Goals for treatment and lipid-lowering impact are similar to those for adults. Monitoring protocols are also the same. Age of initiation of statin pharmacotherapy for males is age 10 years and for females at the onset of menses. Tanner scales measure levels of maturation in children, and the general guide for initiating drug therapy is a Tanner II level of maturation (Daniels & Greer, 2008). Pubescent adolescent females should follow the treatment guidelines for women of childbearing age as discussed later in this chapter. Treatment should consider use of contraception because of the potential teratogenic properties of lipid agents; however, contraceptives also increase lipid levels. Limited studies have not demonstrated alterations in continued maturation, menstrual cycles, or hormone levels in girls who have taken statins for familial dyslipidemias; however, these studies were only 1 to 2 years in duration and did not monitor long-term effects.

Current drug monographs should be referenced for approved pediatric dosages. As in adults, drug interactions do occur. Combination therapy with the exception of a statin with estimibe is generally not prescribed. Fibric-acid medications are only recommended for severely elevated triglyceride levels (>500), but clinical data concerning their use in pediatric populations are limited. Bile-acid sequestrants may be a more suitable first alternative for prepubescent children.

Specific interventions for children with HTN, obesity, diabetes, and insulin resistance are outside the scope of this chapter. However, having a BMI elevation after age 15 through their early 20s increases the odds of developing diabetes and hypertension, which are now recognized as strong predictors for increased cardiovascular risk in this age group (Attard et al, 2013). Dyslipidemic responses are associated with HTN above the 95th percentile for age and gender, BMI greater than the 85th percentile and Hb A1c levels above 7.0. Readers are referred to those topical headers in other areas of the text.

Middle-Aged Men

Men 35 to 65 years old comprise up to one-third of all new CVD deaths. Most of their excessive risk can be attributed to hyperlipidemia, HTN, and cigarette smoking. Men are also predisposed to abdominal obesity, which increases their risk for metabolic syndrome. The frequency of earlier and more significant CV events in younger men has increased over the past few decades (Wilson, 2008). Special attention for cholesterol management in middle-aged men includes consideration of the following:

- Strong evidence of risk reduction from LDL lowering with statin therapy for those with CVD or CV risk equivalents exists. Combination of statin and bile-acid–binding resin is also very useful.
- Fibrates or nicotinic acid may be used as second-line therapy for lipid lowering in men with low HDL and atherogenic dyslipidemia.
- High prevalence of metabolic syndrome requires intensive TLC.
- Factors favoring drug therapy include higher end of age range, obesity, cigarette smoking, positive family history, and very low serum levels of HDL.

Women

Elevated cholesterol levels confer CVD risk in women as well as in men, but the correlation to CVD is lower for women before age 55. Until that age, women are at lower risk for CVD than their male counterparts, in part because of their higher estrogen levels. After age 55, the most common cause of death in both men and women is cardiovascular disease. Cholesterol levels tend to be higher in older women than they are in men. Women younger than 45 years are discussed in the Younger Adults section, and women older than 75 years are discussed in the Older Adults section. This section refers to women in the 45- to 75-year age range.

CVD rates for women approximate those of men only after menopause. The reason for this disparity is not fully

understood. The patterns of risk factors often differ between men and women. BP, LDL cholesterol, and TG rise at an earlier age in adult men than they do in women. At puberty, HDL cholesterol levels decrease in males, but not in females. Because a 10 mg/dL difference in HDL cholesterol may account for a 20% to 30% difference in CVD rates, this difference over the adult life span could account for a large portion of the gender disparity.

Although the presence of bioidentical and conjugated equine estrogen is postulated to raise HDL levels, the results of the Women's Health Initiative study raised serious questions about supplemental or replacement estrogen plus medroxyprogesterone acetate (MPA); HRT is no longer recommended for raising HDL as a primary endpoint (Grady et al, 2009; Rossouw et al, 2002).

Women's CV health risks are generally underappreciated by both providers and patients, although a significant public health outreach to educate both populations has shown gains toward clinical treatment parity with men. Parity, however, has not been reached (Mosca, Barrett-Conner, & Kass Wenger, 2011). The validity of Framingham scores are questioned because the population of women included in the analysis was mostly under age 50 and on average fairly healthy. Data were also gathered without much consideration to ethnicity and metabolic syndrome, which has greater and earlier impact on CVD in women (Gleeson & Crabbe, 2009). The risk of a black woman's death being due to CVD is equal to that of a white male. The prevalence of DM in Hispanic women and HTN in blacks makes the risk for women to be much greater than previously considered (Mosca et al, 2011).

The past decade of research has strengthened the addition of novel markers to gain a better appreciation of CVD risk in women. The Reynolds Risk Score (Ridker, Buring, Rifai, & Cook, 2007) is one tool that incorporates novel markers such as CRP, but it has not been validated extensively in diverse populations (Gleeson & Crabbe, 2009). It has been recently suggested that the Reynolds score may underestimate the risk in women by 21% (DeFillippis et al, 2015). Other novel markers such as homocysteine, coronary artery calcification, and functional capacity tests (including cardiac recovery profiles after exercise) are touted as providing a more refined evaluation of actual risk in women. Mosca's team (2011) has identified that a history of pregnancy-induced hypertension, gestational diabetes and/or pre-eclampsia might double the vascular risks of women in later years. Women with strong family histories of early CVD should be more aggressively treated. Those with higher CRP levels and a risk of metabolic syndrome should also be included in the more aggressive treatment plans (Mosca et al, 2011).

Special attention for cholesterol management in women 45 to 75 years includes consideration of the following:

- For women with CVD or CV risk equivalents (including diabetes), statins are as useful in CV risk reduction via LDL lowering as they are for men. All secondary prevention trials with these drugs have included women.
- Control of risk factors by antihypertensive drugs and beta blockers is indicated. Evidence for use of aspirin in women under age 65 has come under scrutiny, but those with high risk are still encouraged to take it if the individualized adverse risk of taking aspirin is lower than the potential benefit (Mosca et al, 2011).
- Clinical trials of LDL lowering demonstrate increased survival in women but may not be as effective in reducing stroke risks (Brugts et al, 2009).
- LDL-lowering drugs are indicated for women with multiple risk factors
- HRT is not recommended for primary LDL lowering or HDL balance.

Older Adults

Most new CVD events and most coronary deaths occur in older adults (men older than 65 years, women older than 75 years) because they have accumulated more coronary atherosclerosis than have younger age groups. Lowering CVD risk by reducing total cholesterol, and specifically LDL levels, is critical in this population. Angiographic studies have shown that even advanced coronary atherosclerosis may respond to reductions in cholesterol; CV events are reduced even after only a few weeks or months of statin therapy (Tsunekawa et al, 2001). Framingham risk scores are less robust for predicting risk in older adults and measurements of atherosclerosis. Considering that CVD is more prevalent in the older population, more individuals will benefit from risk reduction than in other age groups. Other factors such as concomitant chronic diseases (e.g., congestive heart failure, dementia, advanced cerebrovascular disease, or active malignancy), social circumstances, chronological and functional age, and polypharmacy should be taken into account. Financial considerations must be taken into account, but in an era of Medicare drug plans and low-cost generics, these considerations have decreased in importance . Older adults who are otherwise healthy should have therapy if they present with elevated lipid levels.

How aggressive the therapy is depends, as it does in younger adults, on the degree of CVD risk. As with younger people, the CVD risk reduction occurs in 6 to 12 months, even in those with long-standing disease. No statistically significant differences in side-effect profiles have been noted in elders enrolled in studies. Benefits are still evident after age 75 (Savarese et al, 2013).

The same algorithm based on CVD risk is used in elders; however, older adults are less likely to achieve the reduction in cholesterol with diet therapy alone and are more likely to require some drug therapy. Statins are the first-line drug treatment used in this age group because they are well tolerated in this population. Most statins can be taken once daily and do not add much complexity to already existing treatment regimens. Niacin is not recommended because the side effects of orthostasis are not well tolerated, especially in older patients who may also be on other drugs that can produce BP changes. There is evidence niacin may increase stroke risk (MERCK, 2012). Bile-acid–binding resins have risks for

impaction and constipation and are not a good choice for older people. Special attention for cholesterol management in older adults includes:

- Prevalence of diabetes, a CV risk equivalent, is markedly increased in the older population.
- Emphasis should be given to TLC, especially dietary changes, but drugs are more likely to be needed. Elders with poor appetites and risk of malnutrition are not candidates for strict dietary enforcement.
- Consideration for drug interactions related to polypharmacy is important. Elders may be at higher risk for muscle toxicity when statins are mixed with macrolides and other antibiotics. Thiazide diuretics are associated with increasing hyperlipidemic patterns and might be substituted for by another class of drugs. Providers should consider statins with less cytochrome P450 competition, such as pitavastatin.
- Patients with very limited life expectancy due to other diseases probably do not benefit from antihyperlipidemic drug therapy. Strict enforcement of TLC is also unnecessary.

Young Adults

CVD is rare in this age group except for patients with severe risk factors such as familial hypercholesterolemia, heavy cigarette smoking, and diabetes. Unfortunately, CVD is becoming more common as the obesity and metabolic syndrome epidemic grows. Long-term predictive studies (NCEP, 2001) have shown that elevated cholesterol found in young adults predicts a higher rate of premature CVD in middle age. For this reason, control of risk factors is important in young adults as primary prevention.

The NCEP (2001) recommends doing lipid profiles beginning at age 20. Such early testing provides an opportunity to begin the public health approach to primary prevention. All young adults must be informed if they are at risk for premature CVD so that they can consider actions to prevent or postpone its occurrence. Finally, patients with cholesterol levels in the upper quartile of the population are clearly at high long-term risk and TLC intervention should begin at the earliest possible age. Most young adults with very high LDL cholesterol (greater than 190 mg/dL) are possible candidates for cholesterol-lowering drugs; however, prudence should be exercised in prescribing cholesterol-lowering drugs to young women.

The following recommendations are made based on the Pregnancy Categories:

- Nicotinic acid and fibric acid derivatives are Pregnancy Category C. Risks and benefits should be carefully weighed before giving these drugs to pregnant women.
- All statins are Pregnancy Category X and should not be given to women who have the potential to become pregnant without strong counseling.
- No pregnancy category has been assigned to the bile-acid–binding resins. Women of childbearing age with elevated cholesterol are best managed with lifestyle modifications. If this is not effective, they should probably be referred to a lipid specialist.

- All antihyperlipidemics should be avoided during breastfeeding.

Special attention for cholesterol management in young adults beyond those listed above for women include consideration of the following:

- Persons with heterozygous familial hypercholesterolemia may develop very premature CVD and require intensive LDL-lowering therapy. To achieve a level of less than 100 mg/dL usually requires both TLC and drug therapy.
- CVD is accelerated in this group for patients with type 1 diabetes or in very heavy cigarette smokers. Clinical judgment is required to determine the LDL goal here.
- Most young adults will not meet the multiple risk factors criteria. Non-LDL risk factors in this age group carry a higher long-term risk and should be the focus of management.

African Americans

HMG-CoA reductase gene variance among ethnic groups shows an interesting, more protective lipid phenotype than in other ethnic groups (Chen et al, 2009); however, African Americans have the highest overall CVD mortality rates and the highest out-of-hospital coronary death rates of any other ethnic group in the United States, particularly at young ages. Although the reasons for this excess CV risk have not been fully elucidated, it can be explained in part by the high prevalence and suboptimal control of coronary risk factors. Hypertension, left ventricular hypertrophy, diabetes, cigarette smoking, obesity, and physical inactivity are all more prevalent in African Americans than in whites. The predictability of standard risk factors for CHD by the Framingham risk assessment tool is somewhat suspect due to the fact that African Americans were not heavily represented in the baseline sample; however, the risk of death and other serious consequences is disproportionately higher in African Americans. This might be caused by higher CRP levels (Cushman et al, 2009). The 2013 guidelines do address the black population. The REGARDS study also has better insights into racial differences (Muntner et al, 2014).

Certain differences between African Americans and whites require special attention:

- African American men often have a high normal baseline level of creatinine kinase. The CK level should be documented before starting a statin.
- Hypertension, a powerful CVD risk factor, is more common in African Americans than whites. If present, left ventricular hypertrophy should be considered in the patient treatment plan because it is a powerful predictor of cardiovascular deaths.
- Obesity, especially abdominal obesity, is twice as common in African American women as compared to white women. Metabolic syndrome is a risk factor for CVD.
- Type 2 diabetes, an independent CV risk factor, is more prevalent in African Americans than whites.

- African Americans with established CVD are at particularly high risk for cardiac death. The new cholesterol guidelines have taken this into consideration and agree there is higher cardiovascular risk in this population. Patients from this ethnic group should be educated about this fact when discussing cardiac risks and the decision to start lipid-lowering therapy.
- African Americans are more likely to have multiple risk factors; therefore, LDL-lowering drugs are warranted when LDL is greater than 130 mg/dL after a TLC trial, especially when individualized family cardiovascular event histories are involved.

Hispanic Americans

Hispanic Americans are a heterogeneous ethnic group with origins in many different countries. The genetic researchers have found two general haplotypes that affect lipid processing; one was associated with higher risk factors of overall higher TC, TG, and LDL levels with low HDL levels, whereas the other type had much lower risks (Chen et al, 2009). CHD and cardiovascular disease are about 20% lower among adult Hispanics than among whites (NCEP, 2001) despite the increased prevalence of diabetes, obesity, lower HDL levels, and higher triglyceride levels. While these concomitant conditions may raise Hispanics' CV risk score, the Framingham tool has not been validated in this group and probably overestimates the risk (D'Agostino, Grundy, Sullivan, Wilson, for the CHD Risk Prediction Group, 2001). There are no special considerations for cholesterol management for Hispanic Americans at this time.

Native Americans (American Indians)

Data from the Indian Health Service indicate that cardiovascular disease rates are increasing in Native Americans. Native Americans were not included in the original studies on the metabolism of statins. CVD incidence rates among Native American men and women were almost twice as high as those in the biracial Atherosclerosis Risk in Communities Study (Howard et al, 1999). In addition to increased rates of CVD, cardiovascular events in Native Americans appeared more often to be fatal.

The significant independent predictors of cardiovascular disease common to both Native American men and women were diabetes, age, LDL levels, albuminuria, and HTN. The increasing incidence of CVD may be related to the increasing prevalence of diabetes in this population. As with the Hispanic population, the Framingham tool appears to overestimate the risk of CVD. Nonetheless, efforts to reduce cholesterol and other CV risk factors are important because there is a higher incidence of CVD and a higher mortality rate in this population. Despite limited data suggesting some differences, there is no separate algorithm for Native American populations.

Asian and Pacific Islanders

There is limited information on the risks and benefits of lipid management for the reduction of CVD and cardiovascular disease in the Asian and Pacific Islander populations. The Honolulu Heart Program is an ongoing prospective study of CHD and stroke in a cohort of Japanese American men living in Hawaii. In this study, CHD and cardiovascular mortality are lower than in the general U.S. population and the Framingham tool appears to overestimate the actual risk. The increased incidence of diabetes in native Hawaiians and Pacific Islanders has not generated a separate algorithm. Some providers question whether alternative BMI charts should be used to determine actual risk levels. It should be noted that familial forms of lipid disorders are more highly prevalent than in many other population groups (Cuchel et al, 2014).

Chinese Americans were included in the recent lipid genetic studies (Chen et al, 2009). Even though this population typically has the lowest BMIs when compared to other racial groups, they have high cardiovascular disease rates. East Asians also have a very high prevalence of coronary disease at younger ages in the absence of standard risk factors. This may be related to the high prevalence of insulin resistance, metabolic syndrome, and diabetes in this population at a lower BMI than in whites. For these reasons, general guidelines recommend that special attention be given to early detection of CV risk factors in Asian populations, with emphasis on metabolic syndrome and diabetes. The treatment plan should place increased emphasis on intensive TLC implementation. Of note, low BMI is also associated with increased risk in the Asian population (Chen et al, 2013).

The peoples of India and Bangladesh, carry more body fat than Europeans and other Asians in the same BMI range, yet unexpectedly have a lower rate of CV events until the BMI range of 35 (Chen et al, 2013). The BMI cut points for risk may not apply to this population and need to be considered during personalized risk discussions concerning statin use.

Concomitant Disease States

Drugs used to treat hyperlipidemia may improve the management of some diseases and worsen others. It is not within the scope of this text to discuss all possible diseases that may coexist with hyperlipidemia, but common diseases that may be impacted as a result of drug selection for the treatment of hyperlipidemia are discussed here.

Diabetes Mellitus

Diabetes mellitus is a CV risk equivalent, so the ideal therapeutic treatment goal for LDL cholesterol levels in diabetic patients, particularly type 2, is less than 100 mg/dL. TLC should be started immediately in all patients presenting with diabetes or prediabetes. Most patients with diabetes will require LDL-lowering drugs to achieve target serum LDL levels below 100 mg/dL. If the patient also has high TG, which is common for type 2 diabetics, non-HDL cholesterol becomes a secondary target for therapy. After serum LDL levels are in a desirable range, the focus of treatment can change to reducing serum TG levels. Nicotinic acid has been shown to have a favorable effect on diabetic dyslipidemia. Unfortunately, nicotinic acid can cause increased insulin resistance. Given in low doses, nicotinic acid produces limited deterioration in glucose control and no changes in glycated hemoglobin levels.

The first line of treatment is intensive TLC plus medications. Maximal control of nonlipid risk factors such as HTN and hyperglycemia are also a focus of management. The drugs of choice for treating HTN in patients with diabetes are angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs).

Statins are usually the drugs of choice for lowering serum LDLs. Statins are generally well tolerated in this population and have the advantage of lowering VLDL as well. Bile-acid–binding resins can also be used to lower serum LDLs, but they do not reduce serum VLDL, a lipid fraction commonly elevated in diabetics. Diabetic patients taking bile-acid–binding resins should have TG checked regularly because these medications can elevate serum TG levels.

Additional special attention for lipid management in patients with diabetes includes consideration of the following:

- Fibrates are well tolerated and do not worsen hyperglycemia, but they are best used in patients with lowered LDL cholesterol levels.
- If TG are greater than 200 mg/dL, the non-HDL goal is less than 130 mg/dL.
- Control of nonlipid risk factors is central to management in this population. Metformin may help lower hyperglycemia and facilitate weight loss. Insulin, sulfonylureas, metformin, and glitazones all lower TG. Control of hyperglycemia may eliminate the need for a fibrate medication.

Metabolic Syndrome

Patients with metabolic syndrome have an increased risk for coronary disease. There has been a brief surge of interest in what was called "the obesity paradox" whereby CV survival appeared to be paradoxically better in overweight individuals. This "paradox" has been put to rest after a statistical review demonstrated that it did not exist (Tobias et al, 2014). Elevated TG present one factor within a set of risk factors in patients who are obese (especially abdominal obesity), sedentary, have low HDL cholesterol, are hypertensive, and have fasting blood glucose levels at or above 110 to 125 mg/dL. Expert opinion suggests starting metformin even before diabetes is formally diagnosed for the best long-term outcomes. Some patients may be concerned about media reports that statins induce the conversion of metabolic syndrome into full DM. They should be shown that the benefits of CV risk reduction significantly outweigh the low risk of converting to full glucose intolerance (Walters et al, 2013). In studies with Lipitor, development of DM is related to high doses, but this is considered a class effect in patients with two or more risk factors for CVD. It is also considered something that was probably inevitable and not necessarily triggered by the medication and more likely a genetic trait.

The major focus of management for metabolic syndrome is intensive TLC. Restricting alcohol and avoiding a high-carbohydrate diet form the foundation for triglyceride control in this population. Statins are the drugs of choice because they lower both serum LDL and VLDL remnants. In the presence of low serum HDL cholesterol, nicotinic acid is an alternative therapy used when the serum LDL cholesterol goal has already been achieved. Fibrates can be considered as an alternative option for the treatment of elevated TG.

Hypothyroidism

Untreated hypothyroidism often presents with symptoms that include hypercholesterolemia. Clinically, patients present with elevated cholesterol, high LDL, and mild VLDL elevation. Every patient found to have elevated cholesterol (LDL greater than 160 mg/dL) should be screened for hypothyroidism. Treatment of the primary problem, hypothyroidism, should be initiated and serum lipid levels should be reevaluated after thyroid levels are normal.

Hypertension

HTN and hyperlipidemia commonly occur together. Patients with concomitant HTN and hypercholesterolemia should have both conditions treated aggressively because these two risk factors act synergistically, greatly increasing CVD risk. Management of HTN is discussed in Chapter 40. Lifestyle modifications are the first approach to treatment of both hypertension and hypercholesterolemia. The Dietary Approaches to Stop Hypertension (DASH) diet for HTN also works for hyperlipidemia. Weight control, exercise, lowering sodium consumption, and smoking cessation are lifestyle changes that should be stressed to patients with both disorders.

Diuretics are still considered first-line therapy for HTN with the JNC-8. Thiazide diuretics are the most commonly prescribed agents for HTN. Higher doses of these drugs can cause modest and often transient increases in serum LDL cholesterol and TG, with little or no adverse effects on HDL cholesterol. The effects of loop diuretics are similar to those of thiazides, but serum HDL cholesterol levels are generally lower in patients on furosemide. This may not be a drug effect, but a reflection on the more advanced CV issues of those needing loop diuretics.

Calcium channel blockers, ACE inhibitors, and aldosterone antagonists have little effect on serum lipids. Beta blockers without intrinsic sympathomimetic activity (ISA) tend to reduce HDL cholesterol, increase TG, and have variable effects on total serum cholesterol. These effects are minimal, and should not play a role in the selection of a beta blocker for treating hypertension. ISA beta blockers combined with alpha$_1$ beta blockers (labetalol and carvedilol) have no appreciable effect on lipid levels. Alpha$_1$ blockers and centrally acting agonists provide minimal, beneficial effects on blood lipids by decreasing LDL cholesterol.

Nicotinic acid can cause orthostatic hypotension and should be used with caution in patients who are being treated with antihypertensives that have this same side effect. None of the other classes of drugs used to treat hyperlipidemia have a direct effect on blood pressure. Bile-acid–binding resins may decrease absorption of antihypertensive medications, so their administration should be separated by giving the antihypertensive 1 hour before or 4 hours after the bile-acid–binding resin. Statins have no specific interactions with antihypertensive agents.

Chronic Renal Disease (CKD)

There is an independent relationship between renal disease and CV issues. If CKD patients have eGRF greater than 60 mL/min/1.73m², statins are known to be of benefit. The concerns about individuals with renal function occur as renal function is lost. There are more adverse events as GFR drops; however, statins are not stopped because over a quarter of the deaths in this population are CV related. Use of statins is considered very beneficial. When patients progress to dialysis, however, there is little benefit. Starting individuals on new statin therapy when they are placed on dialysis is not a recommendation (Goff et al, 2013). Fibrates may have a role in mild to moderate disease with a demonstrated risk reduction of 30% and mortality reduction of 40% (Jun et al, 2012).

Cost

In today's health-care environment, the cost-effectiveness of therapy is always an issue. The aggregate cost of CVD in the United States is anticipated to be over $800 billion per year for medication, treatment, and lost wages by the year 2030 according to the authors of the newest cholesterol guidelines. Prevention of CVD could greatly reduce this economic burden, and the management of cholesterol levels is one way to prevent CVD.

Patients in high-risk categories have the greatest likelihood of significant benefit from cholesterol reduction. In men 35 to 64 years and women 35 to 54 years with established CVD, intervention with standard doses of statins has been estimated to save significant amounts of money otherwise spent on CVD events in untreated patients. In older men and women, the cost–benefit ratios are even better. From a public health perspective, the cost of cholesterol treatment is clearly justified for older patients. Patients at lower risk for CVD have a less favorable cost–benefit ratio. For this group, the ratio of cost to savings depends on the drug therapy chosen. When evaluating patients on an individual basis, even low-risk patients may benefit from cholesterol reduction therapy. The more recent links between low to moderate lipid levels in middle-aged adults to higher risk for development of Alzheimer's disease increases the urgency for earlier and more aggressive treatment of hyperlipidemia beyond just CVD issues (Solomon, Kivipelto, Wolozin, Zhou, & Whitner, 2009).

Reduction of major risk factors, like smoking and limited physical activity, have the best cost–benefit ratio for public health and the individual patient. When drug therapy is chosen, the cost includes laboratory assessment and monitoring as well as the price of the medication. Historically, the greatest expense was drug cost. With the marketing of generic drugs, costs associated with the treatment of hyperlipidemia have been reduced significantly. Many major drug companies offer low-cost or free brand-name medications for those with restricted incomes.

MONITORING

The treatment goals must be expanded beyond targeted LDL levels of the ATEP III and become more individualized. The absolute number is not so much the focus as is the percentage of reduction and process toward a better CV risk profile. This trend favors the movement toward changing practice to eliminate the requirement for fasting prior to lipid lab draws (Doran et al, 2014). It appears there may be no clinically significant difference in fasting vs. non-fasting values; however, this recommendation is yet to be substantiated by vigorous research.

Some experts still recommend also including inflammatory marker control, non-HDL targets, HDL-C levels, TG, and peripheral vascular prevention and stroke prevention targets (Ridker & Cook, 2013). For the first time in the 2013 guidelines, a strong emphasis upon patient involvement in therapeutic decision making and lifestyle interventions to include weight control, exercise, smoking cessation, and taking a long-term look at risk rather than just reacting to disease states. Of critical importance to nurse prescribers is that a laboratory value is not the goal; the reduction of risk and the prevention of CV events is the true target.

Monitoring for effectiveness of dietary therapy involves weight loss, BMI reduction, and lipid lowering. Drug therapy is not usually initiated until a 3-month trial of dietary therapy has been completed; the exception is concurrent drug therapy for those patients with DM or metabolic syndrome. Selection of an agent to treat a lipid disorder is based on a minimum of two lipoprotein levels done 1 to 4 weeks apart during maximum dietary therapy and on individualized risk. This provides a baseline for future evaluation of whether a drug needs to be added to improve treatment efficacy. Baseline lab data (liver function, ALT or AST, and CK) should be gathered before drug treatment begins. Serial monitoring of liver labs are no longer indicated for most patients. Specific diagnostic tests for monitoring each drug class are discussed in Chapter 16.

With good medication and adherence to lifestyle changes, patients should show a lowering of cholesterol within 4 to 6 weeks of initiating therapy. Levels of serum LDL cholesterol should be evaluated 6 to 8 weeks after initiating therapy. Nicotinic acid is the exception to this rule, with repeat measurements done when the patient's prescribed dose has been stable for 4 to 6 weeks. For all of these drugs, a second measurement of LDL cholesterol levels is done 6 weeks after the first measurement. A minimum of two measurements is used for establishing the efficacy of the treatment plan. For all treatment regimens, if the dose of a drug is increased, or another drug is added to the treatment regimen, the patient's laboratory data should be evaluated in another 6 to 8 weeks. An aggressive increase in dosing is recommended for those at highest risk for CVD per the new guidelines. After the desired LDL cholesterol range is reached, patients should be followed at 8 to 12 week intervals for 1 year. After 1 year of therapy, during which the patient's response to the treatment regimen has been established and there is no evidence of toxicity, patients should be followed at 4 to 6 month intervals. Myopathies tend not to surface until 9 months into therapy. Evaluation of CK levels after the baseline period is not indicated unless there are symptoms.

Intermittent monitoring of HDL and non-HDL levels is a practice that provides a clearer picture of the actual CVD

risk status for the patient but may not be covered by insurance. Apo levels and Lp-PLA$_2$ can be measured, but this is very expensive. These tests are not recommended by experts for anyone other than those with high risk (Davidson et al, 2011). They have not been demonstrated to be reliable for treatment decisions. Simple calculation of the non-HDL levels can give an indication of apo levels. Attention to reductions in the C-reactive protein levels is more critical if measuring treatment effect. There is not great evidence to re-screen nonrisk patients for CRP levels if the baseline was normal and no other situational changes occur that trigger suspicion that levels have gone up.

OUTCOME EVALUATION

Long-term cholesterol control requires lifelong adherence to a treatment regimen. If accompanied by weight loss and other successful TLC achievements, the medications can be considered for reduction. Discontinuation of treatment is quickly followed by a return of the cholesterol to pretreatment levels without other interventions. Achieving long-term clinical control requires the same interest and attention from the patient and the provider as was given to the initial evaluation and treatment plan. Effective use of follow-up visits and skillful employment of adherence-enhancing techniques are required, including nurturing the patient–provider relationship. The primary care provider can manage hyperlipidemia in most patients. Severe forms of hypercholesterolemia that do not respond to general guideline therapies require consultation with a lipid specialist.

Prescribers may need to intervene with administrators and insurance companies, which retain a prescriptive approach to absolute LDL levels to determine "quality" of care. Absolute levels are no longer recommended as performance standards (Stone et al, 2013).

PATIENT EDUCATION

Patient education should include a discussion of the overall treatment plan and the role of medication therapy. Patients who understand the reasons for their drug therapy may show improved adherence to their medication regimens. Careful education helps clarify that risk scores can provide a false sense of health for those with lab levels of "near" risk. The numbers are not absolutes; both provider and patient should err on the side of caution when deciding on therapeutic alternatives when faced with higher risks.

Patients should be made aware that the tendencies for muscle toxicity appear to run in families. Patients should inquire about statin tolerance issues in their older relatives to establish if a potential family risk for myopathies exists. The onset of muscle pain can occur immediately but frequently does not appear for several months. Reinforcement about reporting myalgias should be addressed with patients at every follow-up appointment.

Some patients may question the reports about cognitive impairment or short-term memory issues, which are now recognized to be reversible after statin treatment is discontinued. Issues with memory may be more associated with life stressors and not the drugs (FDA, 2012a). Of greater import is that even mildly elevated lipids in midlife are linked to dementia in older age (Solomon et al, 2009). The reduction of significant CV events increases the probability of a high quality of elder years as well.

HYPERLIPIDEMIA

PATIENT EDUCATION

Related to the Overall Treatment Plan and Disease Process

☐ Pathophysiology of lipid disorders and their long-term effects on cardiovascular morbidity and mortality

☐ Role of lifestyle modification, especially dietary therapy, in improving outcomes and keeping the number and cost of required drugs down

☐ Importance of adherence to the treatment regimen

☐ Need for regular follow-up visits with the primary care provider

Specific to the Drug Therapy

☐ Reason for the drug(s) being given and the anticipated action of the drug(s) on the disease process

☐ Doses and schedules for taking the drug(s)

☐ Possible adverse reactions, how to prevent them, and what to do if they occur

☐ Interaction between lifestyle modifications and the drug(s)

Reasons for Taking the Drug(s)

Patient education about specific drugs is provided in Chapter 16. Specific information related to hyperlipidemia includes the reasons for drug(s) being taken: Antilipidemics are given to reduce morbidity and mortality from the leading cause of death in the United States—cardiovascular disease. Discuss the risk of cardiovascular disease with the patient while maintaining the potential for good quality of life with adequate treatment.

HYPERLIPIDEMIA—cont'd

PATIENT EDUCATION

Drugs as Part of the Total Treatment Regimen

The expectations should be clear about what the drugs can and cannot do. Drugs are supplements to dietary and other lifestyle modifications, not substitutes for them. Lipid disorders are chronic conditions. Lifestyle modifications and drug regimens need to be incorporated into patients' everyday lives. Discontinuation of treatment will result in return of lipids to pretreatment levels.

Adherence Issues

Nonadherence to the treatment regimen may increase patients' risk for cardiovascular morbidity and reduce their life expectancy. Health-care providers should be aware of potential problems with adherence, discuss the importance of adherence at each follow-up visit, and assist patients in removing barriers to adherence, such as lack of social support and fear of side effects. Utilization of other health team members, especially the dietitian, should be maximized. Patient education booklets available from the American Heart Association and the National Cholesterol Education Program may supplement dietary instruction.

HYPERTENSION

Marylou V. Robinson

Hypertension (HTN) is the most common cardiovascular disease in the United States, and it is also a problem worldwide. The World Health Organization (World Health Report, 2012) reports that 1 out of 3 adults worldwide have suboptimal blood pressure (SBP). Suboptimal blood pressure is thought to be the number-one attributable risk for death throughout the world. According to the 2013 JNC-8 (Eighth Joint National Committee) guideline, blood pressures above 140/90 mm Hg for the general population is considered suboptimal. For nonfrail elders over the age of 60, blood pressure of 150/90 mm Hg is the new cut point (James et al, 2014).

Although the past two decades have seen considerable reduction in deaths from coronary heart disease (CHD) and stroke (CVA), control rates for HTN are still unacceptable. Approximately 30% of adults are still unaware of their HTN, 40% of individuals who have HTN are not in treatment, and 66% of those being treated are not controlled to blood pressures less than 140/90 mm Hg. It is estimated that a reduction of as little as 5 mm Hg of SBP in the general population could result in a 14% reduction in CVA mortality, a 9% reduction in CHD mortality, and a 7% reduction in all-cause mortality in the United States. There is an increasing trend in end-stage renal disease (ESRD). Hypertension is second only to diabetes as the most common cause of ESRD.

PATHOPHYSIOLOGY

Systemic arterial pressure is a function of stroke volume, heart rate, and total peripheral resistance. Alterations in any of these factors result in changes in blood pressure. The major organs involved in regulation of blood pressure are the heart (heart rate [HR] and stroke volume [SV]), the sympathetic nervous system (SNS), total peripheral resistance (TPR), and the kidney (extracellular fluid volume and secretion of renin). Disease processes that affect stroke volume and heart rate include any that increase extracellular fluid volume, the activity of the SNS, or plasma norepinephrine levels and those that produce cardiac rhythm disturbances. Disease processes that affect total peripheral resistance include any that narrow the arteriolar radius or increase blood viscosity. Figure 40-1 shows the relationship of these factors to blood pressure control. In both normotensive and hypertensive patients, blood pressure is maintained by moment-to-moment adjustments in this system.

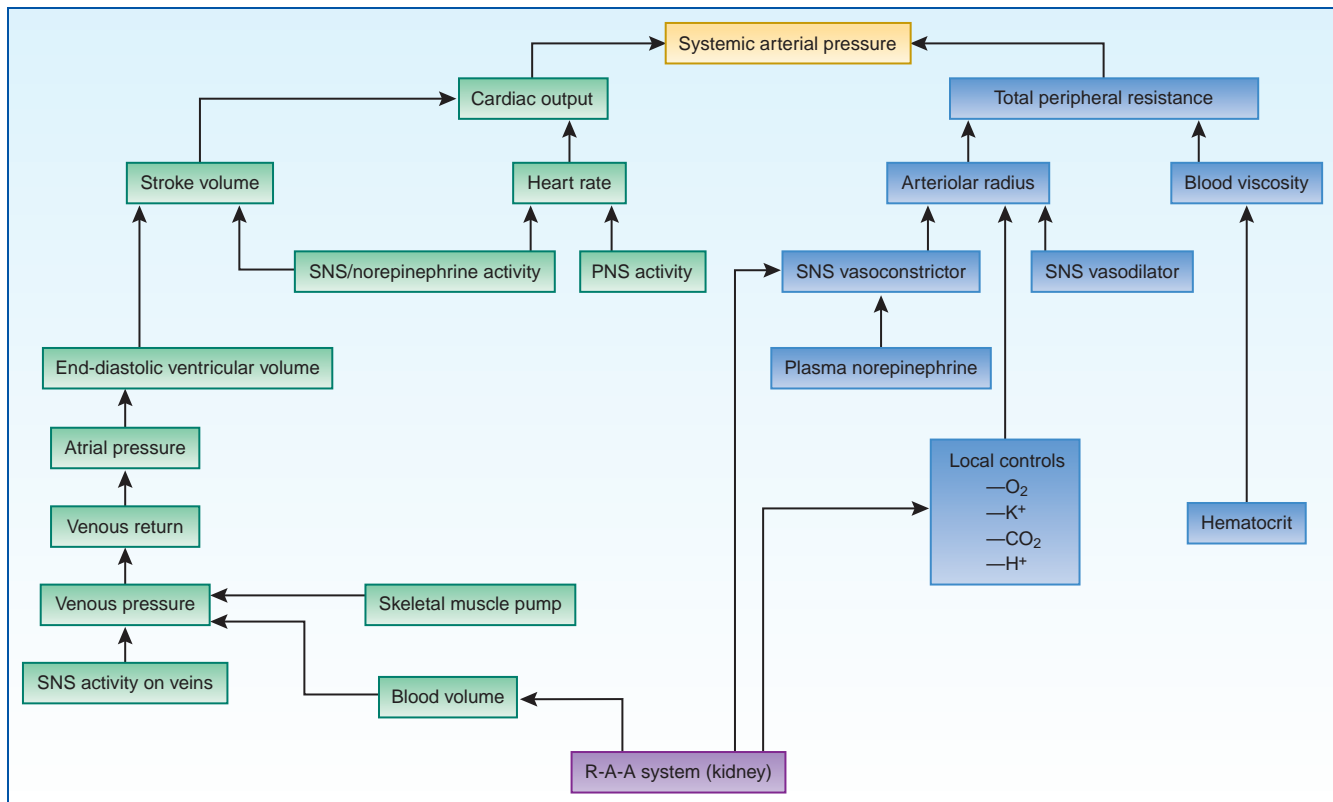
BP naturally drops at night with sleep. Evidence indicates loss of this nocturnal BP "dip" is the best predictor of CV risk. Most patients with HTN do not have an effective "dip" (Hermida, Ayala, Mojón, & Fernández, 2010). There also appears to be a seasonal increase of BP in winter, which is related to an individual's home temperature patterns: the


Figure 40–1. Regulation of blood pressure. Systemic arterial pressure is determined by cardiac output and total peripheral resistance. Increases in cardiac output or total peripheral resistance increase systemic arterial pressure, and decreases in these factors decrease systemic arterial pressure. Antihypertensive drugs act at one or more of these anatomical sites of blood pressure control.

warmer the home, the lower the BP. The clinical significance of this is yet to be determined (Modesti et al, 2013).

Factors That Regulate Blood Pressure

Baroreceptors

Change in BP is sensed by baroreceptors located in the carotid arteries and the arch of the aorta. They are sensitive to stretch so that, when stimulated by an increase in BP, they send inhibitory impulses to the sympathetic vasomotor center in the brainstem. Inhibition of efferent nerves in the SNS that innervate cardiac and vascular smooth muscle results in decreased heart rate, decreased force of contraction, and vasodilation of peripheral arterioles. At the same time, increased parasympathetic nervous system (PNS) activity further reduces HR via the vagus nerve. Decreased BP results in a reverse process. This system works well in the maintenance of BP during normal activities; however, in the presence of long-standing HTN, the baroreceptors adapt to the elevated BP levels and "reset" what the body accepts as "normal" BP. Diminished responsiveness to these baroreceptors is one of the most significant cardiovascular effects of aging and a major factor in the lifetime risk of HTN.

Endothelial Factors

In addition to the actions of baroreceptors, vascular endothelium has the ability to produce vasoactive substances and growth factors. Nitric oxide, an endothelium-derived relaxing factor, helps maintain low arterial tone at rest and inhibits growth of the smooth muscle layer. The vascular endothelium also produces local vasodilators such as prostacyclin and endothelium-derived hyperpolarizing factor. Endothelin, also secreted by the vascular endothelium, is an extremely potent vasoconstrictor and also stimulates vascular smooth muscle growth. Growth of vascular smooth muscle is associated with atherosclerosis and the thickening seen with prolonged exposure to high BP. Endothelial dysfunction may contribute to these changes. Prevention or reversal of endothelial dysfunction may become an important therapeutic area in the future.

Kidneys

The kidneys contribute to BP control by regulation of the renin-angiotensin-aldosterone system. Renin, secreted by the juxtaglomerular apparatus in the kidney, converts angiotensinogen to angiotensin I. Angiotensin I is then converted by angiotensin-converting-enzyme (ACE) in the lungs to angiotensin II, which affects BP in two different ways. Angiotensin II is a potent vasoconstrictor and increases TPR. In addition, it stimulates the adrenal gland to produce aldosterone, which promotes sodium and water retention, thereby increasing extracellular fluid volume. Evidence suggests that angiotensin II also stimulates growth of vascular smooth muscle and may contribute to atherosclerosis and HTN.

Genetic Influences

The level of BP is strongly familial, and studies of rare genetic disorders affecting BP have led to the identification of genetic abnormalities associated with several rare forms of HTN. Genetic polymorphisms have also been discovered that may harbor genes contributing to primary HTN. To date, none of these genetic abnormalities has been shown, either alone or in combination, to be responsible for a clinically significant portion of HTN in the general population.

Although 90% to 95% of all cases of HTN are primary in nature with no identifiable cause, there are identifiable causes of HTN in which a cure may be effected by appropriate diagnosis and treatment. The focus of this chapter is on the diagnosis and management of primary hypertension.

Laboratory Tests and Other Diagnostic Procedures

Confirmation of a diagnosis of HTN is based on BP elevation documented at three different times. Standard measurement techniques, including out-of-office or home blood pressure measurements, can be used when confirming an initially elevated blood pressure and for all subsequent measures during follow-up and treatment (Institute for Clinical Systems Improvement [ICSI], 2012). Children over 3 years of age who are seen in a medical setting should have their BP measured at least once during every health-care visit. The preferred method for children is auscultation; the correct measurement requires using a cuff that is appropriate to the size of the child's upper arm (National Heart, Lung and Blood Institute [NHLBI], 2011).

The "JNC-8" published in late 2013 did not come from the original National Heart, Lung and Blood Institute, which authored the previous JNC recommendations; however, this new document is frequently referenced as the JNC-8 in the literature. The testing recommendations for the initial diagnosis of HTN of the JNC-7, listed below, were not altered and so are included in this chapter as a reliable reference. The recommended tests are used for therapeutic decision making

and baseline values for determination of progression or stabilization of the systemic impact of HTN:

1. A 12-lead ECG.
2. Urinalysis, including urinary albumin or albumin/creatinine ratio. For those patients with diabetes or renal disease, the latter test of albumin should also be done annually. The presence of albuminuria, including microalbuminuria, even in the setting of a normal glomerular filtration rate (GFR), is associated with increased cardiovascular risk.
3. Blood glucose and hematocrit.
4. Serum potassium.
5. Creatinine and the corresponding estimated GFR. There is a strong relationship between decreased GFR and increases in CV morbidity and mortality.
6. Serum calcium.
7. Lipid profile.

Elevated levels of high-sensitivity C-reactive protein (HS-CRP), homocysteine, and heart rate may also be considered in patients with cardiovascular disease (CVD) but without other risk factors. Analysis of data from the Framingham Heart Study cohort demonstrated that those with an LDL-C value within the range associated with low CVD risk, but who had an elevated HS-CRP, had a higher risk of CVD compared to those with a low CRP and a high LDL-C. This was especially true in women; however, reduction in CRP has not led to better outcomes (Mosca et al, 2011). Elevations in homocysteine have also been associated with higher CVD risk but not as strongly as the HS-CRP (Ahluwalia et al, 2013). Treating elevated homocysteine has not resulted in decreased CVD risk, however.

Classification of Blood Pressure for Adults

BP readings have been classified according to a progressive risk of end-organ disease and poor outcomes. The higher the classification, the higher the CV risk. Table 40-1 shows the BP readings that fall into each of these categories per the

Table 40–1   Blood Pressure Classifications and Management

Classification	Systolic BP (mm Hg)	Diastolic BP (mm Hg)	Lifestyle Modification	No Compelling Indication (Drug Therapy)	Compelling Indication (Drug Therapy)
Normal	<120	<80	Encourage	No antihypertensive drug	Drug for compelling indication
Prehypertension	120–139	8–89	Yes	No antihypertensive drug	Drug for compelling indication
Hypertension stage 1	140–159	90–99	Yes	Thiazide-type diuretic for most. May consider ACEI, ARB, CCB, or combination.	Drug(s) for compelling indication. Other antihypertensive drugs
Hypertension stage 2	≥160	≥100	Yes	Two-drug combinations for most. Usually thiazide-type diuretic and ACEI or ARB, or BB, or CCB.	Drug(s) for compelling indication. Other antihypertensive drugs.

ACEI = angiotensen-converting enzyme inhibitor; ARB = angiotensin receptor blocker; BB = beta blocker; CCB = calcium channel blocker.

Source: ACCF/AHA, 2011; James et al, 2014 Arnett et al, 2014).

JNC-7 standards, which were not altered by the JNC-8 (James et al, 2014). This classification is based on the average of two or more properly measured seated BP readings on each of two or more office visits.

The JNC-7 first introduced the evidence that there is a degree of lifetime CV risk associated with BP levels previously thought to be normal. The previously termed "normal" BP of 120/80 changed to a BP reading that is now considered "top of normal." Consistent readings over 120/80 are now scrutinized but not treated with medications until over the new cut points. The JNC-7 introduced a new term: *prehypertension.* This level of BP ranges from 120 to 130 SBP and/or 80 to 89 diastolic blood pressure (DBP). The JNC-8 did not change that range, but softens the requirement to bring a person treated with medications down to less than the previously required 120/80 ideal.

Prehypertension is not directly addressed as a factor in the JNC-8, but importantly was not rejected as a consideration of risk. Prehypertensive individuals benefit from early intervention to adopt healthy lifestyles that might reduce BP, decrease the rate of progression to hypertensive levels as the individual ages, or prevent HTN completely. Longitudinal data obtained from the Framingham Heart Study indicate that BP values in the 130 to 139/85 to 89 ranges are associated with a more than 2-fold increase in relative risk for CVD compared to those with BP below 120/80. This is no longer an absolute goal. Consideration is extended to include persons who had adverse effects such as weakness and orthostasis and thus were less likely to adhere to treatment patterns; therefore, a decrease in BP below 140/90 with strict adherence to the 120/80 goals previously touted is no longer recommended.

Long-term studies show that there are noteworthy differences in those treated and not treated for HTN. The more comorbid the risk factors, the worse the outcomes. For patients less than 65 years of age, the SBP has the best predictive value for poor outcomes regardless of the DBP. For elders, increases in SBP also increase mortality, especially when there are large pulse pressures. The larger the CV risk, the more impact therapy can have. This means that treating mild HTN does not improve outcomes as dramatically as lowering higher BP values. However, the Framingham studies have indicated the long-term impact of HTN on all-cause mortality is understood to be very beneficial no matter the baseline value (American College of Cardiology Foundation/American Heart Association [ACCF/AHA], 2011).

PHARMACODYNAMICS

Because primary HTN has no identifiable cause, the treatment necessarily depends on interfering with normal physiological mechanisms that regulate BP by means of six classes of drugs. The new guidelines emphasize the ACE/ARB family of medications plus diuretics before any other drug group in most cases, which is a change from prior practice (James et al, 2014). How the medications work is discussed below.

Diuretics lower BP by depleting the body of sodium and reducing extracellular fluid volume. Agents that act in the renin-angiotensin-aldosterone system (RAAS) reduce pressure by decreasing sodium and water retention (aldosterone action), by decreasing vasoconstriction (angiotensin direct action), and by increasing vasodilation (bradykinin action). Adrenergic blockers and other drugs acting on the SNS lower blood pressure by reducing peripheral vascular resistance, inhibiting cardiac contractility, and increasing venous pooling in capacitance vessels. Calcium channel blockers act as vasodilators to reduce pressure by relaxing vascular smooth muscle, thereby dilating resistance vessels and increasing the area over which blood must flow, and through their negative inotropic activity to reduce cardiac output. Direct vasodilators produce the same effect as the calcium channel blockers on vascular smooth muscle. Centrally acting agents produce vasodilation mainly through reduction in norepinephrine. The latter two classes are used only in specific situations in which other classes are not appropriate or effective. It is unusual that treatment with any one drug class can achieve the blood pressure goal and so combinations of two or more drug classes are common. More detailed discussions of the pharmacokinetics and pharmacodynamics of each of these classes of drugs are in Chapters 14 and 16.

GOALS OF TREATMENT

The first goal of HTN management is reduction in CV risk. The positive relationship between hypertension and CV risk has been long established. The presence of each additional risk factor is assumed to compound the risk from HTN. Figure 40-2 shows the 10 year risk of classic considerations for coronary heart disease (CHD) related to the major risk factors of total serum cholesterol, serum high-density lipid (HDL) level, smoking, diabetes, and left ventricular hypertrophy (LVH).

Easy and rapid calculation of a Framingham or the new pooled CV risk tool may assist in demonstrating the benefits of treatment to patients. Treatment is initiated for individuals with blood pressure greater than 140/90 in the general population and above 150/90 in elders. Management of any other risk factor beyond HTN is essential and should follow the established guidelines. A positive relationship has also been shown between HTN and end-organ damage to the eyes, brain, and kidneys. The second goal is prevention of this end-organ damage. To meet these two goals, the following are needed:

1. Prevent the rise of BP with age. The prevalence of HTN increases with advancing age (see the Pathophysiology section above) to the point at which more than 50% of adults aged 60 to 69 years and 75% of those aged 70 years and older have HTN. The age-related rise in SBP is the primary cause for this increase.
2. Improve control of HTN to below 140/90 mm Hg in adults and below 150/90 in those greater than age 60 are the new targets. Treating HTN to these targets is associated with a decrease in CV disease complications.
Figure 40–2. Ten-year risk for CHD by SBP and presence of other risk factors. *(Source: Adapted from Anderson, K., Wilson, P., Odell. P., & Kannel, W. [1991]. An updated coronary risk profile: A statement for health professionals.* Circulation, 83, *356–362.)*

Cholesterol	180	240	240	240	240	240
HDL	50	50	35	35	35	35
Smoking	No	No	No	Yes	Yes	Yes
Diabetes	No	No	No	No	Yes	Yes
LVH	No	No	No	No	No	Yes

Under previous American Diabetes Association guidelines for patients with concurrent HTN and diabetes or renal disease, the BP goal was less than 130/80 mm Hg. (The 2015 recommendation is to keep current with the JNC-8 guideline value of 140/90. This decision was made to decrease confusion and to facilitate increased numbers of patients who maintain therapy.) Control should not be relaxed for patients who have been treated to lower target levels based on the JNC-7 if they are not having adverse effects (James et al, 2014).

3. Increase recognition of the importance of controlling isolated systolic hypertension (ISH), as it is the most lethal hypertensive phenotype. Because most persons with HTN, especially those older than 50 years, will achieve control of their DBP once the SBP goal is reached, the primary focus should be on obtaining the SBP goal.

4. Improve recognition of the importance of prehypertension on the development of HTN. Individuals with SBP between 120 and 139 mm Hg and DBP between 80 and 89 mm Hg have a significantly higher risk for developing uncontrolled HTN. Changes in lifestyle are critical.

5. Reduce ethnic, socioeconomic, and regional variations in HTN diagnosis and treatment by improving opportunities for well-tolerated, affordable treatment options, including lifestyle modifications and access to care. The 2013 guidelines specifically address the black population as to the recommended choice of first-line drugs.

6. Recognize that HTN is not only an issue in middle age and older patient groups. It has a real presence in the preadolescent and younger adult population as well. Early intervention can increase long-term outcomes and quality of life in the later years.

Barriers to Goal Achievement

These goals are attainable for a large percentage of patients with HTN with the treatment regimens recommended by the guidelines. Barriers to achievement of these goals include insufficient health education by health-care providers, lack of reimbursement for health education services, and lack of healthy food choices in many schools, worksites, and restaurants. Another factor is nonadherence to the treatment regimen. Chapter 6 focuses on factors that address these and other barriers to health. This chapter discusses treatment regimens that can enable people to control their BP.

RATIONAL DRUG SELECTION

Hypertension presents a unique problem in therapeutic management. It is usually a lifelong disease but is asymptomatic until end-organ damage occurs. For this reason, providers often find themselves prescribing lifestyle modifications or drugs that have disturbing adverse reactions to treat a problem that does not make the patient feel ill. For effective management, the choice of treatment should be low in cost, limited in complexity, and with the fewest possible adverse reactions. Hence the 2013 guidelines allow a more flexible target goal to provide for the maximum number of individuals to achieve at least some hypertension reduction because the lower targets of the JNC-7 may have created a proportion of the population who rejected treatment based on side effects. Management is based on classification of HTN, the presence of comorbid risk factors, and specific patient variables. First, this chapter discusses lifestyle management and stepped therapy, including initial monotherapy, stepping up to multiple drugs, and stepping down when possible. This is followed by specific variations.

Algorithm for Management of Hypertension

Lifestyle Modifications

Of patients with HTN, 30% to 65% are obese, a problem frequently compounded by high sodium intake, sedentary lifestyle, and excessive use of alcohol (American Association of Clinical Endocrinologists [AACE] Hypertension Task Force, 2006). Lifestyle modifications directed at correcting these contributing factors may benefit the patient regardless

of the primary course of the HTN and are an important part of first-line therapy. Multiple well-controlled trials have shown that a weight loss of as little as 5 to 10 kg can have a significant beneficial effect on HTN (American Association of Clinical Endocrinologists [AACE], 2006).

Treatment of HTN should include lifestyle modifications for all treatment groups, but this is especially true for those with prehypertension. Patients with prehypertension are not candidates for drug therapy based on their level of BP but should be "firmly and unambiguously advised to practice lifestyle modification in order to reduce their risk for developing hypertension in the future" (Chobanian et al, 2003). Table 40-2 summarizes the lifestyle modifications recommended in several guidelines. Lifestyle modifications are encouraged to reduce BP, prevent or delay the onset of HTN, improve the efficacy of any drug therapy, and decrease cardiovascular risk. Combining two or more lifestyle modifications can achieve better results than one alone. Making "exercise" an additional vital sign is advocated by the Kaiser Medical System (Coleman et al, 2012). Unfortunately, almost 15% of those heart patients who have already sustained an MI or stroke elect not to engage in any lifestyle changes (Teo et al, 2013).

Stepped Therapy

Patients with all stages of HTN who are not able to achieve a BP below 140/90 mm Hg require drug therapy. Once the decision is made to begin drug therapy at the 150/90 cut point, initial drug choices are based on the presence or absence of compelling indications from concurrent disease processes. Figure 40-3 shows the treatment protocol for hypertension management based on JNC-7 and still maintained in the JNC-8. As a general rule, the following suggestions can lead to progress in achieving the BP goal in a primary care population:

1. Set an appropriate therapeutic BP goal based on individual patients and their compelling indications.

2. Be patient and work on attaining the BP goal over many weeks to months. Moving to lower BP quickly is more likely to produce side effects to the drugs that lead to nonadherence. There is no evidence that faster is better except in cases of extreme values.

3. Titrate BP medications no more often than every 4 to 6 weeks. The body needs time to demonstrate full response to the drug.

4. Do not automatically assume symptoms reported by patients are caused by the drug. What may appear to be adverse responses may have other reasons for occurrence. Assigning all symptoms to drug effects may result in changing a drug that is actually working well. Antihypertensive drugs alleviate more adverse responses than they cause.

5. Plan at the beginning of therapy for the use of more than one drug. A single drug is not likely to provide BP control to goal level if the patient is more than 15/10 mm Hg higher than the goal. Explaining to the patient early in treatment the likelihood of more than one drug decreases the risk for nonadherence.

6. Do not ignore ISH in the elderly. Treat to goal SBP in older adults even if DBP is normal, but go more slowly. Titrate to the target of 150/90.

7. Extracellular fluid volume may need to be controlled in order to achieve BP goals. Include a diuretic in any treatment regimen that includes more than one agent.

(Adapted from ADVANSTAR Medical Economics Healthcare Communications [2004], Reducing cardiovascular risk factors. *Patient Care for the Nurse Practitioner: ACE Activity.* Sponsored by Pfizer Inc.)

Initial Drug Therapy

For most patients, the lowest dose of the initial drug should be used to prevent adverse reactions and too much or too abrupt a reduction in blood pressure. The dose is then slowly

Table 40–2 Lifestyle Modifications

- Lose weight. Loss of as little as 10 lb may significantly reduce blood pressure.
- Limit alcohol intake to no more than 1 oz (30 mL) ethanol (e.g., 24 oz beer, 10 oz wine, 2 oz 100-proof whiskey) per day or 0.5 oz (15 mL) ethanol per day for women and lighter-weight people.
- Increase aerobic physical activity to 30 to 45 min most days of the week. Obese or low-activity patients may need to start with as little as 3 min of activity per day and increase the activity by 1 min each day until the desired 30 to 45 min is achieved.
- Reduce sodium intake to no more than 100 mmol (2,400 mg of sodium or 6 g of sodium chloride) per day. This can often be achieved by not adding salt during cooking or on the table and by watching hidden sources of salt such as canned foods.
- Maintain adequate intake of dietary potassium (approximately 90 mmol per day).
- Maintain adequate intake of dietary calcium and magnesium for general health.
- Stop smoking. The low doses of nicotine found in nicotine replacement therapy (NRT) do not significantly affect blood pressure, and NRT may be used as needed to aid in smoking cessation.
- Adopt the Dietary Approaches to Stop Hypertension (DASH) diet, which is high in fruits, vegetables, and low-fat dairy products as well as low in dietary cholesterol, saturated fat, and total fat.

(2014). 2014 evidence-based guideline for the management of high blood pressure in adults: Report from the panel members appointed to the eighth joint national committee (JNC-8). *Journal of the American Medical Association.* 311(5), 507-520. doi: 10.1001/jama. 2013.284427

titrated upward, based on patient response. If BP remains uncontrolled after 1 to 2 months, the next dosage level should be prescribed. The ideal drug should provide 24 hours of efficacy with at least 50% of the peak effect remaining at the end of the 24 hours. Long-acting formulations are preferred over short-acting because (1) adherence is better with once-daily dosing; (2) for many agents, fewer tablets mean lower cost; (3) control of hypertension is smoother; and (4) the risk of sudden death, heart attack, and stroke because of abrupt changes in blood pressure is lessened.

When the decision is made to begin drug therapy and there are no clear indications for another type of drug, a thiazide-type diuretic has been typically chosen because in the landmark ALLHAT study comparing diuretics with other classes of antihypertensive drugs, diuretics were unsurpassed in preventing CV complications of HTN (Wright et al, 2009). Despite this, diuretics are often underused. Of more concern is that use is declining over time, especially in African Americans who show some of the best data for efficacy (Gerber et al, 2013). New evidence suggests closer consideration of BMI and general fluid status when prescribing diuretics. Those who are obese (a significant percentage of HTN patients) have good response to diuretics. Those who are thin or tend to have lower fluid volume conditions

(e.g., dehydration) are now recognized to have potentially worse outcomes on diuretics (Weber et al, 2013). Those patients would be started on an ACE or calcium channel blocker as their initial therapy.

Current practice guidelines do not recommend beta blockers as first-line therapy because they are weaker antihypertensive agents when it comes to stroke prevention. Some negative evidence in 2005 against atenolol as contributing to increased CV event risk has been overturned by a major meta-analysis that demonstrates a similar effect and risk rate for atenolol and metoprolol (Parker et al, 2012). Beta blockers remain best used as a second or add-on drug.

Chapter 16 discusses specific diuretics and their appropriate use and dosing. In general, the lowest dose that achieves the target BP is best because higher doses are more likely to produce more potassium loss without significant improvement in BP control. The choice of diuretic should be based on level of kidney function. For estimated GFRs higher than the mid 40 mL/min range, a thiazide diuretic should be used; loop diuretics are not as effective as thiazides in this setting. For GFRs that are lower than the mid-40 mL/min range, loop diuretics, sometimes in combination with metolazone, are more appropriate and are most effective when dosed twice daily.

The ALLHAT study (2002) promoted the use of chlorthalidone as the diuretic of choice. This medication was not used in the United States; hence the use of thiazides in most American HTN guidelines. Chlorthalidone has a longer duration of action, 24 to 72 hours, giving rise to the belief it could be better for the nocturnal reduction in BP that best reflects natural patterns. Recent studies intending to foster a switch to chlorthalidone have uncovered evidence this drug has more side effects and adverse reactions than the thiazide class with no true increase in efficacy (Dhalla et al, 2013). It is anticipated the debate will continue over the next several years.

There are compelling indications for use of other specific agents as the initial therapy. Table 40-3 depicts the drug choices appropriate for some compelling indications. Angiotensin-converting enzyme (ACE) inhibitors, for example, are drugs of choice in diabetes mellitus, heart failure, and myocardial infarction (MI). Other concomitant diseases that may affect the choice of drugs are discussed later. In African Americans, calcium channel blockers are suggested as first line BP therapy in lieu of the ACE family due to a common lower renin response in this ethnic group. ACE medications are added to the regimen to cover all pertinent indications.

Some antihypertensive drugs are not well suited for monotherapy because they cause troublesome adverse reactions in almost all patients who take them. These drugs include direct-acting smooth-muscle vasodilators, central alpha$_2$ agonists, and peripheral-adrenergic antagonists. These drugs can be used effectively when combined with other drugs that address these adverse reactions.

When the patient's BP is more than 20 mm Hg above the systolic goal or 10 mm Hg above the diastolic goal, consideration should be given to initial therapy with two drugs, either as separate prescriptions or in fixed-dose combinations. Beginning therapy with more than one drug increases the chances of achieving target BP more rapidly and may produce more BP lowering at lower doses. Older adults, those at risk for orthostatic hypotension (OH), and diabetics with autonomic dysfunction should have initial multidrug therapy begun with caution.

Stepping Up to Multiple Drugs

Most hypertensive patients will require two or more drugs. If the initial monotherapy drug choice is inadequate, several options are considered: (1) maxing out the dose of the first drug, (2) adding another drug, or (3) substitution of a different drug. Evidence demonstrates that addition of a second drug is a better choice than raising the dose of the initial drug. Raising doses always increases the risks and impacts of adverse effects. A synergistic effect of using two drugs together is the standard practice, but three or more may be needed.

Dosing of multiple drugs is implemented on an aggressive schedule when the baseline BP is over 160/90.

The provider must make sure the HTN is actually not controlled on the solo medication. "Pseudo resistance" can trick the provider into upping a dose or adding medications when the actual cause is poor adherence, lifestyle factors, and an irregular/improper dosing schedule (Wright, Rutecki, & Bellone, 2013). OTC meds, NSAID use, an emergency dosing of steroids, or the start of a mental health medication or contraceptives can all appear to be a nonresponse to antihypertensive medication. Taking a rigorous history including very specific questioning as to times and methods of ingestion can reveal nonadherence. Reviewing refill patterns will also provide clues as to adherence. Considering that nearly 40% of patients do not keep to the therapeutic plan within the first year, this potential must be uncovered prior to adding a second medication (Wright et al, 2013).

If the patient is tolerating the first choice well, a second drug is added from another class. The JNC-8 recommends that if an ACE was the first choice, then a diuretic should be added; likewise, if the diuretic was the first choice, an ACE should be added (James et al, 2014). The choice of the second drug may also be influenced by how it might affect the adverse reaction profile of the first drug or by how well these drugs have been shown to work together in clinical studies. An adequate dose of hydralazine results in compensatory tachycardia and salt and water retention. The addition of a beta-adrenergic blocker prevents the tachycardia, and the addition of a diuretic prevents salt and water retention. An ACE inhibitor and a non-dihydropyridine calcium channel blocker may reduce proteinuria in a patient with diabetes better than either drug alone. If a diuretic was not chosen as the first drug, it is usually indicated as the second-step drug because its addition will enhance the effects of most other agents.

Drug formulations that include combinations of medication may permit the best of both worlds; the patient takes just one pill or capsule yet receives the benefit of two drugs, and the combination may cost less than the individual components prescribed separately. The downside is that fixed-dose ratios prevent customization of the regimen. Table 40-4 provides information of selected combinations of drugs frequently used in therapy.

If the patient is having significant adverse reactions or no response from the initial drug, an agent from another class is substituted. For example, a persistent cough may be annoying enough that a patient will not continue to take an

Table 40–4   Common Combinations of Antihypertensive Drugs

Combination*	Fixed-Dose Combination (mg)†	Brand Name
ACEIs and CCBs	Amlodipine/benazepril hydrochloride (2.5/10, 5/10, 10/20)	Lotrel
	Enalapril maleate/felodipine (5/5)	Lexxel
	Trandolapril/verapamil (2/180, 1/240, 2/240, 4/240)	Tarka
ACEIs and diuretics	Benazepril/hydrochlorothiazide (5/6.25, 10/12.4, 20/12.5, 20/25)	Lotensin HCT
	Captopril/hydrochlorothiazide (25/15, 25/25, 50/15, 50/25)	Capozide
	Enalapril maleate/hydrochlorothiazide (5/12.5, 10/25)	Vaseretic
	Lisinopril/hydrochlorothiazide (10/12.5, 20/12.5, 20/25)	Prinzide
	Moexipril HCL/hydrochlorothiazide (7.5/12.5, 15/25)	Uniretic
	Quinapril HCL/hydrochlorothiazide (10/12.5, 20/12.5, 20/25)	Accuretic
ARBs and diuretics	Candesartan cilexetil/hydrochlorothiazide (16/12.5, 32/12.5)	Atacand HCT
	Eprosartan mesylate/hydrochlorothiazide (600/12.5, 600/25)	Teveten/HCT
	Irbesartan/hydrochlorothiazide (150/12.5, 300/12.5)	Avalide
	Losartan potassium/hydrochlorothiazide (50/12.5, 100/25)	Hyzaar
	Telmisartan/hydrochlorothiazide (40/12.5, 80/12.5)	Micardis/HCT
	Valsartan/hydrochlorothiazide (80/12.5, 160/12.5)	Diovan/HCT
BBs and diuretics	Atenolol/chlorthalidone (50/25, 100/25)	Tenoretic
	Bisoprolol fumarate/hydrochlorothiazide (2.5/6.25, 5/6.25, 10/6.25)	Ziac
	Propranolol LA/hydrochlorothiazide (40/25, 80/25)	Inderide
	Metoprolol tartrate/hydrochlorothiazide (50/25, 100/25)	Lopressor HCT
	Nadolol/bendrofluthiazide (40/5, 80/5)	Corzide
	Timolol maleate/hydrochlorothiazide (10/25)	Timolide
Centrally acting drug and diuretic	Methyldopa/hydrochlorothiazide (250/15, 250/25, 500/30, 500/50)	Aldoril
	Reserpine/chlorothiazide (0.125/250, 0.25/500)	Diupres
	Reserpine/hydrochlorothiazide (0.125/25, 0.125/50)	Hydropres
Diuretic and diuretic	Amiloride HCl/hydrochlorothiazide (5/50)	Moduretic
	Spironolactone/hydrochlorothiazide (25/25, 50/50)	Aldactone
	Triamterene/hydrochlorothiazide (37.5/25, 50/25, 75/50)	Dyazide, Maxzide

*Drug abbreviations: ACE = angiotensin-converting enzyme inhibitor; ARB = angiotensin receptor blocker; BB = beta blocker; CCB = calcium channel blocker.

†Some drug combinations are available in multiple fixed doses. Each drug dose is reported in milligrams.

ACE inhibitor. Because they do not affect the kallikrein system, angiotensin II receptor blockers (ARBs) do not produce this cough, nor do they commonly have the problem with angioedema that is a contraindication to the use of an ACE inhibitor. Individuals who do have angioedema with an ACE should not be started on an ARB (Van Rinjinsoever, Kwee-Zuiderwijk & Feenstra, 1998). DRIs can still produce the cough and angioedema, so they may not be the best substitute either. Because the hemodynamic effects are similar, an ARB may be substituted for the ACE inhibitor. Documentation of equal long-term cardiac and renal protection for patients with systolic dysfunction and diabetic nephropathy has now been demonstrated for some ARBs, but they are not used in combination for extra effect; this only produces extra adverse effects, especially on the kidney.

Strong consideration should be given to administration of the medication with the longer half-life at night (Hermida et al, 2010; Wright et al, 2013). This circadian congruent approach yields better outcomes and lower adverse events because it helps return the nocturnal "dip" typically lost in HTN.

Stepping Down

Although HTN is generally accepted to be a lifelong disease, after it has been controlled effectively for at least 1 year, a decrease in the dosage and number of antihypertensive drugs may

be considered. The reduction should be deliberate, slow, and progressive and accompanied by vigilant BP monitoring. Step-down therapy is often successful for patients who also are making lifestyle modifications. Any patient whose drugs have been discontinued should have regularly scheduled follow-up visits because BP usually rises again to hypertensive levels within months to years after the drugs have been stopped. This return of HTN is especially common in the absence of continued improvements in lifestyle. If adherence to lifestyle modifications is not likely, maintaining a low-dose antihypertensive drug may be preferable to complete discontinuance of all drugs.

Patient Variables

The prevalence of hypertension varies with age, gender, race, education, and many other variables. Some of these variables also affect the clinical use and dosing of specific antihypertensive medications. Some of these variables are covered in Table 40-5.

Children and Adolescents

The U.S. Preventive Services Task Force (USPSTF) (2013) does not recommend for or against routine BP screening for pediatric patients. This runs counter to the suggestions of the American Academy of Pediatrics, National Heart, Lung and Blood Institute, Bright Futures, and the National High Blood

Table 40–5   Drug Choice Based on Concomitant Disease States

Disease State	Drug Choice
Compelling Indications Unless Contraindicated	
Diabetes mellitus (type 1) with proteinuria	ACE inhibitors
Heart failure	ACE inhibitors Diuretics
Isolated systolic hypertension (older adults)	Diuretics (preferred) CCB (long-acting DHP)
Myocardial infarction	Beta blockers (non-ISA) ACE inhibitors (with systolic dysfunction)
May Have Favorable Effects on Comorbid Conditions	
Angina	Beta blockers CCB
Atrial tachycardia and fibrillation CA (non-DHP)	Beta blockers CCB (non-DHP)
Cyclosporine-induced hypertension (caution with the dose of cyclosporine)	CCB
Diabetes mellitus (types 1 and 2) with proteinuria	ACE inhibitors (preferred) CCB
Diabetes mellitus (type 2)	Diuretics (low dose)
Dyslipidemia	Alpha blockers
Essential tremor	Beta blockers (non-CS)
Heart failure	Carvedilol Losartan potassium

Table 40–5   Drug Choice Based on Concomitant Disease States—cont'd

Disease State	Drug Choice
Hyperthyroidism	Beta blockers
Migraine	Beta blockers (non-CS) CCB (non-DHP)
Myocardial infarction	Diltiazem hydrochloride Verapamil hydrochloride
Osteoporosis	Thiazides
Preoperative hypertension	Beta blockers
Prostatism (BPH)	Alpha blockers
Renal insufficiency (caution in renovascular hypertension and creatinine 265.2 mmol/L or higher [3 mg/dL])	ACE inhibitors
May Have Unfavorable Effects on Comorbid Conditions (May Be Used With Special Monitoring Unless Contraindicated)	
Bronchospastic disease	Beta blockers
Depression	Beta blockers Central alpha agonists Reserpine (contraindicated)
Diabetes mellitus (types 1 and 2)	Beta blockers Diuretics (high dose)
Dyslipidemia	Beta blockers (non-ISA) Diuretics (high dose)
Gout	Diuretics
Heart block (second and third degree)	Beta blockers (contraindicated) CCB (non-DHP) (contraindicated)
Heart failure	Beta blockers (except carvedilol) CCB(except amlodipine besylate, felodipine)
Liver disease	Labetalol hydrochloride Methyldopa (contraindicated)
Peripheral vascular disease	Beta blockers
Pregnancy	ACE inhibitors (contraindicated) Angiotensin II receptor blockers (contraindicated)
Renal insufficiency	Potassium-sparing agents
Renovascular disease	ACE inhibitors Angiotensin II receptor blockers

ACE = angiotensin-converting enzyme; CCB = calcium channel blockers; CS = cardiac specific; DHP = dihydropyridine; non-ISA = nonintrinsic sympathomimetic action.

Pressure Education Program. Prescribers dealing with children should consider individual risk factors when determining whether uncovering the current 5% rate of HTN in children is within the beneficial target of the particular child they are caring for.

Definitions of hypertension in children and adolescents (age 1 to 17 years) take into account age and height by sex using a percentile system rating for acceptable levels. Blood pressure in the 90th to less than 95th percentile or blood pressure exceeding 120/90 (even if less than 90th percentile) is considered prehypertension in children. Blood pressure in the 95th to 99th percentile is considered hypertension stage 1, and greater than the 99th percentile plus 5 mm Hg is considered

hypertension stage 2 (NHLBI, 2011). Table 40-6 s hows the values consistent with a diagnosis of hypertension for girls and boys based on age and height. Per the 2005–2010 analysis of the National Health and Nutrition Examination Surveys (NHANES), males are less likely to have ideal BP as teens (78% versus 90%) even though females have higher cholesterol levels and lower physical activity scores (Shay et al, 2013).

An identifiable cause for the hypertension is more likely in younger children than it is in adults, and such causes should always be sought. The recreational use of OTC cold medications, illegal purchase of stimulants to help with study sessions, and anabolic steroid abuse must be considered even

Table 40–6 Max Blood Pressure Readings in Children and Adolescents (mm Hg) by Height at 95th Percentile to Diagnose HTN

Age	Girls	Girls	Boys	Boys
	50th Percentile for Height	75th Percentile for Height	50th Percentile for Height	75th Percentile for Height
3	107/67	108/68	109/65	110/66
6	111/74	113/74	114/74	115/75
12	123/80	124/81	123/81	125/82
17	129/84	130/85	136/87	138/87

in grade-school children. Comorbid conditions such as DM 1 or 2, chronic kidney disease (CKD), and a history of glomerulonephritis or Kawasaki disease should trigger monitoring prior to age 3 and medication treatment. Children with ambiguous genitalia need closer monitoring for a strong link with adrenal HTN causes. Those who had umbilical vein catheterizations have links to renal causes of HTN. Children born with cardiac defects typically have a cardiac structural cause for the HTN (Mattoo, 2013; Mitchell et al, 2002). Treat all symptomatic children (headache, CV decompensation, intolerance of physical activity) with medications. Children at stage 2 HTN and those with hyperlipidemia, glucose intolerance, and/or CKD should also be started on medications prior to awaiting lifestyle impacts. Referral to a pediatric hypertension specialist is recommended.

Chronic HTN is becoming more common in adolescence and is generally associated with obesity, sedentary lifestyle, sleep apnea, and a positive family history of HTN and other CVDs. Like adults, children with HTN develop end-organ damage, and appropriate assessment for this damage should occur; however, the negative impact may not be overtly evident for decades. Echocardiography is recommended as a primary tool for evaluating these age groups before the overt conditions arise. One study uncovered LVH in 3% to 40% of children without obvious symptoms (Brady, Fivish, Flynn, & Parekh, 2008). Renal ultrasound is recommended to rule out an occult renal source of HTN.

Lifestyle modifications, especially weight management and increased physical activity, are initially used, with drug therapy reserved for higher levels of BP or for inadequate response to lifestyle modifications. Though weight loss is demonstrated to be helpful, the strong association between weight reduction and lowered BP is not as pronounced in children (Mattoo, 2013). Diet modification is in order, especially considering that less than 1% of U.S. teens have an "ideal diet score" (Shay et al, 2013). Adolescents with BP below the 95th percentile should adopt healthy lifestyles similar to those of adults combating prehypertension. Although the choice of drugs is similar to that for adults, dosages in children should be smaller and adjusted very carefully. The U.S. Food and Drug Administration (FDA)

has published guidelines for pediatric labeling including dosages; this information is published at the FDA website (http://www.fda.gov). Not all hypertensive medications have pediatric approval. The prescriber must verify the most current dosing schedules. ACE inhibitors and ARBs should not be prescribed for pregnant or sexually active girls because of their teratogenic effects (American College of Obstetricians and Gynecologists [ACOG], 2012).

Uncomplicated HTN alone is not sufficient reason to restrict asymptomatic children from participating in physical activities, because exercise may actually lower blood pressure. Family counseling should include the known link between secondhand smoke and the arteriosclerotic changes in children (Mattoo, 2013).

Older Adults

The number of Americans aged 65 and older is increasing faster than that of any other age group. Hypertension is very common in older adults, occurring in 60% to 71% of the population older than 60 years. Among older adults, SBP increases almost linearly with age and is a better predictor of coronary heart disease (CHD), cardiovascular disease (CVD), heart failure, end-stage renal disease (ESRD), and all-cause mortality than is DBP, which increases until about age 55 and then declines. An even better predictor is pulse pressure (SBP minus DBP), which indicates reduced vascular compliance in large arteries. Evidence of this increased risk has led to recognition of the importance of treating ISH in older adults rather than accepting increased blood pressure as a "normal" part of aging. BP control rates (less than 150/90 mm Hg) are only about 20% in older adults with HTN, largely related to poor control of SBP. Benefits of treatment in this age group have been consistently demonstrated in large randomly controlled trials (RCTs) to include reduction of stroke and heart failure. These benefits do not increase when the BP is held under 140/90; hence, the relaxed number for older adults used in the JNC-8. The choice of initial agent is less important than the degree of BP reduction achieved as long as the risk of falls is also considered. The only exceptions to drug selection are the ACE and ARB groups, which are no longer recommended for those over the age of 75 (James et al, 2014).

This recommendation is based on the risks of hyperkalemia and renal considerations.

As in younger patients, therapy should begin with lifestyle modifications. Older adults respond especially well to salt intake reduction and weight loss because they are prone to sodium retention and volume excess. If lifestyle modifications do not achieve the BP goal, drug therapy should begin. In general, the initial dose should be about half that used in younger patients. Use of specific drugs is similar to that recommended in the general algorithm and for individuals with compelling reasons. Thiazide diuretics are recommended because they have been shown in RCTs to reduce morbidity and mortality and because they are less expensive for patients, who are often on fixed incomes. While considering the comments on orthostatic hypotension below, diuretics are still considered especially as a second add-on choice (ACCF/AHA, 2011). Thiazide diuretics are particularly useful for ISH because of their greater effects on SBP than on DBP. Morbidity and mortality are both improved in older adults when SBP is reduced, if DBP is held stable at between 85 and 90 mm Hg.

It is important to monitor potassium levels with the drugs, especially if the patient is also on digoxin. Even mild hypokalemia may be problematic for older adults with coronary artery disease (CAD). Drug combinations that include both a thiazide diuretic and a potassium-sparing diuretic are useful for patients who have repeated episodes of hypokalemia.

The BP goal for older adults is not the same as it is for younger patients. Any reduction in BP has some benefit; and the closer to the ideal goal, the better for the nonfrail elders with the highest risk. More latitude can be given for those with low risk. Among the most frail, there is no link between mortality risk and BP readings (Odden, Peralta, Haan, & Covinsky, 2012). Special considerations should be given to problems with orthostatic hypotension (OH) and cognitive dysfunction related to older adults.

Orthostatic Hypotension (OH)

Measurement of BP in older adults requires consideration of the possibility of pseudohypertension caused by excessive vascular stiffness. In addition, older adults are more likely to experience orthostatic changes, and their BP should be measured standing as well as in the lying position if symptomatic. OH is associated with an increase in age-adjusted mortality; there is a strong correlation between OH and premature death as well as increased numbers of falls and fractures. Severe volume depletion, baroreflex dysfunction, and autonomic insufficiency are common problems in some older adults. Certain vasodilator antihypertensives (e.g., alpha blockers and alpha beta blockers) as well as diuretics and nitrates may exacerbate this problem. Health-care providers should be alert to potential OH symptoms and adjust drug therapy accordingly.

Cognitive Dysfunction and Dementia

Cognitive impairment and dementia occur more commonly in people with HTN. Progression of cognitive impairment may be reduced with effective treatment of the HTN. Narrowing and sclerosis of small penetrating arteries in the subcortical regions of the brain are often found on autopsy of patients with chronic HTN. These changes may contribute to hypoperfusion, loss of autoregulation, compromise of the blood–brain barrier and white matter demyelination, micro infarction, and cognitive decline. Calcium channel blocker therapy might assist in slowing the decline of cognitive function. It does appear that central alpha$_2$ agonists make cognitive dysfunction worse and so should be avoided or, if there is a compelling reason for their use, used with extreme caution. Visual hallucinations have been cited in rare case reports with ACE inhibitors (Doane & Stults, 2013).

Women

There are no demonstrated clinical differences between men and women related to BP outcomes or responses to therapy; this includes elderly women (ACCF/AHA, 2011). Traditional guidelines most likely underestimate a woman's actual risk (Mosca et al, 2011). Women do have some unique variables related to hypertension: sexual dimorphism of BP and HTN prevalence, menopause, use of oral contraceptives and hormone replacements, and pregnancy. Black women shoulder a higher disease burden than the general population. Wu and associates (2014) have documented an increased risk of psoriasis in women who have used beta blockers for more than 6 years, but not with any other drug group.

Sexual Dimorphism and HTN Prevalence

Women have lower SBP levels than men during early adulthood, but the opposite is true after the sixth decade. The prevalence of HTN in women follows this dimorphism. The highest prevalence of HTN occurs in elderly black women, with the rate being more than 75% in black women older than 75 years (Mosca et al, 2011).

Women may have a higher rate of "white coat" hypertension in which the office value differs from a home BP report. If such patients (male or female) do not demonstrate end-organ symptoms, then a 24-hour BP monitoring test can determine if HTN actually does exist. An alternative is having the BP taken at various times of the day at fire stations, health clubs, pharmacies, or health and wellness kiosks. Some patients who do have HTN use the excuse of "white coat" to avoid taking medications.

Menopause

The effect of menopause on BP is controversial. Longitudinal studies have not shown a rise in BP, whereas cross-sectional studies have found significantly higher SBP and DBP in postmenopausal women versus premenopausal women. When there is a rise, it is often attributed to estrogen withdrawal, overproduction of pituitary hormones, weight gain, or a combination of these or other undefined neurohormonal influences. Studies of hormone replacement therapy (HRT) in postmenopausal women have been inconsistent in findings about changes in BP. Overall, HRT-related change in BP is mainly modest and does not preclude HRT use except in individuals with unusually strong responses to the hormones. It is not wise to treat the BP changes with an antihypertensive because HRT use is not a life-critical medication.

Oral Contraceptives

Women taking oral contraceptives have a small but detectable increase in both SBP and DBP, but these are usually within the normal range. Relative risk for HTN is significantly increased (RR = 1.8) in current users compared to those who have never used oral contraceptives. A strong correlation has also been found in HTN risk for women who smoke and take oral contraceptives. Women older than 35 years who smoke should be discouraged from using oral contraceptives and highly encouraged to stop smoking. If HTN develops in women taking oral contraceptives, then these drugs should be discontinued with counseling to consider a nonmedicated form of birth control (IUD, surgery). Blood pressure can return to normal after an initial rise in the first few months. Oral contraceptives are often prescribed on a yearly basis, but a more prudent approach may be to prescribe them semiannually so that BP can be checked every 6 months in high-risk women.

Pregnancy

Hypertensive disorders in pregnancy are a major cause of maternal, fetal, and neonatal morbidity and mortality. Hypertension during pregnancy is classified into five categories:

1. Chronic hypertension: Hypertension that is present and observable before pregnancy or diagnosed before the 20th week of pregnancy. The goal of management for chronic HTN in pregnant women is to minimize short-term risks while avoiding therapy that compromises the fetus. Women in stage 1 HTN are considered at low risk for cardiovascular complications during pregnancy and are best managed by lifestyle modifications only. A meta-analysis of 45 RCTs of treatment with a variety of antihypertensives in stage 1 and stage 2 HTN in pregnancy showed a direct relationship between treatment-induced drops in mean arterial pressure and the proportion of small-for-gestational-age infants. It appears judicious to carefully consider whether to continue antihypertensive drugs during pregnancy with a specialist. In all cases, treatment should be reinstituted if the BP reaches 150 to 160 systolic or 100 to 110 diastolic (ACOG, 2012). Drug selection is then based on the safety of the fetus. Table 40-7 summarizes some treatment options. Methyldopa has been studied the most and is typically recommended for women whose chronic hypertension is first diagnosed in pregnancy. Beta-adrenergic blockers are equally effective and are safe during the second and third trimesters, but their use in the first trimester has been associated with growth retardation in the fetus. Labetalol is equally effective as methyldopa and has fewer side effects. If the hypertension is diagnosed before the pregnancy, diuretics and some antihypertensives may be continued. Chapters 14 and 16 delineate safety issues in pregnancy for various HTN drugs. ACE inhibitors, ARBs, and DRI should never be used in pregnancy.

2. Preeclampsia: Preeclampsia is a pregnancy-specific condition primarily seen in first-gestation mothers. It involves HTN and proteinuria (greater than 300 mg/24 h) after 20 weeks' gestation. Preeclampsia rarely disappears on its own and usually worsens with time. It may be superimposed on existing chronic hypertension. Because of the risk for development of eclampsia, treatment includes bedrest (although strict bedrest is not recommended) (ACOG, 2012), control of BP, seizure prophylaxis, and timely delivery. Antihypertensive therapy is prescribed only for maternal safety

Table 40–7 Antihypertensives in Pregnancy

The report of the NHBPEP Working Group on High Blood Pressure in Pregnancy permits continuation of drug therapy in women with chronic hypertension (except for angiotensin-converting enzyme [ACE] inhibitors). In addition, angiotensin II receptor blockers should not be used during pregnancy. In women with chronic hypertension with diastolic levels of 100 mm Hg or greater (lower when end-organ damage or underlying renal disease is present) and in women with acute hypertension when levels are 150 mm Hg or greater, the following drugs are recommended:

Acceptable Drug	Comments
Alpha beta blockers	Labetalol (C) is equally effective as methyldopa but has fewer adverse responses.
Beta blockers	Atenolol (C) and metoprolol (C) appear to be safe and effective in late pregnancy; labetalol (C) also appears to be effective.
Calcium antagonists	Potential synergism with magnesium sulfate may lead to precipitous hypotension (C).
Central alpha agonists	Methyldopa (C) is the recommended drug of choice.
Direct vasodilators	Hydralazine (C) is the parenteral drug of choice, based on its long history of safety and efficacy.
Diuretics	Diuretics (C) are recommended for chronic hypertension if prescribed before gestation or if patients appear to be salt-sensitive; they are not recommended in pre-eclampsia.

ACE inhibitors (D) and angiotensin II receptor blockers (D) may result in fetal abnormalities including death; these drugs should not be used in pregnancy.

Pregnancy Category C = adverse effects in animals; no controlled trials in humans; use if risk appears justified. Pregnancy Category D = positive evidence of fetal risk.

Source: From the National High Blood Pressure Education Program. (2003). *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.* Rockville, MD: National Institutes of Health; National Heart, Lung and Blood Institute.

because it does not improve perinatal outcomes and may adversely affect utero-placental blood flow. Drug selection depends on time of delivery. If delivery is more than 48 hours away, methyldopa, labetalol, or calcium channel blockers are acceptable. If delivery is imminent, parenteral agents such as hydralazine or labetalol may be used.

3. Chronic HTN with superimposed preeclampsia: This classification is treated like preeclampsia.
4. Gestational HTN: This classification involves HTN without proteinuria occurring after 20 weeks' gestation. It is a temporary diagnosis and requires careful monitoring as it may evolve into preeclampsia. Some bedrest may be useful, but there is insufficient evidence to make a recommendation about the usefulness of salt restriction (ACOG, 2012). HTN that does not resolve in the post-delivery months is treated as new-onset HTN.
5. Transient HTN: This is a retrospective diagnosis and BP is normal by 12 weeks' postpartum. It may be predictive of future primary HTN.

Pregnancy with HTN should generate at least a consultation with a specialist. If the mother returns to the clinic for nonpregnancy-related primary care, attention to BP levels may uncover a need for urgent return to the specialist or for telephonic consultation to coordinate dose adjustments.

Racial and Ethnic Minorities

The prevalence of HTN and the degree of control to target BP among different racial and ethnic groups varies. Native Americans have the same or slightly higher prevalence rates as the white population. Hispanics have the same to slightly lower prevalence rates, despite their increased incidence of obesity and type 2 diabetes mellitus. Asians have the same prevalence and appear to be more responsive to HTN drugs than whites.

The prevalence of hypertension in African Americans is among the highest in the world (Brown, 2006). An estimated 30% of all deaths in this population are attributable to HTN, which develops at younger ages than it does in whites. The average BP is also much higher despite the fact that most black men take multiple medications (Miedema, 2014). The higher rate of severe HTN results in more end-organ damage. The African American stroke rate is 80% higher, the heart disease mortality 50% higher, and the HTN-related ESRD is 320% higher than that of the general population. Many African Americans have the comorbidities of type 2 diabetes or HTN, with up to 14% of adults having both disorders.

In general, this population has lower renin activity, and so the RAAS is thought not to play a major role. Monotherapy with ACE inhibitors is less effective because of this low renin activity; however, in combination with diuretics the therapeutic outcomes are equal (Gerber et al, 2013). In the presence of diabetes mellitus, ACE inhibitors should be used for their renal protective properties. In the presence of MI, ACE continues to be a strong contender to help with HF and left ventricular remodeling protection.

The underlying pathology associated with hypertension in African Americans is thought to be salt sensitivity (Brown, 2006). This increased sensitivity to salt, along with the high prevalence in this population of obesity, cigarette smoking, and type 2 diabetes mellitus, means that lifestyle modifications are especially efficacious. Salt intake should be reduced to less than 6 g per day, and weight should be reduced, if necessary, to approach ideal body weight. If these modifications do not result in achievement of the BP goal, diuretics have been proved in RCTs to reduce morbidity and mortality and are the first agents of choice unless there are compelling reasons to choose another drug class (Gerber et al, 2013).

Calcium channel blockers are recommended as first-line therapy for African Americans (James et al, 2014). The Atherosclerosis Risk in Communities (ARIC) study found, however, that ACE medications are the most commonly prescribed for this group (Miedema, 2014). Monotherapy with most beta-adrenergic blockers is less effective than in whites but should still be used for the post-MI mortality benefit. Despite noted differences in BP response at the population level, race alone is a poor predictor of BP response to any particular class of drugs if they are given in adequate doses and with sufficient time to work. The interracial differences with any drug class are abolished when the drug is combined with a diuretic. Many Americans, both African American and others, have a mixed genetic background, so an assumption of negative response should not preclude the use of any drug class. Individual response monitoring is the key to an optimal therapeutic plan.

The high prevalence of stage 2 hypertension in the African American population means that multidrug therapy is common, which may result in a higher prevalence of adverse responses. For the proportion of African Americans who do not trust the white-dominated medical system, these adverse effects—related to drugs that treat a disease that exists for them only because a medical device (the blood pressure cuff) tells them they have it—increase their distrust, especially when these adverse responses include personal problems such as impotence. All plans should consider racial and ethnic minorities' traditional foods that are high in salt and fat composition.

Racial differences in adverse responses to antihypertensive drugs may occur even in monotherapy. African Americans and Asians, for example, have a 3- to 4-fold higher risk of angioedema (ALLHAT, 2002; Wright et al, 2009), and more cough has been attributed to ACE inhibitors than in whites (Elliot, 1996; Gerber et al, 2013). Unfortunately, insufficient numbers of Mexican Americans and other Hispanic Americans, Native Americans, or Asian/Pacific Islanders have been included in most of the major clinical trials to make strong recommendations about their responses to individual antihypertensives.

Adherence to dietary recommendations also may vary by ethnicity. In a study of nearly 6,000 adults aged 45 to 84 years, there was a significant variation in Dietary Approaches to Stop Hypertension (DASH) goal attainment among ethnic groups (Gao et al, 2009). Chinese Americans

were more likely to meet cholesterol goals but less likely to meet magnesium and potassium goals. African Americans and Hispanics had more problems with calcium intake and had less goal attainment related to saturated fat and magnesium.

Concomitant Diseases and Therapies

Antihypertensive drugs may improve the management of some diseases and worsen that of others (Table 40-5). Selection of an antihypertensive that also treats a concomitant disease can simplify the overall therapeutic regimen, reduce cost, and increase the likelihood of adherence. It is not within the scope of this chapter to discuss all possible diseases that may coexist with HTN, but the most common diseases that benefit from appropriate selection of an antihypertensive are discussed below.

Cerebrovascular Disease

The risk of complications of cerebrovascular disease, including CVA and dementia, increases as a function of BP levels. Contrary to popular belief, most ischemic strokes occur in individuals with prehypertension or stage 1 HTN. No specific drug has been proven to be clinically superior to all others for stroke prevention. Management of BP during an acute stroke is not within the scope of this text. Posthospitalization care should be coordinated with specialty services to set new target BP goals, which might be higher than prestroke targets. Treatment is instituted with a goal to reduce BP gradually.

Coronary Artery Disease

Coexisting CAD and hypertension place patients at especially high risk for cardiovascular morbidity and mortality. Antihypertensive therapy is essential and its benefits well established. Blood pressure should be reduced to a goal of 140/90 mm Hg, with lower BP desirable in patients with angina. Excessively rapid lowering of BP, however, may result in reflex tachycardia and sympathetic stimulation so should be avoided. Lowering DBP below 55 to 60 mm Hg has been associated with increased CV events, including MI (Odden et al, 2012). Antihypertensive drugs that have reflex tachycardia and sympathetic stimulation as adverse reactions (alpha-adrenergic blockers, nitrates, and peripheral vasodilators) are generally avoided. Long-acting calcium channel blockers and beta-adrenergic blockers are especially helpful to patients with concomitant angina. Short-acting calcium channel blockers should not be used. After MI, beta-adrenergic blockers with intrinsic sympathomimetic activity are considered the "gold standard" because they reduce the risk of subsequent MI. This is less definitive for those STEMI patients with lower risks (Nakatani et al, 2013). These recommendations are based on older research done in the pre-reperfusion era (Bangalore et al, 2014). There is increased risk of cardiogenic shock and HF with beta blockers; therefore, this currently espoused quality care indictor is being reviewed. Current guides do not differentiate between the two types of beta blockers. ACE inhibitors and ARBs are also useful after MI, especially with concomitant left ventricular (LV) dysfunction, to prevent heart failure and mortality and reduce ventricular remodeling.

Stable Angina and Silent Ischemia

Therapy in these disorders is directed toward preventing MI and death, reducing symptoms of angina, and preventing the occurrence of ischemia. Unless contraindicated, drug therapy should begin with a beta-adrenergic blocker. Beta-adrenergic blockers reduce symptoms, improve mortality, and reduce cardiac output and heart rate, which decreases myocardial oxygen demand. If angina and BP are not controlled by beta-adrenergic blockers alone, or if these drugs are contraindicated, a long-acting calcium channel blocker may be used. These drugs decrease total peripheral resistance, which leads to reduction in BP and wall tension. Non-dihydropyridine calcium channel blockers also decrease heart rate, but when combined with a beta-adrenergic blocker they may produce severe bradycardia or high degrees of heart block. Therefore, dihydropyridine calcium channel blockers are preferred for combination therapy with a beta-adrenergic blocker. If angina is still not controlled, a nitrate or Relenza can be added. Chapter 28 further discusses the management protocol for angina.

Left Ventricular Hypertrophy

Left ventricular hypertrophy (LVH) is a cardiac adaptation to the increased afterload generated by persistent hypertension. LVH is a major independent risk factor for sudden cardiac death, MI, stroke, and other cardiovascular events. In addition to lifestyle modification with salt reduction and weight loss (Coxson et al, 2013), antihypertensive drugs (except direct vasodilators such as hydralazine and minoxidil) are capable of reducing left ventricular mass and wall thickness and reducing cardiovascular risks. ACE inhibitors have been demonstrated to be the most effective in reducing LV mass in patients with LV hypertrophy. Beta-adrenergic blockers had the least reduction in mass, and intermediate effects occurred with diuretics and calcium channel blockers. The ARB class, but not the DRIs (Gheorghiade et al, 2013), has a similar profile to that of ACE inhibitors. Reduction of LV mass is associated with lower overall CVD risk. The combination of an ACE inhibitor and a diuretic has proved to be most effective in regressing LVH and reducing cardiovascular risks.

Heart Failure

Hypertension is the major cause of LV failure in the United States. Control of BP with lifestyle modifications and drug therapy improves myocardial function and reduces the risk for heart failure and cardiovascular mortality. HTN precedes the development of heart failure in approximately 90% of patients; this is most important in African Americans and older adults. CAD is the cause of heart failure in approximately two-thirds of heart failure patients. A variety of neurohormonal systems, especially the RAAS and SNS, are activated by the LV dysfunction seen in heart failure. Such activation may lead to abnormal ventricular remodeling, further LV enlargement, and reduced cardiac contractility. This progression can be significantly reduced by effective therapy.

New York Class I–III heart failure is a compelling indication for the use of ACE inhibitors. In Class IV failure associated with renal disease, the ACE inhibitor might become counterproductive. The alpha- and beta-adrenergic blocker carvedilol (Coreg) has also been shown to be beneficial when used alone or combined with an ACE inhibitor. The dihydropyridines amlodipine (Norvasc) and felodipine (Plendil) have been demonstrated to be safe for treating angina and hypertension in patients with advanced LV dysfunction when they are used in addition to ACE inhibitors, diuretics, or beta-adrenergic blockers, but other calcium channel blockers are not recommended for these patients. Aldosterone antagonists in low doses (12.5 to 25 mg daily) may provide additional benefits for patients with severe LV dysfunction. Chapter 36 discusses the treatment of heart failure in more detail.

Renal Parenchymal Disease

Hypertension may result from any form of renal disease that reduces the number of functioning nephrons, leading to salt and water retention and then to increased extracellular fluid (ECF) volume. Evaluation of renal function in hypertensive patients should include serum creatinine levels (even small elevations reflect large losses in glomerular filtration rate) and urinalysis to detect proteinuria or hematuria. Reversible causes of renal failure should always be sought out and treated. Newest predictions suggest that over half of the population between age 30 to 64 have risks for developing chronic kidney disease (CKD). Currently 13.2% of the population fall into a reduced renal functional pattern. It is anticipated that 14.4% will have documented CKD by 2020 and 16.7% by 2030 (Hoerger et al, 2015).

Blood pressure goals for patients with CKD also reflect the JNC-8 level. The goal is to maintain below 140/90. Injury to renal tissues does occur with BP above 150/90, but values of 140/80 are more tolerated than previously understood (Peralta et al, 2012). One study included within the JNC-8 guidelines did demonstrate improved renal status with a BP under 130/80 (Klahr et al, 1994), but the JNC recommendation is that if side effects of lowered BP interferes with adherence, the risk of CV adverse effects from HTN must be the primary consideration. Sodium restriction is still recommended for these patients, with a dietary restriction of potassium and phosphorus when creatinine clearance is below 30 mL/min. Consultation with renal specialists may determine lower individualized targets. CKD patients without proteinuria can use ACE, ARB, beta blockers or thiazide diuretics. GFR values below 30 require close re-evaluation of medications used. The JNC-8 recommendation for ACE/ARB medications comes without regard to race.

All classes of antihypertensive drugs are effective, and multiple drugs may be needed. ACE inhibitors have been the most effective in patients with diabetic nephropathy, proteinuria of 1 g or more per 24 hours, and renal insufficiency. Interestingly, ACE inhibitors as a drug class may not have a renal protective effect on CKD patients who do not have proteinuria (Mann, 2013). In patients with serum creatinine levels of 3 mg/dL or more, ACE inhibitors should be used with caution. Thiazide diuretics are not effective with renal insufficiency manifested by serum creatinine levels of 2.5 mg/dL or more; the loop diuretics such as furosemide (Lasix) are needed, often at relatively large doses. Potassium-sparing diuretics should be avoided in renal insufficiency.

Renovascular Disease

Clinical clues to renovascular disease include (1) onset of HTN before age 30 or recent onset of severe HTN after age 55; (2) an abdominal bruit, particularly if it continues into diastole and is lateralized; (3) accelerated or resistant HTN; (4) recurrent (flash) pulmonary edema; (5) renal failure of uncertain etiology; (6) coexisting diffuse atherosclerotic vascular disease, especially in heavy smokers; and (7) acute renal failure precipitated by antihypertensive therapy, especially with ACE inhibitors or ARBs. Patients with renovascular disease may require surgical interventions to stabilize their BP. No specific antihypertensive medications are recommended. Sometimes none are needed postsurgery.

Diabetes Mellitus

HTN is disproportionately increased in diabetics. Persons with HTN are 2.5 times more likely to develop diabetes within 5 years (American Diabetes Association [ADA], 2015). Coexistence of HTN and diabetes is especially concerning because both have strong links to CVD, CVA, progression to renal disease, and diabetic retinopathy. A reduction of as little as 10 mm Hg in SBP has been associated with average reductions in diabetes-related mortality by 15%, MI by 11%, and retinopathy and nephropathy by 13%. The rate of decline in diabetic nephropathy is believed to be related to a continuous function of arterial pressure. Antihypertensive drug therapy should be initiated early, along with lifestyle modifications (especially weight loss), to reach a blood pressure goal between 140/90 and 150/90 mm Hg for all patients with diabetes mellitus. The ADA in 2015 elected to use JNC-8 guideline values because the ACCORD trial (Cushman et al, 2010), which originally highlighted the issues of DM and HTN, did not reveal a real difference in outcomes for either the 140 or 150 cut point. Most DM patients need two or more drugs to reach the goal of maintaining below 140/90.

ACE inhibitors, ARBs, beta-adrenergic blockers, calcium channel blockers, and diuretics in low doses are preferred because of their lower effects on glucose metabolism, lipid profiles, and renal function. Of this group, ACE inhibitors are

On The Horizon

Renal GFR values that incorporate cystatin C levels become more reliable and uncover renal impairment earlier than the standard measurements. This can dramatically increase the number of patients requiring renal dosing of medications (Inkler et al, 2012).

considered best because of their demonstrated reduction in risk for diabetic nephropathy (AACE, 2006; ADA, 2015). They work well alone but are more effective when combined with a thiazide diuretic. This fact is confounded by evidence that thiazide diuretics worsen blood glucose control in some patients and can increase the likelihood of developing diabetes in insulin-resistant patients (AACE, 2006).

If ACE inhibitors are not well tolerated, ARBs may be considered, but not in combination. Both drug groups need to be reduced or stopped when renal function (GFR) drops below 30 mL/min. Beta-adrenergic blockers are beneficial as part of multidrug therapy, but their value as monotherapy is less clear. The third-generation beta blockers such as nebivolol or drugs that block both alpha and beta receptors such as carvedilol may prove to be most beneficial. These agents cause vasodilation and may increase insulin sensitivity (AACE, 2006). Other beta-adrenergic blockers have an adverse effect on peripheral blood flow, prolong hypoglycemia, and mask most hypoglycemic symptoms. The diaphoresis of hypoglycemia is not masked. If there is a compelling reason for a patient with diabetes to use beta blockers, they should be combined with a diuretic.

Calcium channel blockers have also been shown to have some degree of renal protection and are most helpful as part of multidrug therapy. The non-dihydropyridine calcium channel blockers (diltiazem and verapamil) may reduce microalbuminuria to an extent comparable with ACE inhibitors, but the dihydropyridine calcium channel blockers may increase it. The DRIs do not have a renal protective effect (Parving et al, 2012).

Metabolic Syndrome

Metabolic syndrome is a constellation of CV risk factors related to HTN, abdominal obesity, dyslipidemia, and insulin resistance. The prevalence of this syndrome is highly age-dependent; only 7% of adults 20 to 29 years demonstrate metabolic syndrome, whereas 40% or more of Americans older than 60 years demonstrate it. The risk for fatal CHD is increased 4-fold and for CVD is increased 2-fold for individuals with this syndrome, even after adjustment for age. Patients with this syndrome also have a 5- to 9-fold increased risk for developing diabetes. The cornerstone of clinical management of metabolic syndrome in adults is lifestyle modification. Most patients with this syndrome fall into the prehypertension or stage 1 hypertension categories. If BP exceeds 150/90 mm Hg, drug therapy is indicated based on the general hypertension treatment algorithm.

Many obese patients also have sleep apnea. Obstructive apnea increases CV risk. Referral to a sleep study center may demonstrate a HTN benefit from CPAP or nocturnal O_2 therapy (Park, Ramar, & Olson, 2011).

Dyslipidemia

Lifestyle modifications are the first approach to treatment of both dyslipidemia and HTN. Emphasis is placed on control of weight; reducing the excess intake of sodium, saturated fat, cholesterol, and alcohol; and increasing physical activity. When drug therapy is chosen, drug effects on lipid metabolism are the primary consideration. Alpha-adrenergic blockers may decrease serum cholesterol to a limited degree and increase HDL. ACE inhibitors, ARBs, calcium channel blockers, and central adrenergic agonists have neutral effects on lipids. Beta-adrenergic blockers increase triglycerides transiently and reduce levels of HDLs. They are chosen mainly for patients with previous MIs who need their protective effects against sudden cardiac death and recurrent MI. In high doses, thiazide and loop diuretics can cause at least short-term increases in levels of cholesterol, triglycerides, and low-density lipids (LDLs); typically, this effect does not persist. Dietary modifications can reduce some of these effects. Low doses of thiazide diuretics do not produce these lipid effects and can be safely used. The risks for cerebrovascular and coronary events are reduced equally in persons with normal lipid levels and those with elevated lipid levels. Lowering lipid levels also reduces CV risks that are shared in common with HTN. Selection of appropriate cholesterol-lowering drugs is discussed in Chapters 16 and 39.

Respiratory Diseases

Hypertension is relatively common in acute asthma and may be related to exuberant treatment with beta agonists or systemic corticosteroids. Bronchial reactivity is unchanged by ACE inhibitors, which are safe for most patients with asthma. If the patient is one of the 10% to 15% who experience the adverse effect of a cough, ARBs are an alternative. Beta-adrenergic blockers and alpha- and beta-adrenergic blockers may exacerbate asthma and should not be used unless there are compelling reasons for doing so.

Many over-the-counter (OTC) drugs used as decongestants and cold and asthma remedies contain a sympathomimetic drug that can raise blood pressure. They are generally safe when taken in limited doses by patients who are controlled on antihypertensive therapy. Cromolyn sodium, ipratropium bromide, or corticosteroids by inhalation can be used safely for nasal congestion by patients with hypertension.

Clarithromycin (Biaxin) is a macrolide antibiotic commonly prescribed for respiratory infections. Several adverse reactions of concern to hypertensive patients have come to light recently. One of these is the increased risk of cardiovascular morbidity and mortality (Schembri et al, 2013), which is compounded by statin toxicity when combined with clarithromycin (Patel et al, 2013). Clarithromycin has also been linked to acute renal failure in patients on calcium channel blockers (Fleet et al, 2013). The other macrolides do not appear to have these same drug interactions.

Surgery Patients

Beta blockers used to carry a warning to hold prior to surgical procedures. This was modified in 2009 by the American College of Cardiology and the American Heart Association to include only severely ill patients and those undergoing

cardiac-specific surgery (Fleishmann et al, 2009). Additionally, adding beta blockade to patients undergoing surgery was considered potentially beneficial. This has been a contentious issue, however, because some studies have documented CV problems even during noncardiac surgeries (Patel et al, 2013). Prescribers who have patients requiring surgical care should therefore consult the surgeon or anesthesiologist for their suggestions about use in the days leading up to a planned procedure requiring sedation.

Cost

The cost of antihypertensive drug therapy should be considered in drug selection, especially for patients who require multiple drugs. In most cases, generic formulations are acceptable and cheaper than brand-name counterparts. Nongeneric agents are usually more expensive. If the branded agent is equally effective and there are no compelling reasons for its use, cost might be a major factor in choosing the initial therapy. If the branded agent is more effective or there is a compelling reason for its use, cost should be a secondary consideration. Using combinations can also reduce drug cost. Table 40-4 lists some of the more common drugs found in combination tablets. Shopping at different sources to check prices is often worthwhile. Some higher-dose and lower-dose tablets cost the same, and the tablet can be divided to reduce cost.

Treatment costs include not only the price of the drug but also the price of any routine or special laboratory tests, supplemental therapies, clinic visits, and time lost from work for clinic visits. Maintaining contact with a patient and regularly checking BP are important factors in adherence, but they can also add to cost. Teaching the patient how to do home BP monitoring and using telecommunication or e-mail to maintain contact can reduce unnecessary visits.

In an era of cost-consciousness, the cost of treating HTN is always under scrutiny. Managed-care agencies can be reminded, however, that the cost of HTN management that results in good control is lower than the avoidable cost of hypertension-associated heart disease, stroke, and renal failure, which may result in expensive hospitalizations. RCTs have shown that these reductions occur in a relatively short period of time and are sustained for years (Bitton, Choudry, Matlin, Swanton, & Strank, 2013).

MONITORING

The most important monitoring parameter is BP measurement. Equipment used to monitor BP should be regularly inspected and validated. The operator should be trained and regularly retrained in the appropriate technique and the proper patient positioning. Caffeine, exercise, and smoking should be avoided for at least 30 minutes prior to measurement. The person should be seated in a chair (not on the examination table) for at least 5 minutes with feet on the floor and arm supported at heart level. An appropriately sized cuff (cuff bladder encircling at least 80% of the arm) should be used. At least two measurements are taken and the average recorded. The health-care provider should provide to patients verbally and in writing their specific BP numbers and the BP goal of their treatment.

Home or clinic blood pressure measurement in the early morning before the patient has taken the antihypertensive drug(s) provides data about the adequacy of management related to the increase in blood pressure after arising. Measurement in the late afternoon or evening helps to monitor control across the day. Because the stress of a clinic visit may result in higher blood pressure readings in the clinic, blood pressure goals based on home monitoring are usually lower than those based on clinic monitoring. Less-than-optimal BP readings should not lead to the assumption that medication therapy is ineffective. Some cases can be traced to nonadherence to the plan. Uncovering barriers to treatment is part of monitoring. Telemonitoring has been shown to improve patient outcomes (Kerby et al, 2012).

OUTCOME EVALUATION

Evaluation of hypertensive patients has three objectives: (1) to assess lifestyle and identify other cardiovascular risk factors or concomitant disorders that may affect prognosis and guide treatment, (2) to reveal identifiable causes of HTN, and (3) to assess the presence or absence of target organ damage and CVD. Figure 40-2 shows a treatment protocol for HTN management. Evaluation against a reasonable range of BP values occurs throughout the protocol. The main indications for substitution of a drug from a different class are no response and troublesome adverse reactions to initial drug therapy. Specific drugs to substitute have been previously discussed. When a substitution does not result in achievement of the target BP range, drugs from other classes are continually added until the goal is reached.

Goals in children have not been established by evidence other than expert opinion. Targets below the 95th percentile are typical except for children with major CV risk and DM, which drops the target to below the 90th percentile. Adult treatment recommendations are suggested for those under age 30 with DBP above 90 (James et al, 2014).

When standard therapy is not successful in achieving goal BP (refractory hypertension), when a secondary cause of the hypertension is suspected, when the patient has complex concomitant conditions, or when renal failure worsens even with adequate control, referral to an HTN specialist is appropriate (Stafford, Will & Brooks-Gumbert, 2012). Severe HTN (SBP greater than 180 mm Hg and DBP greater than 120 mm Hg) can exist without major end-organ damage and require consultation for care. Referral for immediate hospitalization is indicated with evidence of a hypertensive urgency (DBP greater than 110 mm Hg) or hypertensive emergency (DBP greater than 120 mm Hg) associated with retinal hemorrhages, bulging optic disks,

mental status changes, new-onset heart or renal failure, and unstable angina (Stafford et al, 2012).

Laboratory data and other monitoring parameters related to specific drugs are discussed in Chapters 14 and 16 for each drug class. Annual evaluations for target organ damage should include a 12-lead electrocardiogram (ECG), urinalysis, complete blood count (CBC), blood chemistry (potassium, sodium, creatinine, fasting glucose, total cholesterol), and HDL levels. Optional tests include creatinine clearance, 24-hour urine protein, LDL levels, thyroid-stimulating hormone levels, and limited echocardiography if signs of systemic organ dysfunction are noted on examination. For patients with diabetes, microalbuminuria and glycosylated hemoglobin studies are essential. Physical examination includes fundoscopic examination, neurological examination, and assessment of heart and lung sounds, peripheral pulses, and bruits. It is recommended that HTN patients have a formal ophthalmology exam at baseline and annually.

Adherence Issues

Lack of adherence to a therapeutic regimen to control BP is unfortunately very common. Several factors in HTN management foster this nonadherence. It is hoped that a less stringent acceptable blood pressure range for adults with average risk will improve adherence statistics. Lifestyle modification is a foundation of HTN management, and difficulty in achieving and maintaining lifestyle changes is well documented. Adverse drug reactions and drug costs are also factors in nonadherence. Sexual dysfunction, fatigue, and depression are common adverse reactions to several classes of antihypertensive drugs. A systematic team approach that uses health professionals and community resources can assist in providing the necessary education, support, and follow-up to improve adherence. The ultimate improvement in adherence is related to the patients having a positive experience with, and trust in, their health-care provider. Better communication improves outcomes and empathy builds trust. Table 40-8 details some activities that can improve adherence. Chapter 6 has additional material on improving positive outcomes.

PATIENT EDUCATION

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues. Though severe salt reduction is no longer considered necessary for most patients, Americans have an excessive sodium intake in their diet (Bayer, Johns, & Galen, 2012; Coxson et al, 2013). Keeping a diet diary and then identifying specific reductions that can be accomplished more easily can help. Prepared baby and toddler foods are very heavy in sodium content, requiring parents to read the labels very carefully when selecting products.

Population-based predictive models of limiting sodium to only 1,500 mg/d (U.S. Dietary guidelines; 2010), from the usual 3,600 mg/d, would reduce CV deaths by over 20% over a 10 year period (Coxson et al, 2013). The key is to teach patients about hidden sources of sodium in the diet, as well as to have them self-monitor their general response to salt. If a load causes increased edema, then salt reduction becomes a more important part of the therapeutic plan.

Table 40–8 Factors to Improve Adherence to Therapy

• Be aware of signs of patient nonadherence to antihypertensive therapy and monitor for them.
• Establish the goal of therapy jointly with the patient: to reduce blood pressure to nonhypertensive levels with minimal or no adverse effects.
• Educate patients about the disease and involve them and their families in its treatment; have them measure blood pressure at home.
• Maintain regular contact with patients; consider telecommunication.
• Keep treatment regimen as inexpensive and simple as possible.
• Encourage lifestyle modifications and provide support for them.
• Integrate drug regimen into routine activities of daily living.
• Prescribe drugs according to pharmacological principles, favoring long-acting formulations.
• Be willing to stop unsuccessful therapy and try a different approach.
• Anticipate adverse reactions and adjust therapy to prevent, minimize, or ameliorate them.
• Continue to add effective and tolerated drugs, stepwise, in sufficient doses to achieve the goals of therapy while reducing the likelihood of adverse reactions.
• Encourage a positive attitude about achieving therapeutic goals.
• Use nurse case management and a team approach.

HYPERTENSION

Related to the Overall Treatment Plan and Disease Process

☐ Pathophysiology of hypertension and its long-term effects on target organs

☐ Role of lifestyle modifications in improving prognosis and keeping the number and cost of required drugs down

☐ Importance of adherence to the treatment regimen

☐ Self-monitoring of blood pressure

☐ Indications of target organ damage

☐ Need for regular follow-up visits with the primary care provider

Specific to the Drug Therapy

☐ Reason for taking the drug(s) and the anticipated action of the drug(s) on the disease process

☐ Doses and schedules for taking the drug(s)

☐ Possible adverse reactions and what to do when they occur

☐ Coping mechanisms for complex and costly drug regimens

☐ Interaction between lifestyle modifications and these drugs

Reasons for Taking the Drug(s)

Patient education about specific drugs is provided in Chapters 14 and 16. Specific information related to hypertension includes the reasons for taking the drugs. Antihypertensive drugs are given to reduce mortality and decrease target organ damage. Some drugs do both; most do one or the other. The expectations should be clear about what the drugs can and cannot do. Hypertension is a chronic condition that rarely develops in a short space of time and is not likely to be corrected in a short space of time, if at all. Patients with hypertension must understand the lifelong nature of the disorder and the need to incorporate the treatment regimen into their everyday lives. The risk of target organ damage must be discussed, but hope must be maintained, and the potential for a good quality of life with adequate treatment must be emphasized.

Drugs as Part of the Total Treatment Regimen

The total treatment regimen includes salt reduction and avoidance of excessive fluid intake. Diuretics reduce fluid volume and may interact with dietary sodium reduction, resulting in orthostatic hypotension (OH). Care should be taken not to reduce salt and fluid too quickly. Patients should be taught to report signs and symptoms of fluid volume deficit. Sodium reduction may lead some patients to seek salt substitutes that have potassium as part of their contents. For patients taking ACE inhibitors or ARBs, this choice can result in excessively high potassium levels. Such salt substitutes should be avoided. Nonsalt herbal seasoning is more appropriate.

Vasodilators can produce OH. Tell patients to rise slowly from a supine position to permit the body to redistribute body fluids.

Regular aerobic exercise such as walking or cycling can improve blood pressure control. Gradually increased, regular exercise may lead to improvement in blood pressure level and reduce the drug(s) needed.

Adherence Issues

Nonadherence with the treatment regimen may reduce life expectancy and affect the functioning of target organs. Health-care providers should be aware of the potential problem of nonadherence, discuss the importance of adherence at each follow-up visit, and assist patients in removing barriers to adherence, such as the complexity and cost of the treatment regimen and the presence of adverse reactions.

HYPERTHYROIDISM AND HYPOTHYROIDISM

Marylou V. Robinson

Thyroid disorders are among the most common disease processes seen in primary care. About 5% of U.S. adults have thyroid disease or take thyroid drugs. Untreated thyroid disease can result in long-term complications in every body system, especially the cardiovascular system. Most thyroid disorders involve thyroid gland malfunction, but secondary hypothyroid or hyperthyroid issues can stem from pituitary axis interruptions.

Hyperthyroidism is seen in 2% of women and in one-tenth as many men. It is most common from age 20 to 40. In children and older adults, hyperthyroidism can produce cardiomegaly and heart failure. Elders are also at risk for osteoporosis. In adolescents, hyperthyroidism can interfere with normal growth because of alterations in basic metabolism. Untreated hyperthyroidism in pregnancy increases the risk for first-trimester spontaneous abortion, stillbirths, and neonatal mortality.

Hypothyroidism also is more common in women, with a prevalence of 6 per 1,000. Prevalence increases with aging. Approximately 5% of older adults of both genders manifest evidence of hypothyroidism. In children, hypothyroidism can result in decreased mental and physical growth. In adults, it increases the risk for heart disease related to altered lipoprotein metabolism.

Treatment for these two disorders includes lifestyle management and drug therapy. Pharmacological management includes thyroid hormones to treat hypothyroid conditions and antithyroid agents such as propylthiouracil, methimazole (Tapazole), and radioactive iodine (I^{131}) or strong iodine solutions for hyperthyroid states. These drugs are discussed in detail in Chapter 21. Symptom management may also include other drugs, such as beta blockers, which are discussed in Chapter 14. This chapter discusses the management of hyperthyroidism and hypothyroidism that is usually done in primary care and provides only an overview of specialty-based directives and activities.

THYROID HORMONE SYNTHESIS

The synthesis of thyroid hormones is dependent on the functioning of the hypothalamic-pituitary-thyroid axis. The

secretion of thyrotropin-releasing hormone (TRH) by the hypothalamus in response to cold, stress, and decreased levels of thyroxine (T4) stimulates the synthesis of thyroid-stimulating hormone (TSH) by the anterior pituitary. TSH, in turn, stimulates the thyroid gland to produce thyroid hormones. Thyroid hormones (T4 and triiodothyronine [T3]) are synthesized from iodine and tyrosine molecules by follicular cells in the thyroid gland.

Dietary iodine of about 100 to 150 mcg/d is required for normal thyroid hormone production. In the United States, adequate iodine is found in foodstuffs and in iodized salt. In the past 20 years, food manufacturers have switched to more noniodized salt in frozen meals and bread products. Per the National Health and Nutrition Examination Survey (NHANES) 2007–2008, U.S. average consumption is still adequate; however, 8.8% of the population has moderate to severe iodine deficiency, including an estimated 14.6% of women of reproductive age, especially non-Hispanic black women (Caldwell, Miller, Wang, Jain, & Jones, 2008).

Dietary iodine absorbed from the gastrointestinal tract is carried in the blood as iodide. When it reaches the thyroid gland, it is actively taken up by the iodide pump, located at the base of the thyroid follicles. The iodide pump is controlled by the serum iodide concentration; low concentration increases pump activity and high concentration inhibits it. The iodide is then oxidized within seconds by the thyroid peroxidase enzyme and binds to tyrosine residues in thyroglobin to form monoiodotyrosine and diiodotyrosine. The coupling of these two iodides forms T4 or T3, which is then stored in the thyroglobin.

The thyroid gland mainly produces T4. About 20% of T3 is synthesized and released from the thyroid gland. The remainder is converted from T4 to T3 peripherally when additional thyroid hormone is needed. Conversion of T4 to T3 is stimulated by cold temperatures and stress. Conversion is inhibited by acute and chronic illness, starvation, and some drugs (Table 41-1). Practitioners must, therefore, consider the role of medications, stress, and other disease states when evaluating patients with newly diagnosed thyroid imbalances. T4 and T3 in plasma are reversibly bound to protein, mainly thyroxine-binding globulin. Only a small portion (0.04% of total T4 and 0.4% of total T3) exists in a free form; however, only this free form is clinically active. The amount of active thyroid hormone in the plasma produces a feedback loop that inhibits or further stimulates TRH and TSH secretion to decrease or increase thyroid hormone production.

THYROID FUNCTION TESTS

Several tests can be used to evaluate thyroid function. These tests and their normal values are listed in Table 41-2. The most commonly used tests in primary care are TSH and free T4 values. Serum TSH measurement is the single most reliable test to diagnose the common forms of hypothyroidism and hyperthyroidism. The sensitive or ultrasensitive forms of the TSH test should be used to avoid missing subclinical conditions. Subclinical conditions exist when TSH is normal but free thyroxine (FT4) and free triiodothyronine (FT3) are abnormal. The growing recognition of circadian changes in TSH release have not yet generated normal values based on the time of day for lab testing purposes (LaFranchi, 2012).

Altered serum TSH confirms the diagnosis in all patients with primary hypo- or hyperthyroidism, but it will not reliably identify all hypothyroid patients with secondary (central)

Table 41–1 Drug Effects on Thyroid Function

Drug	Effect on Thyroid Function
Amiodarone	• Releases iodine as drug is metabolized • Inhibits peripheral conversion of T4 to T3 • Can produce thyrotoxicosis in previously euthyroid patients • Can produce hypothyroidism in auto-immune patients
Carbamazepine	Increases metabolism of T4, resulting in decreased total T4
Estrogen	Increases thyroid-binding globulin levels
Glucocorticoids	Impair basal and TRH-stimulated TSH concentration
Levodopa	Chronic administration displaces thyroid hormone from thyroid-binding globulin, resulting in suppressed TSH response
Lithium	Blocks iodine uptake by thyroid gland, resulting in decreased hormone production
Phenytoin	• Decreases TSH response to TRH by 50% • Enhances cellular uptake and metabolism of T4, resulting in decreased total T4
Propranolol	Inhibits peripheral conversion of T4 to T3
Salicylates (in doses >4 g/d)	Suppress TSH response by inhibiting binding of T4 and T3 to thyroid-binding globulin
Theophylline	Beta-adrenergic stimulation of hypothalamus results in increased TSH response
Tyrosine kinase inhibitors	Suppress thyroid function

TRH = thyroid-releasing hormone; TSH = thyroid-stimulating hormone.

Table 41–2 Adult Thyroid Function Tests

Test	Normal Value	Values in Hyperthyroidism	Values in Hypothyroidism
Free thyroxine index (FT4I)	1.3–4.2	High	Low
Free triiodothyronine index (FT3I)	22–56	High	Normal or low
Free T4 (FT4)	0.7–1.86 ng/dL (9–24 pmol/L)	High	Low
Free T3 (FT3)	0.2–0.52 ng/dL (3–8 pmol/L)	High	Low
Thyrotropin-stimulating hormone (TSH)	0.3–5 microUnits/mL	Low	High
Thyrotropin-releasing hormone (TRH)	>6 microUnits/mL in serum TSH 45 min after injection; blunted TSH response (<2 microUnits/mL) in patients >40 yr	No response	Low exaggerated rise

disturbances wherein TSH values may be atypically low, normal, or elevated. When pituitary or hypothalamic disease is suspected as the cause of hypothyroidism, FT4 concentrations should be measured in addition to TSH. When less-sensitive TSH tests are the only ones available, FT4 and FT3 measurement can give additional information to validate the TSH (Garber et al, 2012).

Adult values should not be used to monitor children. Recommended pediatric target values for TSH range from 0.5 to 2.0 mUL and for T4 they range from 9 to 13 μg/dL (LaFranchi, 2012). Age variances are available from clinical labs; therefore, the practitioner is directed to the local laboratory reference values to evaluate pediatric patients.

Abnormal results from other laboratory tests may also suggest hypo- or hyperthyroidism. Hypercholesterolemia, hyponatremia, anemia, elevated creatinine kinase and lactate dehydrogenase, and hyperprolactinemia all suggest possible hypothyroidism. Elevated calcium, alkaline phosphatase, and/or hepatocellular enzymes suggest hyperthyroidism. These laboratory findings justify thyroid function tests, especially if they are sustained for 2 weeks or more, occur in combination, or occur in patients with increased risk for thyroid disease (Bahn et al, 2011; Garber et al, 2012).

Thyroid abnormalities can present with the development of enlarging thyroid tissues called goiters. This tissue growth may be euthyroid (normal functioning), collections of sub-functioning tissue, or focal cellular growths (nodules) that may produce excess amounts of thyroid hormone. The trigger for excess growth may be autoimmune processes or abnormal cellular disturbances. Goiter size or presence of palpable nodules does not correlate with underlying function. Moreover, abnormalities can exist without goiter presence. Generally, the work-up for a goiter will include serum thyroid antibody screens and a baseline ultrasound. Calling the endocrinology team and requesting which exact tests are required before the initial consultation will preclude unnecessary repetition of blood draws.

Suspicion of cancer or determining whether nodules are "hot" or "cold" in terms of production of excess hormone is confirmed with thyroid scanning. The radioisotope I^{123} dose and residual radiation levels used for these tests does not

trigger the same precautions linked with I^{131} used to treat hyperthyroidism. In cases that are not urgent, individuals previously on levothyroxine may be switched to liothyronine to deplete the organ of hormone for 2 to 6 weeks prior to the scan. Ideally, the person stops all hormones for the last 2 weeks in order to facilitate the iodine uptake capacity of the thyroid. A synthetic hormone, thyrotropin alpha (Thyrogen), can be given to lessen hypothyroid-like symptoms of hormone withdrawal. Thyrogen does not interfere with iodine uptake but might cause false-negative results in some individuals compared to the earlier standard practice of inducing a short-term hypothyroid state (New York Thyroid Center, 2011). Timing of scans and dosing of medications should be coordinated with the endocrinology team.

SCREENING

The U.S. Preventive Services Task Force (2010–2011) found that the evidence is insufficient to recommend for or against routine screening for thyroid disease in adults. Testing can detect subclinical thyroid disease in people without symptoms of thyroid dysfunction, but the evidence is poor that treating these individuals changes their health status. Screening high-risk groups such as postpartum women, people with Down syndrome, and older adults is more likely to find subclinical disease, but the progression of subclinical thyroid disease to overt disease in patients without a history of prior thyroid issues is not clearly established.

Subclinical hypothyroidism is associated with poor obstetrical outcomes and poor cognitive development in children; nonetheless, the American College of Obstetricians and Gynecologists (ACOG, 2007, reaffirmed 2010), the American Thyroid Association (ATA), and the American Association of Clinical Endocrinologists (Garber et al, 2012) all state that screening tests in asymptomatic pregnant women is not warranted. TSH measurement before pregnancy in women of childbearing age with known thyroid disease is recommended.

No thyroid function tests should be performed unless disease is suspected by the presence of symptoms or suspicion of undiagnosed disease, including in the elderly, those with

new cardiovascular or mental health issues, and extreme fatigue. Asymptomatic patients should not be screened unless they fall into specific risk groups. In pediatrics, those with failure to thrive or accelerating behavioral or growth issues should be screened.

TSH is suppressed in the critically ill patient, so values obtained in the hospital are not reliable for screening. Also, values for post-acute care patients can spike for a few months during recovery. Anorexic patients may have thyroid gland involution, so their TSH values are also at risk for unreliable diagnosis (Garber et al, 2012). Previously euthyroid patients started on amiodarone will typically have a fluctuations in thyroid levels for 3 to 6 months without overt symptoms. These alterations usually return to normal except in individuals with prior autoimmune diseases who require closer monitoring for a more sustained hyperthyroid condition. These fluctuations should not be considered for treatment unless symptomatic just like other causes of subclinical changes. Do not stop the amiodarone.

HYPERTHYROIDISM

Pathophysiology

Thyrotoxicosis, or hyperthyroidism, occurs when the feedback loop fails and excessive levels of thyroid hormone are circulating. Extreme thyrotoxicosis is called thyroid storm, a life-threatening condition beyond the scope of this text. The cause of excessive secretion may be a hyperfunctioning thyroid nodule, toxic diffuse goiter (Graves' disease), anterior pituitary disorders, toxic multinodular goiter, excess thyroid supplementation, or iodine-induced disease, including amiodarone therapy (Bahn et al, 2011). Identifiable risk factors for hyperthyroid dysfunction include diabetes mellitus,

pernicious anemia, primary adrenal insufficiency, vitiligo, leukotrichia (prematurely gray hair), and drugs or compounds that contain iodine or affect iodine metabolism. Viruses and pregnancy are two of many conditions that can trigger thyroiditis.

By far, the most common hyperthyroid etiology (60% to 90% of all cases) is Graves' disease. Graves' disease is an autoimmune disorder characterized by generation of abnormal immunoglobulin G (IgG) autoantibodies to thyroid peroxidase and thyroglobin. The antibodies bind to the TSH receptors, activating excessive glandular growth and hormone production. Normally, any hyperfunction of the thyroid gland would lead to suppression of TSH and TRH; however, in autoimmune conditions, the feedback system is altered.

The hyperfunction of the thyroid gland with Graves' disease results in a dramatic increase in iodine uptake and subsequent systemic metabolism. The thyroid gland becomes more vascular and enlarges, forming a goiter. A disproportionate increase in T3 production is a hallmark of longer-term overstimulation of the gland. The overproduction leads to a decreased concentration of thyroid-binding globulin and increased circulating levels of free hormone. These hormone levels are responsible for the many thyrotoxic symptoms.

The clinical features of hyperthyroidism are attributable to metabolic effects of increased circulating hormone. Typical effects include heat intolerance and heightened sensitivity to sympathetic nervous system stimulation. Table 41-3 shows the most common systemic effects of hyperthyroidism. Treatment goals are to diminish negative cardiovascular effects while returning the patient to a euthyroid state.

Ophthalmopathy

Many patients with Graves' disease experience ocular symptoms. These symptoms include functional abnormalities

Table 41–3 **Systemic Effects of Hyperthyroidism**

Body System	Clinical Manifestation	Underlying Mechanism
Cardiovascular	Increased cardiac output, decreased peripheral vascular resistance, tachycardia at rest, arrhythmias	Increased metabolism and need to dissipate heat
Respiratory	Dyspnea and reduced vital capacity	Weakness of respiratory muscles
Gastrointestinal	• Increased appetite with concurrent weight loss	Increased utilization of carbohydrates, proteins, and fats to support rapid metabolism
	• Diarrhea, nausea, vomiting, abdominal pain	Increased peristalsis and cholesterol conversion salts
	• Decreased serum lipid levels	Malabsorption of fat, fat stores depleted for energy, increased excretion of cholesterol in feces
	• Decreased tissue stores of glucose, protein, and vitamins	Increased glucose utilization, use of protein as energy source, and impaired conversion of B vitamins to their coenzymes, causing an increased need for water- and fat-soluble vitamins
Integumentary	• Excessive sweating, flushing, warm skin	Need to dissipate heat
	• Temporary hair loss; hair fine, soft, and straight; nails grow away from nail beds	Hyperdynamic circulatory state
Reproductive	Oligomenorrhea or amenorrhea in women; impotence or decreased libido in men	Hypothalamic or pituitary disturbances; increased production of sex hormone–binding globulin

Table 41–3 **Systemic Effects of Hyperthyroidism—cont'd**

Body System	Clinical Manifestation	Underlying Mechanism
Neurological	• Restlessness, short attention span, fatigue, insomnia, emotional lability	Alteration in cerebral metabolism
	• Ocular manifestations, including decreased blinking and fine tremor of the lid	Hyperactivity of sympathetic nervous system
Musculoskeletal	• Hypercalcemia	Excessive bone resorption
	• Loss of muscle mass	Excessive protein catabolism
Endocrine	• Enlarged gland; systolic or continuous bruit of thyroid gland	Hyperactivity of the gland and increased circulation to support that hyperactivity
	• Diminished sensitivity to exogenous insulin	Increased insulin degradation

(e.g., lid lag with upward or downward gaze) related to hyperactivity of the sympathetic nervous system (McCance & Huether, 2014). Other changes involve orbital and periorbital edema and altered fat deposition. More than half of adult Graves' disease patients develop the characteristic wide-eyed stare with protrusion of the globe (exophthalmus). These ocular concerns can exist in tandem. The provider must recognize that the absence of classic exophthalmus does not negate the need for ophthalmological consultation. Ocular changes can result in damage to the cornea, the retina, and optic nerve, any of which may lead to blindness (McCance & Huether, 2015).

Thyroid-related eye issues are caused by a mechanism different from the one that causes hyperthyroidism. Twenty percent of patients with eye involvement that predates the treatment of their hyperthyroidism experience an exacerbation after treatment is initiated. Successful treatment of hyperthyroidism does not necessarily improve eye conditions, but treatment-induced hypothyroidism increases the risk for worsening the eye disorders. Radioactive iodine has the highest risk for post-treatment hypothyroidism, with up to 50% of patients becoming hypothyroid. Antithyroid drugs are much less likely to result in post-treatment hypothyroidism and are often chosen in preference to radiation for patients with ophthalmopathy (Ross, 2012). Patients are also advised to wear sunglasses, use artificial tears, elevate the head of their bed, and use corneal protectors for severe exophthalmos when sleeping. Bedtime diuretics may also be prescribed (Bahn et al, 2011). Consultation with an ophthalmologist experienced in the treatment of orbital disease is required in the management of these cases, because extensive testing, including orbital ultrasonography, CT scanning, or MRI imaging may be necessary. Treatment may include cortico-steroids, retro-orbital irradiation, or surgical intervention.

Myxedema

A small number of patients with Graves' disease experience pretibial myxedema (Graves' dermopathy), characterized by subcutaneous swelling of the anterior portions of the leg and in the hands, with bumpy, erythematous skin. This puts skin integrity at risk. This form of myxedema is not synonymous with myxedema coma from profound hypothyroidism.

Pharmacodynamics

Antithyroid drugs reduce the production of thyroid hormones. Propylthiouracil and methimazole inhibit the synthesis of new thyroid hormone by the thyroid gland but do not inactivate existing or stored hormone. Propylthiouracil also inhibits the peripheral conversion of T4 to T3. Neither of these drugs treats the underlying pathophysiology of hyperthyroidism. Resumption of hormone synthesis occurs quickly after these drugs are withdrawn, because iodine is no longer blocked from use.

A treatment typically requires 6 to 12 months for total reversal of hyperthyroid symptoms. Some authorities advocate high-dose therapy; others favor low doses. Relapse rates are higher in those taking lower doses. Higher doses increase the probabilities for development of post-treatment hypothyroidism. This sequela may not surface for several years. Dosing is covered in Chapter 21.

Trials have shown no clinical outcome differences when methimazole is compared with propylthiouracil; however, the concerns of hepatic toxicity with propylthiouracil have resulted in a withdrawal of the indication for use in children and for those with hepatic issues (U.S. Food and Drug Administration [FDA], 2009, 2010). Methimazole should be preferentially used in almost all cases. Adherence is significantly better for patients on methimazole owing to its once-daily dosing schedule.

Beta blockers address the symptoms of hyperthyroidism by decreasing the response to sympathetic stimulation and are used as adjunct therapy to control uncomfortable or unhealthy tachycardia. Low doses are all that are typically needed, with early-onset symptom management evident. The most commonly prescribed drugs in this class are propranolol, because of its short half-life, and atenolol, because of its once-daily dosing. Patients with unstable hypoglycemia and severe reactive airways dependent on rescue inhalers may do better on the cardio-selective beta blockers such as atenolol. These drugs are gradually withdrawn as the patient becomes euthyroid.

Iodides block peripheral conversion of T4 to T3 and inhibit hormone release. Potassium iodine is mainly used for preoperative preparation before thyroid surgery. Not only are

the levels of circulating hormone reduced but the vascularity of the tissue is also lessened. Dilution in fruit juices can make iodides more palatable and protect the teeth from discoloration. Administration with meals minimizes GI irritation.

Goals of Treatment

The goal of therapy for adult patients with hyperthyroidism is correction of the hypermetabolic state, with a minimum of adverse reactions and with the smallest incidence of resultant hypothyroidism. This means symptom relief and normalization of TSH and FT4 levels. Beta blockers can reduce symptomatic effects in the short term, but definitive therapy usually requires at least the addition of an antithyroid agent or surgery.

Rational Drug Selection

Three main avenues of treatment are used for patients with hyperthyroidism: (1) antithyroid drugs, (2) radioactive iodine, and (3) surgery. Radioactive iodine and the antithyroid drugs are also discussed in Chapter 21. Iodides are sometimes useful as supplemental suppressive drugs or for individuals who refuse I[131] or cannot tolerate surgery. Presurgical use of iodides is indicated for those with cardiovascular compromise or for the elderly. Such use also decreases the immediate post-operative spike in hyperthyroid symptomatology experienced by many.

Lifestyle Management

Lifestyle management is primarily related to diet. The thyroid gland requires adequate amounts of iodine to produce thyroid hormones. Patients should be taught how to recognize iodine sources in their diets. These include iodized salt; seafood products, especially shellfish; and seaweed or kelp. The labels of vitamin supplements that have minerals and many over-the-counter (OTC) cold medications, especially cough syrups, should be screened for iodine.

The potential for nutritional deficits is the major concern, related to the hypermetabolic state. A high-calorie (4,000 to 5,000 kcal/d) diet may be necessary to satisfy hunger and prevent tissue breakdown. To provide this number of calories, six meals a day may be required, as well as snacks that are high in protein; carbohydrates; minerals; and vitamins, particularly vitamins A and B_6 and ascorbic acid. Caffeinated fluids and highly seasoned food should be avoided because they augment the tachycardia and hot flushing symptoms of hyperthyroidism. Because hyperthyroid states deplete bone calcium, supplementation is advised to reduce the risk of osteopenia. Children will require caloric-dense foods to maintain weight.

Other lifestyle concerns include providing adequate rest and avoiding external sources of stress, including work, domestic issues, and undue worry. Circulating catecholamines have more intensive cardiovascular effects in the presence of excessive thyroid hormone. Risks for triggering angina and dysrhythmias are heightened. Insomnia is made worse by any

heat intolerance or sweating. Relaxation therapy and yoga are potentially helpful interventions. Climate control, especially during hot weather, can reduce the burden of feeling hot.

Drug Therapy

Choices in drug therapy are based on patient variables (severity of the disease, duration of the disease, age of the patient, pregnancy, and the likelihood of patient adherence to the treatment regimen) and on drug-related variables. Figure 41-1 depicts some drug choices based on these variables.

The Institute for Safe Medication Practices (2008) has issued an alert not to use the abbreviation PTU for propylthiouracil on prescription forms. The abbreviation has led to fatal confusion with the brand-name drug Purinethol (mercaptopurine), which is used for oncology patients.

Preoperative Preparation

Primary care providers should coordinate dosing and tapering schedules of any thyroid drugs with the endocrine and surgical teams. Preoperative administration of antithyroid drugs is common to avoid precipitating post-operative thyroid storm. The addition of potassium iodide to beta blocker therapy produces more rapid and greater pre-operative control. This combination is especially useful for patients who must undergo surgery fairly quickly and for those who fail to achieve control (resting pulse less than 90 beats/min) on beta blockers alone. The iodide dose is mixed in a full glass of fruit juice, water, broth, or milk 3 times a day for 10 days pre-op.

Patient Variables

Severity of Disease

Antithyroid drugs are prescribed with the intent of achieving spontaneous remission of the disease. Patients most likely to achieve remission are those with mild disease and small goiters (Bahn et al, 2011). Methimazole is the initial drug of choice because of the hepatic risks of propylthiouracil (FDA, 2010), its faster action, and reduced interference with I[131] therapy (Bahn et al, 2011). Because these drugs do not inhibit the action of existing or stored thyroid hormone, full clinical response typically takes 4 to 8 weeks with either drug.

Adult patients with severe disease may require 400 mg daily of propylthiouracil (maintenance doses are typically 100 to 150 mg daily). Methimazole is similarly initiated at the higher doses as well. One advantage to methimazole is that doses may be divided and given every 8 hours if not well tolerated or once-daily dosing may be tried. Pediatric patients receive 0.25 to 1 mg/kg/day of methimazole. If methimazole cannot be taken or is ineffective, then propylthiouracil is dosed at 0.25mg/kg/day.

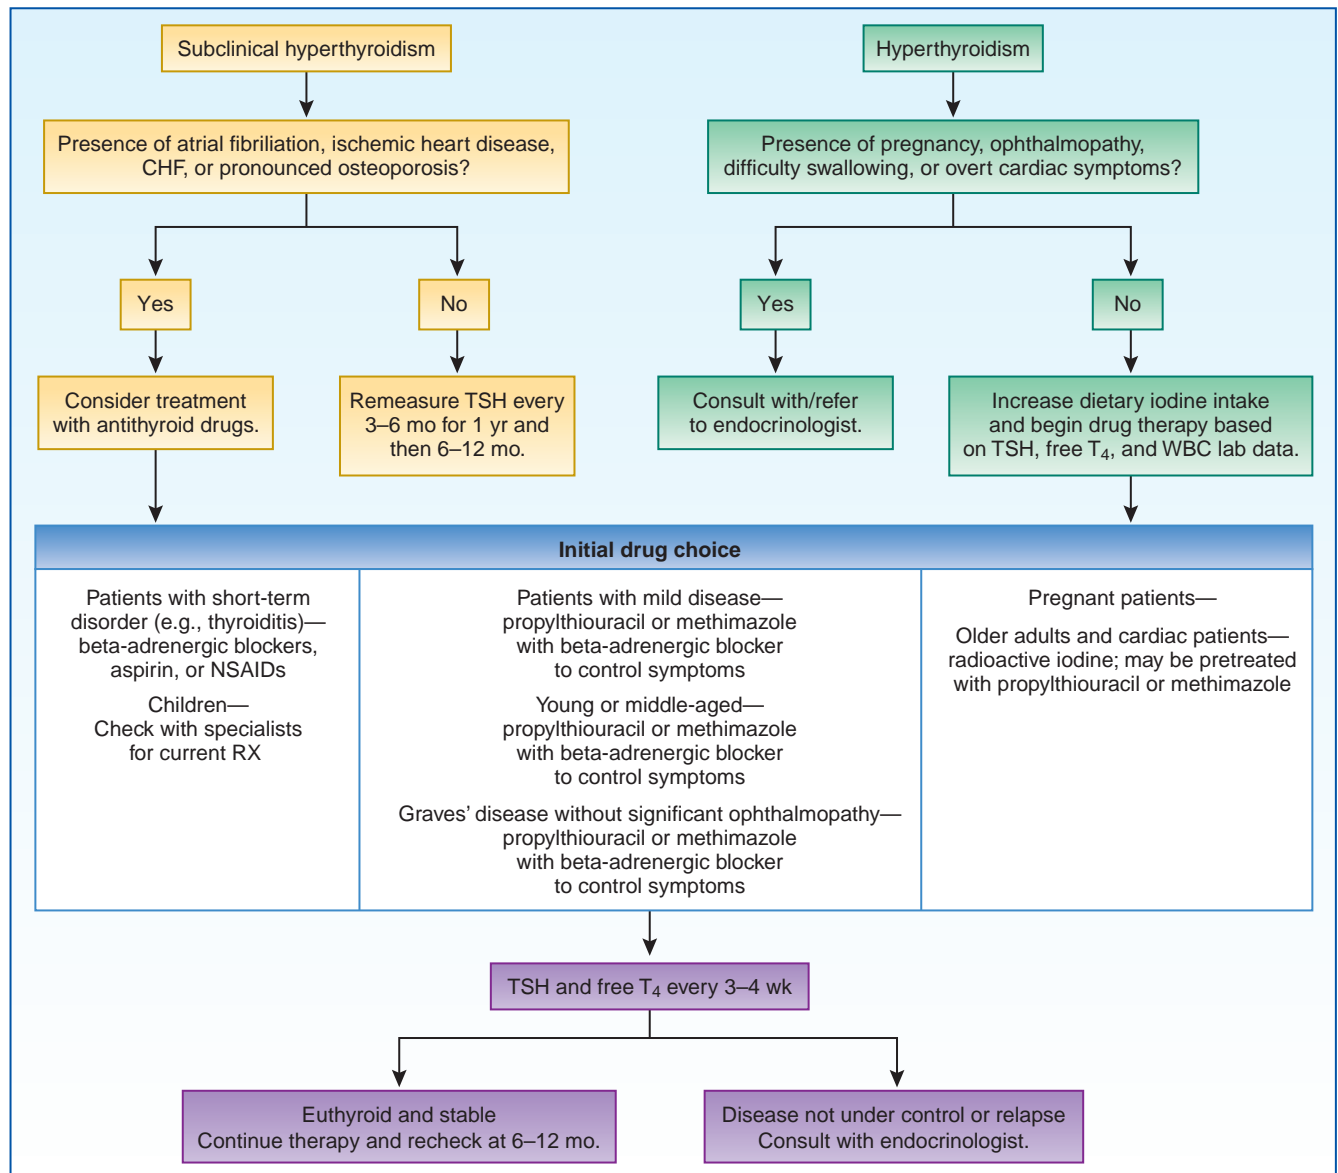
Once control of symptoms and appropriate levels of thyroid hormone production are achieved, the doses of both drugs can be tapered to the lowest amount needed to maintain a euthyroid state. Treatment is continued for 12 to 24 months and then stopped to see if a relapse occurs. Relapse is more common for patients treated less than 12 months. Patients who fail to achieve control of symptoms with antithyroid drugs,


Figure 41–1. Drug therapy algorithm: Hyperthyroidism.

who are unable to tolerate the therapy, or who experience a relapse after completion of therapy are candidates for radioactive iodine or surgery.

In severe thyrotoxic states, adjuvant treatment with iodides may be needed. Excess iodine limits the activity of thyroid peroxidase, thus decreasing iodide oxidation and rapidly blocking the release of T3 and T4 from the thyroid. Patients with Graves' disease are more sensitive to the inhibitory effects of iodine than are healthy individuals. The inhibitory effects of iodides, however, are short-term in some individuals. Potassium iodide is given orally as Lugol's solution (8 mg/drop) or as saturated solution of potassium iodide (SSKI; 35 to 50 mg/drop). The dose of Lugol's solution is 3 to 5 drops, and for SSKI it is 1 drop, both given 3 times a day.

Duration of Disease

Beta blockers without concurrent thioamides provide excellent symptomatic relief for transient disorders (e.g., thyroiditis)

because spontaneous remission is the rule. Atenolol offers the advantages of fewer adverse reactions, based on its beta $_1$ selectivity and once-daily dosing for patients who are less adherent if the regimen is too complex. Propranolol offers the advantage of peripheral blockage of T4 conversion to T3.

Some patients with long-standing hyperthyroidism may be relatively resistant to the effects of beta blockers, so larger and more frequent doses may be necessary. Propranolol is the drug most widely used, with the usual starting dose at 80 to 160 mg/d. Larger doses (360 to 480 mg/d) are sometimes necessary. Adequate doses of these drugs are determined by measuring resting and exercising heart rates and degree of symptom relief. These drugs can be tapered and discontinued once the patient is no longer symptomatic.

Aspirin, NSAIDs, and corticosteroids are also used in subacute thyroiditis to control inflammatory symptoms. Steroids inhibit conversion of T4 to T3, but consistent evidence of any therapeutic help is lacking. These drugs are equally useful for

postpartum thyroiditis, where they are given for 3 months. Dosage is tapered based on symptom relief.

Graves' disease requires longer-duration dosing. Endo-crinologists do not agree on the best treatment for Graves' disease, except in the case of older adults and cardiac patients, for whom I[131] is the treatment of choice. For younger adult or middle-aged patients, an initial 1-year trial of antithyroid drugs is considered a reasonable starting point for treatment. Genovese and associates (2012) claim surgical intervention to be 3 times more successful than I[131]. Surgery is the fastest intervention. Surgery is indicated for goiters over 80 grams in size.

Age of Patient

Older adults are preferentially treated with I[131] due to less tolerance for persistent cardiovascular stress. Elders may be pre-treated with antithyroid drugs to bring them closer to euthyroid status before I[131] therapy is initiated. Most endo-crinologists prefer drug therapy in childhood Graves' disease, waiting until age 10 for I[131] therapy. Propylthiouracil-related hepatic toxicity has triggered the recommendation that only methimazole be used in pediatrics (FDA, 2009). Treatment lasts 6 to 18 months; most patients are treated for at least 1 year. As with adults, relapse is less likely with the longer duration of therapy. A major difference is that pediatric specialists prefer treating to a full hypothyroid state to avoid the potential toxicity of needing an additional antithyroid course of medication in the future and a potential for a lower risk for subsequent thyroid tumors (Rivkees & Dinauer, 2007). This desire for full suppression of thyroid function has driven the increased use of I[131] therapy in children.

Pregnancy

Hyperthyroidism during pregnancy presents special concerns best managed collaboratively by an obstetrician and the endocrinology team. Antithyroid drugs are the treatment of choice but are Pregnancy Category D. Methimazole is lipid-soluble and not protein bound, so it freely crosses the placenta and breast epithelium and is associated with birth defects when used in the first trimester (FDA, 2010). Propylthiouracil, conversely, is 80% to 90% protein bound and ionized at physiological pH. Although it can cause fetal harm, it is preferred in pregnant women because its pharmacokinetics make it less likely to cross the placenta. The lowest possible dose is used to keep the mother's thyroid function at the upper limit of normal. Pregnancy itself has an ameliorating effect on Graves' disease, so the dose of the drug required usually decreases as the pregnancy progresses. In some cases, the drug can be withdrawn 2 to 3 weeks before delivery if laboratory values indicate improved functioning.

Pregnant women with Graves' disease may transfer large amounts of thyroid-stimulating antibody to the fetus and induce fetal thyrotoxicosis. The infant's pediatric provider should be informed of the mother's hyperthyroidism and treatment of this disorder during pregnancy. The infant's thyroid function should be tested at birth.

Postpartum patients who are receiving thioamides should consult their child's provider before choosing to nurse their infants. Breast milk can transfer antithyroid drugs; however, the amount is small, especially with propylthiouracil, and unlikely to induce significant hypothyroidism. The potential risk should be discussed with the parents, and careful monitoring of mother and infant for several months is important.

Pregnant women who do not have overt hyperthyroidism but have comorbid type 1 diabetes, known thyroid antibodies, and chronic hepatitis, should be considered high risk for postpartum thyroiditis and should be monitored during the postpartum period (Bahn et al, 2011).

Adherence

Drug treatment is effective only if the drugs are taken as prescribed. Adherence to a treatment regimen is less likely if it is complex or leads to significant adverse reactions. Antithyroid drugs have limited overt adverse reactions but may need to be taken 3 times daily, making the treatment regimen complex. This complexity is especially problematic if the treatment regimen also involves a beta blocker that has significant adverse reactions and must also be taken 3 times daily, but on a different schedule. To facilitate adherence, both methimazole and atenolol can be given once daily. Both have fewer adverse reactions than other drugs in their classes.

Drug-Related Variables

Cost

The actual retail price of the thioamides can vary significantly. Propylthiouracil prices are typically affordable, but methimazole is one-third lower in price. Therapy extends for weeks or months. I[131] therapy is more expensive than drug therapy but lower in cost than surgery.

Adverse Reactions

A rare (0.3% to 0.6%) but potentially fatal complication of antithyroid drug therapy is agranulocytosis. The risk increases with age, beginning at about age 40, and is dose-independent for propylthiouracil and dose-dependent for methimazole. Patients taking less than 30 mg/d of methimazole typically do not experience this adverse reaction, making it the safer of the two drugs. The propylthiouracil hepatic concerns also make methimazole a safer alternative for all age groups, especially those with polypharmacy.

Monitoring

Monitoring therapy includes attention to clinical status and thyroid function test results. Clinical status is assessed by watching weight, degree of heat tolerance, appetite, anxiety level, energy level, resting heart rate, and skin texture and temperature. For patients with ophthalmopathy, assessment also includes changes in visual acuity, increasing corneal dryness, and adherence to suggestions such as use of sunglasses. Ophthalmic appointments should be scheduled frequently to monitor for complications that can include cataract development, corneal scarring, and retinal detachments.

The same tests that are used to diagnose hyperthyroidism are used to monitor the effectiveness of treatment. The

amount of circulating thyroid hormone is monitored by changes in TSH and free T4. Initially, patients are seen every 3 to 4 weeks, with levels drawn until the patients are euthyroid. TSH may remain low for several weeks after actual euthyroid status is achieved. Once normal, the frequency of visits decreases, with testing of TSH only, and clinical evaluation is done at 3 and 6 months and then annually, based on symptom relief (Bahn et al, 2011). TSH provides the earliest evidence of overtreatment or development of hypothyroidism.

Pregnant patients are usually monitored at each visit because the progression of pregnancy is associated with altered thyroid hormone production. Dosage adjustments are commonly required. Pregnant patients with Graves' disease may have thyroid-stimulating antibodies in their circulation that can cross the placenta and affect the fetus. Measurement of maternal thyroid-stimulating antibody may be useful to assess potential fetal risk.

Though routine monitoring of white blood cell (WBC) counts is not necessary, it is important during the first 4 months of thioamide therapy, especially in those over age 40 with any febrile illness (Bahn et al, 2011). Mild leukopenia is common but does not require discontinuance of the drug. Leukocyte counts below 1,500 mm³ are indications for stopping therapy. Agranulocytosis usually occurs within 2 months and rarely beyond 4 months after initiation of therapy. Onset is rapid, so it is prudent to obtain a baseline WBC count before initiating therapy.

Special monitoring for I¹³¹ patients is not indicated. Half of the dose is gone in a week. After 2 months only 1% remains in the body. Long-term effects do not appear to include localized, or distant, cancers related to the radiation exposure (Sisson, et al, 2011), even in children (Rivkees & Dinaur, 2007).

Outcome Evaluation

Figure 41-1 shows the drug treatment protocol for hyperthyroidism. Evaluation is based on reduction of clinical symptoms and normalization of TSH and free T4 levels. The main indications for substituting surgery or I¹³¹ are a patient's failure to achieve control of symptoms with antithyroid drugs, an inability to tolerate the therapy, and relapse after completion of therapy. Having persistently high antibody titers after discontinuation of an antithyroid drug is predictive of relapse. Postmenopausal women should be screened for any associated bone loss.

Consultation with or referral is appropriate when:

1. Patients require surgery or I¹³¹
2. Hyperthyroidism occurs during pregnancy and lactation or when those on antithyroid drugs become pregnant
3. Patients develop ophthalmopathy or visual impairment
4. Patients have an obstruction to swallowing or desire post-treatment cosmetic improvement
5. Patients with heart failure, rapid atrial fibrillation, or angina need a cardiology consultation

Patient Education

Patient education should include discussion of information related to the overall treatment plan, as well as that specific to the drug therapy. Understanding the reasons for taking the drug, the expected duration of therapy, and anticipated side effects can help with adherence issues. Patients need to anticipate weight gain if they do not adjust diets to a normal metabolic rate. They should have lifelong monitoring of thyroid function.

Patients receiving I¹³¹ should be instructed on dietary and OTC sources of iodine, such as multivitamins with minerals and cough syrups. They require education that reduced levels of iodine before scans and treatments facilitate better I¹³¹ uptake. Patients should delay return to work and limit use of public transportation for a day to limit radiation exposure of others. In the home and at work, individuals are instructed to keep others at arm's length—a distance of about 3 feet—for the next 2 to 3 days. Forcing fluids to help excrete the ions and flushing toilets twice to reduce residual elements in the reservoir also is suggested for 2 to 3 days. Eating utensils should not be shared. Disposable plates and utensils are recommended, which will preclude the need to wash dishes separately. Sleeping alone and avoiding close personal contact, especially with infants and pregnant women, should be practiced for 5 to 11 days. Saliva, vaginal secretions, tears, and sweat are possible sources of contamination during that period. Those patients receiving very high doses for cancer treatment are given a wallet card to carry in the highly unlikely chance of setting off radiation detection alarms at some worksites and federal buildings (Sisson et al, 2011).

HYPERTHYROIDISM — PATIENT EDUCATION

Related to the Overall Treatment Plan and Disease Process

- Understanding the pathophysiology of hyperthyroidism and its prognosis
- Role of iodine intake in thyroid hormone production
- Importance of adherence to the treatment regimen
- Need to take the drug for at least 1 year
- Indications of relapse or complications that need to be reported
- Importance of discussing pregnancy or the potential for pregnancy with the primary care provider
- Need for regular follow-up visits with the primary care provider

Specific to the Drug Therapy

- Discussion of the reasons for taking the drug(s) and the anticipated action of the drug(s) on the disease process. It is especially important to inform the patient that antithyroid drugs take 4 to 8 weeks to have a noticeable effect.
- Doses and schedules for taking the drug(s)
- Possible adverse reactions and what to do when they occur
- Patient education specific to antithyroid drugs is provided in Chapter 21.
- Patient education specific to beta-adrenergic blockers is provided in Chapter 14.

SUBCLINICAL HYPERTHYROIDISM

Subclinical hyperthyroidism is characterized by a serum TSH level less than 0.5 microUnits/mL and normal FT4 and FT3. Exogenous TSH suppression or endogenous production of thyroid hormones appears to be sufficient in this disorder to keep FT4 and FT3 levels normal but to suppress pituitary TSH production and secretion. It can be the result of high-dose glucocorticoids or iodine deficiency. It is estimated that up to 25% of concurrent estrogen replacement patients might fall into this category, with smokers at even greater risk. Self-medication with "natural thyroid health supplements" can be the cause. The clinical significance is the potential for progression to overt hyperthyroidism, exacerbation of any concurrent cardiac problems, and a decrease in bone mineral density if it is more than a transient situation. It is more commonly found in regions with iodine deficiency.

Professionals differ on their views as to whether to screen for and/or treat this disorder. Patients with subclinical hyperthyroidism attributable to nodular thyroid disease warrant treatment. Postmenopausal women, who are already at risk for osteoporosis, are also treated. In older adults, the relative risk for atrial fibrillation increases 3-fold for those with subclinical hyperthyroidism, so treatment is prudent. In most patients, no treatment is necessary unless the source of the disorder is exuberant exogenous hormone replacement. In that case, dosage adjustment is indicated (Bahn et al, 2011).

Patients with subclinical hyperthyroidism should have periodic clinical and laboratory assessments. Persistent rather than transient hormonal abnormalities are more often associated with clinical problems. Data are unreliable about an association with dementia risk. Suppressed TSH is also linked with sleep disturbances; however, many patients report enhanced well-being at these levels. If sustained TSH suppression (less than 0.1 microUnits/mL) is established for those on replacement therapy, then dosage reduction is appropriate to avoid long-term consequences.

HYPOTHYROIDISM

Pathophysiology

The underlying mechanisms that cause hypothyroidism can be primary or secondary. Primary disorders include the following:

- Defective hormone synthesis resulting from autoimmune thyroiditis, endemic iodine deficiency, or antithyroid drugs that were used to treat hyperthyroidism
- Congenital defects or loss of tissue after treatment for hyperthyroidism

Secondary causes of hypothyroidism, which are less common, include conditions that cause either pituitary or hypothalamic failure. In secondary disorders, the TSH response is inadequate so that the gland is normal or reduced in size, with both T3 and T4 synthesis equally reduced.

Primary hypothyroidism is based on the hypothalamic-pituitary-thyroid gland feedback system and occurs when the hypothalamus responds to a decreased thyroid hormone level with an increase in TRH, resulting in increased TSH secretion, which in turn stimulates thyroid gland enlargement, goiter formation, and preferential synthesis of T3 over T4. Of all patients with hypothyroidism, 95% have primary thyroid disease.

Primary Disease

Hashimoto's thyroiditis is an immune-mediated disorder in which all components of the thyroid gland are injured, but especially the TSH receptors. Antibodies generated to attack glandular antigens impair TSH response, hormone synthesis, and hormone release. Some patients have mild disease and may remain euthyroid; approximately 70% go on to develop permanent hypothyroidism.

Postpartum thyroiditis with hypothyroid characteristics affects up to 7% of postpartum women. Antibody production in this disorder peaks 3 to 4 months after delivery and then declines. Symptoms resolve spontaneously in 95% of patients, and most return to euthyroid states without therapy.

Subacute thyroiditis is an inflammation of the thyroid often preceded by a viral infection. It is accompanied by fever, tenderness, and enlargement of the gland. Elevated levels of thyroid hormone are due to the release of stored thyroglobin related to the inflammatory process. Symptoms last 2 to 4 months. Anti-inflammatory agents such as NSAIDs may be used to address the inflammation. Beta blockers are used to reduce tachycardia. There is usually spontaneous remission of the disorder, but it can become chronic.

Congenital hypothyroidism occurs in infants as a result of absent thyroid tissue (thyroid dysgenesis in 90% of cases) and hereditary defects in thyroid hormone synthesis. It is more common in females. Because thyroid hormone is essential for embryonic growth, especially of brain tissue, an infant with no T4 during fetal life will be mentally impaired. This condition can be modulated with administration of T4 immediately after birth. Capillary blood screening of all infants in the United States and Canada before discharge from the hospital or birthing center tests for this disorder. Infants suspected of the disorder are referred immediately to a pediatric endocrinologist. Infants may be initially asymptomatic due to maternal T4 levels.

Endemic iodine deficiency has not been a problem in the United States since the early 1900s. Iodized table salt largely eliminated this form of hypothyroidism. The recent return to home gardens and preferential shopping for local produce might create subsets of patients in the traditional goiter regions of the Great Lakes and across the northern tier of states.

Secondary Disease

Secondary hypothyroidism most commonly is a result of a pituitary disorder. The net result is inadequate TSH production, resulting in poor production of both T3 And T4. Commonly associated pituitary disorders linked with secondary hypothyroidism include Cushing's syndrome, acromegaly, and pituitary adenomas. Other secondary causes include the administration of drugs that reduce

thyroid hormone production (see Table 41-1) and the treatment of hyperthyroidism.

Regardless of the etiology, the clinical features of hypothyroidism are attributable to the metabolic effects of decreased circulating levels of thyroid hormone. The patient develops a low basal metabolic rate, cold intolerance, lethargy, and a slightly lowered body temperature. Table 41-4 shows the most common systemic effects of hypothyroidism.

Long-standing undertreated hypothyroidism often results in myxedema, a condition similar to the pretibial myxedema seen in Graves' disease. It is a result of connective tissues being separated by an increased amount of protein and mucopolysaccharides. These protein complexes bind water, producing pitting, boggy edema, especially around the eyes, hands, and shins and in the supraclavicular fossae. They also produce thickening of the tongue and the laryngeal-pharyngeal membranes, resulting in thick, slurred speech and hoarseness. The medical emergency of myxedema coma can occur, signaling severe hypothyroidism. Signs and symptoms include hypoventilation, hypotension, hypoglycemia, and lactic acidosis. Older adults with vascular disease and untreated hypothyroidism are especially at risk. This critical care state is beyond the scope of this text.

Pharmacodynamics

For patients who are clinically hypothyroid, replacement therapy with thyroid hormones is indicated. Administration of synthetic thyroid hormones (levothyroxine [T4], liothyronine [T3], and liotrix [a 4:1 or 3:1 mixture of T4 and T3]) produces the same effects on body tissues as the body's own thyroid hormones, including the negative feedback required to reduce further secretion of TSH. Dosing schedules for these drugs are provided in Chapter 21. These drugs are inexpensive and relatively free of adverse reactions, but there are conditions in which they are contraindicated or to be used with caution.

Goals of Treatment

The therapeutic goal for patients with hypothyroidism is correction of the hypometabolic state and normalization of

Table 41–4 Systemic Effects of Hypothyroidism

Body System	Clinical Manifestation	Underlying Mechanism
Cardiovascular	Reduced stroke volume and heart rate (reduced cardiac output); increased peripheral vascular resistance to maintain blood pressure; decreased blood flow to tissue; sinus bradycardia; ECG changes	Decreased metabolic demands and loss of regulatory and rate-setting effects of thyroid hormone
Hematologic	Decreased red blood cell mass (normocytic/normochromic anemia); macrocytic anemia associated with B_{12} deficiency and inadequate folate or iron absorption	Decreased basal metabolic rate and oxygen requirements, decreased production of erythropoietin. Possible association between thyroid hormone and hematologic response to B_{12}
Respiratory	Dyspnea, hypoventilation, CO_2 retention	Myxedematous changes in respiratory muscles
Gastrointestinal	Decreased appetite, constipation, weight gain, fluid retention; decreased protein metabolism (lightly positive nitrogen balance); decreased glucose absorption; elevated serum lipid levels	Decreased metabolic demand; reduced peristaltic activity; increased capillary permeability to proteins; depressed insulin degradation; depressed lipid synthesis and degradation
Renal	Increased total body water; reduced erythropoietin production; dilutional hyponatremia	Reduced blood flow and glomerular filtration rate, leading to decreased excretion of water
Integumentary	Dry, flaky skin; dry, brittle hair; reduced growth of nails and hair; slow wound healing; myxedema; cool skin	Reduced sweat and sebaceous gland secretion; increased hyaluronic acid binds water and causes a puffy appearance; decreased circulation to skin; reduced tissue regeneration
Reproductive	Anovulation, decreased libido, high incidence of spontaneous abortion in women; decreased libido and oligospermia in men	Increased estriol formation in women, decreased androgen secretion in men, decreased levels of sex hormone–binding globulin in both genders
Neurologic	Confusion, slow speech and thinking; memory loss; hearing loss; night blindness; slow; clumsy movements; cerebellar ataxia	Decreased cerebral blood flow, resulting in cerebral hypoxia
Musculoskeletal	Muscle and joint aching and stiffness; reduced deep tendon reflexes; increased bone density	Decreased innervation of muscles; decreased bone formation and resorption
Endocrine	Increased TSH production; decreased cortisol turnover rate but normal serum cortisol levels	Impaired thyroid hormone synthesis; decreased deactivation of cortisol

ECG = electrocardiogram; TSH = thyroid-stimulating hormone.

TSH and T4 levels with a minimum of adverse reactions. Adequate hormone replacement should improve fatigue, facilitate weight loss, and reduce cardiovascular and neurological complications.

Rational Drug Selection

Thyroid hormones were originally ground-up thyroid glands of animals. Such preparations are still available today. Because the pharmacokinetics and concentration of hormones in these drugs are highly variable, they have been replaced in practice with synthetic formulations. Patients may prefer the "natural" forms like Armour. There are also OTC "natural" supplements that sometimes contain actual thyroid hormones. The focus of this chapter is the synthetic thyroid hormones.

Drug Therapy

Patients develop the symptoms of hypothyroidism slowly and are often quite low in thyroid hormone before they are diagnosed. These patients have adapted to a low level of hormone and become very sensitive to the effects of synthetic thyroid hormone replacement. Treatment, therefore, should be gradual. The first signs of clinical response to therapy are a modest weight loss, an increase in pulse rate, and resolution of constipation. Other symptoms, such as myxedema, cardiovascular problems, and elevated creatinine kinase levels, take more time to improve. Most patients feel better in about 2 weeks, with clinical resolution occurring in about 3 months.

All of the synthetic forms of thyroid hormone have been successfully used to treat hypothyroidism. Drug choice is based on patient and drug variables. Figure 41-2 depicts the treatment algorithm based on these variables. All patients with TSH greater than 10 microUnits/mL should be treated (Garber et al, 2012).

Patient Variables

Age and Gender

Women older than 50 with markedly elevated TSH levels (greater than or equal to 10 microUnits/mL) have the highest risk for complications from hypothyroidism, such as cardiac conditions associated with altered lipid metabolism. Research evidence is not sufficient to recommend or discourage treatment for patients with lower TSH levels, but the best option is to treat patients with symptoms and previously recognized lipid or CV disorders.

Men, younger women, and patients with a mildly elevated TSH level (6 to 9 micro Units/mL) have a lower risk for complications. At a minimum, these patients should have TSH levels drawn every 2 to 5 years to see if the disease progresses to the point at which treatment is appropriate. Symptomatic patients should be treated.

The most common presentation in pediatrics is a goiter. The disease should be considered when slowing growth patterns, decreasing school performance, and delayed puberty are evident. Children with genetic disorders like Down, Turner, or Klinefelter syndromes need closer screening. One-third of childhood head and neck cancer survivors develop thyroid disorders (LaFranchi, 2012). Because children clear T4 faster than adults, dosages are typically higher.

Pregnancy

Untreated overt hypothyroidism during pregnancy may increase the incidence of maternal hypertension, pre-eclampsia, anemia, postpartum hemorrhage, cardiac ventricular dysfunction, spontaneous abortion, fetal death or stillbirth, low birth weight, and possibly abnormal fetal brain development (Garber et al, 2012). Evidence from a population-based study suggests that even mild, asymptomatic, untreated maternal hypothyroidism during pregnancy may have an adverse effect on cognitive function in the offspring. These outcomes can be avoided by thyroid hormone replacement. Because thyroid hormones are Pregnancy Category A, replacement is advised for all pregnant women even with mild disease. Therapy begun before pregnancy should not be stopped. The increased metabolic rate common to pregnancy often requires higher doses. Increasing a patient's maintenance dose by 25% usually provides adequate coverage. TSH levels should then be checked in 4 weeks to determine the need for any further dosage adjustment. ATA, AACE, and ACOG all recommend levothyroxine, because the combination T4 and T3 medications lower maternal TSH levels, potentially resulting in fetal neurological suppression.

Concomitant Diseases

Concomitant disease state patients should be comanaged with the endocrine team. Thyroid hormone replacement is generally contraindicated after recent *myocardial infarction.* If hypothyroidism is a complicating or causative factor of the cardiac problem, judicious use of small doses may be indicated in consultation with cardiology. *Coronary artery disease* may worsen when thyroid hormones are given because the increased heart rate increases oxygen demand by the heart muscle and decreases the oxygen supply by decreasing the diastolic filling time. The lowest possible dose is used, with careful monitoring for indications of worsening cardiovascular disease. Although both levothyroxine and liothyronine have content stability, liothyronine is 3 to 4 times more active than levothyroxine, making it more likely to produce cardiotoxicity. In patients with *angina,* the initiation of thyroid hormone replacement may precipitate unstable angina. Beta-adrenergic blockers may be concurrently administered to decrease this risk.

Long-term use of levothyroxine therapy in women has been associated with decreased bone density in the hip and spine. Postmenopausal women with *osteoporosis* and not on estrogen replacement require the lowest effective doses and scheduled DEXA screens (see Chaps. 21 and 38).

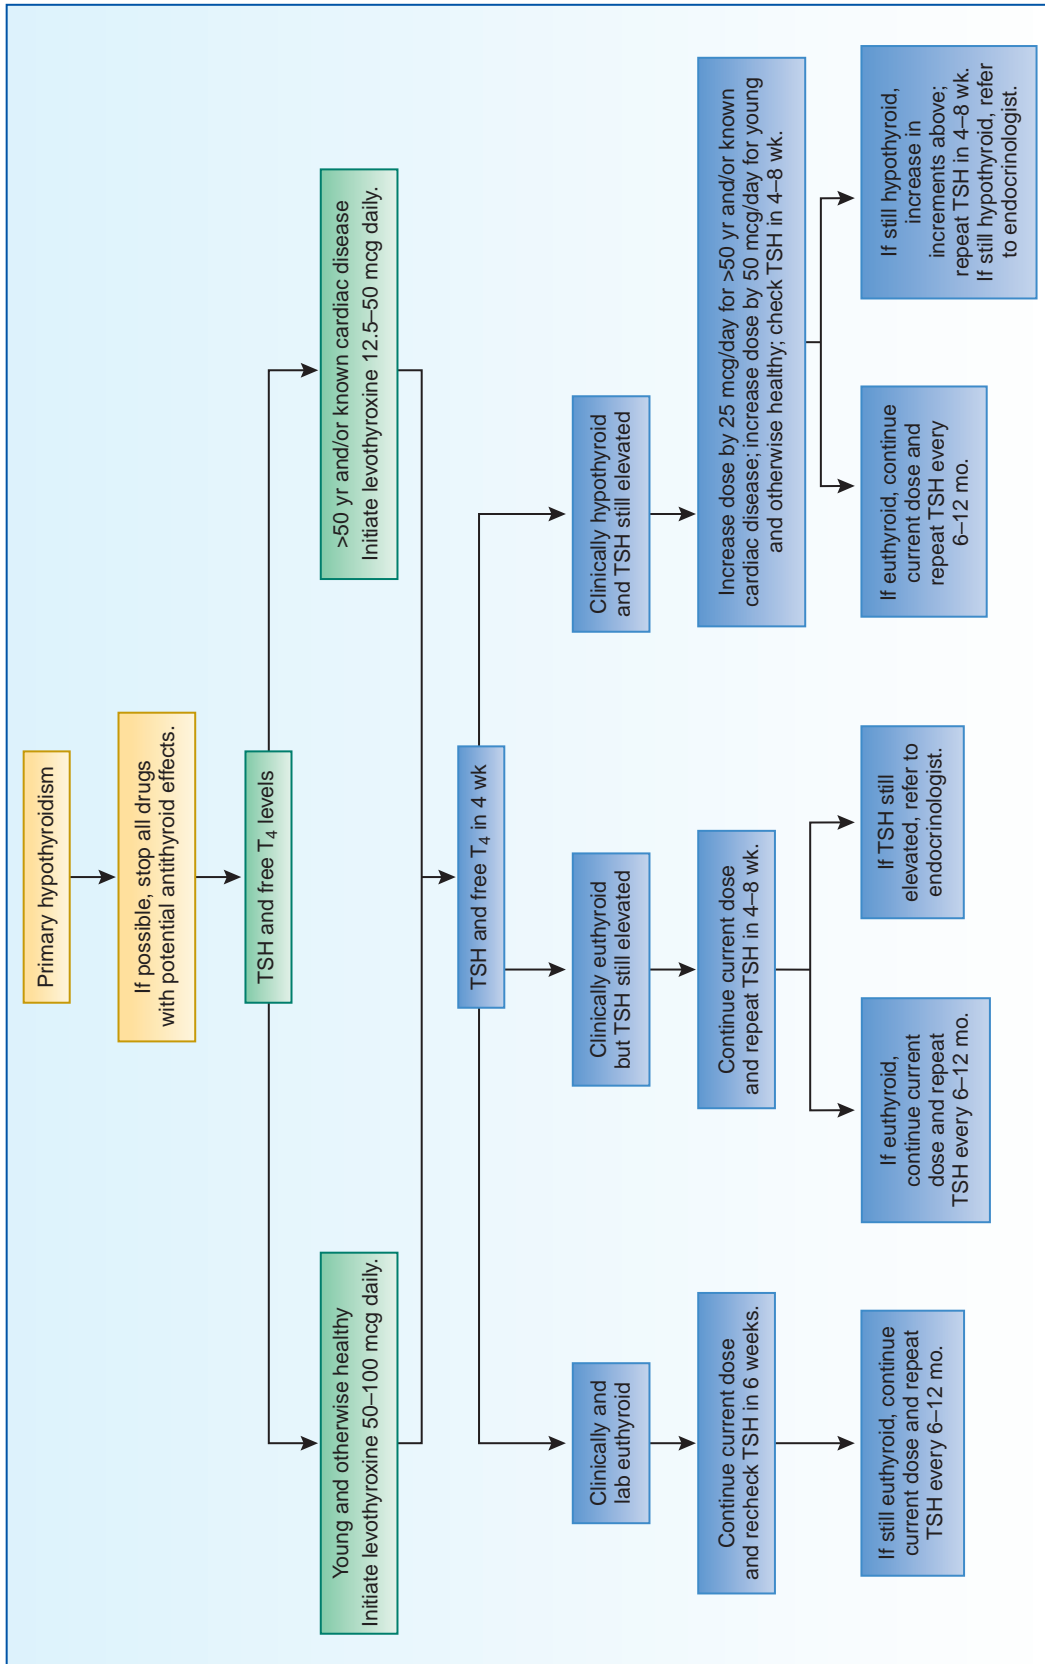
Approximately 10% of patients with *type 1 diabetes mellitus* develop chronic thyroiditis, with an insidious onset of subclinical hypothyroidism (Garber et al, 2012). Up to 25% of women with this disorder will develop postpartum thyroiditis. Patients with diabetes should be routinely examined for the development of goiter and altered TSH levels. Levothyroxine is the drug of choice.


Figure 41–2. Drug therapy algorithm: Hypothyroidism.

Some patients with *infertility* and *menstrual irregularities* have underlying chronic thyroiditis with subclinical hypothyroidism. If these patients have elevated TSH levels, then levothyroxine replacement therapy may normalize the menstrual cycle and restore fertility.

A few patients who are diagnosed with new-onset *depression* have primary hypothyroidism. The work-up for depression should include TSH measurement and treatment with appropriate doses of levothyroxine. Sometimes patients who have depression are treated with antidepressants plus levothyroxine even though they have normal thyroid function tests. There is no evidence that thyroid hormone has any effect on depression without TSH abnormalities. All patients on lithium require periodic thyroid evaluation because lithium may induce goiter and hypothyroidism (Garber et al, 2012).

Levothyroxine is the drug of choice for treating *congenital hypothyroidism*. Tablets may be crushed and added to infant formula. This is discussed in Chapter 21 with the added caution concerning soy-based formulas. Congenital hypothyroidism requires referral to a pediatric endocrinologist.

Drug-Related Variables

Pharmacokinetics

Levothyroxine has a longer half-life and can be safely withheld for up to 2 weeks, if necessary, without significantly altering the patient's thyroid status. The bioequivalence of levothyroxine preparations is based on total T_4 measurement, which some specialty groups have historically claimed is not the same as therapeutic equivalence. All groups recommend the patient should consistently receive the same generic product from the same manufacturer if generics are used. The dosing variables are discussed in Chapter 21. Elders are started on lower doses and pediatric patients on higher ones. Due to metabolic and steady-state profiles, titrations in dosage initially occur after 4 weeks, but any future titrations should occur at no sooner than 6 week intervals.

T4 is not clinically active until the iodine splits off in the peripheral tissues to form T3. It is more natural to supplement T4, because this allows the body to regulate the active hormone level without artificially high supplementation of T3. When T4 absorption or conversion is suspect, then T3 becomes a rational choice.

Malabsorptive states and patient age can change absorption of thyroid hormone. Because levothyroxine has a narrow therapeutic range, small differences in absorption can result in clinical changes. The surge in soy-based products (recognized for potential thyroid impact) generated concerns that have not come to fruition, except for infants (Messina & Redmond, 2006). Drug interactions also present a problem. Table 21-34 in Chapter 21 lists these interactions.

Those with known large gastric pH changes may benefit from the liquid capsule preparation of T4 (Tirosint). H2 blockers and PPI drug use have not been demonstrated to alter absorption (Garber et al, 2012).

There has been a resurgence of interest in the use of combination thyroid hormones to treat hypothyroidism. A 2006 meta-analysis concluded that physiological combinations of levothyroxine plus liothyronine did not offer any objective advantage over levothyroxine alone (Groszinski-Glasberg, Fraser, Nashshoni, Weizman, & Leibovici, 2006). However, there is new recognition that up to 16% of the population may have a genetic polymorphism that has improved physical and psychological well-being with combination therapy (Panicker, et al, 2009). However, current guidelines have not adopted any changes to therapy suggestions based on this (Garber et al, 2012).

If there is a need to rapidly correct a hypothyroid state, liothyronine is preferable because of its rapid onset and dissipation of action. These advantages must be weighed, however, against the wide swings in T3 levels and possible cardiotoxicity. Thyroid cancer survivors may also need to have higher T3 supplementation; autoimmune patients do not.

Cost

Generic forms of all the thyroid hormones are less expensive than brand names. Costs range between $4.00 for generic levothyroxine to 3 to 4 times that price for brand-name drugs. Like branded levothyroxine, Cytomel is more expensive, but natural products (e.g., Armour) can be similar in cost to generic levothyroxine.

Monitoring

Monitoring thyroid replacement therapy has three parameters: clinical symptoms, TSH, and free T4. Despite some controversy, clinical symptoms alone are generally not an effective monitoring parameter because they do not correlate well with laboratory findings.

The most accurate monitoring parameter is a sensitive TSH test because it correlates most closely with physiological measurements of thyroid hormone effect. TSH is evaluated at initiation of therapy and every 4 to 8 weeks after therapy has begun until the patient achieves stable euthyroid status. Normalized and stable TSH levels often take 6 to 12 months to achieve. TSH is also repeated 6 to 8 weeks after any dosage adjustment because it takes approximately this amount of time for the new dosage to stabilize, especially with smaller doses (Garber et al, 2012). Once the patient is euthyroid and stable, TSH monitoring occurs every 12 months, depending on symptoms and stability.

Controversy exists as to the cutoff range of TSH at which treatment should initially begin. Providers should be attuned to the fact that the diagnostic cut point for hypothyroid disease and the therapeutic range for treatment differ in practice. The current practice is that the TSH should remain between 0.3 and 3.0 microUnits/mL during therapy, preferably between 1.0 and 2.0. If the TSH level falls below the lower limit of normal or becomes undetectable, the dose of thyroid hormone used for replacement is excessive. Measurement of free T4 can help to determine how excessive the dose is. FT4 may correlate poorly with physiological status during the initial therapy period. It is more reliable once the patient is stable (e.g., after 12 months).

Levothyroxine is the easiest to monitor with standard TSH and free T4 laboratory measurements of thyroid function.

Monitoring liothyronine therapy is more difficult; it is best monitored as a TSH suppressor. Liotrix offers no clear monitoring benefit over either of these other drugs on any of these parameters. During pregnancy, elevated estrogen increases thyroid-binding globulin levels, which alters total T4 values but not FT4. During pregnancy, both TSH and FT4 levels are evaluated to determine appropriate replacement dosage. Tests are done at 8 weeks and 6 months of gestation. The goal is to normalize TSH and maintain FT4 at the upper limits of normal. Women with hypothyroidism who become pregnant may have their thyroid function change. In general, the dosage of thyroid hormone may need to be increased, and these patients should have their serum TSH level evaluated every 6 weeks during pregnancy and in the postpartum period to ensure that the dose of levothyroxine is appropriate.

Anemia is a frequent concomitant disease with hypothyroidism. A complete blood count (CBC) should be drawn at initiation of therapy. After a thorough work-up of any anemia to assess for other possible causes (e.g., iron deficiency, blood loss, vitamin B_{12} or folic acid deficiency), hypothyroidism should be treated with standard thyroid hormone replacement. Management of anemia, including monitoring parameters, is discussed in Chapter 27.

Other common concomitant disorders that require monitoring include hypercholesterolemia and hypertension. T4 supplementation modulates the lipid disturbances triggered by low thyroid levels. Management of these disorders, including monitoring parameters, is discussed in Chapters 39 and 40. Planned weight loss to control lipids and blood pressure may trigger less need for thyroid supplementation.

Outcome Evaluation

Figure 41-2 shows the drug treatment protocol for hypothyroidism. Evaluation is based on reduction of clinical symptoms such as goiter size and normalization of TSH and FT4 levels. Although most health-care providers can diagnose and treat hypothyroidism, certain situations suggest referral to a clinical endocrinologist experienced in the spectrum of thyroid disease:

- Patients age 18 years or under
- Patients unresponsive to therapy
- Pregnant and lactating patients
- Cardiac patients
- Presence of goiter, nodule, or other structural changes in the thyroid gland
- Presence of autoimmune or other endocrine diseases
- Failure to achieve control of symptoms or normalized TSH within 12 months by standard doses despite patient adherence to the treatment regimen
- Relapse after a period of stability on a standard dose
- Pending surgery; careful anesthesia planning is required because clearance of anesthetics is reduced

Patient Education

Patient education should discuss the overall treatment plan, reasons for taking the drug, dietary considerations, and the negative aspects of keeping TSH levels too low. Patients need to be aware of the typical permanence of drug therapy. Thyroid products are best taken 1 hour before breakfast or at least 2 hours after an evening meal. Coffee can decrease absorption of T4 by 27% to 30%. Some individuals are sensitive to a large intake of cabbage and other goiterogenic products.

SUBCLINICAL HYPOTHYROIDISM

Subclinical hypothyroidism refers to mildly increased serum TSH levels in the setting of normal FT4 and FT3. It is a common disorder, ranging from 4% to 10% of the adult population, with increased frequency in women, older adults, and those

PATIENT EDUCATION

HYPOTHYROIDISM

Related to the Overall Treatment Plan and Disease Process

Understanding the pathophysiology of hypothyroidism and its prognosis.

Role of iodine intake in thyroid hormone production.

Importance of adherence to the treatment regimen.

Length of time the drug will need to be taken. For those with thyroiditis, this may be less than 12 months. For many with primary hypothyroidism, the treatment will be lifelong. The patient should be informed not to stop taking the drug without first consulting the health-care provider.

Indications of relapse or complications that need to be reported.

Importance of discussing pregnancy or the potential for pregnancy with the primary care provider.

Need to wear a medical identification bracelet stating that patient is taking thyroid hormone replacement and to inform any provider who sees him or her that this is the case. This is especially important if this provider prescribes any new drugs for the patient.

Need for regular follow-up visits with the primary care provider, which will include laboratory monitoring of thyroid function to determine the status of the hypothyroidism and any needed dosage adjustments of the drug therapy.

Specific to the Drug Therapy

Discussion of the reasons for taking the drug(s) and the anticipated action of the drug(s) on the disease process. It is especially important to inform the patient that thyroid hormone replacement may take 4 to 8 weeks to have a noticeable effect.

Doses and schedules for taking the drug(s).

Possible adverse reactions (e.g., rapid heart rate, cardiac arrhythmias, chest pain, insomnia, diarrhea, or heat intolerance) and what to do when they occur.

Additional patient education specific to thyroid hormones is provided in Chapter 21.

with higher dietary iodine intake (NHANNES III). Subclinical hypothyroidism is usually asymptomatic and discovered on routine thyroid screening. The most common cause is Hashimoto's disease. Progression to overt hypothyroidism is reported to vary from 3% to 20%.

Potential risks for this condition, besides progression to hypothyroidism, include cardiovascular disease, hyperlipidemia, and neuropsychiatric effects. The ATA and ACCE (Garber et al, 2012) recommend treatment for patients with TSH levels of 5 to 10 microUnits/mL who also have goiter or positive thyroid peroxidase antibodies. These patients have the highest rate of conversion to overt hypothyroidism. Lower than full replacement doses are needed. As with overt hypothyroidism, the target TSH level should be between 0.3 and 3.0 microUnits/mL. Once this level is achieved, an annual evaluation is sufficient.

PNEUMONIA

Anne Hedger

Pneumonia affects more than 5 million people a year in the United States, making it one of the more commonly seen medical problems and the eighth leading cause of death in the United States; yet there has been a significant decrease in death rates relative to previous years (National Center for Health Statistics, 2011). As in most bacterial illnesses, those patients at the extremes of age are most severely affected, with infants and older adults often requiring hospitalization and IV antibiotics. Pertinent issues in managing health-care–associated pneumonia (HCAP) include the increased risk of infection from drug-resistant isolates of the usual community-acquired pathogens and an increased risk of infection with less common, usually hospital-associated pathogens (Mandell et al, 2007).

ADULT PATIENTS WITH PNEUMONIA

Pathophysiology

Pneumonia develops when an organism invades the lung parenchyma and the host defenses are depressed. Bacterial pneumonia results when the lung's primary defense mechanisms are altered, either by a viral infection or by immunological problems. Chronically ill patients of all ages are more prone to pneumonia, usually because of their underlying medical problem. There may be other origins of pneumonia besides bacterial organisms, such as viral, fungal, rickettsial, and parasitic organisms; inflammatory processes; and inhalation of toxic substances.

Pneumonia should be considered in any patient who presents with respiratory symptoms such as cough, dyspnea, or sputum production. Fever or abnormal breath sounds, such as crackles, would strengthen the suspicion of pneumonia. Chest radiographs assist in confirming the diagnosis of pneumonia versus other respiratory disorders such as lung abscess or tuberculosis (Mandell et al, 2007). However, given the limitations of diagnostic testing, most community-acquired pneumonia (CAP) is still treated empirically (Mandell et al, 2007).

The predominant organism found in pneumonia depends on the age and health status of the patient. For all ages (except neonates), *Streptococcus pneumoniae* is the organism most commonly found in pneumonia (Mandell et al, 2007). *S. pneumoniae* is identified as the causative organism in 60% to 75% of adults with bacterial pneumonia, based on sputum culture. Nontypeable *Haemophilus influenzae* and *Moraxella catarrhalis* are common pathogens in patients with underlying lung disease. *Staphylococcus aureus* has become a common co-pathogen in influenza-associated pneumonia. *Mycoplasma pneumoniae,* a pathogen difficult to detect on Gram's stain or culture, is another common cause of pneumonia. In many patients viruses are the cause of pneumonia; viruses are identified in 18% to 36% of pneumonia cases (Mandell et al, 2007). It must be noted that the responsible organism is not identified in up to 50% of patients with CAP (American Thoracic Society [ATS], 2001). Table 42-1 lists the common pathological agents for CAP at different ages.

In the past, practitioners attempted to determine the most likely pathogen by the clinical presentation of the patient, using terms like *typical* and *atypical.* Typical infections were those caused by *S. pneumoniae, H. influenzae, S. aureus,* or gram-negative bacteria. The presentation of typical pneumonia included fever, chills, yellow or green sputum, pleuritic chest pain, and lobar consolidation on chest x-rays; the presentation of atypical pneumonia included a gradual onset of cough, no or scant sputum, low-grade fever, myalgias, arthralgias, and lack of consolidation on x-rays. It was thought that patients with atypical pneumonia most likely had *M. pneumoniae, Legionella pneumophila,* or a viral infection. In clinical practice, these classifications have little usefulness, as numerous studies have shown that few reliable clinical features distinguish between the different bacterial pathogens (ATS, 2001).

Goals of Treatment

The ultimate goal of treatment for all patients is the return to the respiratory status they had before the illness. Initially, patients who are responding to empirical antibiotic therapy should show improved clinical condition in 48 to 72 hours. Fever should resolve in 2 to 4 days, and leukocytosis usually resolves by day 4 of treatment (ATS, 2001; Mandell et al, 2007). The patient's chest x-ray may actually deteriorate, however, and not return to baseline for weeks or months. In previously healthy adults younger than age 50 years, 66% of patients with pneumonia return to baseline chest x-rays within 4 weeks. In older patients or those who have previously had respiratory or other chronic illness, only 26% of patients have normal chest x-rays by the fourth week of treatment (ATS, 2001). Children may require 6 to 8 weeks for the chest x-ray to return to normal (Bradley et al, 2011). Therefore, a clear chest x-ray may not be the best indicator of successful treatment initially. The best indicator of improvement in clinical status is that the overall clinical manifestations of pneumonia (e.g., fever and increased white blood cell [WBC] count) should improve. Older patients, those with multiple coexisting illnesses, and those with increased severity of disease will have delayed resolution of clinical signs and symptoms (level II evidence) (ATS, 2001).

Rational Drug Selection

Clinical Guidelines

In 1993, the American Thoracic Society (ATS) issued guidelines for the initial management of adults with CAP that discuss the diagnosis, assessment of severity, and initial antimicrobial therapy; these guidelines were revised and updated in 2001. In 2007, the Infectious Diseases Society of America and the American Thoracic Society published a consensus document on the management of community-acquired pneumonia (Mandell et al, 2007). The original ATS guidelines published in 2001 are similar to those used in Europe and Canada and break down the treatment into severely ill and not severely ill patients, patients who require hospitalization, and those who require intensive care unit (ICU) hospitalization (ATS, 2001; Mandell et al, 2007; Riley, Aronsky, & Dean, 2004). These categories include the following:

1. Previously healthy outpatients with no history of cardiopulmonary disease and no modifying factors such as risk for drug-resistant streptococcal pneumonia (DSRP) (excludes those with HIV).
2. Outpatients with cardiopulmonary disease (congestive heart failure or chronic obstructive pulmonary disease [COPD]), diabetes, liver or renal disease, alcoholism, malignancies, asplenia, immunosuppression, use of antimicrobials in the past 3 months, and/or modifying factors (risk factors for DSRP [age greater than 65] or gram-negative bacteria).

Table 42–1 Community-Acquired Pneumonia: Common Pathogens by Age

Age	Common Pathogens
Neonates	Coliform bacteria, cytomegalovirus, enterovirus, group B streptococci, herpes virus, *Mycoplasma hominis, Ureaplasma urealyticum*
Infants 4–16 weeks	Cytomegalovirus, influenza virus, parainfluenza virus, respiratory syncytial virus (RSV), *Chlamydia trachomatis, Haemophilus influenzae, Staphylococcus aureus, Streptococcus pneumoniae, U. urealyticum*
Children up to 5 years	Adenovirus, group A streptococci, influenza virus, RSV, *H. influenzae, S. aureus, S. pneumoniae*
Children over 5 years through adolescence	Influenza virus, varicella, *Chlamydia pneumoniae, H. influenzae, Legionella pneumophila, Mycoplasma pneumoniae, S. pneumoniae*
Adults group I: no cardiopulmonary disease and no modifying factors	Respiratory viruses, *C. pneumoniae, H. influenzae, M. pneumoniae, S. pneumoniae;* other (1%): endemic fungi, *Legionella* spp., *Mycobacterium tuberculosis, S. aureus*
Adults group II: with cardiopulmonary disease and/or modifying factors	Aerobic gram-negative bacilli, respiratory viruses, *H. influenzae, S. aureus, S. pneumoniae* (including DSRP); other (1%): endemic fungi, *Legionella Moraxella catarrhalis, M. tuberculosis, Mycoplasma pneumoniae,* mixed infection

DSRP = drug-resistant streptococcal pneumonia; RSV = respiratory syncytial virus.

3. Inpatients not admitted to the ICU who have the following:
   a. Cardiopulmonary disease and/or other modifying factors, such as having recently stayed at a nursing home.
   b. No cardiopulmonary disease and no other modifying factors.
4. ICU-admitted patients who have the following:
   a. No risks for *Pseudomonas aeruginosa*
   b. Risks for *P. aeruginosa*

Basically, the practitioner needs to take into consideration the comorbidities of the patient (cardiopulmonary disease), the severity of the illness at initial presentation, and the treatment setting (outpatient or hospital). In the 1993 ATS guidelines, age was a factor in decision making, but studies have found that age alone has little impact on the bacterial etiology of pneumonia (ATS, 2001). The only exception is that patients over age 65 are at risk for DSRP, which automatically places them in group 2, but age does not affect susceptibility to other organisms. Because most primary care practitioners are in the ambulatory setting, the first two categories, which cover the treatment of the outpatient, are discussed here.

In selecting treatment, the practitioner must also decide whether to treat the patient on an outpatient basis or in a hospital. The presence of any one of the following warrants admission to a hospital: respiratory rate greater than 30, temperature above 101°F, a PaO$_2$ less than 60 mm Hg, or a PaCO$_2$ greater than 50 mm Hg on room air. Age over 65 years, presence of coexisting illnesses such as COPD, diabetes mellitus, and chronic renal failure, congestive heart failure, chronic liver disease, alcohol abuse, and malnutrition all increase mortality of pneumonia and should warrant consideration for initial treatment as an inpatient (ATS, 2001). A severity-of-illness scale such as CURB-65 may be used to guide hospital admission decision making. The CURB-65 criteria evaluate confusion, uremia, respiratory rate, low blood pressure, and age 65 years or greater; patients with a score of 2 or above require either hospitalization or intensive home health services (Mandell et al, 2007). Even in the absence of any of these complicating factors or findings, the severity of the overall clinical picture may warrant hospitalization.

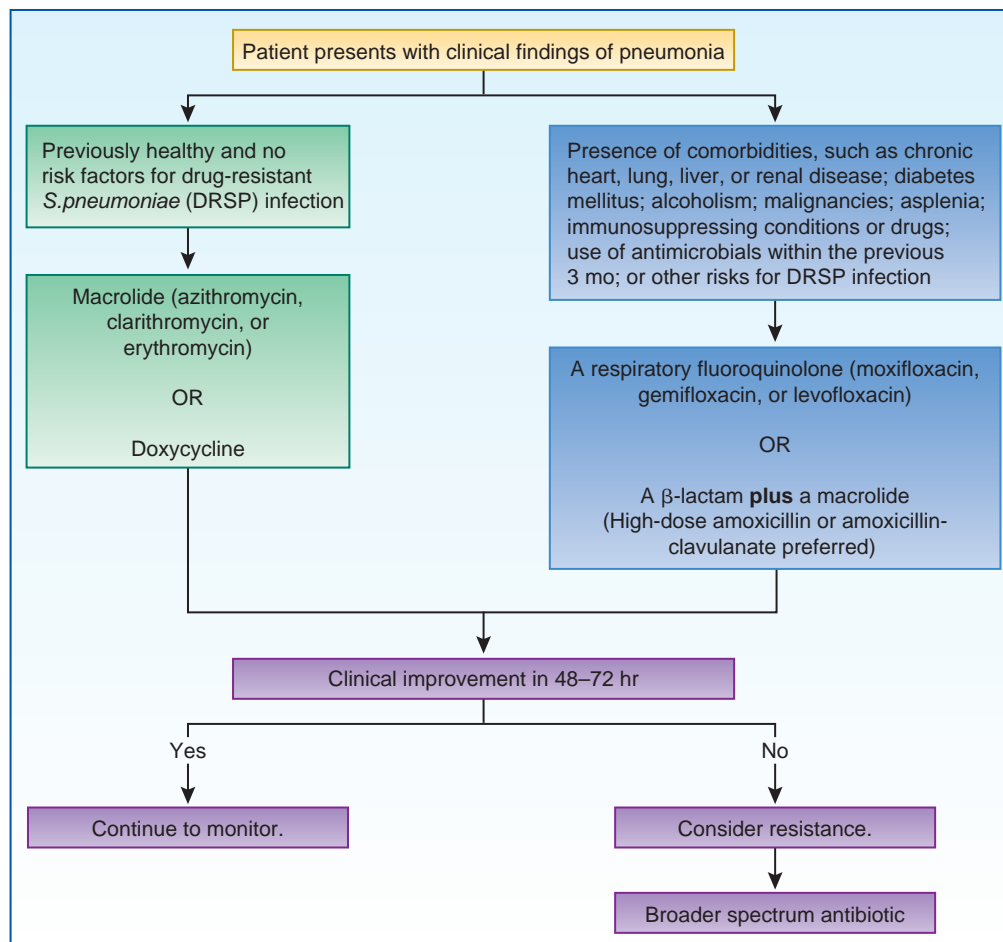
If the patient can be treated on an outpatient basis, the practitioner, using the ATS guidelines, determines the appropriate treatment based on the modifying factors that increase the risk of infection with specific pathogens. The treatment decision is based on the slightly different organisms found in each group. Figure 42-1 is an outpatient treatment algorithm for adults with CAP.


Figure 42–1. Treatment algorithm: Outpatient treatment of adults with community-acquired pneumonia.

Dosing Regimen

Initial empirical therapy for the previously healthy outpatient with no cardiopulmonary disease, no antibiotics in the past 3 months (no risk for DRSP), and no modifying factors (group 1) is to treat with an advanced-generation macrolide (level I evidence), such as azithromycin or clarithromycin, with doxycycline (level III evidence) a second choice if the patient is allergic or intolerant to macrolides. Erythromycin is the least expensive macrolide, whereas the ATS guidelines note that the newer macrolides have a lower incidence of gastrointestinal (GI) side effects and require fewer doses, improving the likelihood of patient compliance with therapy (Mandell et al, 2007). Azithromycin 500 mg on day 1, followed by 250 mg/d for days 2 to 5 is one choice (about $25 per course of treatment with generic medication), with clarithromycin 250 to 500 mg twice a day for 7 to 10 days (about $73 for 10 days of treatment, either strength) also an appropriate choice. Erythromycin 500 mg given PO qid for 7 to 10 days is the least expensive (about $17 for 7 days of treatment). Patients may also be prescribed erythromycin 333 mg tid (about $16 for 10 days) or 500 mg bid ($15 for 10 days). If patients have GI upset from the erythromycin at a dose of 500 mg qid, they may respond to 250 mg of erythromycin given qid.

The patient should begin to exhibit clinical response in 48 to 72 hours; therefore, unless the patient is deteriorating, treatment should not be altered for 72 hours (level III evidence) (ATS, 2001). Length of treatment with community-acquired pneumonia should be for a minimum of 5 days (level I evidence) and the patient should be afebrile for 48 to 72 hours with vitals signs, including oxygen saturation, within normal limits (Mandell et al, 2007).

Presence of comorbidities, such as chronic heart, lung, liver, or renal disease; diabetes mellitus; alcoholism; malignancies; asplenia; immunosuppressant conditions or use of immunosuppressant drugs; use of antimicrobials within the previous 3 months; or other risk for DRSP infection requires a respiratory fluoroquinolone such as moxifloxacin, gemifloxacin, or levofloxacin (Mandell et al, 2007). An alternative treatment in patients with comorbidities is a beta lactam *plus* a macrolide (level I evidence). High-dose amoxicillin (1 gm tid) or amoxicillin/clavulanate (Augmentin) is the preferred choice (Mandell et al, 2007). Alternatives include cefpodoxime, cefuroxime, or parenteral ceftriaxone followed by oral cefpodoxime. Doxycycline may be used as an alternative to the macrolide (level II evidence). In regions with a high rate (125%) of infection with high-level (MIC 16 mg/mL) macrolide-resistant *S. pneumoniae,* consider use of a respiratory fluoroquinolone (levofloxacin, gemifloxacin, or moxifloxacin) or a beta lactam plus a macrolide (level III evidence). The patient should begin to demonstrate clinical improvement in 48 to 72 hours and length of treatment is a minimum of 5 days.

If the patient is over age 60 years or has comorbidities, is stable enough for home therapy, but oral intake is not assured, home parenteral therapy is an option. The drugs of choice for these patients are ceftriaxone (Rocephin) 1 g daily via IV or IM or levofloxacin 500 mg IV daily. Consider adding a macrolide to ceftriaxone for coverage against atypical pathogens if indicated. Once clinical response is observed, the patient is switched to oral therapy, as described previously. Although parenteral therapy is expensive, it is still much more cost-effective than a hospital stay.

Patient Variables

Patient With Nursing Home–Acquired Pneumonia

Pneumonia is a common illness among patients residing in nursing homes, with a significant 30-day morbidity rate of 10% to 30% (Mills, Nelson, Winslow, & Springer, 2009). Patients with nursing home–acquired pneumonias are classified by the ATS guidelines as group 2 patients, with nursing home residence considered a modifying factor. *S. pneumoniae* is the most common pathogen in nursing home–acquired pneumonia (up to 48%), but patients may also have *S. aureus* (up to 33%)*, H. influenzae* (up to 22%), aerobic gram-negative pathogens, Enterobacteriaceae, *Mycobacterium tuberculosis,* and certain viral agents (adenovirus, respiratory syncytial virus [RSV], and influenza) (Mills et al., 2009). Anaerobes should be considered if the patient has poor dentition or a swallowing disorder (ATS, 2001; Muder, Agahbabian, Loeb, Solot, & Higbee, 2004). These pathogens should be part of the differential for treating a patient who resides in a long-term care facility, yet the ATS recommends that nursing home patients should be initially treated in the same fashion as other group 2 patients. Note the 2007 consensus statement does not directly address nursing home–acquired pneumonia.

Pregnant Patient With Pneumonia

Pregnant women are at a slightly higher risk for infections than are other women because of diminished lymphocyte function and decreased functional residual capacity of the lung during pregnancy (Sheffield & Cunningham, 2009). The prevalence of pneumonia in pregnancy is 0.5 to 1.5 cases per 1,000 pregnancies (Sheffield & Cunningham, 2009). Risk factors that appear to be associated with antepartum pneumonia include anemia, prior lung disease, and illicit drug use. The pathogens found in CAP are also the predominant pathogens in antepartum patients with pneumonia; the main pathogens causing pneumonia are *S. pneumoniae, H. influenzae, M. pneumoniae,* and viruses (Larson & Powrie, 2014). Viruses such as influenza (both type A and type B), varicella, and measles are associated with significant morbidity for pregnant women with pneumonia. Maternal mortality is high for varicella-zoster pneumonia, at 40% (Larson & Powrie, 2014). During the H1N1 influenza pandemic of 2009, infected pregnant women were found to be at high risk for hospitalization and severe complications, specifically pneumonia leading to acute respiratory distress syndrome (Centers for Disease Control and Prevention [CDC], 2009; Jamieson et al, 2009; Sheffield & Cunningham, 2009).

A review of the effects of pneumonia on pregnant patients suggests that maternal and fetal morbidity remain a concern. The complications found were maternal death, fetal death, and preterm labor, with preterm labor rates as high as 44% in some studies (Sheffield & Cunningham, 2009). Pregnant

women with pneumonia may require hospitalization, treatment with the appropriate antimicrobial/antiviral, and consultation with a perinatologist as occult onset of preterm labor may occur (Larson & Powrie, 2014). Antibiotic therapy for the pregnant patient is similar to treatment of other adults with CAP: the macrolides erythromycin, azithromycin, and clarithromycin are safe during pregnancy, although erythromycin or azithromycin is the first choice, as each is Pregnancy Category B, whereas clarithromycin is Pregnancy Category C. Sheffield and Cunningham (2009) report a 99% treatment success rate among previously healthy pregnant women treated with macrolides. Doxycycline, a tetracycline, is not used during pregnancy because it may cause discoloration of deciduous teeth in neonates. Fluoroquinolones are avoided during pregnancy due to concerns for fetal malformations, based on animal studies. Women with comorbid conditions or recent antibiotics should be treated with a beta lactam plus a macrolide (Larson & Powrie, 2014; Mandell et al, 2007).

Prevention of viral causes of pneumonia is key to the health of the pregnant patient. The patient who has not previously had varicella should receive the varicella vaccine prior to planning a pregnancy (measles/mumps/rubella [MMR] cannot be given during pregnancy). The pregnant or postpartum patient should receive an influenza vaccine in the fall of the year, and any patient with a chronic medical condition should receive a pneumococcal vaccine.

Lifestyle Modifications

Although the mainstay of treatment is antibiotic therapy, other measures improve outcome. Adequate hydration enables the patient to liquefy any secretions present. Also, patients who are ill with pneumonia often are anorectic and have decreased fluid intake, so education regarding "pushing" fluids is helpful. Rest is one aspect of therapy that younger, working patients may have a hard time accepting. Encouraging patients to not work for a few days will speed the healing process. Tobacco smoke irritates the lungs and increases the coughing associated with the pneumonia. The patient and other household members should refrain from smoking.

Monitoring

The practitioner needs to monitor the patient's clinical status closely. Early identification of the need for hospitalization will enhance the outcome of the illness. The patient's fever, respiratory status, hydration, and activity tolerance all need to be monitored for early signs of either improvement or deterioration.

Outcome Evaluation

As previously mentioned, the patient needs to be monitored for response to empirical antibiotic therapy. The patient should become afebrile in 2 to 4 days. Leukocytosis most often resolves by the fourth day of treatment. Radiographic improvement usually requires more time and is not an indicator of improvement. If the chest x-ray worsens yet the patient

shows clinical improvement, that is the natural progression of the disease. Up to 15% of patients do not respond to appropriate initial empiric antibiotic therapy (Mandell et al, 2007). In severe CAP, if the radiographic findings worsen *and* the clinical picture worsens, then that is a predictor of increased morbidity and mortality (ATS, 2001; Mandell et al, 2007).

If no improvement in clinical status occurs within 72 hours, the practitioner needs to consider that the pathogen is not being treated appropriately. Two possibilities exist. One is that the antibiotic chosen is not treating the pathogen. Another consideration is that the pathogen is resistant to the antibiotic chosen. In an era of increasing antibiotic resistance, the practitioner is always choosing between the narrowest treatment spectrum and the shotgun approach to treatment. There are more powerful oral antibiotics available than those the ATS recommends for empirical therapy, but if all practitioners routinely overprescribe them, then resistance will soon develop. Therefore, the prudent practice is to start with the recommendation and save the broader-spectrum antibiotics for true cases of resistance.

Patient Education

Patient education related to pneumonia should focus on the following:

1. The patient should understand that pneumonia might be bacterial, viral, or mycoplasmal and the expected course of improvement for each. The patient should know that the initial clinical picture might not clearly indicate what type of pathogen is causing the pneumonia. The response to treatment will help to clarify the pathogen.
2. The patient should understand the antibiotic that is prescribed, including expected adverse reactions, drug interactions, and length of treatment.
3. Lifestyle modifications, such as increased hydration, smoking cessation, and rest, should all be discussed.
4. Symptoms of worsening status should be described and the patient told to notify the practitioner or seek urgent care if symptoms worsen rather than improve. Patients should be told to expect clinical improvement in 48 to 72 hours.

Patient education should also focus on prevention.

PEDIATRIC PATIENTS WITH PNEUMONIA

Pneumonia in the pediatric patient can cause the infant or child to become quite ill very rapidly. In the postneonatal period (28 days through 11 months after birth), pneumonia is the seventh highest cause of death in the United States (National Center for Health Statistics, 2011). Specific pathogens are more likely at certain ages (Bradley et al, 2011). In children, treatment is determined by the organism most likely to be causing the pneumonia or by positive cultures for a specific organism. Children may be treated on an outpatient basis if their clinical condition is stable. Indications for hospitalization in children

beyond early infancy include moderate to severe respiratory distress, failure to respond to oral antibiotics, lobar consolidation in more than one lobe, immunosuppression, empyema, abscess or pneumatocele, or underlying cardiopulmonary disease. Pneumonia is the second highest reason for admission through the emergency department in children and adolescents, following just behind asthma in a 2004 Healthcare Cost and Utilization Project (Merrill & Owens, 2007). This section focuses on the outpatient treatment of pneumonia in children. Neonates (children less than 30 days old) with pneumonia require hospitalization, with few exceptions; therefore, this group is not discussed in this chapter.

Pathophysiology

S. pneumoniae is the most common cause of bacterial pneumonia in children of all ages (Bradley et al, 2011). The pneumococcal vaccine has demonstrated a decreased overall incidence and prevalence of invasive pneumococcal disease and pneumococcal pneumonia (CDC, 2012b). Following the introduction of PCV7 in 2000, the rates of invasive pneumococcal disease in children less than 5 years of age decreased from 80 cases per 100,000 to less than 1 case per 100,000 by 2007. Subsequently, the replacement of PCV7 with PCV13 in 2010 was approved by the Food and Drug Administration (FDA) on the basis of studies that demonstrated safety and ability comparable to that of PCV7 to elicit antibodies (CDC, 2012b) and remains recommended for all children younger than 59 months old. In children, the most common organisms after *S. pneumoniae* vary according to age (see Table 42-1).

S. pneumoniae is rarely found in neonates, whereas perinatal infection from group B streptococci is often the leading pathogen in this age group. *C. trachomatis,* another perinatal infection, can occur in 5% to 20% of 3 to 16 week-old infants whose mother has untreated disease at the time of birth. Viral infections should also be considered, with mixed viral-bacterial pneumonia identified in up to 30% of children hospitalized with pneumonia (Bradley et al., 2011; Michelow et al, 2004). In a study of children less than age 5 years with radiologically confirmed community-acquired pneumonia diagnosed in the emergency department, the viral pathogens identified were the following: respiratory syncytial virus (RSV) accounted for 23.1%; human metapneumovirus, 8.3%; adenovirus, 3.4%; influenza A, 2.9%; and parainfluenza, 2.9% (Wolf et al, 2010). The clinical findings or age can often differentiate among the pathogens that cause pneumonia in children.

Goals of Treatment

The goals of treatment for pediatric patients with pneumonia are the same as the goals for adults with pneumonia.

Rational Drug Selection

Patient Variables

Infants With Chlamydial Pneumonia

Infants who are 2 to 19 weeks old and who present as afebrile, with a repetitive staccato cough and tachypnea, cervical adenopathy, and rales, are likely to have chlamydial pneumonia (American Academy of Pediatrics [AAP], 2012a). Wheezing is rare. Chest x-ray will show hyperinflation and bilateral diffuse infiltrates. The patient may also have nasal stuffiness and otitis media. Diagnosis is confirmed by detecting chlamydia-specific immunoglobulin M (IgM) in serum (1:32 or greater is diagnostic) (AAP, 2012a).

Drug Therapy

The standard treatment for infants with confirmed chlamydial pneumonia is erythromycin (EryPed) 50 mg/kg daily for 14 days or oral azithromycin (Zithromax) 20 mg/kg/d for 3 days (AAP, 2012a; Bradley et al, 2011). These infants can usually be treated as outpatients if they are able to eat and maintain hydration. An association between the use of erythromycin and hypertropic pyloric stenosis in infants less than 6 weeks of age has been reported. The AAP *Redbook* notes there is limited data on the use of azithromycin to treat chlamydial infections in infants (AAP, 2012a). The AAP continues to advise use of erythromycin for treatment of diseases caused by *C. trachomatis,* and recommends any cases of pyloric stenosis associated with the use of erythromycin or azithromycin be reported to Medwatch (AAP, 2012a). A diagnosis of *C. trachomatis* infection in an infant should prompt treatment of the mother and her sexual partner(s). See Table 42-2 for drugs commonly used with patients with CAP.

Children With Bacterial Pneumonia

Bacterial pneumonia in children usually occurs as a secondary infection following a viral infection. Primary bacterial

Table 42–2 ❂ Drugs Commonly Used: Community-Acquired Pneumonia

Drug	Dose	Length of Treatment	Strengths Available	Comments
Amoxicillin (Amoxil, Trimox)	*Adults and children ≥16 yr:* 875 mg q12h or 500 mg q8h *Children:* 80–100 mg/ kg/d divided bid or tid	*Adults:* 7–14 days *Children:* 7–14 days	Tablets: 500, 875 mg Capsules: 250, 500 mg Chewable tablets: 125, 200, 250, 400 mg Powder for suspension: 50, 125, 200, 250, 400 mg/ 5 mL	
Amoxicillin/ clavulanate (Augmentin)	*Adults:* 875 mg q12h *Children <3 mo:* 30 mg/ kg/d of amoxicillin divided q12h *Children >3 mo:* 80–90 mg/kg/d of amoxicillin divided q12h Use Augmentin ES-600 formula or combine Augmentin and amoxicillin to equal amoxicillin 80–90 mg/kg/d	10–14 days for all patients	Tablets: 250 mg amoxicillin with 125 mg clavulanate, 500 mg amoxicillin with 125 mg clavulanate, 875 mg amoxicillin with 125 mg clavulanate Chewable tablets: 125 mg amoxicillin with 31.25 mg clavulanate, 200 mg amoxicillin with 28.5 mg clavulanate, 250 mg amoxicillin with 62.5 mg clavulanate, 400 mg amoxicillin with 57 mg clavulanate Suspension: 125 mg amoxicillin with 31.25 mg clavulanate/5 mL, 200 mg amoxicillin with 28.5 mg clavulanate/5 mL, 250 mg amoxicillin with 62.5 mg clavulanate/5 mL, 400 mg amoxicillin with 57 mg clavulanate/5 mL, 400 mg amoxicillin with 57 mg clavulanate Augmentin ES-600 600 mg amoxicillin with 42.9 mg clavulanate per 5 mL	Children's dose is based on amoxicillin content. Because of the clavulanate content, two 250 mg tablets are not the same as one 500 mg tablet. Because of the different clavulanate levels in the suspensions, it is not appropriate to dose the 125 or the 250 mg/5-mL suspensions twice a day. Children should not be given the 250 mg tablet until they are >40 kg. In children, if combining Augmentin and amoxicillin, do not exceed 6.4 mg/kg/d of clavulanate.
Azithromycin (Zithromax)	*Adults:* 500 mg on day 1, then 250 mg daily for days 2–5 *Children:* day 1, 10 mg/kg, followed by 5 mg/kg on days 2–5	5 days	Capsules: 250 mg, Z-pak: six 250 mg tablets with instructions for daily dosing Suspension: 100, 200 mg/ 5 mL	
Ceftriaxone (Rocephin)	*Adults:* 1–2 g every 12–24 h *Children:* 50–100 mg/kg/d up to 2 g/d	Based on clinical response, switch to oral therapy when able	Powder for Injection: 250 mg, 500 mg 1 g	Broad spectrum Expensive but less expensive than hospitalization
Erythromycin base (E-Mycin, Ery-Tab)	*Adults:* 250–500 mg q6h or 333 mg q8h *or* 500 mg q12h *Children:* 30–50 mg/kg/d divided into tid dosing	*Adults:* 7–14 days *Children:* 10–14 days	Tablets: 250, 333, 500 mg	Should be taken with food to decrease GI upset
Erythromycin estolate (Ilosone)	*Adults:* 250–500 mg q6h or 333 mg q8h *or* 500 mg q12h *Children:* 30–50 mg/kg/d divided into tid dosing	*Adults:* 7–14 days *Children:* 10–14 days	Tablets: 500 mg Capsules: 250 mg Suspension: 125, 250 mg/ 5 mL	Should be taken with food to decrease GI upset

Continued

Table 42–2 � **Drugs Commonly Used: Community-Acquired Pneumonia—cont'd**

Drug	Dose	Length of Treatment	Strengths Available	Comments
Erythromycin ethylsuccinate (E.E.S., EryPed)	*Adults:* 400–800 mg q6h–12h *Children:* 30–50 mg/kg/d divided in q6h *or* q12h dosing	*Adults:* 7–14 days *Children:* 10–14 days	Tablets: 400 mg Chewable tablets: 200 mg Drops: 100 mg/2.5 mL Suspension: 200, 400 mg/ 5 mL	Should be taken with food to decrease GI upset
Gatifloxacin (Tequin)	*Adults ≥18 yr:* 400 mg daily	7–14 days	Tablets: 400 mg	Expensive
Levofloxacin (Levaquin)	*Adults:* 500 mg once a day	7–14 days	Tablets: 250, 500 mg Injection: 500 mg	Expensive
Moxifloxacin (Avelox)	*Adults ≥18 yr:* 400 mg once a day	7–14 days	Tablets: 400 mg	Expensive
Ofloxacin (Floxin)	*Adults ≥18 yr:* 400 mg q12h	10 days	Tablets: 400 mg	Expensive
Sparfloxacin (Zagam)	*Adults ≥18 yr:* 400 mg PO day 1 then 200 mg PO daily for 10 days	10 days	200 mg tablets	Expensive

pneumonia is less common. The viral infection affects the lung defenses, setting the stage for secondary bacterial infection. Prior to universal PCV7 vaccination, the pathogen was identified as *S. pneumoniae* in 73% of bacterial pneumonia cases and in 24% to 33% of all cases of childhood pneumonia (Michelow et al, 2004).

The prevalence of *S. pneumoniae* is decreasing, but it remains the leading cause of bacterial pneumonia in children, especially in those under age 5 (Su-Ting & Tancredi, 2010). The emergence of drug-resistant *S. pneumonia* is increasingly prevalent (CDC, 2012b). The clinical findings may include the following: fever (usually high), cough, shaking and chills, tachypnea, tachycardia, cyanosis, fine crackles (rales), decreased breath sounds, abdominal pain, and vomiting. Oxygen saturation less than 94% may be present. Symptoms can worsen suddenly, and children can become quite ill. Definitive diagnosis of a bacterial infection is difficult to obtain without positive culture on sputum aspirate, although a chest x-ray demonstrates lobar consolidation (Bradley et al, 2011). Blood cultures are not routinely necessary in nontoxic, fully immunized children managed in the outpatient setting but are recommended if these children fail to demonstrate clinical improvement or if there is clinical deterioration after initiation of antibiotic therapy (Bradley et al, 2011). A complete blood count is no longer recommended for routine outpatient management of pneumonia but may be warranted if the pneumonia presentation is severe (Bradley et al, 2011). If pneumatoceles are seen on chest x-ray, suspect staphylococcal pneumonia.

Drug Therapy

If *S. pneumoniae* is the suspected organism based on the clinical picture in previously healthy, appropriately immunized infants, preschool, school-aged, and adolescent children, high-dose amoxicillin (90 mg/kg daily, divided in two doses) is the drug of choice for 7 to 10 days of outpatient treatment

(Bradley et al, 2011)). If highly resistant pneumococci are in the community, the practitioner may choose between IV or IM ceftriaxone (50 mg/kg in one daily dose) or cefotaxime (150 mg/kg/d every 8 hours) followed by appropriate oral therapy after 1 or 2 doses (Bradley et al, 2011). Vancomycin has not been shown to be more effective than a third-generation cephalosporin with DRSP, yet is recommended if clinical, laboratory, or imaging characteristics are consistent with an infection caused by *S. aureus* (Bradley et al, 2011). Patients who are treated early in the course of the illness usually respond to high-dose amoxicillin. *S. pneumonia* may be resistant to macrolides (AAP, 2009c) but are recommended for CAP caused by atypical pathogens (Bradley et al, 2011). Macrolides are not considered first-line therapy for children under age 5 due to the most common pathogen being either *pneumococcus* or a virus (Bradley et al, 2011).

If *S. aureus* is the confirmed or highly suspected organism, the preferred oral regimen for methicillin-susceptible cases is cephalexin (75 to 100 mg/kg/d in 3 to 4 doses) or an alternative of clindamycin (30 to 40 mg/kg/d in 3 to 4 doses), with cefazolin, oxacillin, clindamycin, or vancomycin in hospitalized cases (Bradley et al, 2011). Vancomycin would be added to the regimen if methicillin-resistant *S. aureus* (MRSA) is suspected. Patients with *S. aureus* pneumonia are usually quite ill and require hospitalization for at least a few days. They may require a chest tube if there is significant empyema.

Children and Adolescents With Mycoplasma Pneumonia

Mycoplasma pneumonia is the most common type in children over age 5 years, with approximately 10% of school-age children presenting with symptoms consistent with atypical or mycoplasma infection (AAP, 2012b). The disease is usually mild. The typical history includes upper respiratory symptoms, fever, dry cough, malaise, sore throat, headache, and possibly chills. Symptoms often last for 3 to 4 weeks (AAP, 2012b). A

maculopapular rash may develop in up to 10% of children with mycoplasma pneumonia (AAP, 2012b). *M. pneumoniae* may be associated with asthma exacerbation. The patient may have been treated with amoxicillin for "bronchitis" without improvement. Chest x-ray reveals bronchovascular markings with areas of atelectasis. A polymerase chain reaction (PCR) test for *M. pneumoniae* is the standard, with 80% to 100% sensitivity and specificity, as a culture may take up to 21 days (AAP, 2012b). Serum cold hemagglutinin titers are nonspecific and only positive in 50% of children with mycoplasma pneumonia (AAP, 2012b).

Drug Therapy

Mycoplasma pneumonia is usually mild and will resolve without treatment, although observation data indicate children will have a shorter duration of symptoms and fewer relapses if treated with an antimicrobial (AAP, 2009b). The treatment of choice for mycoplasma pneumonia is a macrolide. The preferred oral treatment is azithromycin (10 mg/kg on day 1 and 5 mg/kg on days 2 through 5), though as an alternative clarithromycin (15mg/kg/day in 2 doses) or erythromycin (40 to 50 mg/kg daily is given qid or tid or, for larger children, 333 mg PO tid for 10 days) is an option (AAP, 2012b; Bradley et al, 2011). Erythromycin is inexpensive and provides good coverage for other atypical organisms. Azithromycin (Zithromax) is also packaged in a "Z-pak," a 5-day dose pack for older children or children over 50 kg; printed on the package are instructions to take two 250 mg capsules on day 1 and one capsule daily thereafter. Because mycoplasmas lack a cell wall, they are inherently resistant to beta lactam agents.

Monitoring

Patients with bacterial pneumonia need to be monitored closely for clinical improvement or deterioration. If children are being treated with the appropriate antibiotic, they often show rapid improvement, much faster than adults. Children can also deteriorate rapidly, and any infant or young child who is not hospitalized needs to be seen in the clinic the following day for reassessment. Recommendations are that families receive clear instructions regarding the symptoms of deterioration in respiratory status.

If cultures are drawn, results are usually available in 24 hours, and the practitioner needs to determine (1) if the appropriate antibiotic has been chosen and (2) the level of resistance the organism has to the chosen antibiotic. If the patient is improving clinically, there is no need for repeat blood counts or cultures. If the patient is not improving or the clinical condition worsens, a chest x-ray can determine if effusions or empyema are developing. Routine chest radiographs are not recommended for the confirmation of suspected CAP in pediatric patients well enough to be treated in the outpatient setting but should be obtained in those with suspected or documented hypoxemia, significant respiratory distress, those who have failed initial antibiotic therapy, and those who are being admitted (Bradley et al, 2011).

Patients with mycoplasma pneumonia should be monitored for clinical improvement. The cough may last for weeks after the infection is treated. *M. pneumoniae* can spread to the blood, central nervous system, heart, skin, and joints, so monitoring for these complications is prudent. A child with sickle cell disease who contracts mycoplasma pneumonia develops a more severe pulmonary disease than the average child.

All children with pneumonia need monitoring of their hydration status. Nutritional intake should also be assessed in infants who may be ill for a few days. The parents' ability to successfully administer medication and their ability to monitor their child's status are essential to the successful outpatient treatment of children with pneumonia.

Outcome Evaluation

Like the adult patient, the child with pneumonia must be monitored for response to the antibiotic therapy. The child should become afebrile in 24 to 48 hours. There may be a residual cough for weeks, which should lessen with time. If the child's clinical status fails to improve in 48 to 72 hours, then the treatment plan must be reconsidered. There may be bacterial resistance to the antibiotic, or the patient might have mycoplasma pneumonia, which requires a macrolide antibiotic.

Patient Education

Patient education when a child has bacterial pneumonia focuses on the following:

1. How to assess the child's respiratory status and signs of respiratory deterioration. Clear instructions, such as "If breathing over __ breaths per minute, call the practitioner," help parents monitor their child at home.
2. A clear plan of where the parents should take a child whose status worsens during the evening or night. Given the variable insurance rules regarding afterhours care, the practitioner needs to explain to parents how to access high-quality pediatric after-hours care in the event of deterioration in the child's status. Not all urgent-care clinics are equipped to handle a child in respiratory distress, and an emergency room is probably the best place for the child to be assessed. Use of the emergency 911 system for respiratory distress should be discussed with families, with clear guidelines given as to what constitutes respiratory distress.
3. How to administer medication appropriately. Make sure the parents have a medicine syringe to accurately administer the oral medications. Some medications must be taken on an empty stomach and others must be taken with food, and the parents need to be reminded about any special instructions regarding the administration of the antibiotic.
4. The parents need to know how to assess hydration and what parameters are expected for urine output. Instructions that clearly define minimum output are the easiest to understand; for example, "Your infant should have a wet diaper every 6 to 8 hours at a minimum."

SMOKING CESSATION

Benjamin J. Miller

The current rate of adults over age 18 years who smoke cigarettes in the United States is 18%, representing a steady decline in smoking rates from a high of 41.9% in 1965 (National Center for Health Statistics, 2013). Tobacco is the leading cause of preventable illness and death in the United States, contributing to more than 443,000 deaths annually, including an estimated 49,000 deaths from secondhand exposure (National Cancer Institute, National Institute of Health, 2012). Tobacco use contributes to the development of cancers, cerebrovascular disease, cardiovascular disease, dental disease, gastrointestinal (GI) disorders, and respiratory disease, making it the most preventable health problem in developed countries. Smokers who do not quit by age 35 have a 50% chance of dying from a tobacco-related disease.

Patients' tobacco use needs to be addressed by all primary care providers, especially those who care for children; the 2006 National Survey on Drug Use & Health indicated that 7.1% of middle school students and 23.2% of high school students use tobacco in some form (Centers for Disease Control [CDC], 2012). Secondhand or environmental exposure to tobacco smoke also poses a health hazard to nonsmokers, and the health-care provider plays an important role in educating parents of young children about the effects of secondhand smoke. Education about secondhand smoke should be used as an opportunity to offer tobacco cessation to the smoking family member, thereby decreasing the health risks for the whole family.

A review of the physiological and psychological process of addiction will assist the health-care provider in understanding the rationale for pharmacological intervention. Tobacco smoke contains many different chemicals, many of them known health hazards (ammonia, formaldehyde, carbon monoxide, benzene, arsenic, and lead). The addictive component in tobacco is nicotine. Nicotine has all the components of an addictive substance, similar to those of heroin, in which "addiction is characterized by compulsive drug seeking and use, even in the face of negative health consequences" (National Institute on Drug Abuse, 2006).

The many forms of tobacco include cigarettes, pipes, cigars, smokeless tobacco, electronic cigarettes, and snuff, and patients can be addicted to any of them (see Box 43-1). The health-care provider needs to assess if the patient is using any form of tobacco and address cessation in the patient's plan of care. Although behavioral modification also plays an essential role in quitting, it is discussed only briefly as a component of the treatment plan because this chapter focuses on pharmacological management. According to a recent meta-analysis of 38 studies with more than 15,000 participants, the success rate of smoking cessation will increase   by 16% with combined behavioral therapy/pharmacological management versus pharmacological management alone (Stead & Lancaster, 2012).

TOBACCO-CESSATION THERAPIES

The future looks promising for tobacco-cessation therapies. Currently, a sublingual form of nicotine replacement, in a 2 mg or 4 mg dose, is available in Europe and Canada. Scientists are also investigating the potential of a vaccine that stimulates antibodies that block nicotine receptors in the brain and will be used to prevent relapse in smokers who quit. A recent study examining nicotine vaccinations found the vaccines were safe and well tolerated; however, insufficient antibodies developed that would lead to a significant long-term effect on relapse prevention (Tonstad et al, 2013).

PATHOPHYSIOLOGY

Nicotine is a naturally occurring substance that is soluble in water and lipids. It is readily absorbed from many sites, including the lungs, mucosa, skin, and GI tract.

Nicotine Delivery

Nicotine is absorbed rapidly from tobacco smoke into the pulmonary circulation. It is then transported via the bloodstream to the brain, where it reaches the nicotine cholinergic receptors in 10 to 15 seconds after a puff. The mean time to peak concentration in the bloodstream is 7 to 8 minutes. Each puff contributes to maintaining the nicotine concentration. With each cigarette averaging 10 puffs, the pack-a-day smoker reinforces the blood nicotine level 200 times per day, with each puff providing distinct reinforcement of the habit. Smokeless tobacco is absorbed more slowly from the oral or nasal cavity.

BOX 43–1 ELECTRONIC CIGARETTES

Electronic cigarettes or e-cigarettes are growing in popularity as an alternative to traditional tobacco use, with U.S. sales expected to exceed $1 billion in 2013. E-cigarettes are battery-operated devices that deliver nicotine via inhaled vapor, eliminating the harmful tars and carbon monoxide. At present, there is considerable controversy over the health implications of e-cigarettes, which has attracted the attention of the FDA and the CDC (Sutfin, McCoy, Morrell, Hoeppner, & Wolfson, 2013).

Because of the ability to regulate the nicotine content, there may be a role for e-cigarettes in nicotine replacement therapy and tobacco cessation. In a small study of 86 tobacco users, the use of 18 mg of nicotine resulted in a significant decrease in withdrawal symptoms compared to a control group (Dawkins, Turner, Hasna, & Soar, 2012). These data suggest there may be a future role for e-cigarettes; however, no evidence-based recommendations can be made at this time. Further study of the potential toxic effects of e-cigarette chemicals is warranted before large scale studies occur.

Nicotinic Receptors

The neuronal nicotinic receptors appear to be complex, with the complexity contributing to the different responses to nicotine agonists. Chronic use of nicotine results in an increased number of brain nicotinic receptors, which appears to be an important factor in the development of tolerance of and dependence on nicotine.

Nicotine has both stimulant and depressant effects in the central nervous system (CNS). The stimulant effect is exerted mainly at the cortex, producing increased alertness and cognitive performance. Nicotine activates the nucleus accumbens "reward" system in the limbic system, causing increased extracellular fluid dopamine levels in the region. This increases the "reinforcing" quality of nicotine. IV administration of nicotine activates neurohormonal pathways, releasing acetylcholine, norepinephrine, dopamine, serotonin, vasopressin, beta endorphins, growth hormone, and adrenocorticotropic hormone (ACTH).

Nicotine Withdrawal Syndrome

Nicotine withdrawal syndrome is characterized by craving, nervousness, irritability, impatience, hostility, labile mood, difficulty in concentrating, restlessness, and anxiety. Physical symptoms include decreased heart rate, increased appetite, and weight gain averaging 8 to 11 pounds (Aubin, Farley, Lycett, Lahmek, & Aveyard, 2012). Somatic complaints such as myalgia, headache, constipation, and fatigue are common. The urge to smoke is closely related to low blood nicotine levels, which bring on early morning withdrawal symptoms. The smoker may not be smoking to achieve the effects of nicotine but rather to avoid withdrawal symptoms.

GOALS OF TREATMENT

A critical step in treatment of tobacco use is identifying patients who are ready to quit. Every health-care encounter should encompass screening for tobacco use and assessment for the readiness to quit. The initial intervention for treatment of tobacco use includes the Advise, Assess, and Refer (AAR) approach, which involves a conversation with the patient, assessing readiness to quit, and then giving the patient a referral to a tobacco treatment specialist or local tobacco quit line. In a recent study by Vidrene and colleagues (2013), a novel approach to smoking treatment focuses on making a referral to a tobacco quit line that contacts the patient, which resulted in a 13-fold increase in treatment compared to those who were given information and asked to make a call.

The goal of tobacco cessation treatment is the complete discontinuation of tobacco. It can be achieved either "cold turkey" without pharmacological intervention or by using nicotine replacement therapy, which is then gradually reduced over time to zero. If bupropion (Zyban) is used, the goal is for the patient to be tobacco-free at the end of the 7 to 12 weeks of therapy. Twelve weeks is the recommended treatment length if varenicline (Chantix) is prescribed.

RATIONAL DRUG SELECTION

The pharmacological management of tobacco cessation involves three different treatment modalities: nicotine replacement therapy, the antidepressant bupropion, and the nicotine receptor partial agonist varenicline. The combination of bupropion and nicotine replacement via a nicotine patch or lozenge may provide higher long-term rates of smoking cessation (Jorenby et al, 1999; Piper et al, 2009; Steinberg et al, 2009); however, one recent study suggests there is no superiority of combined therapy when controlling for behavioral modification (Stapleton et al, 2013). All of the nicotine replacement therapy products deliver nicotine to the CNS at a lower dose and slower rate than do tobacco cigarettes, and all the products can double quit rates (Abramowicz, 2003). Varenicline (Chantix) has a reported a continuous abstinence rate of 43.9% after 9 to 12 weeks of therapy (Garrison & Dugan, 2009).

Nicotine Replacement Therapy

Nicotine replacement therapy comes in five different forms: gum, lozenge, transdermal patch, inhaler, and nasal spray. The gum and transdermal patch Nicotrol, the transdermal patch Habitrol, and the lozenge Commit are available over-the-counter (OTC); the inhaler (Nicotrol Inhaler) and the spray (Nicotrol NS) are by prescription. Although the patient can self-treat with the OTC products, the health-care provider should educate the patient regarding their proper use to ensure successful treatment. Nicotine replacement does not achieve the same peak levels of nicotine as does smoking, but it does achieve a level high enough to suppress nicotine withdrawal symptoms. Nicotine replacement therapy is recommended for patients who smoke more than 20 cigarettes per day (one pack), patients who smoke within 30 minutes of awakening in the morning, and patients who have tried to quit previously and have failed because of strong withdrawal symptoms and craving within the first week of quitting. Cooper and colleagues (2004) found that patients treated with nicotine replacement therapy combined with nonpharmacological interventions (behavioral counseling or telephone intervention contact) reported greatest adherence to treatment.

Nicotine polacrilex gum is Pregnancy Category C, and transdermal nicotine is Pregnancy Category D, as nicotine is associated with decreased fetal breathing movements, probably caused by decreased placental perfusion. Nicotine replacement therapy is contraindicated for people with a hypersensitivity to nicotine and should be used with caution in persons immediately after myocardial infarction (MI) and in patients with life-threatening arrhythmias and severe or worsening angina pectoris because of increases in heart rate.

Nicotine Gum

Nicotine gum improves smoking cessation rates by 40% to 60% compared with controls through 12 months of follow-up. The active ingredient in nicotine gum (Nicorette) is nicotine polacrilex, a nicotine resin complex. The nicotine is bound to an ion-exchange resin that is released only during chewing. The medication is administered when the patient places a piece of gum in his or her mouth and chews slowly five to eight times, until a peppery taste appears. The patient then "parks" the gum in the buccal space. Intermittent chewing and parking the gum over a period of 30 minutes promotes slow buccal absorption. Chewing too quickly causes an excess amount of nicotine to be released into the bloodstream, producing nausea, throat irritation, and hiccoughs. The patient should avoid smoking while chewing nicotine gum because toxicity symptoms may occur (nausea, vomiting, and headache). Nicotine gum should not be the first-line choice for patients with temporomandibular joint (TMJ) disease or peptic ulcer disease on account of adverse effects.

Nicotine polacrilex gum takes 30 minutes to reach its peak serum concentration. The patient who is just beginning a tobacco-cessation program should chew one piece of 2 or 4 mg gum per hour. Abstinence rates appear to be higher when the patient chews the gum on a fixed schedule of every hour or every 2 hours. The patient who smokes more than 25 cigarettes per day should be started on the 4 mg dose initially and not exceed the maximum number of pieces per day of gum (30/d of 2 mg, 20/d of 4 mg). Acidic foods (coffee, soft drinks, juice) interfere with the buccal absorption of nicotine from nicotine polacrilex and should be avoided for 15 minutes before, during, and after chewing the gum.

After the patient has successfully quit smoking for 6 weeks, a gradual weaning of the gum dosage should begin. Suggestions for a gradual withdrawal of treatment are as follows:

1. Weeks 7 to 9, chew one piece of gum every 2 to 4 hours.
2. Weeks 10 to 12, chew one piece of gum every 4 to 8 hours.
3. After 12 weeks, discontinue nicotine gum and suggest substituting sugarless gum if needed.

Online support for quitting smoking is available from the brand-name drug manufacturer at www.nicorette.com; the program includes tools for dealing with cravings and lapses.

Nicotine Lozenge

Nicotine polacrilex lozenge (Nicorette Lozenge) is indicated as an adjunct in smoking-cessation therapy. The usual dose is either a 2 mg or 4 mg lozenge, based on how early in the day the smoker smoked the first cigarette. If a smoker has the first cigarette of the day 30 minutes or more after awakening, then the 2 mg lozenge is indicated. The 4 mg lozenge is used if the smoker has the first cigarette within 30 minutes of arising. The lozenge dissolves over 20 to 30 minutes with peak serum levels of nicotine reached in 20 to 30 minutes after the lozenge dissolves in the mouth. The patient should not chew or swallow the lozenge because there is a significant first-pass metabolism that will decrease bioavailability (Abramowicz, 2003). The patient should use 1 lozenge every 1 to 2 hours for

the first 6 weeks, at least 9 lozenges per day with a maximum of 20 lozenges per day. Dosing should taper based on a set schedule similar to that for nicotine polacrilex gum:

1. Weeks 1 to 6, one lozenge every 1 to 2 hours.
2. Weeks 7 to 9, one lozenge every 2 to 4 hours.
3. Weeks 10 to 12, one lozenge every 4 to 8 hours.

CLINICAL PEARL

Nicotine Gum
Patients complain about the taste of the nicotine gum. Suggest that the patient try the flavored variety, which patients seem to tolerate better.

The patient should not eat or drink for 15 minutes before or while the lozenge is dissolving in the mouth. There may be a tingling sensation in the mouth as the lozenge dissolves. Online quitting support is available at http://www.nicorette.com/.

Nicotine Transdermal System

The transdermal nicotine system, or "patch," provides a slow, cutaneous absorption of nicotine over many hours. The patch is applied to clean, nonhairy skin on the upper body or upper arm when the patient wakes up. Peak nicotine levels occur in 2 to 6 hours (brand-dependent) and then gradually decrease. Once the patch is removed, nicotine levels in the blood reach a nondetectable level in 10 to 12 hours in nonsmokers. There are different strengths of patches available and patches that are for 16-hour and for 24-hour use, allowing for dose regulation (Table 43-1). The 16-hour patch works well for the light to average smoker but is not effective for early morning withdrawal symptoms. The 24-hour patch provides a steady-state blood level of nicotine, with minimum peaks and troughs, and avoids morning withdrawal symptoms. The disadvantage of the 24-hour patch is that there are more adverse effects, including sleep disruption. Evaluating the patient's smoking habit and determining if early morning withdrawal is an issue will enable the provider to recommend the best transdermal system for the patient. Transdermal nicotine approximately doubles 6- to 12-month abstinence rates over those produced by placebo interventions.

The transdermal nicotine system has the advantage of delivering a steady-state level of nicotine that prevents nicotine withdrawal symptoms while allowing the smoker to work on the behavioral aspects of quitting. Unlike nicotine gum, the patch has the advantage of not reinforcing the oral aspects of smoking. Patients appreciate the ease of administration and once-daily dosing. Weaning off the transdermal nicotine system is accomplished by decreasing the dose of the patch on a scheduled basis. Longer duration of use and weaning, rather than abrupt withdrawal of the nicotine patch, had the greatest effectiveness in a review of nicotine replacement for smoking cessation (Silagy, Lancaster, Stead, Mant, & Fowler, 2004).

One disadvantage of the nicotine patch is that patients report they are unable to self-regulate the dose if they are exhibiting withdrawal symptoms. This makes the patch less effective for highly dependent smokers, and a highly dependent smoker who is started on a transdermal nicotine system should be started on a high-dose, 24-hour system to decrease withdrawal symptoms. The patient *must* refrain from smoking while using the nicotine patch because life-threatening dysrhythmias or acute myocardial infarction may occur.

The most common adverse effect of the nicotine patch is skin irritation, with 35% to 47% of patients reporting some skin irritation during clinical trials. Advising the patient to change the site every day and not to reuse the site within a week can minimize this problem. The amount of skin irritation differs with the brand and dose used, so a change may alleviate the problem. If the patient exhibits symptoms of sleep disturbance or insomnia while using the transdermal nicotine system, first determine whether the patient has signs of too high a dose or early morning withdrawal. Delayed onset of sleep is usually associated with too high a dose and early awakening is associated with withdrawal symptoms. The provider can either switch the patient from the 24-hour to the 16-hour patch to decrease the dose or, if the patient is already using the 16-hour patch, decrease the dose. If withdrawal is the problem, then increase the patch from a 16-hour to a 24-hour or increase the dose of the patch. The patient needs to be aware that some adjustment of the dose may be necessary to provide effective relief of symptoms with minimum adverse effects. Advise the patient to report any adverse effects so that adjustments can be made.

Other adverse effects observed include symptoms of nicotine toxicity (headache, nausea, and vomiting) with higher-dose patches and with smoking while using a patch. If symptoms of toxicity occur, remove the patch and flush the skin area with water. *Do not use soap,* which increases nicotine absorption from the site. Nicotine will continue to be delivered into the bloodstream for a number of hours because there is a deposit of nicotine under the skin. Patients should report any symptoms of toxicity immediately to their healthcare provider. Generic transdermal nicotine is available at substantial savings to the patient.

Nicotine Nasal Spray

Nicotine nasal spray (Nicotrol NS) is an inhaled form of nicotine replacement therapy. The usual dose is 1 to 2 sprays in each nostril per hour, not to exceed 5 doses (10 sprays) per

---

CLINICAL PEARL

Nicotine Patch
Advise patients to dispose of used nicotine patches out of the reach of children or animals. Enough nicotine is left in a *used* patch to lead to toxic levels in a child or small animal.

Table 43–1 ⊗ Drugs Commonly Used: Smoking Cessation

Drug	Strength Available	Dosage	Comments
Nicotine Gum			
Nicotine polacrilex (Nicorette)	2, 4 mg	If smoking <20–25 cigarettes/d: chew one 2 mg piece every 1–2 h (at least 9/d), max of 30/d If smoking >20–25 cigarettes/d: chew one 4 mg piece every 1–2 h (at least 9/d), max of 20/d After 6 wk decrease dose to 1 every 2–4 h for 3 wk, then 1 piece every 4–8 h for 3 wk, and then discontinue Alternative: After 6 wk, gradually wean the dose by decreasing one piece of gum/d every 4–7 days	Abstinence rates are higher if gum is chewed on a scheduled basis, rather than prn. Acidic foods and drinks interfere with absorption, so they should be avoided during and for 15 min before and after chewing nicotine gum. The use of nicotine gum for longer than 6 mo is not recommended.
Nicotine Transdermal Patch			
Habitrol (OTC)	21 mg/d 14 mg/d 7 mg/d	If >10 cigarettes/d: 21 mg/d for first 6 wk, 14 mg/d for next 2 wk, and 7 mg/d for final 2 If ≤10 cigarettes/d: 14 mg/d for 6 wk, then 7 mg/d for final 2–4 wk *Length of treatment:* 8–12 wk	24-h patch Apply to clean, nonhairy area on upper body or upper arm upon waking. Rotate application site.
Nicoderm CQ (OTC)	21 mg/d 14 mg/d 7 mg d	21 mg/d for first 6 wk, 14 mg/d for next 2 wk, and 7 mg/d for final 2 wk *Low-dose regimen:** 14 mg/d for 6 wk, then 7 mg/d for final 2–4 wk *Length of treatment:* 8–12 wk	24-h patch Apply to clean, nonhairy area on upper body or upper arm upon waking. May remove after 16–24 h.
Nicotrol Step-Down Patch (OTC)	15 mg/6 h 10 mg/16 h 5 mg/16 h	15 mg/16 h for first 6 wk, 10 mg/16 h for 2 wk, then 5 mg/16 h for final 2 wk *Alternative:* Use 15 mg/16 h patch daily for 6 wk, then discontinue *Length of treatment:* 10 wk	16-h patch Apply to clean, nonhairy area on upper body or upper arm upon waking. Remove after 16 h (before bed).
Prostep (OTC)	22 mg/d 11 mg/d	22 mg/d for 4–8 wk, then 11 mg/d for 2–4 wk *Low-dose regimen*:* 11 mg/d for 4–8 wk *Length of treatment:* 6–12 wk	24-h patch Apply to clean, nonhairy area on upper body or upper arm upon waking.
Nicotine Nasal Spray			
Nicotrol NS (Rx)	0.5 mg/spray 1 dose = 1 mg, or 1 spray in each nostril	Start with 1–2 doses (2–4 sprays)/h, max of 5 sprays/h, 40 sprays/d *Length of treatment:* max 3 mo	Can be used ad lib. Advise patient not to sniff, inhale, or swallow the spray.
Nicotine Inhaler			
Nicotrol inhaler (Rx)	10 mg/cartridge (4 mg nicotine delivered)	Patient puffs on mouthpiece frequently and continuously for 20 min. Initially, begins with at least 6 cartridges/d (max 16 cartridges/d) for the first 3–6 wk. Gradually decrease over 12 wk *Length of treatment:* max 6 mo	Provides oral stimulation similar to smoking.
Nicotinic Receptor Partial Agonists			
Varenicline (Chantix)	Strength: 0.5, 1.0 mg	*Patients ≥18 yr:* 0.5 mg PO daily for the first 3 d, then 0.5 mg bid days 4–7. On day 8 increase to 1.0 mg bid. *Length of treatment:* 12 wk; may continue for another 12 wk	Start 1 wk before quit date. Take on full stomach with a glass of water. Reduce dose if intolerable nausea or other side effects occur. Monitor closely for signs of mood change or suicide ideation.
Antidepressant			
Bupropion (Zyban) (Rx)	150 mg tablet	*Patients ≥ 18 yr:* Begin 150 mg/d 1–2 wk prior to quit date. Increase dose to 150 mg bid (at least 8 h apart) after 3 d. *Length of treatment:* 7–12 wk	May be combined with nicotine replacement. Avoid bedtime dosing, which may cause insomnia. Do not use with other forms of bupropion. Monitor closely for signs of mood change or suicide ideation.

*Low-dose therapy is used for patients weighing less than 100 lb, patients with cardiovascular disease, and patients who smoke one-half pack per day or less.

OTC = over the counter.

hour and not to exceed 40 doses (80 sprays) per day. The advantage to nicotine nasal spray is rapid achievement of peak blood levels, with peak levels reached in 4 to 15 minutes after a single 1 mg (2 spray) dose. This speed is advantageous for patients who report severe withdrawal symptoms because the rate of absorption into the bloodstream is similar to that of smoking cigarettes, providing immediate relief of withdrawal symptoms through self-administration. Patients can have a sense of control over their nicotine cravings.

Patients need to be instructed *not to inhale, swallow, or sniff* the spray, unlike many other inhaled medications. The most common adverse effect is nasopharyngeal and ocular mucosa irritation. The use of nicotine nasal spray can cause serious arrhythmias and elevated blood pressure and should be avoided immediately after MI because it may cause angina. If the patient is experiencing any cardiac symptoms, then nicotine nasal spray (Nicotrol NS) can be abruptly discontinued, an advantage of this delivery system over the longer-acting nicotine products.

With nicotine nasal spray, there is potential for abuse, as patients report a "head rush" and the sensation of feeling good, similar to that of cigarette smoking. Careful monitoring of the use of nicotine spray and advising patients of the potential for replacing their cigarette addiction with an addiction to the nicotine spray can help to avoid this problem. Three months is the recommended maximum length of treatment with nicotine nasal spray.

Nicotine Inhaler

The nicotine (Nicotrol) inhaler is a unique delivery method of nicotine replacement therapy in that the medication stimulates the act of smoking a cigarette. The inhaler consists of two parts, a cartridge containing 10 mg of nicotine (4 mg of delivered drug) and a mouthpiece. The patient puffs continuously on the inhaler for 20 minutes, providing the nicotine equivalent of two cigarettes. The patient should use at least 6 cartridges per day for 3 to 6 weeks. A maximum of 16 cartridges is used for the first 12 weeks. After 12 weeks the dose is reduced gradually, with a maximum of 6 months of treatment. Adverse effects include coughing, mouth and throat irritation, and dyspepsia.

Antidepressants

Antidepressants are thought to be helpful in smoking cessation because of the relationship between depressed mood and smoking behavior. During tobacco withdrawal, patients often exhibit depressed and anxious moods. Several antidepressants, including bupropion, doxepin, and nortriptyline, have been shown to be effective in smoking cessation. This chapter discusses bupropion (Zyban), currently the only antidepressant approved by the U.S. Food and Drug Administration (FDA) for smoking cessation.

Bupropion

Bupropion is chemically unrelated to other antidepressants, and the mechanism by which it enhances the ability to abstain from smoking is unknown. It is presumed that bupropion's action as a weak inhibitor of neuronal uptake of dopamine and norepinephrine accounts for its ability to assist in smoking cessation. Bupropion is started 1 to 2 weeks before the quit-smoking date. The patient begins taking 150 mg daily for 3 days and then increases the dose to 150 mg twice a day at least 8 hours apart, avoiding bedtime dosing. On the quit day, the patient can quit cold turkey or use a nicotine replacement therapy along with the bupropion. Bupropion and the nicotine patch are a successful combination, more successful than the nicotine patch alone. Therapy continues for 7 to 12 weeks, although treatment may be extended an additional 12 weeks up to 6 months if smoking cessation is successful. If the patient has not made significant progress toward quitting by week 7 of treatment, it is unlikely he or she will successfully quit during the attempt and bupropion (Zyban) should be discontinued.

Bupropion is contraindicated in patients with seizure disorders, bulimia, and anorexia nervosa and within 14 days of the use of monoamine oxidase inhibitors (MAOIs). Bupropion should not be used in patients with a history of stroke, brain tumor, brain surgery, or history of closed head injury (Abramowicz, 2003). Frequency of dosing is reduced in patients with renal failure, as the drug and drug metabolites may accumulate. Bupropion should be used with caution in patients with hepatic cirrhosis, with the dose decreased to 150 mg every other day. Although it is Pregnancy Category B, it is not recommended during pregnancy or for use in children under age 18. Nondrug treatments should be tried first in pregnant patients. If used with nicotine replacement therapy, the patient should be monitored for hypertension. Bupropion is the active ingredient in Wellbutrin, used to treat depression. The concurrent use of bupropion (Zyban) and Wellbutrin is contraindicated. The most frequent adverse effects of bupropion are insomnia (40%), dizziness (10%), and dry mouth (10%). Constipation is also a reported adverse effect, and the patient should be advised to increase fiber and fluid intake during treatment.

Bupropion is the active ingredient in the antidepressant Wellbutrin and as such has received a Black-Box Warning regarding increased risk of suicide ideation and suicidality in children, adolescents, and young adults. Zyban is not approved for smoking cessation in children under 18 years of age. Patients prescribed Zyban should be monitored closely for signs of suicide ideation when treatment is started.

Nicotinic Receptor Partial Agonists

Varenicline (Chantix) was approved by the FDA in 2006 as a pharmacological aid to quit smoking. Varenicline is a partial agonist/antagonist with affinity and selectivity for alpha(4) beta(2) (α4β2) nicotinic acetylcholine receptors. Its mechanism of action appears to be its action as an agonist on the α4β2 receptors, as well as an antagonist preventing nicotine from binding to the receptors. Varenicline is highly selective to the α4β2 and is moderately selective to the 5-HT3 receptor.

By preventing binding of nicotine to the nicotinic receptors, there is less dopaminergic reinforcement and reward for smoking, as well as decreased withdrawal symptoms with smoking cessation. The patient experiences reduced cravings and decreased satisfaction with smoking.

To begin smoking cessation therapy with varenicline (Chantix), the patient chooses a quit date and varenicline is started 1 week before the scheduled quit date. Varenicline reaches steady state in 4 days from the onset of therapy. A titration of varenicline up to 1 mg twice a day is required, with the manufacturer suggesting a schedule of 0.5 mg once a day for the first 3 days, then 0.5 mg twice a day on days 4 to 7. The dose may be increased to 1 mg twice a day on day 8 and continue throughout treatment. Varenicline is administered with a full glass of water after eating. Treatment should continue for 12 weeks. If the patient has successfully quit smoking, treatment with an additional 12 weeks of therapy is thought to increase the long-term likelihood of abstinence.

Nausea is the most common adverse effect reported when taking varenicline, with 16% to 41% of patients reporting nausea compared to placebo in double-blind trials (Garrison & Dugan, 2009). Patients also report insomnia and headache at higher rates than placebo when taking varenicline. The most concerning adverse effect of varenicline has been found in post-marketing surveillance related to changes in behavior, agitation, depressed mood, suicidal ideation, and actual suicidal behavior (FDA, 2008). These concerns prompted a modification of the label highlighting a warning regarding neuropsychiatric symptoms and noting that Chantix was not studied in patients with preexisting serious psychiatric illness such as schizophrenia, bipolar disorder, and major depressive disorder, therefore safety in these patients had not been established.

Varenicline (Chantix) is Pregnancy Category C and is not recommended for pregnant or nursing women. Varenicline should not be prescribed for children under 18 years of age. Pharmacokinetic properties of varenicline in a small study ($N = 16$) of the elderly appears to be similar to those in younger adults, although as a renally eliminated drug, dosing may need to be adjusted in older patients with decreased renal function.

Alpha$_2$ Adrenergic Agonists

Clonidine has been used as a second-line treatment for smoking cessation, although this is not an approved indication by the FDA. Clonidine is available in tablets and patch and may be used in patients who refuse or cannot tolerate nicotine replacement, varenicline, or bupropion. The starting dose is 0.1 mg/d, increasing slowly to a maximum of 0.3 mg/d. Side effects are the same as if using clonidine for hypertension: dry mouth, sedation, dizziness, and hypotension (Abramowicz, 2003).

Combination Therapy

The Agency for Health Care Policy and Research (AHCPR) has published *Smoking Cessation: Clinical Practice Guidelines* (Fiore et al, 2008), which recommends that the provider

consider combining multiple first-line medications (level A evidence) for smoking cessation:

- Long-term (more than 14 weeks) nicotine patch plus other nicotine replacement therapy (NRT) (gum and spray)
- The nicotine patch plus the nicotine inhaler
- The nicotine patch plus bupropion SR (sustained release)

Steinberg and colleagues (2009) evaluated the use of triple-medication therapy (nicotine patch at 21 mg/d, nicotine oral inhaler to be used as needed, and bupropion 150 mg/d) in medically ill smokers, including those with cardiovascular disease, chronic pulmonary disease, cancer, hypertension, diabetes, and current pulmonary infection. The study found that patients who used a combination of nicotine patch, nicotine inhaler, and bupropion had a 16% higher abstinence rate at 6 months than did those who used nicotine patch alone (35% versus 19% [CI 1% to 31%]), with no higher incidence of adverse effects (Steinberg et al, 2009). This study is significant because it addresses the concerns of providers about prescribing smoking-cessation medications to patients with chronic illness, as well as validating the use of combination therapies.

Nonpharmacological Treatment of Nicotine Addiction

The AHCPR *Smoking Cessation: Clinical Practice Guidelines* recommends a number of nonpharmacological interventions (Fiore et al, 2008):

1. Smoking-cessation interventions should include either individual or group counseling. There is strong evidence (level A) that a combination of medication and counseling is more effective than is either method alone.
2. Smokers should be offered access to support through a telephone hot line, help line, or online support group, when feasible, as a self-help intervention.
3. Smoking-cessation interventions should include problem solving, skills training, relapse prevention, and stress management to increase cessation success rates.

The provider needs to consider quit rates and cost-effectiveness when determining what nonpharmacological smoking cessation therapy to recommend. Higher quit rates are found with more intensive therapies and use of multiple therapies, for example, combining behavioral counseling and individualized computer reports (Lerman, Patterson, & Berrettini, 2005; Ramon & Bruguera, 2009), a combination of counseling and pharmacological therapies, or a combination of pharmacological therapies (Fiore et al, 2008).

Other nonpharmacological therapies include hypnosis, acupuncture, and massage. Self-massage of the ear or hand with circular or stroking motions decreases feelings of anxiety, depressed mood, withdrawal cravings, and craving intensity in smoking patients attempting to quit (Hernandez-Reif, Field, & Hare, 1999). Relaxation and exercise are also central

to smoking-cessation therapy to counter the anxiety that is associated with nicotine withdrawal and to decrease the amount of weight gained during cessation. The successful treatment of the smoker who desires to quit will include a variety of treatment modalities, both pharmacological and nonpharmacological.

Patient Variables

Pregnant Women

A pregnant woman who smokes places herself and her fetus in danger. Smoking is associated with low birth weight and prematurity, as well as increased perinatal mortality. Smoking cessation during pregnancy is ideal for the developing fetus. Pregnant smokers are advised to quit smoking without the use of nicotine replacement therapy. The benefits and risks of nicotine replacement therapy have not been studied on pregnant patients, but the risk of smoking is thought to outweigh the short-term risk of low-dose nicotine replacement. Therefore, the FDA has classified nicotine gum as a Pregnancy Category C medication; the transdermal patch and inhaled forms continue to be classified as Pregnancy Category D. The manufacturer of Nicorette gum continues to recommend that nonpharmacological measures be used first. Bupropion (Zyban) and varenicline (Chantix) are not recommended during pregnancy.

Children

Children should never receive nicotine replacement products, bupropion, or varenicline for tobacco cessation. Their use is usually experimental, and children are rarely addicted to nicotine. Primary education about tobacco use is the appropriate method to be used with children who may be tempted to smoke. Toxic levels of nicotine are reached quickly in children, and all nicotine products should remain out of their reach. Adults should be advised to dispose of used nicotine patches in a safe manner so that children cannot touch or play with the used patch.

Adolescents

Adolescent patients pose a challenge because most adult smokers began as teenage smokers. The American Academy of Pediatrics, in *Guidelines for Adolescent Preventive Services* and *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents,* recommends screening for tobacco use beginning at the 11- to 14-year-old well-child care visit (Hagan, Shaw, & Duncan, 2008). Physically and psychologically, adolescents can be addicted to tobacco (Prokhorov, Pallonen, Fava, Ding, & Niaura, 1996). The peer group norm can lead teens to use tobacco, even when they know it is illegal and a poor choice for them to make. Tobacco-cessation programs in this age group need to be geared toward identifying the teen smoker early and providing support for quitting.

The provider who identifies a teen smoker who is ready to quit can choose a variety of options. It is essential for the teen to have a peer support group of other teen nonsmokers. Many schools have drug and alcohol counselors who organize support groups in the school. There has been minimal research in adolescents regarding nicotine replacement therapy. Because adolescent smokers report the same nicotine withdrawal and cravings as do adults, a teenager who smokes 20 or more cigarettes per day warrants the trial use of nicotine replacement. Transdermal nicotine replacement has been studied in adolescent patients and may be the best choice for treatment.

> **● CLINICAL PEARL ●**
>
> **Constipation and Tobacco Cessation**
> Many patients experience constipation during tobacco cessation as the stimulating effects of nicotine on the GI system are decreased. Increased dietary fiber, increased fluids, and use of a bulk-producing laxative (Metamucil or Citrucel) or osmotic laxative (Miralax) will help with this problem.

Buying tobacco products is illegal for adolescents under age 18, although a study of 4,078 adolescents found that 50% of respondents stated they could easily access nicotine replacement products (Klesges, Johnson, Somes, Zbikowski, & Robinson, 2003). Writing a prescription for the product and having the parent purchase the product will allow the patient access to nicotine replacement therapy legally. The adolescent needs to have clear directions regarding not smoking while using nicotine replacement and the symptoms of nicotine toxicity. Careful education and monitoring of the patient throughout therapy will decrease adverse outcomes.

MONITORING

The patient needs to be monitored closely during all phases of tobacco cessation. As patients begin therapy, they need to be monitored for signs of nicotine withdrawal or, in the case of nicotine replacement, nicotine toxicity (see Box 43-2). The dose of nicotine replacement can be adjusted up or down, based on a patient's clinical symptoms. As patients are weaned down on the dose of nicotine replacement (every 2 to 3 weeks), they need to be monitored for increasing withdrawal symptoms. After patients are weaned off nicotine replacement, they need to be continually assessed as to their abstinence from tobacco. It is not unusual for patients to

BOX 43–2 NICOTINE POISONING

Nicotine poisoning is a concern if children or pets ingest nicotine replacement products. There has been a rise in nicotine poisonings since e-cigarettes have appeared on the market (Chatham-Stephens et al, 2014). Ingesting even a small amount of nicotine may be toxic to young children. Symptoms of nicotine poisoning include nausea, vomiting, increased salivation, headache, and sweating. Seizures and respiratory failure may occur (Toxnet, 2014). Treatment for nicotine poisoning for mild toxicity is supportive (IV fluids, observation). Treatment for severe toxicity includes IV fluids, airway support, and mechanical ventilation, with atropine given for bradycardia or muscarinic signs (Toxnet, 2014).

relapse, and the health-care provider needs to provide support for their repeated attempts to quit.

Patients who are using varenicline for tobacco cessation need to be monitored for neuropsychiatric symptoms such as changes in behavior, agitation, depressed mood, suicidal ideation, and suicidal behavior. Patients and family members need to be informed to stop taking varenicline and report symptoms to their health-care provider immediately.

Smoking alters the metabolism of several medications, and patients taking them need to be monitored closely and the dosage of their medications adjusted accordingly as they successfully quit. Both smoking and nicotine can increase circulating cortisol and catecholamines. Patients taking adrenergic agonists (isoproterenol, phenylephrine) or adrenergic blockers (beta blockers) must be monitored closely as they decrease their nicotine dependence. Smoking may reduce the diuretic effects of furosemide and reduce cardiac output, and smoking cessation may reverse these actions. Glutethimide (Doriden) absorption may be decreased with smoking cessation. First-pass metabolism of propoxyphene (Darvocet) may be decreased with smoking cessation. Smoking cessation potentiates theophylline, insulin, pentazocine, oxazepam, tricyclic antidepressants (e.g., imipramine), caffeine, and acetaminophen. Careful assessment of medications that the patient is taking prior to beginning a tobacco-cessation program will decrease the adverse effects during cessation.

OUTCOME EVALUATION

The goal of tobacco cessation is for the patient to be nicotine free at the end of treatment. Understanding that nicotine is highly addictive and that there are behavioral patterns ingrained in a smoker's habit can help define successful treatment. The patient who quits smoking cold turkey and is successful over the long term clearly has a positive outcome. The patient who uses nicotine replacement, bupropion, or varenicline for a number of weeks and then is tobacco-free for a long period of time (more than 12 months) also has a positive outcome.

The reality of tobacco-cessation treatment is that many patients relapse. Recognizing that many smokers quit for a while 2 or 3 times before successfully achieving long-term cessation will enable the patient and the provider to view any period of abstinence as one step closer to long-term success. By supporting patients during this process and assuring them that they are not failures if they begin smoking again, the health-care provider preserves an environment in which patients can again attempt quitting when they are ready.

PATIENT EDUCATION

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues.

Patients should be taught that there is a relationship between smoking cessation and development of mouth ulcers, not related to the smoking-cessation medications. Forty percent of quitters develop mouth ulcers in the first 2 weeks after quitting, with most ulcers (60%) resolving by 4 weeks. The more dependent quitters are more likely to report ulcers (McRobbie, Hajek, & Gillison, 2004).

Educational Resources

Many resources pertaining to tobacco cessation are available for providers and patients. The American Lung Association (ALA) has local chapters that can provide posters; written educational materials to promote tobacco cessation; and materials for the Great American Smokeout, an annual anti-smoking event. Both the American Cancer Society (ACS) and the American Heart Association (AHA) have local chapters that can also provide educational materials to health-care providers. There are Web sites devoted to tobacco cessation that health-care providers can access. The key AHCPR *Clinical Guidelines* are available at http://www.ahrq.gov/clinic/tobacco. Smoking support information with links to multiple resources is available at the ALA Web site, http://www.lungusa.org. At the RxList Web site, http://www.rxlist.com, the provider can type in a medication and print or e-mail the patient information about the medication. With the abundance of resources available to the health-care provider, patient education should be easily incorporated into the care of the patient.

SMOKING CESSATION

PATIENT EDUCATION

Related to the Overall Treatment Plan/Disease Process

☐ Education regarding the physical and psychological aspects of tobacco addiction

☐ Role of lifestyle modifications

☐ Importance of adherence to the treatment regimen

☐ Need for regular follow-up visits with the primary care provider

Specific to the Drug Therapy

☐ Doses and schedules for taking the drug

☐ Possible adverse effects and what to do if they occur

☐ Interactions between other treatment modalities and these drugs

Reasons for Taking the Drug(s)

These drugs are given to help a person stop smoking. The medications that are used for smoking cessation need to be used as prescribed; overuse or underuse will increase treatment failure or lead to adverse effects. The patient needs to understand the danger of nicotine toxicity, know the symptoms, and have clear instructions to cease the medication and notify the health-care provider. The patient must not smoke while using a nicotine replacement. Nicotine replacement products, even after they are used, can be toxic to children and to pets; therefore, all of the products need to be handled carefully and disposed of properly after use.

Drugs as Part of the Total Treatment Regimen

The total treatment regimen includes nonpharmacological strategies. Nonpharmacological strategies such as relaxation, acupuncture, massage, exercise, and group therapy should be discussed and patients encouraged to incorporate multiple strategies to help them be successful.

A weight gain of 5 to 8 lb is common during tobacco cessation. Patients need to avoid strict diets during tobacco cessation and increase exercise during cessation treatment. After they have been tobacco-free for a few months, they can then work on weight reduction. Encouraging exercise during treatment will decrease the amount of weight gained.

Adherence Issues

Patients should know that having quit before and resumed their habit does not predict that they cannot be successful and that patients often quit for a while and then lapse 2 or 3 times before they succeed.

Many patients need external motivation to be successful at tobacco cessation. Identifying each patient's motivation and reminding her or him of it at each visit will assist patients in refocusing their goals when they feel like giving up. Common motivators include the health of their children or spouse and their own health. Pointing out the cost savings of quitting smoking, which can add up to over $250 a month for a pack-a-day smoker in New York City, where cigarettes are $9.00 a pack, can also help patients focus on their goal. Have them place a photo of what they will buy with their savings in a prominent place (the refrigerator or bathroom mirror) as a reminder.

SEXUALLY TRANSMITTED INFECTIONS AND VAGINITIS

Theresa Granger

Two common conditions seen by nurse practitioner providers are sexually transmitted infections (STIs) and vaginitis. The Centers for Disease Control and Prevention (CDC) has surveillance teams across the United States (West, Midwest, Northeast, and Southern regions) monitoring sexually transmitted infection rates. From this surveillance, the CDC collects demographic, regional, and infection rate data and provides treatment recommendations for those infections being monitored. In addition, due to the nationwide mandatory provider reporting of many of the sexually transmitted infections to the CDC, their recommendations remain the gold standard for patient and partner treatment of STIs. This chapter synthesizes the most recent CDC information available and provides the nurse practitioner with the most current treatment recommendations for sexually transmitted infections.

Vaginitis is an inflammation of the vagina that may be caused by STIs or may be the result of other factors. This chapter also discusses the pharmacological management of vaginitis.

SEXUALLY TRANSMITTED INFECTIONS

Management of STIs requires (a) recognizing and responding to vulnerable populations with high rates of sexually transmitted infections, (b) an understanding of drug resistance, and (c) an awareness of the escalating costs of treatment to the patient and to the health-care system. The estimated cost to our health-care system to monitor and treat infected individuals is approximately $17 billion dollars annually (CDC, 2011). In 2012, there were 1,422,976 cases of *Chlamydia trachomatis* infection, 334,826 cases of gonorrhea, 15,667 cases of primary and secondary syphilis, and 322 cases of congenital syphilis reported to the CDC (CDC Division of STD Prevention, 2014).

Populations at Risk

When screening for and treating STIs, nurse practitioners must be able to identify populations most at risk. The adolescent, young adult, and gay and bisexual male populations continue to be among those highest at risk. According to the CDC (2011), over half of the estimated 19 million new sexually transmitted infections occurring annually are among those individuals between the ages of 15 and 24. In the 2011 data gathered, men who have sex with men (MSM) accounted for 72% of all primary and secondary syphilis cases. The most reported infection rates, gonorrhea (62%) and chlamydia (71%), occur among 15- to 24-year-old individuals. Race and ethnic disparities in STI rates are present, with prevalence of

chlamydia, gonorrhea, and syphilis all higher in the black population (CDC Division of STD Prevention, 2014).

The number of patients requiring services for STIs has increased in proportion to those who are sexually active. Not every infected individual chooses to seek treatment. The reasons why those infected with STIs do not seek treatment vary and can be complicated. For example, homophobia and social stigma may be some reasons why certain high-risk groups (MSM) fail to seek appropriate care and treatment (CDC, 2011). Thus, it is important for the nurse practitioner to remain as empathetic and nonjudgmental as possible when treating vulnerable individuals.

Viral STIs such as the human papilloma and herpes simplex viruses are incurable and tend to produce lifelong periods of exacerbations and remissions. Women are at high risk for infertility if certain sexually transmitted infections remain untreated. This can pose a treatment challenge for the nurse practitioner because many of these infections can be "silent" and do not produce many symptoms until complications have occurred. Thus, it is important for nurse practitioners to screen early and often in susceptible, high-risk individuals.

Sexual health history is critical in order to determine the risk of STI. It has been suggested that many providers do not routinely obtain a sexual history (Swygard & Cohen, 2012). When conducting a health history, questioning the patient using the 5 P approach can be helpful in identifying patients at risk: (1) Partners, (2) Prevention of pregnancy, (3) Protection from STDs, (4) Practices, and (5) Past history of STDs (CDC, 2010, p 3).

STI as Precursor to Cancer

Scientific identification of the viral genotype of human papilloma virus (HPV) has enabled primary care providers to view cancer of the cervix in women and anus in men and women as an STI. Although more than 30 types of HPV can infect the genital tract, genotypes 16, 18, 31, 33, and 35 have been strongly associated with cervical neoplasia, with 16 and 18 being the most prevalent (CDC, 2010). Within the past decade, cervical cancer screening rates have increased and mortality rates have decreased (CDC, 2012b). This has been attributed to women receiving cervical cancer screening via Pap tests at regular intervals. According to the data analyzed by race and ethnicity, cervical screening rates are highest among the black (80%), white (75%), and Hispanic (75%) groups. Blacks have the highest cervical cancer death rates. Because most HPV infections are asymptomatic, early diagnosis and treatment of suspicious lesions are essential to prevent the spread of potentially cancerous lesions.

In 2009, the American College of Obstetricians and Gynecologists (ACOG) revised its cancer screening guidelines to recommend that the first cervical screening be performed at 21 years of age. Rescreening can be less frequent than previously recommended (ACOG, 2009; Wright et al, 2007). However, nurse practitioners should be aware of the fact that these guidelines are for women considered to be average risk (CDC, 2012c). Risk factors that may indicate the need for more frequent screening include HIV infection; immunosuppression; history of diethylstilbestrol (DES) exposure in utero; and abnormal Pap test results such as cervical intraepithelial neoplasia (CIN) 2, CIN 3, or history of cervical cancer.

HIV is another form of cancer that can be transmitted sexually. The mechanism of action behind the interrelated nature of sexually transmitted infections can be complex. Gonorrhea, chlamydia, and syphilis are thought to facilitate the transmission of HIV infection (CDC, 2010) in susceptible individuals. The incidence of syphilis is highest in those infected with HIV. Genital ulcerations can also increase HIV risk (Swygard & Cohen, 2012).

Hepatitis C is an example of another virus that can be transmitted sexually that has the potential to cause liver cancer and other complications. At-risk individuals should be routinely tested and receive counseling on how to prevent contracting the virus and how to prevent spreading the virus to others (CDC, 2012a).

Pathophysiology

The pathogenic potential of the viruses and bacteria capable of causing STIs and overall general discomfort depends on several factors. Age of host, sex of patient, number of sexual partners, pregnancy, immune system status, and coexisting infections are examples of the numerous factors to be considered when managing STIs. Age of the host is, perhaps, one of the most important factors for the nurse practitioner to consider.

Prepubertal, lactating, and postmenopausal women lack the vaginal effects of estrogen (Markusen & Barclay, 2003). This estrogen deficit results in a thin vaginal mucosa and vaginal epithelium. As a result, the vaginal area becomes more susceptible to infection and trauma. In addition to lacking the effects of estrogen, the pH of the vagina can be abnormally high (5.0 to 7.0) for some women and the normally acidogenic flora of the vagina may be replaced by mixed flora, which predisposes to infection. The normally acidic environment of the vagina (pH 3.5 to 4.1) promotes growth of the normal flora and helps prevents growth of infectious or irritative organisms. Although most women grow between three and eight types of bacteria, which are considered part of the "normal flora," lactobacilli and corynebacteria are the most common organisms (Markusen & Barclay, 2003). Treatments such as antibiotic therapy or behaviors such as having multiple sex partners triggers a nonphysiological response, and the "normal flora" of the vagina becomes disturbed enough to produce pathological symptoms. Postmenopausal women may experience vulvovaginal pain as a direct result of decreased estrogen production, which results in a thin, superficial epithelium. Some of the irritative symptoms may also be caused by infection. This reduced layer of epithelial cells can make the woman more vulnerable to infection and trauma (atrophic vaginitis). Infection can be from a woman's own perineal bacterial flora, and trauma can be a result of normal sexual relations. Other common irritants to the vaginal ecosystem are "forgotten" tampons, douches, contraceptive preparations, diabetes mellitus, and even stress.

In women, STIs are a common cause of vaginitis. Presenting symptoms often include discharge and vaginal irritation. However, it is important to note that not all vaginitis is infectious and that those infected with an STI are often asymptomatic. The differential diagnosis of vaginal discharge is presented in Table 44-1. Treatments for infectious vaginitis that may be acquired without sexual contact as well as for noninfectious vaginitis are discussed later in this chapter.

Genital contact between people is required for transmission of most STIs, although fomite transmission (such as through vibrators, toilet seats, and bath towels) can occur with hardier organisms. Women tend to experience more morbidity than men because of the secretions deposited into the vaginal vault during intercourse. This does not mean that men are not without risk. Transmission from one partner to the other can be facilitated or impeded by alterations in vaginal pH, the presence of inflammation caused by spermicides, and the mucosal integrity of either partner. Bacteria and viruses can invade the mucosal lining of the oral, genital, or anal tract. All bodily secretions, especially blood, have the potential to transmit infection from human to human.

Goals of Treatment

There are four main goals of STI treatment. There is ample literature to validate that STIs are preventable through safe sexual behavior. Therefore, the first goal of therapy is to educate patients about high-risk behaviors and screen those at risk. As a form of primary prevention, vaccinations should also be offered to eligible individuals. Currently, only two vaccines providing protection against viral STIs are available (hepatitis B and HPV vaccines). Prevention of long-term sequelae due to unsafe sex practices and, where possible, eradicating the responsible organism(s) are the second goals of therapy. Potential complications of STIs are tubal occlusion leading

to infertility and ectopic pregnancy, neonatal morbidity and mortality caused by transmission during pregnancy and parturition, genital cancers, and possible exposure to HIV because of its association with other STIs. The third goal of therapy is to choose the most specific, cost-effective drug that has the best regimen for adherence, after verifying pregnancy status in all women of childbearing age. The fourth goal of therapy is to reduce morbidity and provide comfort for those chronic conditions that are not curable.

Rational Drug Selection
Guidelines

Treatment for STIs is based on national guidelines recommended by the CDC (2010). Nurse practitioners and other health-care providers play a crucial role in the diagnosis, treatment, and counseling of STIs. The treatment information presented in this chapter is consistent with the CDC's *Sexually Transmitted Diseases Treatment Guidelines.* Specific treatments for STIs mentioned in this chapter are outlined in Table 44-2. The CDC guidelines in their entirety can be accessed from the following Web site: http://www.cdc.gov/STD/treatment/. There are new CDC guidelines being published in 2015.

Syphilis

Syphilis is a systemic disease caused by *Treponema pallidum* that has been present in society for centuries. Syphilis is spread by direct contact of the mucosal tissue with infected lesions. Diagnostic symptoms may present as early as 5 days and as late as 90 days after exposure to the organism. Primary syphilis infection presents with ulcer or chancre at the site of infection. Secondary infection manifestations include rash, mucocutaneous lesions, adenopathy, and neurologic complications. Not all vaginal "warts" are attributed to HPV disease; anogenital condylomata lata are a common symptom of secondary syphilis as well as a generalized papulosquamous eruption.

Table 44–1 Differential Diagnosis of Vaginal Discharge

Discharge Appearance	Symptoms	pH	Diagnostic Tests	Microscope Findings	Disease/Syndrome
White, curdy	+ Burn, itch	<4.5	Culture/KOH	Budding yeast hyphae	Moniliasis Candidiasis
Mucopurulent, thick	+ Irritating	Normal	DNA/culture	WBCs >10/hpf	GC/Chlamydiasis
Thin, white, odor	+ Itch, odor a big issue	>4.5	+Amine/culture-change in vaginal flora	"Clue cells" (coccoid bacteria that obscure epithelial cell borders)	Bacterial vaginosis (BV)
Blood-tinged, purulent	+ Itch, dysuria, foul odor	<4.5	Wet mount = + Trichomonads	Trichomonads >10 WBCs/hpf	Trichomoniasis
Nonspecific, white	+ Pruritus, burn	3.5–4.5	Culture reports change in normal flora	4 + *Lactobacillus*	Cytological
Scanty, may be white or yellow	+ Burn, sore, cracks	>5–7	Culture is negative	Several epithelial cells	Atrophic
White	None	3.8–4.2	Not necessary	1–2 + *Lactobacillus*	Normal

Table 44–2 ❀ Drugs Commonly Used: Sexually Transmitted Infections

Pathogen	First Choice	Alternative Choice
Bacterial Pathogens Syphilis, primary, secondary, and early latent (tertiary)	Benzathine penicillin G *Adults including pregnant women:* 2.4 million units (IM) in a single dose *Children:* 50,000 units/kg in one dose up to the adult dose of 2.4 million units	Pregnant patients allergic to penicillin should be desensitized. Nonpregnant: use doxycycline 100 mg bid for 14 days *or* tetracycline 500 mg qid for 14 days.
Syphilis, late latent or unknown	3 weekly doses of benzathine penicillin G 2.4 million units (total 7.2 million units) *Children:* 50,000 units/kg IM weekly for 3 weeks (total 150,000 units/kg up to adult dose of 7.2 million units)	Pregnant patients: 2.4 million units of benzathine penicillin weekly × 3 weeks
Gonococcal infections (uncomplicated infections of cervix, urethra, and rectum)	Ceftriaxone 250 mg intramuscular single-dose injection *plus* azithromycin 1 g orally in a single dose *or* doxycycline 100 mg orally twice daily × 7 days (azithromycin is recommended over doxycycline)	Cefixime 400 mg orally in a single dose *plus* azithromycin 1 g orally in a single dose *or* doxycycline 100 mg orally twice daily × 7 days (test-of-cure in 1 week). If patient has severe cephalosporin allergy: increase azithromycin to 2 g orally in a single dose (monitor for nausea and vomiting).
Gonococcal infections (pharynx)	Ceftriaxone 250 mg intramuscular single dose injection *plus* azithromycin 1 g orally in a single dose or doxycycline 100 mg orally twice daily for 7 days	Note: Do not use oral cefixime
Chlamydia (adults and adolescents)	Azithromycin 1 g orally in a single dose *or* doxycycline 100 mg twice daily for 7 days	Erythromycin base 500 mg orally 4× daily for 7 days *or* erythromycin ethylsuccinate 800 mg orally 4× a day for 7 days *or* ofloxacin 300 mg orally twice daily for 7 days *or* levofloxacin 500 mg orally once daily for 7 days
Chlamydia (pregnancy)	Azithromycin 1 g orally in a single dose *or* amoxicillin 500 mg orally 3× daily for 7 days	Erythromycin base 500 mg orally 4× a day for 7 days *or* erythromycin ethylsuccinate 800 mg orally 4× a day for 7 days *or* erythromycin ethylsuccinate 400 mg orally 4× a day for 7 days *or* erythromycin base 250 mg orally 4× a day for 14 days
Chancroid	Azithromycin 1 g orally in a single dose *or* ceftriaxone 250 mg single-dose intramuscular injection *or* ciprofloxacin 500 mg orally twice daily for 3 days *or* erythromycin base 500 mg PO 3× daily for 7 days	Ciprofloxacin is not for patients under 18 years of age or for those who are pregnant *or* lactating
Granuloma inguinale (donovanosis)	Doxycycline 100 mg orally twice daily for at least 3 weeks or until ulcers have completely healed	Ciprofloxacin 750 orally twice daily for 3 weeks *or* erythromycin base 500 mg orally 4× a day for 3 weeks *or* azithromycin 1 g orally weekly for 3 weeks *or* trimethoprim-sulfamethoxazole one double-strength (160 mg/800 mg) tablet orally twice daily for 3 weeks. Note: Treat for a minimum of 3 weeks. Continue treatment until all lesions have healed.
Lymphogranuloma venereum	Doxycycline 100 mg orally twice daily for 21 days Do not use doxycycline in pregnant *or* lactating women	Erythromycin base 500 mg orally 4× daily for 21 days
Bacterial vaginosis	Metronidazole 500 mg orally twice daily for 7 days *or* clindamycin cream 2% 5 g intravaginally (one applicator) at bedtime for 7 days *or* metronidazole gel 0.75% 5 g (one applicator) intravaginally at bedtime for 5 days *Pregnant women:* metronidazole 500 mg bid for 7 days *or* metronidazole 250 mg tid for 7 days *or* clindamycin 300 mg bid for 7 days	Tinidazole 2 g orally once daily for 2 days *or* tinidazole 1 g orally once daily for 5 days *or* clindamycin 300 mg orally twice daily for 7 days *or* clindamycin ovules 100 mg intravaginally at bedtime for 3 days
Viral Pathogens Herpes Simplex types 1 and 2	**First Episode** Acyclovir 400 mg orally 3× daily for 7–10 days *or* acyclovir 200 mg orally 5× daily for 7–10 days *or* famciclovir 250 mg orally 3× daily for	**Recurring Episodes** Treatment for recurrent genital herpes can be administered either episodically to ameliorate or shorten duration of lesions or continuously as

Table 44–2 ❋ **Drugs Commonly Used: Sexually Transmitted Infections—cont'd**

Pathogen	First Choice	Alternative Choice
	7–10 days *or* valacyclovir 1 g twice a day for 7–10 days Note: Treatment can be extended if complete healing does not occur after 10 days of therapy.	suppressive therapy to reduce frequency of recurrences. Episodic therapy: Acyclovir 400 mg orally 3× times daily for 5 days *or* acyclovir 800 mg orally twice daily for 5 days *or* acyclovir 800 mg orally 3× times daily for 2 days *or* famciclovir 125 mg orally twice daily for 5 days *or* famciclovir 1 g orally twice daily for 1 day *or* valacyclovir 500 mg orally twice daily for 3 days *or* valacyclovir 1 g orally once a day for 5 days. Suppression is same dosage but given: acyclovir 400 mg orally twice daily; famciclovir 250 mg orally twice daily; valacyclovir 500 mg once daily; valacyclovir 1 g once daily.
Human Papillomavirus		
Human papillomavirus (HPV) (vaginal)	Due to the risk of vaginal perforation and fistula formation, cryotherapy is not recommended in the vaginal area. TCA or BCA 80%–90% in small amounts should be applied directly to wart area. Use talc, sodium bicarbonate, or liquid soap to remove unreacted acid. Repeat weekly if needed.	Cervical lesions: Biopsy lesions and refer for treatment.
Human papillomavirus (HPV) (external genital)	Patient-applied treatments (can be expensive for the patient): 1. Podofilox 0.5% solution or gel. Apply with cotton swab to visible warts twice a day for 3 days followed by 4 days of no treatment. Repeat for up to four cycles. 2. Imiquimod 5% cream. Apply once daily at bedtime three times a week for up to 16 weeks. Wash treatment area with soap/water 6 to 10 hours after application. 3. Sinecatechin 15% ointment. Apply 0.5 cm strand of ointment to each wart three times daily. Do not use for more than 16 weeks. Provider-applied treatments 1. Cryotherapy (only for the nurse practitioner who has been specially trained) 2. Pedophyllin resin 10%–25% applied to each wart. Wash preparation off 1–4 hours after application. Can repeat weekly if needed (do not use if patient is pregnant). 3. Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80%–90% (widely used, but have not been widely studied; use with caution). Apply weekly if needed. Neutralize acid with soap or sodium bicarbonate. 4. Surgical removal.	Urethreal meatus warts 1. Cryotherapy with liquid nitrogen 2. Podophyllin 10%–25% in compound tincture of benzoin. Repeat weekly if needed. (Do not use during pregnancy.) Anal warts 1. Cryotherapy with liquid nitrogen
Fungal Pathogen	**Intravaginal**	**Oral**
Candidia albicans	Over-the counter agents: Butoconazole 2% cream 5 g for 3 days Clotrimazole 1% cream 5 g for 7–14 days Clotrimazole 2% cream 5 g for 3 days Miconazole 2% cream 5 g for 7 days Miconazole 4% cream 5 gfor 3 days Miconazole 100 mg vaginal suppository for 7 days Miconazole 200 mg vaginal suppository for 3 days Miconazole 1,200 mg vaginal suppository for 1 day Tioconazole 6.5% ointment 5 grams as a single dose Prescription Agents: Butoconazole 2% cream (single dose) 5 g intravaginally for 1 day	Fluconazole 150 mg orally as a single-dose tablet. Note: Cream and ointments may weaken condoms and diaphragms.

Continued

Table 44–2 ❀ **Drugs Commonly Used: Sexually Transmitted Infections—cont'd**

Pathogen	First Choice	Alternative Choice
	Nystatin 100,000 unit vaginal tablet for 14 days Terconazole 0.4% cream 5 g for 7 days Terconazole 0.8% cream 5 g for 3 days Terconazole 80 mg suppository for 3 days	
Pathogen **PROTOZOAN PATHOGEN**	**First Choice**	**Alternative Choice**
Trichomoniasis	Metronidazole 2 g orally as a single dose or tinidazole 2 g orally as a single dose	Metronidazole 500 mg orally twice a day for 7 days
ECTOPARASITIC PATHOGENS		
Pubic lice	Permethrin 1% cream rinse applied to affected areas, wash off in 10 minutes *or* pyrethrins with piperonyl butoxide applied to affected areas and washed off in 10 minutes	Alternative regimens: Malathion 0.5% lotion applied for 8–12 hours, then washed off *or* ivermectin 250 mcg/kg orally repeated in 2 wk The use of ivermectin is contraindicated in pregnancy, lactation, and children.
Scabies	Permethrin cream 5% applied to all areas of body from neck down and washed off 8–14 hours after application *or* ivermectin 200 mcg/kg orally, repeated in 2 weeks Permethrin is the preferred agent.	Lindane 1% 1 oz of lotion or 30 g of cream applied in a thin layer to affected areas. Wash off after 8 hours. Note: Lindane is not recommended as first-line therapy because of toxicity and risk of seizures. Only use if pt. cannot tolerate other therapies. Lindane should *not* be used immediately after a bath or shower, or in persons with dermatitis, women who are pregnant/lactating, and children <2 yr.

BCA = bichloroacetic acid; TCA = trichloroacetic acid.

Tertiary infections with syphilis present with cardiac, neurological, ophthalmic, auditory, or gummatous lesions. Neurosyphilis may occur at any stage but most commonly presents in the latent stage.

Treatment of latent syphilis is intended to prevent occurrence or progression of late complications. Latent infections lack clinical symptoms and are detected by serological testing. Misdiagnosis or delayed diagnosis is possible because of the low level of suspicion in many family practice settings. All patients with syphilis should be tested for HIV (CDC, 2010).

All women should be screened for syphilis early in pregnancy, with many states mandating screening with the first prenatal visit (CDC, 2010). Untreated syphilis infections can lead to infection of the fetus or perinatal death. In communities and populations with a high prevalence of syphilis, patients are screened at 28 to 32 weeks' gestation and at delivery to avoid possible neonatal transmission (CDC, 2010). The high-risk category for repeated screening is described as a person who has a history of multiple sex partners, a history of current or recent STIs, a user of street drugs (Hatcher, Trussell, & Kowal, 2008), or men who have sex with men (MSM) (CDC, 2010).

Parenteral penicillin G (rather than oral penicillin) has been used effectively for more than 50 years and is the preferred drug for the treatment of all stages of syphilis. Dosing information can be found in Table 44-2. Patients who are allergic to penicillin may be treated with 14 days of doxycycline or tetracycline. Doxycycline causes less gastrointestinal upset and for this reason may have better compliance rates than tetracycline (CDC, 2010).

Parenteral penicillin G is the only therapy with documented efficacy for syphilis during pregnancy, with dosing being the same as for nonpregnant patients (CDC, 2010). Pregnant women with syphilis in any stage who report penicillin allergy should be desensitized and treated with penicillin.

Gonorrhea

First isolated in 1879, the gram-negative intracellular diplococcus *Neisseria gonorrhoeae* can be transmitted through the urethra, rectum, pharynx, vagina, or eye. In the United States, an estimated 700,000 new *N. gonorrhoeae* infections occur each year (CDC, 2010) with the highest reported cases being in the southern region of the United States. Men tend to be symptomatic when infected (Swygard & Cohen, 2012). Many infected women have no symptoms until complications, such as pelvic inflammatory disease (PID), have occurred (CDC, 2010). The incubation period can be 2 days to 2 weeks. Patients infected with gonorrhea are often co-infected with chlamydia. This finding led to the recommendation that patients being treated for gonorrhea also need treatment for chlamydia (CDC, 2010). The reverse statement is also true, that patients being treated for chlamydia should receive treatment for gonorrhea. Table 44-2 outlines the specific treatment regimen recommended for the treatment of gonorrhea.

Complications of gonococcal infection include PID, tubal scarring, infertility, ectopic pregnancy, salpingitis, or

disseminated gonococcal (GC) infection. Disseminated GC infection is characterized by pustular dermatitis, asymmetrical arthralgia, tenosynovitis, or septic arthritis. An infected pregnant woman is at risk for endometritis after procedures such as therapeutic abortions, chorionic villus sampling, or dilation and curettage. Between 30% and 50% of newborns of women with GC cervicitis develop GC conjunctivitis. In addition, gonococcal infections may facilitate the transmission of HIV infection (CDC, 2010).

Due to the increased resistance to fluoroquinolones across the United States, the drug class is no longer recommended for the treatment of gonorrhea (CDC, 2012). In addition, it is important for nurse practitioners to remember that co-infection with chlamydia and syphilis often occurs. For these reasons, the CDC recommends combination treatment with ceftriaxone IM or oral cefixime, plus either oral azithromycin or doxycycline. Combination treatment should eradicate co-existing organisms. Azithromycin is the preferred agent over doxycycline. Persons with severe cephalosporin allergies should be treated only after consultation with an infectious disease specialist (CDC, 2010).

Pregnant patients are treated with ceftriaxone 250 mg IM or cefixime 400 mg orally. Pregnant patients may also be treated with high-dose azithromycin (2 g) if they cannot tolerate cephalosporins (CDC, 2010). However, azithromycin in high doses can cause nausea and vomiting in all individuals.

Sexual partners require treatment, including those without symptoms, if they had sexual contact with the patient during the 60 days preceding the onset of symptoms or diagnosis of the infection (Swygard & Cohen, 2012). To prevent reinfection, patients and their partners should abstain from intercourse until therapy is completed. Women have a high rate of reinfection in the 6 months after treatment. Recommendations include retesting men and women 3 months after treatment regardless of whether the sex partner has been treated (CDC, 2010; Swygard & Cohen, 2012). Rescreening in 12 months after the initial diagnosis has been made is also recommended. A test-of-cure in 1 week is recommended if oral cefixime is used to treat infections of the cervix, urethra, and rectum (CDC, 2012d).

Chlamydia

The most commonly reported sexually transmitted infection in the United States is *Chlamydia trachomatis* (often termed *chlamydia*) with approximately 1.8 million infections annually (Torrone, Papp, & Weinstock, 2014). *C. trachomatis* is an often asymptomatic disease that causes serious sequelae, such as PID, ectopic pregnancy, and infertility. In susceptible individuals, chlamydia infections can facilitate the transmission of HIV infection (CDC, 2010). Some women who have uncomplicated cervical infections already have subclinical upper reproductive tract infections. Asymptomatic infection is common among both men and women. However, the rate of infection in women is over twice that of reported cases in men (CDC, 2010). Currently, economically disadvantaged women ages 16 to 24 years of age are at the highest risk, with one in seven sexually active non-Hispanic black women ages

14 to 24 years infected with chlamydia in 2012 (Torrone et al, 2014).

As explained previously, co-infection with gonorrhea often occurs. Therefore, dual therapy for gonorrhea and chlamydial infections is the treatment standard for both men and women. This chapter outlines the treatment recommendations for adolescents and adults. Treatment of the infection in infants is not discussed.

The CDC recommended treatment for chlamydia infection is outlined in Table 44-2. Azithromycin as a single dose or doxycycline for 7 days are the recommended regimens (CDC, 2010). Either treatment is efficacious, although the single-dose azithromycin may have a higher compliance rate (CDC, 2010), but it carries a higher risk of nausea and vomiting.

Pregnant women are treated with either azithromycin or amoxicillin (see Table 44-2). Doxycycline is contraindicated in pregnancy. Alternative therapy with erythromycin is recommended for pregnant women, but adverse reactions and gastrointestinal side effects make it a less desirable option.

Except in pregnant women or in those who have been noncompliant, a test-of-cure (repeat testing 3 weeks after completing therapy) is not recommended for persons treated with the recommended or alternative regimens (CDC, 2010). High-risk, pregnant individuals should be retested during the third trimester to decrease the possibility of the infection being passed during delivery. Pregnant women should have follow-up testing after treatment and should be retested 3 months after treatment (CDC, 2010). The majority of post-treatment infections result from reinfection. To minimize transmission, persons being treated for chlamydia should be instructed to abstain from sexual intercourse for 7 days after single-dose therapy or until completion of a 7-day regimen. Treatment of sex partners will also help to minimize the risk of reinfection.

All sexual partners in the past 60 days should be tested and treated. The most recent partner, even if more than 60 days has elapsed, should be evaluated. Expedited partner therapy is recommended to decrease reinfection (CDC, 2010).

Chancroid

Chancroid, caused by *Haemophilus ducreyi,* is endemic in some areas of the United States and is common in many of the world's poorest regions, such as areas of Africa, Asia, and the Caribbean (WHO, 2010). Co-infection with HIV, syphilis, and herpes simplex virus (HSV) can occur. Diagnosis is difficult because of the lack of available and sensitive testing media. As a result, treatment is initiated when the following criteria are satisfied: (1) one or more painful ulcers, (2) negative tests for syphilis and HSV, and (3) the appearance of ulcers with suppurative inguinal adenopathy.

Chancroid usually starts as a small papule that rapidly becomes pustular and then eventually ulcerates. The ulcer enlarges and begins to develop ragged and uneven borders and is surrounded by an erythematous rim. Unlike syphilis, chancroid lesions are tender. Treatment recommendations include oral azithromycin or ceftriaxone (IM) or oral ciprofloxacin or erythromycin (CDC, 2010). Pregnant women are treated with

azithromycin, ceftriaxone, or erythromycin. Ciprofloxacin is contraindicated in pregnancy. Patients should be re-examined 3 to 7 days after therapy is started (CDC, 2010). Ulcers usually improve symptomatically after 3 days but may take up to 2 weeks to heal. Although treatment is successful, there still may be significant scarring. Poor response to treatment may indicate the patient is co-infected with another STI, has HIV, or the pathogen is resistant. Healing may be slower for uncircumcised men with ulcers under their foreskin.

In those men who are uncircumcised or who have HIV, response to treatment may be suboptimal. Therefore, patients should have HIV testing at the time of chancroid diagnosis (CDC, 2010). Follow-up is recommended because lack of response may indicate presence of HIV disease due to the fact that chancroid is considered a cofactor for HIV transmission. Patients should be retested for syphilis and HIV at 3-month intervals after the diagnosis of chancroid if the initial test results were negative (CDC, 2010). If the lymphadenopathy is fluctuant, incision and drainage may be necessary to enhance healing.

Sexual partners should be examined and treated if they have had sexual contact with the patient in the 10 days preceding diagnosis.

Granuloma Inguinale (Donovanosis)

Granuloma inguinale is a rare, genital ulcerative disease caused by the intracellular gram-negative bacterium *Klebsiella granulomatis* (formerly known as *Calymmatobacterium granulomatis*). This infection results in painless, slow-progressing ulcers without lymphadenopathy that bleed easily on contact. Granuloma inguinale usually affects the skin and mucous membranes in the genital region and results in nodular lesions that progress to large, beefy lesions that are difficult to heal. The ulcers progressively expand and are locally destructive. The mode of transmission of granuloma inguinale primarily occurs through sexual contact; however, it may have low infectious capabilities because repeated exposure is necessary for clinical infection to occur. Additionally, granuloma inguinale may also be obtained through the fecal route or by passage through an infected birth canal (CDC, 2006). Most infections are endemic in tropical and developing areas of India, Papua New Guinea, central Australia, and southern Africa.

The treatment for granuloma inguinale is outlined in Table 44-2. The current recommended antibiotic treatment is doxycycline (CDC, 2010). Alternatives include ciprofloxacin, erythromycin, azithromycin, or trimethoprim/sulfmethoxazole. Treatment is a minimum of 3 weeks or until all lesions have completely healed (CDC, 2010). Relapse is common within 6 to 18 months despite the best therapy. Although treatment stops the progression of lesions, prolonged therapy may be required to permit granulation and re-epithelialization of the ulcers. Sex partners should have clinical signs and symptoms prior to initiation of therapy.

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is caused by *C. trachomatis* serovars L1, L2, or L3. LGV infection manifestations share characteristics with chancroid, such as unilateral tender lymphadenopathy and self-limited genital ulcers. Homosexual men may present with proctocolitis and women with perianal inflammation, with the complication being strictures or fistulas. LGV can become an invasive systemic infection, and if it is not treated early, LGV proctocolitis may lead to chronic, colorectal fistulas and strictures.

The treatment for lymphogranuloma vereneum is outlined in Table 44-2. The diagnosis is made serologically and the recommended treatment is doxycycline. An alternative treatment is erythromycin base (CDC, 2010). Pregnant women are treated with erythromycin. Local lesions (buboes) may require incision and drainage. Patients may need further testing to rule out the high rate of coexisting STIs. Sexual partners who had contact with the patient in the past 60 days should be examined and treated (CDC, 2010).

Bacterial Vaginosis

Accounting for approximately 50% of all vaginitis cases in women, bacterial vaginosis (BV) is the most prevalent of vaginal infections (Sobel, 2012a). BV is caused by a replacement of the normal hydrogen-peroxide-producing lactobacilli present in the vaginal flora by an overgrowth of organisms such as *Prevotella* spp., *Mobiluncus* spp., *Gardnerella vaginalis,* or *Mycoplasma hominis.* The normally acidic vaginal environment is important in preventing the overgrowth of other organisms, which tends to occur when the pH is raised. Relapses and recurrences of the infection are common.

Although BV is not considered an STI, the majority of women infected are sexually active. Women with BV are also at risk for other sexually transmitted illnesses. BV is associated with having multiple sex partners, douching, and lack of vaginal lactobacilli. BV has caused endometritis and PID after invasive procedures such as endometrial biopsy, intrauterine device insertion, cesarean delivery, hysterectomy, and therapeutic abortion. Bacterial vaginosis is also a risk factor for contracting HIV, HSV-2, gonorrhea, and chlamydia (Sobel, 2012a).

BV can be diagnosed by the use of clinical criteria or Gram's stain criteria and must include three of the four following signs and symptoms (CDC, 2010): (1) a homogeneous, white, noninflammatory discharge that smoothly coats the vaginal walls; (2) a vaginal pH greater than 4.5; (3) a positive whiff test (fishy odor) with 10% potassium hydroxide (KOH); or (4) the presence of "clue cells" (vaginal epithelial cell peppered with coccoid bacteria) under high-power microscopy. The Pap smear is not reliable for the diagnosis of BV (Sobel, 2012a). In addition, obtaining cultures is also not reliable because there is no bacteria diagnostic of BV.

Due to the fact that asymptomatic women tend to spontaneously improve, treatment should be reserved for symptomatic women (Sobel, 2012a). However, nurse practitioner providers should use clinical judgment and individualize treatment to each patient and patient situation. Treatment of asymptomatic, pregnant women preparing to undergo termination of pregnancy is recommended.

The recommended metronidazole regimens are outlined in Table 44-2. Metronidazole orally, metronidazole gel, or clindamycin cream are the current CDC (2010) recommendations. Topical vaginal metronidazole is thought to be as

effective as oral metronidazole (Sobel, 2012a). Vaginal clindamycin cream may be less effective than the metronidazole regimen. However, the drug provides an option for women unable to have metronidazole. It is important to note that clindamycin cream can weaken condoms, especially those made with latex. The use of probiotics to treat BV is controversial, and there is no current evidence to support this as a treatment option (Sobel, 2012a).

When mixed with alcohol, metronidazole has the potential to cause disulfiram-like reactions. Alcohol should not be consumed during or for at least 1 day following completion of metronidazole therapy (American Society of Health-System Pharmacists, 2010; CDC, 2010). Clindamycin cream is oil-based and may weaken latex condoms and diaphragms. Due to the fact that treatment of the sex partner has not been shown to be effective in preventing recurring infections, routine treatment of sexual contacts is not recommended. BV during pregnancy is associated with premature rupture of membranes, preterm labor, preterm birth, and postpartum endometriosis. For this reason, pregnant women should be screened for BV once the diagnosis of pregnancy is made. Current data do not support the use of topical agents to treat BV during pregnancy. There has been evidence to show adverse events after the use of clindamycin cream. For this reason, treatment of BV in the pregnant woman should be oral, rather than topical, with a medication that is safe during pregnancy. Oral metronidazole can be safely prescribed for pregnant women with bacterial vaginosis (CDC, 2010).

Due to the frequent relapses and reinfection that can occur, it is important for the nurse practitioner to have a treatment regimen available, as many women will need suppressive therapy (Sobel, 2012a). Current experts feel that three documented episodes of BV in the past 12 months make a woman a candidate for long-term treatment with metronidazole gel: 0.75% twice weekly for 4 to 6 months. Vaginal boric acid (not oral) 600 mg for 21 days, along with oral metronidazole for 7 days, is another treatment option.

Vulvovaginal Candidiasis

Vulvovaginal candidiasis (VVC) may be caused by several yeast species, although *Candida albicans* is the most common. It is estimated that 75% of women will have at least one episode of VVC, and 40% to 45% will have two or more episodes (CDC, 2010). For many women, a recent history of antibiotic use is most often the cause. The patient with chronic recurrent infections should be screened for diabetes (Sobel, 2012b). Candida vaginitis is not considered a sexually transmitted infection. However, sexually active women can be at risk for contracting the infection. Table 44-2 outlines the treatment for candida vaginitis.

Vulvar itching with a history of "cottage cheese-like" discharge are the primary complaints seen in those having the infection. The diagnosis for VVC in a woman can be made by wet preparation (saline, 10% KOH), Gram's stain, or culture. In addition, a low vaginal pH (4 to 4.5) can help to distinguish candida from other vaginal infections (bacterial vaginosis or trichomonas, for example) (Sobel, 2012b).

The azoles as a drug class are among the most effective treatments, with oral and topical treatments being equally effective (Sobel, 2012b). However, many women prefer oral treatment over topical. Oral fluconazole is available as a generic medication and may be cheaper than topical treatments. Oral azole agents stimulate the cytochrome P450 (CYP450) enzyme system in the liver and have potential drug interactions with calcium channel antagonists, cisapride, warfarin, oral hypoglycemic agents, phenytoin, protease inhibitors, theophylline, and rifampin.

The recommended creams and suppositories for the treatment of VVC are oil-based and may weaken latex condoms and diaphragms. Self-medication with over-the-counter (OTC) preparations is advised only for women who have been previously diagnosed with VVC and who have a recurrence of the same symptoms. Those patients experiencing severe pruritus may benefit from the temporary use (48 hours) of a low-potency topical steroid (Sobel, 2012b).

VVC often occurs during pregnancy. Only topical azole therapies, applied for 7 days, are recommended for use by pregnant, symptomatic women. Oral azoles are contraindicated in pregnancy.

Severe vulvovaginitis, characterized by extensive vulvar erythema, edema, excoriation, and fissure formation, may not clear with standard short therapy. Thus, longer doses may be needed. In severe cases, 7 to 14 days of topical therapy, or fluconazole 100 mg, 150 mg, or 200 mg orally every third day for a total of 3 doses, can be used (CDC, 2010). Oral fluconazole (100 mg, 150 mg, or 200 mg) weekly for 6 months can also be used for suppression of the infection (CDC, 2010; Sobel, 2012b). Due to the lack of data demonstrating effectiveness, the use of probiotics is not recommended (Sobel, 2012b).

Herpes Simplex Virus Type 1 and Herpes Simplex Virus Type 2

Genital herpes is incurable and tends to be recurrent although the periods of exacerbation and remission are highly variable. Two serotypes of HSV have been identified: HSV-1 and HSV-2. Most recurrences are a result of HSV-2. At present, approximately 50 million people have genital HSV infection. Most persons infected with HSV-2 have not been diagnosed and shed the virus in the genital tract without obvious symptoms (CDC, 2010). HSV-2 infections can also cause recurrent BV (Swygard & Cohen, 2012). Table 44-2 outlines the treatment of genital herpes.

Due the recurring nature of extremely painful vesicles during outbreaks, restoring and preserving quality of life is important in the patient with genital herpes. Suppressive therapy is recommended for patients experiencing six or more outbreaks each year. Most patients experience fewer episodes after 1 year of suppressive therapy. However, suppressive treatment can be effective in patients with less frequent attacks. Suppressive antiviral therapy reduces, but does not eliminate, subclinical viral shedding. Systemic treatment with oral acyclovir, famciclovir, and valacyclovir are the mainstays of treatment for genital herpes. Antiviral therapy for recurrent genital herpes can be administered episodically or continuously as suppressive therapy. Episodic therapy is effective in

shortening the duration of outbreaks if started within the first 24 hours of lesion outbreaks or during the prodromal phase (burning, itching, and tingling) that often precedes outbreaks. In order for the antiviral treatment to be effective, the nurse practitioner provider should supply the patient receiving episodic treatment for HSV with a prescription to self-medicate immediately when symptoms begin. Consider reassessing the need for suppressive therapy annually by temporarily discontinuing the drug to see if outbreaks occur.

Patients with HIV infection or those who are immunocompromised due to other causes may have prolonged or severe, painful episodes of genital, perianal, or oral herpes. Drug choices and dosing for HSV in the HIV patient are the same as for those with a first episode (or initial outbreak). Episodic or suppressive therapy with oral antiviral agents is beneficial.

Perinatal transmission of HSV is low (less than 1%) in women who have a history of genital HSV, but because recurrent herpes is common in pregnant women there is concern for transmission to the neonate at birth (CDC, 2010). The safety of acyclovir, valacyclovir, and famciclovir in pregnant women has not been well established. However, acyclovir can be administered orally to pregnant women with first-episode genital herpes or severe recurrent herpes (CDC, 2010). Perinatal transmission of HSV is 30% to 50% if women are infected near delivery and can be life-threatening; therefore protected sex is necessary if sex partners are infected (CDC, 2010). Cesarean delivery does not ensure protection from HSV-2 infection. Pregnant women with HSV require careful management by an obstetrical specialist during pregnancy and delivery.

Human Papillomavirus

According to the CDC, by the age of 50 more than 80% of American women will have contracted at least one strain of genital HPV. Both men and women can be carriers of HPV (CDC, 2010). Most HPV infections are asymptomatic or not visible but can lead to the development of anogenital cancers. For this reason, aggressive screening and treatment is often warranted, particularly in high-risk individuals. Reports indicate that more than 40 viral types can infect the genital area in men and women. HPV types 6 and 11 are considered low risk and cause 90% of all genital warts. Patients with visible warts may be infected with several types simultaneously.

HPV types (16, 18, 31, 33, and 35) are associated with cervical neoplasia and detected through the Pap smear process in women (CDC, 2010). HPV types 16 and 18 cause approximately 70% of cervical cancers. Lesions may be penile, scrotal, cervical, vaginal, urethral, oral, or perianal. Table 44-2 outlines the treatment for HPV.

Genital warts are usually flat, papular, or pedunculated growths on the genital mucosa. Diagnosis of genital warts is made by visual inspection and may be confirmed by biopsy. Biopsy is recommended in certain circumstances (for example, if the diagnosis is uncertain; the lesions do not respond to standard therapy; the disease worsens during therapy; the patient is immunocompromised; or warts are pigmented, indurated, fixed, bleeding, or ulcerated).

The application of 3% to 5% acetic acid usually turns HPV-infected genital mucosal tissue to a whitish color. However, acetic acid application is not a specific test for HPV infection, and the specificity and sensitivity of this procedure for screening have not been defined. Therefore, the routine use of this procedure for screening to detect HPV infection is not recommended (CDC, 2006). However, those clinicians who are experienced in the management of genital warts have determined that this test is useful for identifying flat genital warts.

In addition to the external genitalia (that is, penis, vulva, scrotum, perineum, and perianal skin), genital warts can occur on the uterine cervix and in the vagina, urethra, anus, and mouth. Intra-anal warts are observed predominantly in patients who have had receptive anal intercourse. These warts are distinct from perianal warts, which can occur in men and women who do not have a history of anal sex. Genital warts are usually asymptomatic, but depending on the size and anatomical location, lesions can be painful, friable, or pruritic.

HPV types 16, 18, 31, 33, and 35 are found occasionally in visible genital warts and have been associated with external genital squamous intra-epithelial neoplasia. These HPV types also have been associated with vaginal, anal, and cervical intra-epithelial neoplasia (CIN). They have also been associated with anogenital and some head and neck squamous cell carcinomas. Patients who have visible genital warts are frequently infected simultaneously with multiple HPV types (CDC, 2006). Management of HPV involves removing warts if the patient is symptomatic due to location, size, and number of warts and monitoring for the development of cancer cells especially in patients with abnormal Pap test results.

The primary goal of treating visible genital warts is the removal of the warts. In the majority of patients, treatment can induce wart-free periods. If left untreated, visible genital warts might resolve spontaneously, remain unchanged, or increase in size or number. Treatment possibly reduces, but does not eliminate, HPV infection. So far, existing data indicate that currently available therapies for genital warts might reduce, but probably do not eradicate, HPV infections.

The patient's symptoms, number of warts, where the warts are on the body, and size of warts are some of the factors that need to be considered in selecting a treatment modality. Other factors include cost of treatment, patient preference, the experience of the provider, and access to wart morphology. In general, warts located on moist surfaces or areas such as the armpits, underneath pendulous breasts, groin, creases of the neck, or skinfolds respond better to topical treatment than do warts on skin surfaces that are drier. The majority of patients will need more than one treatment and most respond within 3 months of therapy. Treatment regimens are classified as either patient-applied or provider-applied.

For external genital warts, the CDC (2010) recommends patient-applied therapy with podofilox 0.5% solution or gel or imiquimod 5% cream. These therapies need to be applied several times a week and can be costly. Provider-applied management includes cryotherapy with liquid nitrogen or cryoprobe or podophyllin resin 10% to 25% in a compound tincture of benzoin or trichloroacetic acid (TCA) or bichloroacetic acid

(BCA) 80% to 90%. An alternative provider-applied management includes the use of intralesional interferon or laser surgery. Surgical referral should be considered by the nurse practitioner when the size, number of warts, ineffective response to topical treatments, and location of warts make it difficult to treat effectively. Imiquimod, podophyllin, and podofilox should not be used during pregnancy. Because genital warts can proliferate and become friable during pregnancy, many specialist recommend their removal during pregnancy.

There is no evidence to suggest that one treatment is superior to another. Only trained nurse practitioners should administer cryotherapy. Treatment regimens should be changed if warts do not resolve in three to six treatments. Treatment of these lesions may result in chronic pain syndromes of the vulva, but these are extremely rare. In the absence of genital warts or cervical squamous intra-epithelial lesion (SIL), the CDC does not recommend treatment for subclinical genital HPV infection.

Currently in the United States, two vaccines to prevent HPV infection are currently on the market: Gardasil and Cervarix (CDC, 2010). Cervarix (a bivalent vaccine) provides protection against HPV types 16 and 18 and is licensed for use in females 11 to 25 years of age. Gardasil (a quadrivalent vaccine) provides protection from HPV types 6, 11, 16, and 18 and is licensed for both males and females ages 9 to 26 years. These vaccines can be costly, but children and adolescents less than 19 years of age can receive assistance through the Vaccines for Children (VFC) program (http://www.cdc.gov/vaccines/programs/vfc/index.html). A nine-valent HPV vaccine (HPV9) is currently undergoing FDA review for approval and protects against HPV strains 6, 11, 16, 18, 31, 33, 45, 52, and 58.

Trichomoniasis

Trichomonas spp. are protozoa, and protozoan infections require a different therapeutic approach. Men are rarely symptomatic but may harbor *Trichomonas* in the prostate gland for years if left untreated. Many women have a malodorous, yellow-green vaginal discharge with vulvar irritation. However, some women have minimal discharge and may be asymptomatic. An increase in vaginal pH in women may increase the risk of *Trichomonas* infection in men (Swygard & Cohen, 2012).

The availability of rapid testing has increased the sensitivity and specificity significantly compared to the use of microscopy, which requires provider experience and immediate evaluation of wet prepared slides to capture the classic *Trichomonas* movement. The diagnosis is therefore often missed because wet mounts must be viewed quickly. The wet-prep method is not a sensitive test in men (CDC, 2010; Swygard & Cohen, 2012). Urine sediment microscopy may frequently demonstrate this organism fortuitously. Table 44-2 outlines the treatments for trichomoniasis.

The treatment regimen for trichomoniasis includes oral metronidazole or tinidazole (CDC, 2010). Patients need to be advised to avoid consuming alcohol during treatment with metronidazole. In doing so, a disulfiram reaction may occur. Rescreening for *T. vaginalis* 3 months after treatment may be considered in sexually active women, due to a high (17%) reinfection rate (CDC, 2010).

Pregnant women who are infected with vaginal trichomoniasis are at risk of preterm labor, premature rupture of membranes, and low birth weight (CDC, 2010). Treatment for symptomatic women or asymptomatic women in any stage of pregnancy is oral metronidazole (CDC, 2010). The safety of tinidazole in pregnancy has not been well evaluated. Pregnant women should be followed up in 1 month.

Sexual partners should be treated for trichomoniasis and patients should be instructed to abstain from intercourse until both partners are treated and asymptomatic (CDC, 2010).

Pediculosis Pubis (Genital Lice)

Pediculosis pubis (i.e., genital lice), commonly called crabs, is an ectoparasitic infection that is treated differently based on where the lice are found (e.g., scalp, body, or the pubic area). Pubic lice are generally sexually transmitted, with teenagers and young adults being those most commonly affected (Goldstein & Goldstein, 2011).

The organism is genetically programmed to attach to hair of different diameters. Considerable resistance to medication for treatment of head lice has been seen, but pediculosis can be eradicated by the methods listed in Table 44-2. Pubic itching is the primary complaint and the organism can be resistant to treatment (Goldstein & Goldstein, 2011). Retreatment in one week of symptomatic individuals is recommended.

Pubic lice may be treated with pyrethrins: permethrin 1%, pyrethrin lotion, or shampoo. Advise the patient to thoroughly saturate hair with the medication. Leave medication on for 10 minutes, then thoroughly rinse off with water. Dry off with a clean towel (CDC, Division of Parasitic Diseases, 2008a; Goldstein & Goldstein, 2011). Reapply in 7 days if needed.

Resistance to pediculicides is becoming more frequent and widespread. Malathion 0.5% lotion or oral ivermectin are reasonable options and may be used when treatment failure is believed to have occurred or if resistance is suspected (CDC, 2006; Goldstein & Goldstein, 2011). Further discussion of the treatment of body lice is included in Chapter 32.

According to Goldstein & Goldstein (2011), sexual partners should be treated at the same time to avoid reinfection. Treatment of nonsexual contacts is not needed.

Decontamination of household and personal items with hot washing or dry-cleaning is usually adequate. Pubic lice cannot live away from the body for more than 72 hours, and fumigating the home is not necessary if the above-mentioned methods are observed.

Scabies

Sarcoptes scabiei is the parasite involved in scabies. The most common predominant symptom is severe, nocturnal pruritus. After a person is infested with scabies for the first time, sensitization can take up to several weeks to develop. Pruritus can then occur within 24 hours following a subsequent infestation. Direct contact from person to person is needed to contract the parasite (Goldstein & Goldstein, 2012). Scabies can be passed sexually in adults, but adults and particularly children may

become infected by sleeping on infected sheets in motels and hotels. If scabies has been contracted via sexual contact, the skin adjacent to the nipples, periumbilical area, waist, genitalia, buttocks, and thighs is commonly affected. Although it is possible to obtain skin scrapings from patients, the diagnosis can be made through history and physical examination alone. Table 44-2 outlines the treatments for scabies.

Permethrin 5% cream (Elimite, Acticin) is the drug of choice for the treatment of scabies, especially in pregnant women or young children. The cream is massaged into the skin from the neck to the soles of the feet. It should be left on for 8 to 14 hours and then washed off in the shower. A repeat application in 1 to 2 weeks is recommended (Goldstein & Goldstein, 2012).

Oral ivermectin is another alternative. The use of ivermectin is not recommended in pregnant or lactating women, and children (Goldstein & Goldstein, 2012). However, ivermectin is considered the drug of choice for nursing home outbreaks or when topical treatment is not practical. Ivermectin may need to be repeated in 2 weeks. Ivermectin is not active against nits. Topical ivermectin (Sklice) is not currently approved for scabies treatment.

Although treatment with lindane is an option, the routine use of this treatment is discouraged due to the adverse-effect profile. Lindane can cause seizures and is contraindicated in pregnant women and children.

The itching experienced due to a scabies infection can be quite severe. Therefore, in addition to eradicating the mite, treatment with antihistamines and topical low- or medium-dose corticosteroids to control the itching can be helpful (Goldstein & Goldstein, 2012). Nonsedating antihistamines can be used during the day. Sedating antihistamines can be used at night, which will also aid in sleep.

Bedding and clothing should be decontaminated or removed from body contact for at least 72 hours. Patient education is important when treating ectoparasitic infections. The rash and pruritus of scabies can persist for up to 2 weeks after treatment. Sexual contacts and family members may be in the incubation period (4 weeks). For this reason, all family members and close contacts need simultaneous treatment to prevent recurrence. Reinfection from family members or fomites might occur in the absence of appropriate contact treatment and decontamination of bedding and clothing. The treatment of scabies is discussed in depth in Chapter 32.

Special Treatment Situations

The following sections describe certain treatment situations that warrant special consideration: pregnant women and adolescents, those with pelvic inflammatory disease (PID), sexual assault victims, men who have sex with men, and women who have sex with women. Delay in treatment of PID or treatment with the wrong antibiotic can result in continued spread of the organism. A woman who presents for care with signs of PID needs treatment as though she has all types of infection, including gonorrhea, chlamydia, and BV. The sexual assault victim needs urgent evaluation, with testing, prophylactic antibiotics, and emergency contraception offered.

Pregnancy

All pregnant women and their sexual partners should be asked routinely about STIs, counseled about the possibility of perinatal infection, and ensured prompt access to treatment. At the first prenatal visit, women should be screened for syphilis, HBsAg, chlamydia, gonorrhea, and hepatitis C and should receive a Pap test (CDC, 2010; Swygard & Cohen, 2012). Pregnant women should be screened for HIV in the first and third trimesters (CDC, 2010).

A pregnant woman with an STI requiring treatment may present as a treatment challenge for the nurse practitioner. Consultation with an expert or referral for treatment is recommended. All women of childbearing age should have a documented pregnancy test before beginning any treatment. Ciprofloxacin, ofloxacin, and doxycycline are all contraindicated in pregnancy.

Children

STIs in children, if acquired after the neonatal period, should raise the index of suspicion about the possibility of child abuse. Sexual abuse is the most frequent cause of gonococcal infection in preadolescent children (CDC, 2010). Specially trained nurse practitioners or other health providers must perform extensive evaluation and referral to a child abuse specialist in order to effectively evaluate and treat this population.

The use of fluoroquinolones in children younger than 18 years is generally not recommended. Therapy with this particular class of drugs has caused articular cartilage damage in some studies utilizing young animals.

Adolescents

Adolescents have the highest risk for acquiring HPV, chlamydia, and gonorrhea. Reasons cited for these risks include (1) engaging in frequent unprotected intercourse, (2) being biologically more susceptible to infection, (3) having partnerships of limited duration, and (4) difficulty gaining access to care.

Adolescents in most states can consent to the confidential diagnosis and treatment of STIs. In these states, nurse practitioners need to be aware that screening, treatment, and counseling for STIs can be provided to adolescents without parental consent or knowledge. Nurse practitioners should check the appropriate state laws. The CDC resources for this can be found online: http://wwwn.cdc.gov/nndss/script/downloads.aspx.

Pelvic Inflammatory Disease

Delay in treatment of STIs and other diseases (bacterial vaginosis) can result in pelvic inflammatory disease (PID) and infertility. Pelvic inflammatory disease, by definition, is an acute infection of the upper genital tract (Wiesenfeld, 2012). Organisms that cause PID can be sexually transmitted (*N. gonorrhoeae*, chlamydia, and bacterial vaginosos), part of the normal flora (*G. vaginalis* and *Haemophilus influenzae*), or can be atypical agents (cytomegalovirus and *Mycoplasma hominis*) not generally associated with sexual activity.

PID is difficult to diagnose due to (1) the wide variation in signs and symptoms and (2) the fact that more than one organism may be involved. Empirical treatment of PID

should be initiated if the following minimum criteria are met and no other cause for the symptoms (e.g., appendicitis) can be found: (1) uterine/adnexal tenderness or (2) cervical motion tenderness. Additional criteria that support the diagnosis of PID include (1) oral temperature higher than 38.3°C, (2) abnormal cervical or vaginal mucopurulent discharge, (3) presence of white blood cells upon saline microscopy examination, (4) elevated erythrocyte sedimentation rate, (5) elevated C-reactive protein, and (6) laboratory-documented cervical infection with gonorrhea or chlamydia.

Treatment for PID is a multidrug regimen that provides empiric, broad-spectrum coverage of the most likely pathogens. The nurse practitioner who suspects PID must begin treatment immediately to avoid the life-altering complications that can occur. Prevention of long-term complications has been linked directly with immediate administration of appropriate antibiotics. A woman who presents for care with signs and symptoms suggestive of PID needs to be treated as if she has all types of infection. A pregnancy test should be obtained and the results known before beginning treatment. All pregnant women with PID should be hospitalized and treated with intravenous antibiotics. In addition, a woman may need intravenous antibiotics and/or hospitalization if her temperature is high or if she cannot tolerate oral drugs (due to nausea and vomiting).

The outpatient treatment for mild to moderate PID includes a single intramuscular dose of cefoxitin 2 g plus a single dose of oral probenecid 1 g plus oral doxycycline 100 mg twice daily for 14 days. Metronidazole orally 500 mg twice a day for 14 days should also be added. An expert should be consulted when treating the penicillin-allergic patient with PID (Wiesenfeld, 2012). The primary care nurse practitioner should hospitalize and refer all patients with severe pelvic inflammatory disease as well as all pregnant women with PID regardless of the severity of infection.

The transition from IV therapy to oral therapy can usually be initiated within 24 hours of clinical improvement. Consider changing patients who fail to respond to oral therapy within 72 hours to parenteral therapy. The PID patient should show substantial clinical improvement within 3 days after initiation of therapy. Patients who do not improve within this time period usually require hospitalization, additional diagnostic testing, and surgical intervention.

Sexual Assault

Trichomoniasis, bacterial vaginosis, gonorrhea, and chlamydial infection are the most frequently diagnosed infections among women who have been sexually assaulted. Screening and treating sexual assault victims requires specialized training. Except in rare cases, evaluation and treatment of sexual assault victims should not be attempted by untrained providers (Bates, 2012). The information presented in this section is directed toward adults and does not include the treatment of sexual assault/abuse in children. In addition, the information is not meant to replace the specialized training needed to treat these patients.

Testing for chlamydia and gonorrhea via nucleic acid amplification testing and wet mount for bacterial vaginosis, trichomoniasis, and candida is recommended (Bates, 2012). Testing for HIV, hepatitis, and syphilis should also be considered. A pregnancy test should be done in all women of childbearing age and emergency contraception should be offered. Empiric treatment for gonorrhea, chlamydia, and trichomoniasis is recommended. Prophylactic treatment for HIV is controversial but should also be considered.

Sexual assault victims should be evaluated for ingestion of date rape and other drugs via blood and urine samples. In certain cases, hair samples can also be used. Alcohol and benzodiazepines are drugs commonly used (Bates, 2012).

The date rape drug Rohypnol (flunitrazepam) is available illegally in the United States. This drug has been associated with an increased incidence of adolescent date rape (American Academy of Pediatrics [AAP], 2009). Flunitrazepam, a very rapid onset benzodiazepine with amnesic properties, is a tasteless drug that can go undetected if added to any drink (Kosten, 2009). The tasteless properties of these drugs make the victim incapable of protecting him- or herself. Due to the amnesic properties of the drug, the sexual assault victim is unable to remember the events of the incident after the drug effects have worn off. These drugs, in the amounts most commonly used, produce intoxication and can produce fatalities if used with other respiratory depressants (such as large amounts of alcohol or opioids).

Men Who Have Sex With Men

The CDC (2010) recommendations include at least annual STI screening (or 3- to 6-month intervals for those at high risk) for HIV, syphilis, urethral/rectal/pharyngeal gonorrhea, chlamydia, and HBsAg in men who have sex with men (MSM).

Vaccinations against hepatitis A and B are recommended for all MSM in whom previous infection or immunization cannot be documented. Men should be offered the HPV quadrivalent vaccine, regardless of their sexual orientation.

The same STI treatment principles applied to heterosexuals are relevant to men having sex with men. If the nurse practitioner treats for gonorrhea, then treatment for possible co-infection with chlamydia should be prescribed. The reverse statement is also true.

Women Who Have Sex With Women

CDC (2010) data on women who have sex with women is limited. However, it is important to consider this population when screening for and treating sexually transmitted infections. A great majority of women have also had sex with men (Carroll, 2013). Screening for STIs should be performed in symptomatic women (Swygard & Cohen, 2012). The rates of screening for cervical cancer among these women are lower than that of heterosexual women.

Bacterial vaginosis is more common among women with female partners. For this reason, treatment of female partners is recommended. Sexual acts using shared penetrative devices (including hands and fingers) present a possible means for the

transmission of infected cervico-vaginal secretions. Transmission of HPV (including the types attributed to cancer) can occur through skin-to-skin or skin-to-mucosa contact (Carroll, 2013).

Hepatitis

Serological testing is necessary for all suspected cases of hepatitis. In the United States almost half of all reported hepatitis A cases have no specific risk factors identified. However, among adults with identified risk factors, the majority of cases are among MSM, persons who use illegal drugs, and international travelers (CDC, 2006). Only about 1.8% of patients die from liver disease as a result of hepatitis A, but there is considerable morbidity, well worth the cost and inconve -nience of two vaccine injections. Currently two products are available for the prevention of hepatitis A (HAV) infection: hepatitis A vaccine and immune globulin (Ig) for IM administration. No specific treatment therapy is available for persons with acute hepatitis A or B; treatment is supportive.

Chronic infections of hepatitis B occur in 1% to 6% of infected adults; however, they occur in 90% of infected newborns. The risk for premature death from either cirrhosis or hepatocellular carcinoma among persons infected with hepatitis B is between 15% and 25% (CDC, 2006). Hepatitis B virus (HBV) is passed through vertical transmission. Sexual transmission among adults accounts for most HBV infections in the United States. Prevention aimed at several groups is necessary. Prevention strategies include screening all pregnant women, vaccinating all newborns, vaccinating older children at high risk (e.g., Alaskan Natives, Pacific Islanders) and residents in households with first-generation immigrants from countries that have high levels of endemic disease, vaccinating children aged 11 and 12 who do not fit into the preceding categories, and vaccinating teens and adults at high risk (sexual behaviors confer increased risk). Hepatitis A and B are the only vaccines available for preventable hepatitis diseases. There is no vaccine for hepatitis C.

Two products have been approved for hepatitis B prevention: hepatitis B immune globulin (HBIG) and hepatitis B vaccine. HBIG provides 3 to 6 months of temporary protection from hepatitis B infection. There are two monovalent hepatitis B vaccines for use in adolescents and adults: Recombivax HB and Engerix-B. There is also a combination vaccine of hepatitis A and B for use in adults, Twinrix. See Chapter 19 or www.cdc.gov/vaccines for more information.

Hepatitis C virus (HCV) is the most common chronic blood-borne infection in the United States. HCV transmission occurs by direct percutaneous exposure to infected blood, as well as by occupational, perinatal, and sexual exposure. Sexual transmission of HCV accounts for up to 15% to 20% of HCV infections (CDC, 2007a). Furthermore, co-infection with HIV increases the risk for sexual transmission of HCV. Newly infected persons with HCV commonly are either asymptomatic or have a mild clinical illness and may not seek medical care. HCV RNA can be detected within 1 to 3 weeks of exposure. Chronic HCV infections develop in 60% to 85% of HCV-infected persons. Of these, 60% to 70% have evidence of active liver disease. No vaccine is available for HCV, and prophylaxis with immune globulin is not effective in preventing HCV infection after exposure (CDC, 2006).

HIV

The immunosuppressive pathology of HIV predisposes some infected individuals to STIs. HIV affects the immune system, which in turn has an impact on diagnostic testing and evaluation of some of these infections. In addition, those infected with HIV often have a suboptimal response to treatment or present as treatment failures when infected with an STI. As a result, HIV-infected patients who have concurrent STI infections may require longer, more aggressive courses of therapy. When included as part of the treatment recommendations, nurse practitioners should consider prescribing suppressive therapy (HSV vaccine) sooner rather than later. Treatment of HIV infection is covered in Chapter 37.

Penicillin Allergy

Individuals infected with an STI but who have an allergy to penicillin also present as a treatment challenge. There are no CDC recommendations or proven alternatives to penicillin for the treatment of neurosyphilis, congenital syphilis, or syphilis in pregnant women. Penicillin is also the treatment of choice in HIV-infected patients. However, the administration of penicillin to those allergic to the drug can cause severe, immediate anaphylaxis, which can be fatal. As a general rule, penicillin should never be used in penicillin-allergic patients. Those patients needing penicillin should be referred to allergy specialists who can safely perform allergy skin testing and acute desensitization to eliminate anaphylactic sensitivity.

Monitoring

Drug sensitivity, patient intolerance, and noncompliance with drugs requiring multiple daily doses frequently necessitate use of alternate drugs. Although treatments for most STIs are quite effective, follow-up is necessary, particularly in high-risk or noncompliant individuals. Each nurse practitioner should use clinical judgment when deciding who and when to screen and rescreen. Generally speaking, experts recommend rescreening in women and men at 3-month intervals because recurrence is common with many of these infections (Swygard & Cohen, 2012).

Viral STIs present a challenge for most health-care providers. Patient education, appropriate viral testing, and evaluation of possible concurrent infections are necessary components of any management. It is important to be sure that all sexual partners have been treated and that the organism in question has either been eradicated or brought under control. Asymptomatic partners may be resistant to treatment and may require education and assistance from the local health department.

Laboratories are required by law to report most STIs to the state, so patients need to know that they will be contacted for verification of treatment. In addition, nurse practitioner providers should educate themselves about which sexually transmitted infections they are legally required to report. This

information can be found on the CDC's National Notifiable Diseases Surveillance System Web site: wwwn.cdc.gov/nndss/default.aspx.

Although it may improve treatment and recurrence rates, partner-delivery of patient medications is not recommended and is not legal in many states (Swygard & Cohen, 2012). Partners of those infected patients should be evaluated and promptly treated.

Outcome Evaluation

Infection in the genital tract with chlamydia or gonorrhea, if not treated in a timely manner, may ascend and invade the fallopian tubes, thus causing life-threatening PID and sepsis. Patients and their sexual partners should abstain from intercourse until 7 days after a single-dose treatment or upon successful completion of treatment (Swygard & Cohen, 2012).

A pregnant patient with an untreated STI may spontaneously abort and hemorrhage. Sepsis and bleeding require hospitalization and parenteral therapy. Consultation and referral to a gynecologist must be completed swiftly to prevent further complications. The specialist, in turn, will need information that only the nurse practitioner may possess: the patient's full past medical history, laboratory findings, previous treatments, and drug allergies.

Patient Education

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and potential compliance issues (Box 44-1). Partner education is also important to consider. Assessment of the barriers to drug adherence need to be explored and discussed with the patient.

VAGINITIS

Vagnitis symptoms among women are extremely common which often results in self-diagnosis and treatment with

> ### BOX 44–1 VACCINE-PREVENTABLE SEXUALLY TRANSMITTED INFECTIONS
>
> Many of the sexually transmitted infections are vaccine preventable (HAV, HBV, and HPV). Due to growing public health concerns, escalating costs of treatment, and lack of insurance, preventing infections is, in most cases, easier and less expensive than treatment. Whenever possible, patients should be educated early and often regarding the type of vaccines that they would be successful candidates to receive. Currently, there is no approved vaccine available for hepatitis C virus (HCV). Prophylaxis treatment after exposure to the virus has not been shown to be effective (CDC, 2010).

over-the-counter agents (Sobel, 2012c). The three diseases most frequently associated with vaginal discharge are trichomoniasis, bacterial vaginosis, and candidiasis (CDC, 2010; Sobel, 2012c). *C. trachomatis* and *N. gonorrhoeae* are less frequent causative organisms. Other, less common causes are cervicitis, atrophic vaginitis, foreign body resulting in secondary infection, irritants, and allergies (Sobel, 2012c). Treatment without an appropriate history and examination is not recommended as self-diagnosis can be inaccurate.

Diagnosing vaginal discharge and vulvar conditions requires a thorough history and examination of the area affected. Not all practitioners are adept at microscopy; however, microscopy skills are essential for a proper diagnosis of the patient with vaginitis. The diagnosis may be elusive without prompt examination of vaginal discharge.

This chapter earlier discussed the most common STIs and their treatment. Vaginal infections can be sexually transmitted, but some may also be acquired without sexual contact: VVC, some types of bacterial vaginosis, cytolytic vaginosis, atrophic vaginitis with secondary bacterial infection, and some types of streptococcal infections. *Staphylococcus aureus,* found in toxic shock syndrome, is associated with foreign bodies (tampons) inadvertently left during menses. Treatment of vulvovaginal infections is discussed separately from those vulvovaginal conditions that present with vaginal burning, pruritus, and dyspareunia, yet are not infectious.

Pathophysiology

Normal vaginal discharge contains desquamated vaginal epithelial cells, cervical secretions, lactic acid, and bacteria that are both anaerobic and aerobic. Vaginal microflora, predominantly *Lactobacillus,* appear under the microscope as unclumped, rod-like organisms. Estrogen fluctuations, age influence, and infections may alter the delicate balance. The most common infections are due to bacteria, yeast, and parasites. Conditions not covered earlier in the chapter are discussed here.

Cytolytic Vaginosis

In cytolytic vaginosis, an overgrowth of *Lactobacillus* occurs late in the menstrual cycle. It is frequently treated as a chronic yeast infection. Diagnosis is made by absence of *Trichomonas,* hyphae, clue cells, and white blood cells under microscopy. The pH may be as low as 3.5, and treatment is aimed at raising the pH rather than eradicating all bacteria. Treatments that involve douching of medications are discouraged. Instead, patients are encouraged to make vaginal suppositories from clear gelatin capsules (size 0) filled with sodium bicarbonate (baking soda) and dose twice weekly in the last week of the menstrual cycle.

Atrophic Vaginitis

Atrophic vaginitis with secondary infection occurs due to estrogen deficiencies. As a result, the thinned vaginal epithelium

SEXUALLY TRANSMITTED INFECTIONS

Related to the Overall Treatment Plan/Disease Process

☐ Importance of routine Pap smears in women and testicular self-examinations (TSE) in men

☐ Prevention of high-risk sexual behaviors

☐ Avoidance of sexual intercourse until the organism is either eradicated (bacterial) or under control (viral)

☐ Include immunization against selected STDs as part of treatment regimen

Specific to the Drug Therapy

☐ Many OTC products are available to treat symptoms.

☐ Douching is no longer recommended because of the potential for pelvic infection and destroying the normal flora of *Lactobacillus.*

☐ BV must be diagnosed and treated on the same day in patients suspected of being pregnant (BV may cause preterm labor).

☐ Importance of assessment of pregnancy status in all women of childbearing years *before* prescribing

☐ Choosing a generic agent that has daily or twice-daily dosing increases patient compliance with treatment.

Reasons for Taking the Drug(s)

☐ Prevention of serious complications such as PID and infertility

☐ Prevention of transmission of infection to the uninfected (public health issue)

☐ Prevention of dyspareunia, which affects normal sexual relations

Drugs as Part of the Total Treatment Regimen

☐ Importance of seeking treatment when symptoms appear

☐ Importance of culturing asymptomatic young persons (aged 15 to 24) every 6 months

Adherence Issues

☐ Importance of following the labeled instructions to totally eradicate the infection

☐ Importance of finishing the full course of antibiotics

☐ Importance of contacting the health-care provider if side effects or rash appears

☐ The potential for drug interactions (the macrolides with antifungal, systemic antifungals, and birth control pills)

---

has reduced defenses against common perineal bacteria. Culturing is necessary, as well as microscopy. See Table 44-2 for treatment once the infecting organism is diagnosed and Table 44-3 for treatment of the underlying atrophic conditions.

Toxic Shock Syndrome

S. aureus associated with toxic shock syndrome (TSS) can be life-threatening. A patient with TSS requires immediate referral for hospitalization. *S. aureus* commonly colonizes skin and mucous membranes in humans. TSS has been associated with use of tampons and intravaginal contraceptive devices in women and occurs as a complication of skin abscesses or surgery. Risk groups include menstruating women, women using barrier contraceptive devices, persons who have undergone nasal surgery, and persons with postoperative staphylococcal wound infections (CDC, 2007). Some women harbor *S. aureus* in their normal vaginal secretions but experience no symptoms until using tampons sets up an anaerobic climate. Criteria for making this diagnosis and treatment are based on CDC guidelines and include four of the following five diagnostic criteria: fever of 38.9°C (102°F) or higher, presence of a diffuse macular erythroderma, desquamation 1 to 2 weeks after onset of illness (palms and soles), hypotension (orthostatic changes of 15 mm Hg diastolic pressure or syncope), and involvement of three or more organ systems (GI, muscular, mucous membrane, renal, hepatic, hematological, and central nervous system [CNS]) (CDC, 2007).

Noninfectious Vaginal Conditions

Noninfectious vaginal conditions may result from the following:

1. Normal cyclical hormonal changes, which occur at midcycle under high estrogen levels, and premenses, which is under progestin dominance. The changes in amount of vaginal secretions may concern some women, and microscopy may be necessary to reassure the patient and to rule out pathological organisms.

Table 44–3 Treatment for Noninfectious Vulvovaginal Conditions

Condition	Drug Used	Nondrug Treatment
Chemical or other irritants, spermicidals, douching solutions	Systemic steroid burst Medrol Dosepak	Avoid products with color and fragrance. Always use sanitary pads. Treat urinary incontinence with hygiene and disposable pads. Referral to urology for surgical correction.
Allergic, hypersensitivity, contact dermatitis, lichen simplex, foreign body	Steroid burst if severe reaction occurs Topical preferred over systemic	Avoidance and education about use of excessive hygiene measures. Use of Crisco (vegetable shortening) and avoidance of detergents in older women.
Desquamative inflammatory vaginitis (steroid responsive)	If short course is helpful, consult about length of therapy; need tissue diagnosis	Avoid harsh scrubbing, soaps, and other over-the-counter vaginal products.
Erosive lichen planus	Steroids are usually necessary; need tissue diagnosis and consult or refer	Avoid excessive hygiene measures; there are "vulvar" specialists in gynecology.
Collagen vascular disease, Behçet's and pemphigus syndromes	Refer aggressive and painful lesions for diagnosis and treatment May use low-dose (25–50 mg) tricyclic antidepressants for pain control	Support groups may be helpful for some patients.
Hormonal Changes (normal responses)		
1. Midcycle	None	If culture and microscopy clear, then educate and reassure patient.
2. After intercourse	None	If culture and microscopy are clear, then educate and reassure.
3. Atrophic	Vaginal lubricants and moisturizers are first-line treatments. In women without a history of breast cancer, low-dose vaginal estrogen therapy is preferred over systemic estrogen therapy: ≤50 mcg estradiol or <0.3 mg conjugated estrogens/ ≤0.5 g cream.	May require 3–6 mo of therapy for full therapeutic benefit. Can use topical treatments indefinitely. All postmenopausal women experiencing vaginal bleeding should be evaluated for cancer.
Epithelial disorders (previously called dystrophies), lichen sclerosus (white lesions)	Clobetasol 0.05% ointment daily at night for 6–12 weeks and then 1–3 times per week for maintenance.	Biopsy is required for diagnosis. Support group may be helpful for some patients. Women are at high risk for developing squamous cell cancer of the vulva. Steroid creams should be avoided because they can contain irritants not found in ointments.

M., Teichman, J. M., Elston, D. M., & Sea, J. (2010). Noninfectious penile lesions. *Journal of the American Academy of Family Physicians, 81*(2).

2. Irritant or allergic products, such as those found in hygiene and contraceptive products (e.g., spermicides and latex).
3. Atrophic conditions, such as those associated with the postpartum period and breastfeeding and those associated with postmenopausal vaginal atrophy.

Other Conditions

Less common and more worrisome are inflammatory, collagen, and epidermal sclerosing conditions, which are commonly diagnosed in older women: inflammatory conditions related to trauma from excessive washing, wiping, and scratching; inflammatory conditions reflecting collagen-vascular disease; and inflammatory conditions associated with white or pigmented lesions that may be dysplastic or cancers.

Goals of Treatment

The goals of treatment are to treat the infection or inflammation, prevent reinfection, and prevent complications of the infection or inflammation. The infection cannot be treated without an accurate diagnosis. Patients often call the office numerous times for prescriptions for yeast infections, yet frequently they do not have monilial vaginitis. Telephone diagnoses run the risk of being incorrect. As a result, patients often spend money on ineffective medications. In addition, prescribing an ineffective antibiotic exposes the patient to potential side effects, adverse effects, and drug-drug interactions.

For patients aged 15 to 24, there is a probability the complaint is related to a sexually transmitted infection. For patients age 50 to 70, vaginal symptoms are more often related to atrophy of the genital tissues, vulvar presentation of collagen-vascular disease, or cancer. However, sexually transmitted

infections can still occur in the geriatric population. The prudent nurse practitioner should include these infections as part of the differential diagnosis of the geriatric women with vaginal complaints, particularly those women with new sexual partners.

Reinfection occurs when the etiology of the vaginal irritation is not known. If lack of estrogen is making the vaginal tissues thin and vulnerable to bleeding, then treatment with an antibiotic alone allows the infection to recur. Treatment with vaginal estrogen or the vaginal ring thickens the vaginal epithelium and permits natural defenses (intact mucous membranes) to prevail.

Complications of the infection can occur when symptoms of itching and irritation go untreated and the affected tissues thicken and lose elasticity (lichenification). When vulvar tissues become inflamed and heal, they often shrink in size so that the vagina will not allow sexual penetration. Early and aggressive treatment of conditions such as lichen sclerosus delays permanent hardening of the epidermis and dermal layers of the vulva.

Rational Drug Selection

Guidelines

Treatment of STI infections is guided by the CDC but should not replace nurse practitioner clinical judgment. Treatment for nuisance infections may vary according to severity of patient symptoms or health-care provider preference.

All recommended treatments have the potential to be costly for the patient and for the health-care system and are not without side effects, adverse effects, and drug-drug interactions (Lexicomp, 2013). For example, the concurrent use of penicillin G with tetracycline, erythromycin, and doxycycline is not recommended. In addition, penicillin and doxycycline both have the potential to interfere with estrogen-containing oral contraceptives. For this reason, a backup method of contraception is recommended. The use of erythromycin with oral azoles is not recommended due to the cardiac adverse effects that can occur. Metronidazole in both oral and gel preparations has the potential to cause seizures. Finally, ciprofloxacin has been known to cause tendonitis and tendon rupture in all age groups. Photosensitivity reactions can also occur and patients should be educated to take precautions when in the sun.

Cost

Many fungal infections are easily eradicated with topical antifungals such as miconazole, which is available OTC. Maximizing the use of OTC agents is a more cost-effective approach for the patient, especially for those without insurance, to cover the cost of a written prescription.

Patient Variables

There are many variables to consider when preparing a patient treatment plan. Generic drugs are more cost-effective for the patient. Prescribing the shortest possible course of treatment with an agent that has the potential to cause the least amount of side effects and drug-drug interactions will also improve compliance rates. Oral medications are often preferred over vaginal creams and suppositories, which can be messy and uncomfortable for the patient.

Drug Variables

Many vulvovaginal conditions can successfully be treated topically, thus avoiding the potential side effects and adverse effects of oral medications. Use of intravaginal antibiotics and antifungals generally does not affect the absorption of oral contraceptives or other medications that patients may be taking. Low-dose topical steroids can be used for longer periods without suppressing the adrenal gland and reducing total body immunity. When used around vaginal tissues, low-dose topical steroids are preferred over higher, more potent doses due to the potential adverse effects that can occur.

Monitoring

There are many factors to consider when screening, rescreening, and performing test-of-cures. When in doubt, the nurse practitioner should rescreen. Nurse practitioners should use clinical judgment and individualize the approach used while being mindful of the recommended guidelines and available resources. Over-the-phone treatment is not recommended. Experts do not advise treating the patient and his/her partner without conducting an appropriate history and physical examination.

Outcome Evaluation

When a patient has a dermal condition that the practitioner has not seen before, a consultation or referral is strongly recommended. Consultation is also necessary when pigmented or white lesions are seen during examination. If patients remember that they were born with pigmented lesions (birthmarks), then biopsy is generally not necessary.

When patients do not respond to initial or follow-up treatments, consider referral. If the provider is not adept or comfortable with vulvar biopsies, then referral for specialty care is necessary. When conditions of the vulva appear in the very young (patients aged 1 to 12), in the older adult (patients age 60 or older), or in the pregnant patient, referral is recommended.

Patient Education

When treating the patient with an STI, extensive education is often needed and should be thoroughly documented in the patient's medical record. Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues.

VAGINITIS

PATIENT EDUCATION

Related to the Overall Treatment Plan/Disease Process

☐ Knowledge of many causes of vaginal irritation, ranging from allergy to inflammatory conditions associated with local and systemic disease

☐ Knowledge of the physiological changes in vaginal epithelium from age 12 to 50

☐ Hygiene issues such as types of clothing for underwear, wiping correctly, and emptying bladder before and after intercourse

Specific to the Drug Therapy

☐ Many OTC products that were previously under prescriptive authority are available to treat symptoms and are still efficacious.

☐ Douching is no longer recommended because of the potential for pelvic infection and its destruction of the normal flora of *Lactobacillus.*

Reasons for Taking the Drug(s)

☐ Prevention of dyspareunia, which affects normal sexual relations

☐ Control of miserable chronic conditions like lichen sclerosus

Drugs as Part of the Total Treatment Regimen

☐ Importance of seeking treatment when symptoms first appear to obtain the correct diagnosis

☐ Drug treatment early may prevent long-term morbidity (atrophy, sclerosis, and cancers).

Adherence Issues

☐ Importance of following the labeled instructions to totally eradicate the infection

☐ Importance of contacting the health-care provider if side effects or rash appears

☐ Potential for drug interactions (the macrolides with antifungal, systemic antifungals, and birth control pills)

TUBERCULOSIS

Teri Moser Woo

Tuberculosis (TB) presents a serious threat to global health, with 8.6 million people developing TB and 1.3 million deaths in 2012 (World Health Organization [WHO], 2013). Nearly one-third of the world population is infected with Mycobacterium tuberculosis. In 1993, the World Health Organization (WHO) declared a global emergency concerning TB, the number-one infectious disease killer worldwide. WHO has a goal to reduce prevalence of and deaths from TB by 50% by 2015 compared to a 1990 baseline, and eliminate TB as a public health problem by 2050 (WHO, 2013). By 2012, the TB mortality rate had decreased by 45%, but the prevalence rate has only dropped by 37% worldwide (WHO, 2013).

In the past 20 years, TB incidence in the United States decreased significantly from 10.4 cases per 100,000 in 1992 to 3.2 cases per 100,000 in 2012 (Centers for Disease Control and Prevention [CDC], 2013a). Yet TB continues to present a significant health problem; in 2012 there were 9,945 TB cases reported to the Centers for Disease Control and Prevention (CDC) from all 50 states, the District of Columbia (DC), and the U.S.-affiliated Pacific Islands (CDC, 2013b).

TB infection rates vary among racial and ethnic populations in the United States, with Asians having the highest rate of 18.9 cases per 100,000 in 2012 compared to 0.8 cases per 100,000 persons identifying themselves as white (CDC, 2013a). The majority of cases of TB in the United States in 2012 were in foreign-born persons (CDC, 2013b).

Canada reported 1,686 cases of new active or recurrent TB in 2012 (Public Health Agency of Canada, 2014). The majority of cases (64%) of TB in Canada are among foreign-born people. Canadian-born aboriginal people have a higher incidence (21.2% of cases) of TB than Canadian-born non-aboriginal peoples (11.8% of cases) (Public Health Agency of Canada, 2014).

In the United States, federal funding for TB programs decreased in the 1970s, with states and the federal government spending less money on TB prevention. Because of decreased funding and the growing worldwide HIV epidemic, the emergence of drug-resistant TB was inevitable. In the 1990s, the U.S. Congress increased funding for TB, and the CDC established three National Model TB Centers (in San Francisco, Newark, and New York City) and a National Tuberculosis

Surveillance Network. The CDC Division of Tuberculosis Elimination has developed and funded from 2013 through 2017 five Regional TB Training and Medical Consultation Centers to provide education and consultation to TB programs and providers in all 50 states and U.S. territories.

Acquired resistance to TB medications stems from inadequate or inappropriate prescribed treatment regimens or from patient noncompliance. Surveillance indicates cases of multidrug-resistant (resistance to at least isoniazid and rifampin) TB decreased from 2.5% of TB cases in 1993 to 1.1% in 2012. Cases of extensively drug-resistant (XDR) TB (resistance to isoniazid and rifampin plus resistance to any fluoroquinolone and at least one of three injectable second-line anti-TB drugs [i.e., amikacin, kanamycin, or capreomycin]) decreased from ten cases in 1993 to two cases in 2012 (CDC, 2013b). In Canada, 9.5% of TB isolates were resistant to at least one first-line antituberculosis drug in 2009, predominately (85%) isoniazid (INH), and 1.4% of isolates were resistant to multiple drugs (Public Health Agency of Canada, 2010).

Global data indicate 3.6% of newly diagnosed TB cases and 20% of cases in those who were previously treated for TB had multiple-drug-resistant (MDR) TB (WHO, 2013). The problem of MDR TB is worldwide, with the highest rates of MDR TB in eastern Europe and central Asia; MDR TB accounts for up to 20% of new cases and 50% of those previously treated (WHO, 2013). WHO is concerned with MDR TB and has partnered with the International Union Against Tuberculosis and Lung Disease (IUATLD), and the Bill and Melinda Gates Foundation to develop a Call to Action, including a goal of universal access to MDR/XDR-TB diagnosis and treatment by 2015.

Both the diagnosis and treatment of TB have become complex. Diagnostic criteria depend not only on the results of testing but also on the patient's immigration and immune status. Multidrug regimens that vary according to the patient's risk factors require the practitioner to be familiar with a wide variety of treatment regimens. Compliance with long treatment courses is an issue in the treatment of TB. Noncompliance leads to the emergence of drug-resistant TB. This chapter addresses the treatment of TB and strategies to increase compliance with the treatment regimen, as well as the drug regimen used for TB prevention.

PATHOPHYSIOLOGY

TB is an infectious disease caused by *M. tuberculosis,* an organism that is inhaled into the alveolus, where it is ingested by the pulmonary macrophage. The bacilli multiply and spread to local pulmonary areas and to extrathoracic organs via the lymphatic system. The infected macrophage releases a substance that attracts T lymphocytes. The infected macrophage presents antigens from the phagocytosed bacilli to the lymphocytes, producing a series of committed immune effector cells. This causes a delayed hypersensitivity and, combined with the newly activated macrophages, leads to intracellular killing of the bacilli and granuloma formation.

M. tuberculosis and most of the other mycobacteria grow quite slowly, with a doubling time of 18 hours. Thus, skin test reactivity does not occur until 4 to 6 weeks after infection,

with longer intervals noted. Colonies on culture media do not appear for 3 to 5 weeks, creating delays in culture confirmation and testing for drug susceptibility.

Infection is spread almost exclusively by aerosolization of contaminated lung secretions. This organism primarily affects the pulmonary tissue, although extrapulmonary TB is not uncommon, especially in immunocompromised patients. Patients with cavitary lung disease cough frequently and, therefore, are particularly infectious. The aerosolized droplets can remain suspended in room air for many hours. The skin and respiratory mucous membranes of a healthy, normally exposed person are resistant to invasion. The problem occurs with heavy or prolonged exposure to an infected or immunocompromised person. The very young and the very old or debilitated are also more susceptible because of decreased host defenses.

Pulmonary TB presents with the classic symptoms of TB: cough with productive, purulent secretions, often with blood streaks. Other symptoms include wide temperature variations, malaise, fatigue, wasting, chest pain, and dyspnea. Sweating, including night sweats, is common.

Extrapulmonary TB presents with a more problematic set of symptoms, often mimicking other diseases. Lymphatic TB may present initially as unilateral, painless, cervical lymphadenopathy. TB bacilli can also settle in the genitourinary tract, bones or joints, meninges, gastrointestinal (GI) tract, and pericardium. When these extrapulmonary sites are infected, the symptoms are often vague and difficult to define. The suspicion of TB and intradermal testing as part of a work-up for other diseases may lead to a quicker diagnosis. Also of concern is that the tuberculin skin test can be negative 20% to 25% of the time. Appropriate biopsy and culture of affected tissues or cerebrospinal fluid—which usually require consultation with a specialist in infectious diseases—increase the likelihood of an accurate diagnosis.

GOALS OF TREATMENT

The initial goal of treatment in TB is an accurate diagnosis. This requires a practitioner who understands the current guidelines for screening and puts TB high on the differential list for any pulmonary or other illness with vague presenting symptoms. A second goal is the patient's completion of the recommended therapy, because failure to complete therapy can lead to drug-resistant TB. Finally, the effectiveness of treatment must be evaluated. Effective treatment of TB is not only intended to treat the sick patient but also to prevent the transmission of *M. tuberculosis* to the public.

Patients who have positive sputum cultures at the beginning of treatment should have monthly cultures, and the culture should convert to negative. A final chest x-ray is needed for documentation of baseline for future films, but the x-ray is not as important as the sputum examination (American Thoracic Society [ATS], 2003).

In patients with radiographic abnormalities consistent with TB, an effort should be made to establish a diagnosis via sputum culture. The CDC and the Canadian guidelines recommend that three sputum specimens should be obtained if

pulmonary involvement is suspected (CDC, 2003a; Canadian Thoracic Society and The Public Health Agency of Canada, 2013). Nucleic acid amplification tests for the diagnosis of TB and to determine drug resistance is sensitive and provides a more rapid result than traditional culture. Bronchoscopy may be necessary to obtain an accurate diagnosis. If presumptive treatment is the only option, the key indicators for response to therapy are the chest x-ray findings. Improvement should be noted within the first 3 months of therapy. If there is no improvement, then either resistance or inaccurate diagnosis must be considered. The CDC recommends that all patients with TB have testing for HIV infection at the time treatment is initiated, if not earlier (CDC, 2003a).

RATIONAL DRUG SELECTION

Risk Stratification

Although anyone may become infected with TB, some populations are identified as being at greater risk: children up to age 4 years, the infirm elderly, and immunocompromised patients, including those with HIV infection or AIDS and organ transplant recipients. Foreign-born people are also at higher risk, accounting for 63% of U.S. TB cases in 2011 (CDC, 2013b) and 64% percent of Canadian cases (Public Health Agency of Canada, 2014). The top five countries of origin for foreign-born TB cases from 2000 to 2012 were Mexico, the Philippines, India, Vietnam, and China (CDC, 2013c). Canadian statistics reflect the immigration patterns of the country, with the world regions of the Western Pacific, Southeast Asia, and Africa accounting for the highest prevalence of foreign-born TB cases (Canadian Thoracic Society and The Public Health Agency of Canada, 2013). In the United States and Canada, certain populations are identified as being at higher risk, specifically medically underserved, low-income populations, including high-risk racial or ethnic minority populations; people who are homeless; blacks; Hispanics; and Native Americans/Canadian aboriginal peoples. Nonwhite patients have a peak incidence of TB between ages 25 and 44, significantly younger than that of whites, which is over age 70. Residents of long-term-care facilities (nursing homes, prisons, and mental institutions) are also at higher risk.

Screening

Targeted screening for TB is usually based on the patient's presenting with an identified risk factor. In some areas of the country, routine TB testing is part of all health maintenance visits because of an increased incidence of TB in the area. Patients identified as being at risk are those with compromised immune systems (e.g., HIV-positive or undergoing immunosuppressive therapy or prolonged adrenocorticosteroid therapy), close contacts of patients with newly diagnosed infectious TB, injection drug users known to be HIV seronegative, foreign-born persons from high-prevalence countries, medically underserved low-income populations, and residents and staff of long-term-care facilities or prisons. All health-care providers should be screened routinely.

Two screening methods for TB may be used, the tuberculin skin test (TST) or interferon-gamma release assays (QuantiFERON-TB Gold test and T-SPOT.TB test). The most commonly used screening test is an intradermal injection of TB protein antigens (such as purified protein derivative [PPD]). In 48 to 72 hours, an induration response is considered positive, based on the population being tested. The CDC in the United States and Public Health Agency of Canada have slightly different criteria for positive tuberculin skin test results. The CDC (2012) states that for adults and children with HIV infection, close contacts of people with infectious TB and patients with fibrotic lesions on chest x-ray (especially in upper lung regions), an induration of 5 mm or more is considered positive. A reaction of 10 mm or more is considered positive for other high-risk adults and children, including infants and children under age 4. For people not considered at risk for TB infection, a reaction of 15 mm or more is considered positive.

The Canadian criteria for a positive skin test are the following: an induration of 5 to 9 mm is considered positive in patients with HIV infection, close contacts of contagious cases within the past 2 years, children suspected of having TB, patients with abnormal chest x-ray with fibronodular disease or immune suppression, and patients with end-stage renal disease; a greater than 10 mm induration is positive in all other cases (Canadian Thoracic Society and The Public Health Agency of Canada, 2013).

In 2005, the U.S. Food and Drug Administration (FDA) approved QuantiFERON-TB Gold as an aid in diagnosing *M. tuberculosis* infection, both latent and active (Mazurek et al, 2005). Health Canada approved QuantiFERON-TB in 2006. The QuantiFERON-TB Gold (QFT-G) is an enzyme-linked immunoassay (ELISA) test that tests for the proteins present in *M. tuberculosis* that are absent from bacille Calmette-Guérin (BCG) vaccines (Mazurek et al, 2005). The T-SPOT. TB test is an in vitro immunoassay test that measures T cells primed to *M. tuberculosis* antigens; it was FDA-approved in 2008 (Oxford Immunotec, 2014). A positive QFT-G or T-SPOT test should be treated in the same manner as a positive TST: the patient needs a medical evaluation, including a chest x-ray, to rule out latent versus active TB infection.

A new, fully automated test, Xpert MTB/RIF, has been developed and is being recommended by WHO for initial screening in patients with suspected MDR-TB or HIV/TB (WHO, 2013b). Xpert MTB/RIF can detect TB and rifampin-resistant TB, with results available within 24 hours. The test is expected to triple the number of drug-resistant cases of TB identified and double the number of TB cases diagnosed in HIV patients. Development and rollout of the testing worldwide is being partially funded by the Bill and Melinda Gates Foundation to keep the costs within the ability of resource-poor countries to use the technology (WHO, 2013b).

Drug Therapy for Infectious Tuberculosis

Treatment of infectious TB requires the practitioner to apply three basic principles, as recommended by the ATS,

CDC, and the Infectious Diseases Society of America (CDC, 2003b):

1. Treatment regimens must contain multiple drugs to which the organisms are susceptible.
2. The drugs must be taken regularly.
3. Drug therapy must continue for a sufficient period of time.

Another fundamental principle of managing TB patients is never to add a single drug to a failing treatment regimen (ATS, 2003).

Many combinations of drugs and frequencies of administration are possible, but the initial phase of treatment is critical to prevent drug resistance and improve outcomes. Treatment for TB has two phases: the first phase or initiation phase (bactericidal or intensive phase), which lasts for 2 months, and the continuation phase (sterilizing phase), which lasts for 4 to 7 months (Blumberg, Leonard, & Jasmer, 2005). This chapter discusses the treatment regimens that may be used. As newer medications are approved, these regimens may change, but the basic principles remain (Table 45-1).

Table 45–1 Drug Regimens for Culture-Positive Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

Initial Phase			Continuation Phase			Rating (Evidence)		
Regimen	Drugs	Interval and Doses‡ (Minimal Duration)	Regimen	Drugs	Interval and Doses‡ (Minimal Duration)	Range of Total Doses (Minimal Duration)	HIV–	HIV+
1	INH RIF PZA EMB	7 d/wk for 56 doses (8 wk) or 5 d/wk for 40 doses (8 wk)¶	1a	INF/RIF	7 d/wk for 126 doses (18 wk) or 5 d/wk for 90 doses (18 wk)¶	182–130 (26 wk)	A (I)	A (II)
			1b	INH/RIF	Twice weekly for 36 doses (18 wk)	92–76 (26 wk)	A (I)	A (II)*
			1c**	INH/RPT	Once weekly for 18 doses (18 wk)	74–58 (26 wk)	B (I)	E (I)
2	INH	7 d/wk for 14 doses (2 wk). Then twice weekly for 12 doses (6 wk) or 5 d/wk for 10 doses (2 wk).¶ Then twice weekly for 12 doses (6 wk)	2a	INH/RIF	Twice weekly for 36 doses (18 wk)	62–58 (26 wk)	A (II)	B (II)*
	RIF PZA EMB		2b**	INH/RPT	Once weekly for 18 doses (18 wk)	44–408 (26 wk)	B (I)	E (I)
3	INH RIF PZA EMB	Three times weekly for 24 doses (8 wk)	3a	INH/RIF	Three times weekly for 54 doses (18 wk)	78 (26 wk)	B (I)	B (II)
4	INH RIF	7 d/wk for 56 doses (8 wk) or 5 days/wk for 40 doses (8 wk)¶	4a	INH/RIF	7 d/wk for 217 doses (31 wk) or 5 d/wk for 155 doses (31 wk)¶	273–195 (39 wk)	C (I)	C (II)
	EMB		4b	INH/RIF	Twice weekly for 62 doses (31 wk)	118–102 (39 wk)	C (I)	C (II)

EMB = ethambutol; INH = isoniazid; PZA = pyrazinamide; RIF = rifampin; RPT = rifapentine.

*Definitions of evidence ratings: A = preferred; B = acceptable alternative; C = offer when A and B cannot be given; E = should never be given.

†Definition of evidence ratings: I = randomized clinical trial; II = data from clinical trials that were not randomized or were conducted in other populations; III = expert opinion.

‡When DOT is used, drugs may be given 5 d/wk and the necessary number of doses adjusted accordingly. Although no studies compare five with seven doses, extensive experience indicates this would be an effective practice.

§Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7 months' continuation phase (31 weeks either 217 doses [daily] or 62 doses [twice weekly]).

¶Five-day-a-week administration is always given by DOT. Rating for 5 d/wk regimens is A III.

♯Not recommended for HIV-infected patients with CD4+ cell counts <100 cells/mcL.

**Options 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph (see text). For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.

Source: Centers for Disease Control and Prevention. (2003). Treatment of tuberculosis, American Thoracic Society, CDC, and Infectious Diseases Society of America. *Morbidity and Mortality Weekly Report, 52*(RR-11).

There are several combination drugs available to treat TB. Combination tablets offer ease of dosing with one tablet, but may be more expensive than single-ingredient tablets. Rifater tablets contain 120 mg rifampin, 50 mg isoniazid, and 300 mg pyrazinamide and cost $259 for 60 tablets. Rifamate or IsonaRif capsules contain 300 mg rifampin and 150 mg isoniazid and the generic form costs $60 for 60 capsules, which is a 30-day supply for adults. In comparison, rifampin 300 mg capsules cost $47 for 60 capsules, and isoniazid 300 mg tablets are $8 for 60 tablets, for a total of $55 for a 30-day supply. The $200 difference in cost is significant for clients who must pay all or a large part of their drug costs. The ATS (2003) guidelines note that no evidence supports combination medications over single-ingredient drugs, although the combination drugs may be preferable if directly observed therapy (DOT) is not used.

Six-Month Regimen

A 6-month regimen is recommended for patients who adhere to treatment and have fully susceptible organisms. This regimen consists of 2 months of four-drug therapy administered daily: isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB), followed by 4 months of INH and RIF. Alternative regimens for the first 2 months of therapy include the same four drugs (INH, RIF, PZA, and EMB) given (regimen 2) daily for 2 weeks followed by twice weekly for 6 weeks; or (regimen 3) three times a week for 8 weeks (CDC, 2003a). This four-drug therapy is effective even when the infecting organism is resistant to INH. Dosing for the continuation phase (after the initial 2 mo) should consist of INH and RIF (regimen 1) daily, (regimen 2) twice weekly, and (regimen 3) three times weekly for 4 months (CDC, 2003a). Streptomycin is substituted for EMB in children too young to be monitored for visual acuity.

This 6-month treatment can be used in patients who have HIV infection and patients who are not infected with HIV. Patients who have HIV infection should be monitored for treatment response, and their therapy should be prolonged if the response is suboptimal. The continuation phase of treatment should be followed for an additional 3 months for patients who have cavitation on the initial or follow-up chest radiograph and are still culture-positive after the initial 2 months of treatment (CDC, 2003a).

Nine-Month Regimen

A 9-month regimen of INH and RIF may be used for patients who cannot take PZA or who have isolates resistant to PZA. EMB (streptomycin in young children) should also be included in the treatment protocol for the first 2 months, followed by INH and RIF given either daily or twice weekly for 7 months (CDC, 2003a). Dosages for the drugs commonly used for treatment and prevention are shown in Table 45-2.

		Doses*				
Drug	**Preparation**	**Adults/ Children†**	**Daily**	**1 ×/wk**	**2 ×/wk**	**3 ×/wk**
Bedaquiline	Tablets (100 mg)	*Adults*	400 mg qd for 2 weeks followed by 200 mg 3 times a week for 22 weeks			400 mg qd for 2 weeks followed by 200 mg 3 times a week for 22 weeks

*Dose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as adults.

　†For purposes of this document, adult dosing begins at age 15 years.

　‡Dose may need to be adjusted when there is concomitant use of protease inhibitors or nonnucleoside reverse transcriptase inhibitors.

　§The drug can likely be used safely in older children but should be used with caution in children less than 5 years of age in whom visual acuity cannot be monitored. In younger children, EMB at the dose of 15 mg/kg/d can be used if there is suspected or proven resistance to INH of RIF.

　¶*Note*: Although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that few patients can tolerate this amount. Serum concentration measurements are often useful in determining the optimal dose for a given patient.

　#The single daily dose can be given at bedtime or with the main meal.

　**Dose: 15 mg/kg/d (1 g) and 10 mg/kg in persons more than 59 years of age (750 mg). Usual dose: 750–1,000 mg administered IM or IV, given as a single dose 5–7 d/wk and reduced to two or three times per week after the first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.

　††The long-term (more than several weeks) use of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both INH and RIF. The optimal dose is not known.

　‡‡The long-term (more than several weeks) use of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

　§§The long-term (more than several weeks) use of gatifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.

Drug Therapy for Drug-Resistant Tuberculosis

Drug-resistant TB has been increasing worldwide for the past 20 years. Microbial resistance to anti-TB drugs may be either primary or acquired. Primary resistance occurs in the patient who has never been treated for TB. Risk factors for primary resistance include exposure to a patient who has drug-resistant TB, immigration from a country with a high prevalence of drug-resistant TB, and a greater than 4% incidence of resistant TB in the community.

Acquired or secondary resistance occurs in a patient who has been previously treated for TB. Poorly or inadequately treated TB is the leading cause of secondary resistance, with prevalence of MDR TB greater than 20% of new diagnosed cases and 50% of those previously treated for TB (WHO, 2013). Extensively resistant TB (resistant to multiple second-line drugs) is found in 9.6% of MDR TB globally and in 1.1% of cases in the United States (CDC, 2013b; WHO, 2013). Extensively resistant TB is resistant both to isoniazid and rifampin and to any fluoroquinolone drug and at least one of three second-line injectable drugs (amikacin, kanamycin, or capreomycin). Drug resistance can be proved only by susceptibility testing.

For treatment of drug- or multidrug-resistant TB, the administration of at least two drugs to which susceptibility has been demonstrated is recommended. For isolated INH resistance, the 6-month, four-drug (INH, RIF, EMB, PZA) protocol is recommended (ATS, 2003).

If INH resistance is documented in a patient on a 9 month regimen (without PZA), then INH should be discontinued. If EMB was included in the initial regimen, then treatment with RIF and EMB should continue for a minimum of 12 months. If the initial treatment did not include EMB, then testing for drug susceptibility should be repeated, and INH needs to be discontinued and two new drugs should be added. The regimen may need to be adjusted when drug susceptibility test results are available.

If a patient is resistant to multiple first-line drugs (INH, RIF, EMB, PZA), then at least three new drugs that the organism is susceptible to should be administered. These second-line drugs include capreomycin (Capastat), cycloserine (Seromycin), EMBionamide (Trecator), kanamycin (Kantrex), para-aminosalicylic acid (Sodium P.A.S.), levofloxacin (Levaquin), and moxifloxacin (Avelox) (see Table 45-2). This regimen should be followed until sputum cultures are clear; then the patient should have 12 months of two-drug therapy. Often, 24 months of therapy are given to patients who have TB that is resistant to multiple first-line drugs. Patients with resistant TB should have their medications administered via DOT (Box 45-1).

Bedaquiline fumarate (Sirturo) has received a provisional approval from the U.S. Food and Drug Administration for use as part of a four-drug regimen for laboratory-confirmed

pulmonary MDR TB in adults (Mase, Chorba, Loube, & Castro, 2013). Bedaquiline (400 mg) is given once a day for 2 weeks, followed by 200 mg three times a week for 22 weeks (Mase et al, 2013). The effectiveness and safety of treatment beyond 24 weeks have not been studied.

Second-line treatment usually requires injectable medications, which complicates the treatment regimen. Fluoroquinolones such as levofloxacin, moxifloxacin, and gatifloxacin are all active against *M. tuberculosis*. Based on the evidence so far, levofloxacin is the preferred oral fluoroquinolone for treating drug-resistant TB or when first-line agents cannot be used because of intolerance (CDC, 2003b). Patients with extensively resistant TB require broader coverage including parenteral cycloserine (Seromycin) and a fluoroquinolone. In a recent study of 48 patients with extensively resistant disease, patients were prescribed an average of 5.3±1.3 antimycobacterial agents for which either susceptibility had been documented or the duration of prior exposure had not exceeded 1 month and susceptibility had not been tested, leading to a 60% cure rate (Mitnick et al, 2008). Any patient whose TB demonstrates resistance must be seen by an infectious disease specialist who treats patients with TB. Inadequate treatment is one of the leading causes of secondary resistant TB.

Algorithm

Treatment of TB begins with an accurate diagnosis. Once a screening test for TB is considered positive, treatment begins, even if a definitive diagnosis of TB has not been made. Therapy may be altered, based on the patient's risk factors or on the sensitivity of the organisms to the medications being used. DOT should be considered at any point of therapy based on patient history and local drug-resistance pattern. A treatment algorithm is presented in Figure 45-1.

Extrapulmonary Tuberculosis

Extrapulmonary TB is often difficult to diagnose. Once a bacteriological examination has determined a diagnosis of TB, the treatment is basically the same as for pulmonary TB. Although little research has been done regarding the effectiveness of shortened treatment for extrapulmonary TB, the ATS guidelines (2003) recommend 6 to 9 months of therapy as probably effective. Infants and children with miliary TB, bone or joint TB, and TB meningitis should receive 12 months of therapy.

Response to treatment is more difficult to monitor in patients with extrapulmonary TB than in those with pulmonary TB and must often be determined based on clinical and radiographic improvement. Bacteriological evaluation of extrapulmonary sites often requires invasive procedures to evaluate treatment. Referral to an infectious disease specialist is usually necessary to ensure optimal treatment.

Patient Variables

Pregnancy and Lactation

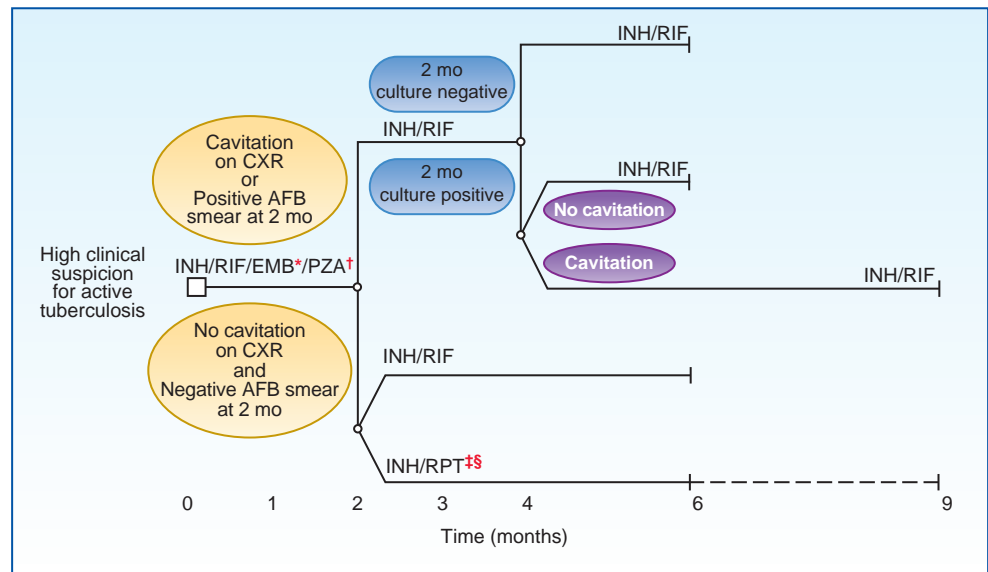
TB infection during pregnancy presents in the same manner as does TB in nonpregnant patients. The clinical symptoms include cough, weight loss, fever, malaise and fatigue, and hemoptysis. Eighty-five percent of patients have upper lobe disease; extrapulmonary TB is rare in pregnant patients. TB screening during pregnancy is recommended for all patients. Positive results are the same as for nonpregnant patients. Patients who have active untreated TB at the time of delivery need to be placed in respiratory isolation and separated from their infants. Therefore, it is best to treat TB prior to delivery.

The initial treatment regimen for pregnant women is INH and RIF. EMB should be included unless INH resistance is unlikely. The length of therapy is 6 months. Pyridoxine (vitamin B_6) 25 mg/d should be added to the regimen in pregnant or lactating patients to decrease the incidence of peripheral neuropathy associated with INH (ATS, 2003).

Pregnant patients have a 2.5-fold higher risk of INH-induced hepatitis than other patients (Riley, 1997). RIF may also be associated with maternal hepatitis. Monthly monitoring of liver function tests will detect any change in liver function indicating hepatitis.

INH, RIF, and EMB all cross the placenta, but these drugs have not been demonstrated to have teratogenic effects (ATS, 2003). Streptomycin and other aminoglycosides are contraindicated because of harmful effects on the fetus, including congenital deafness and altered ear development. Streptomycin is Pregnancy Category D.

PZA is recommended for routine use in pregnant women by WHO, but the drug has not been used routinely in the United States due to a lack of safety studies. Some U.S. public health officials are using PZA in pregnant women without reported adverse effects (CDC, 2003a). If PZA is not included in the initial treatment regimen, then 9 months of therapy needs to be considered.

Breastfeeding is not contraindicated during treatment. Small amounts of INH and RIF are excreted into breast milk, but these amounts are well below the therapeutic dose. EMB and PZA are both excreted in very small amounts as well. The risk of toxic reactions in the infant may be further minimized


Patients in whom tuberculosis is proved or strongly suspected should have treatment initiated with isoniazid, rifampin, pyrazinamide, and ethambutol for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment have been completed. If cavities were seen on the initial chest radiograph or the acid-fast smear is positive at completion of 2 months of treatment, the continuation phase of treatment should consist of isoniazid and rifampin daily or twice weekly for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial chest radiograph and the culture at the time of completion of 2 months of therapy is positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the CD4+ cell count is <100/µL, the continuation phase should consist of daily or 3 times weekly isoniazid and rifampin. In HIV-uninfected patients having no cavitation on chest radiograph and negative acid-fast smears at completion of 2 months of treatment, the continuation phase may consist of either once weekly isoniazid and rifapentine, or daily or twice weekly isoniazid and rifampin, to complete a total of 6 months (bottom). Patients receiving isoniazid and rifapentine, and whose 2-month cultures are positive, should have treatment extended by an additional 3 months (total of 9 months).

*EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance.

†PZA may be discontinued after it has been taken for 2 months (56 doses).

‡RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis.
§Therapy should be extended to 9 months if 2-month culture is positive.

CXR = chest radiograph; EMB = ethambutol; INH = isoniazid; PZA = pyrazinamide; RIF = rifampin; RPT = rifapentine.

Figure 45–1. Treatment algorithm for TB.

if the mother breastfeeds just prior to taking a dose of TB medication. Breastfeeding does not provide effective treatment for active or latent TB infection in a nursing infant; therefore, newborns should be evaluated for congenital TB (ATS, 2003; Public Health Agency of Canada, 2013). Pyridoxine (vitamin B$_6$) 25 mg/d is recommended in lactating women taking INH (ATS, 2003).

Pediatric Patients

Primary Pulmonary Tuberculosis

Children pose challenges in the treatment of TB because older infants and children may present with a positive screening test and are asymptomatic yet may have primary pulmonary TB. A chest x-ray may be normal or demonstrate minimum abnormalities (infiltrates with hilar adenopathy). WHO published guidelines for diagnosis of TB in children, which include the following: (1) careful history, including TB contacts; (2) clinical examination, including growth assessment; (2) TB skin test; (3) bacteriological confirmation whenever possible; (4) chest x-ray for pulmonary TB or evaluation

for extrapulmonary TB (lymph node biopsy, lumbar puncture if meningitis is suspected, etc.); and (5) HIV testing in high-prevalence areas (WHO, 2006).

Obtaining sputum cultures for confirmatory diagnosis is difficult in young children; use of drug susceptibility testing from the presumed source case can guide the choice of drugs in children (CDC, 2003a). If drug resistance is suspected or if no source case is available, attempts to isolate organisms via three morning gastric lavages, bronchoalveolar lavage, or tissue biopsy should be considered. In infants and children under age 3 years with primary pulmonary infection, the disease may be progressive and merge with miliary TB or progressive central nervous system (CNS) disease to produce TB meningitis. Children under age 13 years usually have paucibacillary pulmonary disease (low organism numbers), and cavitating disease is rare (less than 6% of cases) (WHO, 2006). Primary infection in older children and adolescents presents with an upper lobe infiltrate and cavitation without calcification. Progressive disease does occur in immunocompromised children of all ages.

Progressive Pulmonary Tuberculosis

Progressive pulmonary TB in children occurs when the primary infection is not contained and produces bronchopneumonia or when the lesions involve a whole lobe (usually middle or lower) and cavitation develops. Weight loss, fever, night sweats, malaise, hemoptysis, and productive cough are common symptoms.

Miliary Tuberculosis

Infants and children under age 3 years frequently develop miliary TB, which is widespread dissemination with infection of multiple organs. The lesions are the size of millet seeds, thus the name *miliary* TB. The infant or child is quite ill, often with a sudden onset, and may have a high fever, weakness, malaise, anorexia, hepatosplenomegaly, and night sweats. A chest x-ray reveals diffuse miliary infiltrates. A tuberculin skin test (PPD) may be nonreactive as a result of anergy. The child may need a liver or bone marrow biopsy to determine an accurate diagnosis.

Tuberculosis Meningitis

TB meningitis is the most serious complication of TB. It usually occurs in young children (younger than 5 years) and within 6 months of primary infection. The disease has three stages: prodromal (lasts 1 wk), neurological involvement, and then increasing neurological involvement resulting from increasing intracranial pressure. The skin test (PPD) is positive in two-thirds of cases, but anergy may be present in very ill patients.

Drug Therapy

Drug therapy for pediatric patients depends on the infection or disease category, as noted in Table 45-3. The standard anti-TB drugs INH and RIF are used for asymptomatic infection and for 6 to 9 months. Multidrug regimens, as noted in Table 45-3, are used for progressive disease. EMB may be used in pediatric patients if risk of drug-resistant organisms is present (ATS, 2003). DOT should be used for all children with TB (ATS, 2003). If children are not able to swallow pills, administrating medications requires crushing the pills, and tolerance must be monitored. Parents should not be relied on to correctly administer TB treatment.

Adverse Reactions

RIF and INH can be administered to children safely, with minimal adverse reactions. Patients should be monitored for liver function alterations, especially if the patient presents with a flu-like illness. Pyridoxine deficiency associated with INH can be prevented in infants, children, and adolescents with 25 mg/d of vitamin B$_6$ supplementation (ATS, 2003; Public Health Authority of Canada, 2009). EMB is an effective drug, but its main limitation is ocular toxicity, which causes optic neuritis, leading to blurred vision, color blindness, and visual field constriction. Although the visual changes associated with EMB are reversible, it should not be prescribed to children under age 6 years whose visual changes cannot be accurately monitored. Streptomycin can be used in children in place of EMB, but it is used for only a short time (12 weeks or less), and patients should be monitored for

Table 45–3 Treatment of Tuberculosis in Infants, Children, and Adolescents

Disease Category	Drug Therapy	Comments
Asymptomatic infection (positive skin test only)	*9-mo regimen:* INH-susceptible: INH daily	Twice-weekly therapy may be used if daily therapy is not feasible.
	INH-resistant: RIF daily	Children with INH-resistant TB should be treated for 12 mo.
Pulmonary disease	*6 mo regimen:* INH, RIF, and PZA daily for first 2 mo, followed by 4 mo of INH and RIF daily *or* INH, RIF, and PZA daily for 2 mo, followed by 4 mo of INH and RIF twice weekly *9 mo regimen:* 9 mo of INH and RIF daily *or* 1 mo of INH and RIF daily, followed by 8 mo of INH and RIF twice weekly	If drug resistance is a concern, then a 4-drug regimen is used (INH, RIF, PZA, and ETH or streptomycin) for the first 2 mo.
Extrapulmonary TB (meningitis, miliary, bone, and joint)	*12-mo regimen:* INH, RIF, PZA, and streptomycin daily for 2 mo, followed by 10 mo of INH and RIF daily or INH, RIF, PYZ, and streptomycin daily, followed by INH and RIF twice weekly	4-drug therapy is used for the first 2 mo of treatment, until drug susceptibility is known.
Extrapulmonary TB (other than meningitis, miliary, bone, or joint)	Same as for pulmonary disease	

ETH = ethionamide; INH = isoniazid; PZA = pyrazinamide; RIF = rifabutin.
    DOT (directly observed therapy) should be used for all children with tuberculosis. Parents should not be relied on to administer medications (CDC, 2003a).

ototoxicity and nephrotoxicity. PZA is used in multidrug therapy in children and has few adverse reactions.

Newborn Infants

Management of the newborn infant whose mother (or other household contact) has TB is based on individual considerations. Infants born to mothers with active disease are at high risk for TB in the first year of life (CDC, 2003a). Unfortunately, in infants, the skin test may not be positive until age 6 months.

If the mother has a positive PPD but no evidence of active disease, then the family and household contacts must be investigated. If no evidence of active disease is found in the mother or extended family, the infant needs to have a Mantoux (5 TU PPD) skin test at 4 to 6 weeks of age and at 3 to 4 months of age. If the TB status of household contacts cannot be evaluated, the infant may be started on INH (10 mg/kg/d).

If the mother has newly diagnosed TB but is not contagious at delivery, the newborn infant requires a chest x-ray and Mantoux test at age 4 to 6 weeks. If these are negative, then the child is monitored at age 3 to 4 months and again at 6 months with repeat Mantoux skin tests. INH is started at birth and discontinued at 3 to 4 months (some sources say 6 months) if the PPD is negative and the family has no active disease. The infant should receive INH even if the initial chest x-ray and PPD are negative because cell-mediated immunity of a degree sufficient to mount a significant reaction to skin testing can develop as late as age 6 months in an infant infected at birth. The mother may breastfeed. The infant should be examined carefully at monthly intervals. In cases of poor compliance, maternal positive sputum, or uncertain supervision, the infant may be given bacille Calmette-Guérin (BCG) vaccine. BCG does not prevent TB but may decrease the severity of the disease.

If the mother has active disease and is contagious at the time of delivery, the infant and mother should be separated until the mother is no longer contagious. The infant is managed the same as if the maternal disease were not contagious at the time of delivery.

If the mother has hematogenous spread of TB (bone, meningitis, or miliary TB), congenital TB is possible. If the infant is suspected of having congenital TB, INH is given for 6 months. If the PPD is positive at 6 months, then the INH is continued until age 9 months. As for any mother with active disease at delivery, a chest x-ray and Mantoux skin test should be done shortly after birth, and the infant should be monitored closely, with monthly assessments.

The HIV-Positive Patient

In 2012, 1.1 million (13%) of the 8.6 million patients worldwide who were HIV-positive developed TB (2013a). There were 320,000 deaths from TB among HIV-infected persons worldwide in 2012 (WHO, 2013a). In the early stages of HIV infection, the clinical manifestations of TB are similar to those of a normal host. As the T-lymphocyte count decreases, changes occur:

1. A steady reduction in the percentage of patients will have a positive TB skin test, decreasing to 10% to 20% in patients with advanced AIDS.

2. Extrapulmonary TB increases, with 60% to 80% of patients with CD4 counts below 50 demonstrating extrapulmonary infection.
3. Changing patterns of disease are noted on chest x-ray, although 56% of HIV/AIDS patients with TB still present with upper lobe disease (Refaie, Chaudry, Alfakir, & Khan, 2010).

The treatment regimen for patients with HIV infection or AIDS as well as TB is the same as it is for uninfected adults (6 mo regimen, with initial 2 mo, four-drug [INH, RIF, PZA, and EMB] phase followed by 2 mo of INH and RIF). Two exceptions to this recommendation for the patient who is HIV-positive are that (1) once-weekly RIF should not be used in any HIV-infected patient, and (2) twice-weekly INH-RIF or rifabutin should not be used for patients with CD4 counts lower than 100/mcL.

Patients who are HIV-positive with TB have lower mortality if they are on antiretroviral therapy during treatment for TB (CDC, 2013d). It is recommended that antiretroviral therapy be started within 2 weeks of starting TB treatment in patients with CD4 counts less than 50 cells/mm ^{3}. Therefore, patients with HIV infection or AIDS are usually on multiple drugs besides the anti-TB medication, requiring dosage adjustment and monitoring for interactions between the medications. RIF is known to alter the liver's metabolism of many drugs, leading to treatment failure or suboptimal response in the patient on multiple antiretroviral medications. A complex drug interaction also takes place between RIF and protease inhibitors that can create a therapeutic challenge, possibly leading to changes in the antiretroviral regimen. All HIV-infected patients who are undergoing treatment with isoniazid should be on pyridoxine (vitamin B_6) 25 to 50 mg daily or 50 to 100 mg twice weekly to reduce the occurrence of isoniazid-induced side effects in the central and peripheral nervous system.

Providing an optimal outcome to a patient with HIV infection or AIDS with TB will require referral to an infectious disease specialist. Recommendations regarding treating HIV-infected patients with TB change frequently as new antiretroviral agents are introduced; providers can find up-to-date information at the CDC's Division of Tuberculosis Elimination site (http://www.cdc.gov/tb/).

MONITORING

Patients with positive pretreatment sputum for *M. tuberculosis* are best monitored by repeat sputum cultures monthly until sputum cultures are negative. After 2 months of treatment with INH and RIF, more than 80% of patients who had positive sputum cultures at the beginning of treatment should have converted to negative. Patients should be monitored monthly and should have a sputum smear and culture at the end of the course of treatment. DOT should be considered for all cases of TB.

Radiographic monitoring is not as important as sputum examination during the course of treatment (ATS, 2003). At the completion of treatment, a chest x-ray should be done to provide a baseline for comparison with any future films.

In patients with negative pretreatment sputum yet having radiographic findings consistent with TB, an extensive effort to make a microbiological diagnosis is necessary. These patients most likely need medical evaluation by a pulmonologist. Bronchoscopy to perform biopsies and bronchoalveolar lavage should be considered to confirm the diagnosis of TB. If presumptive treatment is started without sputum cultures, then the chest x-rays should be repeated. Failure to show improvement of the lesions on the chest film after 3 months of therapy strongly suggests a misdiagnosis or a lesion that is an old TB lesion (not currently active).

Adverse Reactions to the Medications

Patients should also be monitored for adverse reactions to the medications used to treat TB by means of a baseline measurement of hepatic enzymes, bilirubin, serum creatinine, a complete blood count (CBC), and platelet count. Patients who are taking PZA require a baseline serum uric acid. A baseline ophthalmology examination for visual acuity and a red-green color examination are required for patients on EMB. These baseline tests are used to determine any underlying abnormality that would affect the treatment regimen. Children generally do not require baseline laboratory tests, except visual acuity, unless they have some underlying medical condition that may complicate the treatment regimen.

INH has a Black-Box Warning regarding the development of severe and sometimes fatal hepatitis, even after many months of treatment. The risk is age-related, with the highest incidence in persons aged 50 to 64 years (23 cases per 1,000). Increased risk for hepatitis is associated with daily alcohol use, chronic liver disease, and IV drug use. Black and Hispanic women, as well as any woman during the postpartum period who takes INH, may have increased risk of developing fatal hepatitis. All patients taking INH should have monthly symptom reviews to screen for hepatitis. Symptoms to screen for include unexplained anorexia, nausea, vomiting, dark urine, icterus, rash, persistent paresthesias of hands or feet, fatigue, weakness, fever longer than 3 days, or abdominal tenderness especially in the right upper quadrant. Liver enzymes should be measured in patients over age 35 years prior to starting INH and then periodically throughout treatment.

Once treatment is begun, patients are monitored clinically for adverse reactions. They usually do not need routine laboratory tests unless laboratory abnormalities are present prior to beginning therapy. Patients should be told of the symptoms associated with the most common adverse reactions to the medications. They should report all flu-like illness immediately and see their health-care provider at least monthly during treatment. At the monthly visit, the provider should ask specific questions regarding adverse reactions to the medication and follow any positive answer with confirming laboratory tests.

Adult patients treated for TB are at risk for peripheral neuropathy associated with INH therapy; therefore, they also need 25 to 50 mg per day of pyridoxine (vitamin B$_6$) to decrease the likelihood of developing this serious but avoidable adverse reaction.

OUTCOME EVALUATION

Because of the lengthy treatment time for TB and the increased incidence of resistant organisms found with inadequate treatment, health-care providers should include both the actual sputum culture evaluation and the patient's compliance with the medication regimen in judging the success of the treatment. Ideally, the patient will have TB-free sputum within the first 2 months of treatment and a clear sputum culture throughout the rest of the treatment. After treatment, no standard follow-up is required. If a patient is immunosuppressed, reevaluation is suggested 6 months after treatment has been completed. Any relapse is most likely to occur within the first 2 years after treatment.

PATIENT EDUCATION

Extensive patient education is essential to successful TB treatment. Administration should be explained, including the instructions to take isoniazid on an empty stomach because food reduces bioavailability. The patient must also understand the purpose for the long, multidrug treatment regimen and be a partner in the process. Compliance is a major issue in TB treatment; therefore, all teaching should have the underlying theme of taking all medication as scheduled. The lengthy treatment requires that education be repeated and reviewed at the monthly visits. Because patients may be illiterate or understand little English, education should be presented in a variety of media, such as videotapes in a patient's primary language. Peer health counselors may also be helpful in educating patients with TB.

PREVENTION OF TUBERCULOSIS

Most patients infected with the tubercle bacillus never develop active TB. Approximately 90% to 95% of those infected are able to mount an immune response that prevents active TB infection (CDC, 2005). The goal of preventive therapy is early identification of patients at risk of developing active TB so that they can be treated with drugs to prevent their conversion to active disease. Patients at risk for developing active TB include those who have been newly exposed to persons with active TB, those who convert from negative to positive on indirect testing, and those who have dormant infections that are at risk for reactivation (Jereb et al, 2011).

Skin testing with PPD or Mantoux is a necessary screening test to determine if the patient has been infected. Evaluation of the results of the skin test is based on the likelihood of

infection and the risk of active TB if infection has occurred. If the patient is HIV-positive or has fibrotic lesions on chest x-ray, a reaction of 5 mm or more is considered positive. A reaction of 10 mm or more is considered positive in other at-risk patients, including infants and children. In patients who are not in any high-risk category or high-risk environment, a result of 15 mm or more is considered positive. The interferon-gamma release assays (QuantiFERON-TB Gold test and T-SPOT.TB test) may also be used to detect TB and results are available within 24 hours. A positive result indicates a patient has been infected; additional evaluation is necessary to determine if the disease is latent or active. Further evaluation would include chest x-ray, HIV testing, and other testing determined by patient risk status.

Patients are considered high risk if they have the following medical conditions: diabetes mellitus, prolonged therapy with adrenocorticosteroids, immunosuppressive therapy, hematological or reticuloendothelial diseases such as leukemia or Hodgkin's disease, injection drug use by a patient known to be HIV-seronegative, end-stage renal disease, and any clinical presentation that consists of substantial rapid weight loss or chronic malnutrition. A person who is in a high-incidence group with a skin test reaction of 10 mm or more is a candidate for preventive therapy, even without any of these risk factors. High-incidence groups include foreign-born people from high-prevalence countries; medically underserved, low-income populations; and residents of long-term-care facilities.

Pathophysiology

Most cases of TB in the United States and Canada occur from reactivation of latent infection acquired at an earlier time, months or years before, when the patient's immune system was able to mount a sufficient defense. The patient has no outward sign of ever having been infected by TB. All that remains to identify that the patient was exposed to TB is a positive tuberculin skin test or interferon-gamma release assays (QuantiFERON-TBGold test and T-SPOT.TB test). Reactivation, leading to active infection, occurs in patients who, for whatever reason, cannot muster a sufficient immune response.

Drug Therapy

The preferred drug therapy for TB prevention consists of a combination of INH and rifapentine (CDC, 2013e). The treatment, referred to as the "12 Dose Regimen," consists of INH 15 mg/kg (maximum 900 mg) and rifapentine (RPT) 900 mg (for adults more than or equal to 50 kg) administered once weekly utilizing DOT (CDC, 2011). INH may also be used as self-administered monotherapy to treat latent TB. INH is given in a single daily dose of 300 mg for adults and 10 to 15 mg/kg for children, not to exceed 300 mg. Or INH may be given as a twice-weekly dose of 10 to 15 mg/kg (maximum 900 mg/dose) in adults and 20 to 30 mg/kg (maximum

900 mg/dose) for children (CDC, 2013e). DOT is recommended for twice-weekly INH dosing.

The standard length of treatment for monotherapy with INH is 9 months (CDC, 2013e; Jereb et al, 2011). Patients who are HIV positive should receive 12 months of therapy. The preferred therapy in children age 2 years to 11 years is 9 months of INH (CDC, 2011). Shortened 2 month therapy that combines RIF and PZB is no longer recommended because of high rates of hospitalization and death from liver injury associated with the treatment (CDC, 2003b). Treatment regimens for latent TB are found in Table 45-4.

The INH should be dispensed in monthly allotments, with the patient's compliance monitored at least monthly. For patients who may have questionable adherence, DOT is recommended. If resources prohibit daily DOT, then INH may be given twice a week at the dose of 15 mg/kg, utilizing DOT to monitor adherence.

Prior to beginning drug therapy with INH or RIF/RPT, evaluate the patient as follows:

1. Exclude active TB by both radiographic and bacteriological tests. All patients with a positive skin test require a chest x-ray to rule out pulmonary TB. If the chest x-ray is consistent with pulmonary TB, then an extensive evaluation to rule out active disease is necessary. Bacteriologic studies of the sputum and comparisons with old x-rays are helpful in gaining a clear clinical picture of when the patient has active disease. Because of the risk of developing INH resistance when only INH is used for active disease, patients with any suspicion of active disease should be started on multidrug therapy until the final diagnosis is clarified.
2. Determine if the patient has a history of adequate TB preventive therapy.
3. Determine if the patient has had prior INH therapy to decide if the patient has had adequate drug therapy.
4. Look for any contraindications to the administration of INH therapy: previous INH-induced hepatitis, history of severe INH reactions, or liver disease of any etiology.

Table 45–4 Latent TB Treatment Regimens

Drug	Duration	Dosing Schedule	Total Number of Doses
Isoniazid (INH) and rifapentine	3 months	Once weekly*	12
INH	9 months	Daily Twice weekly*	270 76
INH	6 months	Daily Twice weekly*	180 52
Rifampin	4 months	Daily	120

Derived from Centers for Disease Control and Prevention (CDC). (2013e). Latent TB infection. Retrieved from http://www.cdc.gov/tb/topic/treatment/ltbi.htm

*Directly Observed Therapy recommended.

5. Identify patients who require special cautions. They include patients over age 35 years as well as patients with daily alcohol use, previous problems with INH therapy, current chronic liver disease, and injection drug use. Other patients requiring cautions include pregnant women and patients at higher risk for developing fatal hepatitis (women, particularly black and Hispanic women). Hepatitis risk is also increased in the postpartum period.

Monitoring

Patients receiving preventive TB therapy with INH or via DOT with weekly INH/RPT should be monitored at least monthly. At monthly visits, the health-care provider should carefully assess the patient's compliance and ask the patient about symptoms of adverse effects of INH, specifically liver damage. A standardized form should be used to evaluate the patient for symptoms of liver damage, including unexplained anorexia; nausea; vomiting; dark urine; icterus; rash; persistent paresthesias of the hands and feet; persistent fatigue, weakness, or fever for more than 3 days' duration; and abdominal tenderness. If these or other signs or symptoms occur during preventive therapy, patients should contact their health-care provider immediately.

Of those receiving INH therapy, 10% to 20% will have mildly abnormal liver enzymes, which usually resolve even if the INH is continued. Patients over age 35 years have the highest frequency of hepatitis; therefore, a baseline transaminase should be obtained before therapy is begun for such patients, and the study should be repeated monthly during therapy. If values are greater than 3 to 5 times normal, then INH should be discontinued. Other patients at risk for developing hepatitis are those who have chronic liver disease, those who inject drugs, and those who use alcohol daily. Monthly liver function tests are not a substitute for monthly clinical evaluations of the patient on preventive therapy.

Outcome Evaluation

The success of preventive TB therapy is determined by the absence of active disease and by whether the patient has been compliant with the prescribed drug treatment. Because patients who are receiving preventive therapy often do not feel ill or have any overt symptoms, compliance with the long treatment regimen is even more difficult than it is for patients with active TB.

Patient Education

Education for patients receiving preventive TB therapy is similar to education for those receiving treatment for active TB. The key difference is stressing the need for months of treatment to a patient who often has no symptoms and feels well. Education should occur in the patient's primary language and at an appropriate literacy level. Patients must understand that adherence to the treatment regimen is essential, and the health-care team cannot emphasize it enough.

On The Horizon | DRUGS IN THE PIPELINE

Significant TB drug research has been spawned by the Global Alliance for TB Drug Development, which was established in 2000 to address the need for new and better TB drug treatment (www.tballiance.org). Child-appropriate formulations of the standard four-drug therapy (isoniazid + rifampin + pyrazinamide + ethambutol) are currently in development and undergoing phase I clinical trials, as current formulations require either crushing of tablets or cannot easily be measured in the mg/kg dose required for infants less than 5 kg. The following are currently in early phase II trials:

- A combination of bedaquiline, clofazamine, and PA-824 in a less than 4-month, all-oral regimen for MDR TB. PA-824 is a nitroimidazole, a novel antibacterial class.
- A combination of bedaquiline, pyrazinamide, and PA-824 in a less than 4-month, all-oral regimen for MDR TB.
- A combination of bedaquiline, clofazimine, pyrazinamide, and PA-824 in a less than 4-month, all-oral regimen for MDR TB.
- A combination of bedaquiline, clofazimine, and pyrazinamide in a less than 4-month, all-oral regimen for MDR TB.

Late phase II trials include a combination of PA-824, moxifloxacin, and pyrazinamide that is showing promise for curing TB and some forms of MDR TB in 4 months using an oral regimen that can be administered in a fixed dose. Phase III trials include investigation of a combination of isoniazid, rifampin, pyrazinamide, and moxifloxacin that is demonstrating promise in shortening the length of TB treatment from 6 months to 4 months. Another phase III trial is investigating a combination of ethambutol, rifampin, pyrazinamide, and moxifloxacin in a 4-month regimen to treat TB.

The Global Alliance continues to focus funds and scientific energy toward developing drugs that simplify and shorten treatment regimens, are effective against MDR TB, are compatible with antiretroviral therapies for HIV, and expand the pediatric formulations available.

TUBERCULOSIS

PATIENT EDUCATION

Related to the Overall Treatment Plan and Disease Process

☐ A clear description of the pathophysiology and mode of transmission of TB: patients need to understand that they can be infectious to their close contacts if they do not receive adequate treatment.

☐ A thorough outline of the complete treatment regimen, including an estimated length of time for treatment: patients need to know up front that they will be receiving months and possibly more than a year of treatment.

☐ Importance of adherence to the treatment regimen.

☐ Importance of regularly scheduled follow-up appointments.

Specific to the Drug Therapy

☐ A written plan of the medication schedule is essential, especially with multidrug regimens.

☐ Possible adverse effects of the medications and the importance of reporting immediately to the health-care provider any vague, flu-like symptoms.

Reasons for Taking the Drug(s)

☐ The drugs are given to prevent or eliminate infection by *M. tuberculosis*.

Drugs as Part of the Total Treatment Regimen

Tuberculosis medications are a part of the total treatment regimen, which also includes strict pulmonary care.

Adherence Issues

Extensive patient education is essential to successful treatment. The patient must understand the purpose for the long, multidrug treatment regimen and be a partner in the treatment. Adherence is a major issue; therefore, all teaching should have the underlying theme of taking all medication as scheduled. The long period of treatment requires education that is repeated and reviewed at the monthly visits. To teach patients who may be illiterate or who understand English only minimally, education should be conducted in a variety of media, such as videos in the patient's primary language. Peer health counselors may also help to educate patients with TB. DOT may enhance compliance with and adherence to therapy.

UPPER RESPIRATORY INFECTIONS, OTITIS MEDIA, AND OTITIS EXTERNA

Teri Moser Woo

Upper respiratory infections (URIs) are the most common minor acute illnesses seen in primary care. The most common secondary infections seen with viral URIs are sinusitis and, in children, otitis media (OM). Practitioners encounter these illnesses countless times among their patients and should be aware of the pathogens commonly found and the pharmacological and nonpharmacological management of these illnesses. This chapter discusses the pharmacological management of these acute illnesses, as well as the management of otitis externa (OE).

VIRAL UPPER RESPIRATORY INFECTION

Viral URIs, also known as common colds, are the most frequent disease seen in a primary care practice and also the number-one cause of absenteeism from work and school. The frequency of viral URIs varies with age, with adults averaging 2 to 3 colds a year (Chow et al, 2012) and children aged 1 to 5 averaging 7 or 8 (Friedman & Sexton, 2009). Infants have an average of 6 or 7 colds per year, but being in day care increases their incidence of colds to 9 to 11 in the first year of life. Overall, the common cold accounts for 22 million missed school days and 20 million missed workdays in the United States due to caring for an ill child. (Bramley, Lerner, & Sames, 2002). The total economic cost of the common cold is estimated to be more than $40 billion, when costs of medical care, medications (including OTC medications), and loss of productive work time are factored in (Fendrick, Monto, Nightengale, & Sarnes, 2003).

A viral URI usually starts with the symptoms of nasal congestion, rhinorrhea, malaise, and scratchy throat. The nasal discharge typically starts out thin and clear and then thickens and progresses to a green or yellow color. Respiratory symptoms

generally peak in severity on days 3 to 6 and then improve but may persist for 10 to 12 days (Wald et al, 2013). Generalized muscle aches may be present, but fever is usually absent in adults. Young children may have a low-grade fever for 24 to 48 hours (Wald et al, 2013). Fever in adults or a high fever (greater than or equal to 39°F) in children suggests influenza or a secondary infection, such as sinusitis or OM. URI symptoms are irritating but not severe. More severe symptoms should be investigated for secondary infection or other bacterial infection. Most patients are symptom-free in 7 to 10 days from the beginning of the illness.

Pathophysiology

The rhinovirus is the most common cause of the common cold (American Academy of Pediatrics [AAP], 2012a). There are more than 100 serotypes of rhinovirus (AAP, 2012a); therefore, even though immunity is produced by rhinoviral infections, the patient can quickly become infected with another strain of rhinovirus. The common story heard in the clinic is that the patient has just gotten over a cold and now it has come back. Other viruses causing the common cold include, but are not limited to, adenovirus, respiratory syncytial virus, parainfluenza virus, influenza viral strains and human metapneumovirus (Pappas & Hendley, 2009). These viruses are transmitted between people by airborne droplets or by direct transmission of the virus in secretions via hand contact.

Goals of Treatment

Viral URIs are self-limiting and require no treatment other than symptomatic relief; therefore, the major goal in treating a patient with a viral URI is relieving irritating symptoms, specifically nasal congestion.

Rational Drug Selection

Drug Therapy

Although viral URI (the common cold) is a self-limited disease that requires no treatment, a huge industry touts nonprescription medications for treatment of colds. First, note that antibiotics have no place in the treatment of the common cold. Using antibiotics for a viral infection increases the likelihood of antimicrobial resistance to secondary bacterial infections that may occur in the upper respiratory tract. Antihistamines have not been shown to alter the course of a common cold, yet many over-the-counter (OTC) cold preparations contain some form of antihistamine, probably for their "drying" effect.

The mainstay of pharmacological management for a cold is the decongestant, either systemic or topical. Decongestants cause vasoconstriction of the capillaries in the nasal mucous membranes. This results in shrinkage of the mucous membrane, which promotes drainage and decreases the nasal stuffiness that accompanies a URI. Dosing of common decongestants can be found in Table 46-1. Topical decongestants

Table 46–1 ❖ Drugs Commonly Used: Viral Upper Respiratory Infections

Drug	Adult Dose	Pediatric Dose	Strengths Available	Comments
Oral Decongestants				
Pseudoephedrine HCI (Sudafed, Genafed, Pseudo Tabs, Pediacare)	60 mg q4–6h Extended release: 120 mg q12h	*Children 6–12 yr:* 30 mg q4–6h	Tablets: 30, 60 mg	Adults: do not exceed 120 mg in 24 h
		Children 2–5 yr: 15 mg q4–6h *Infants–2 yr:* 1 mg/kg or 0.1 mL/kg of 7.5 mg/ 0.8 mL drops	Extended release: 120 mg Liquid: 15 mg/5 mL, 30 mg/5mL Drops: 7.5 mg/0.8 mL Capsules: 60 mg	Children: do not exceed 4 doses/d *Not recommended in children under age 4 yr
Pseudoephedrine sulfate (Afrin, Drixoral Non-Drowsy)	120 mg q12h	Not for use in children <12 yr	Extended release: 120 mg	Do not crush or chew
Phenylephrine (Sudafed PE)	*Adults:* 10 mg q4h Maximum of 60 mg/24 h	*Children 2–6 yr:* 2.5–5 mg every 12 h *Children >6 yr:* 5–10 mg q12h	Tablet: 10 mg Chewable tablet: 10 mg Dissolving tablet: 10 mg	*Decongestants are not recommended in children <age 4 yr
Topical Decongestants				
Phenylephrine HCI (Neo-Synephrine, Nostril, Sinex, Alconefrin, Rhinall)	2–3 sprays each nostril; repeat q3–4h	*Children 6–12 yr:* 2 sprays each nostril q4h *Children >6 mo:* 1 to 2 drops each nostril q3h	Spray: 0.125%, 0.16%, 0.25%, 0.5%, 1% Drops: 0.25%, 0.5%, 1%	Do not use for longer than 3 d because of rebound congestion; rarely used in young children.
Oxymetazoline HCI (Afrin, 12 Hour Nasal, Dristan Long Lasting, Allerest 12 Hour, Afrin Children's Nose Drops)	2 or 3 sprays or drops of 0.05% solution in each nostril bid or q10–12h	*Children ≥6 yr:* 2 or 3 drops of 0.025% solution in each nostril bid, morning and evening	Solution: 0.05%, 0.025%	Do not use for longer than 3 d because of rebound congestion. Do not use in children <6 yr.

(Afrin, Neo-Synephrine) may be helpful for temporary relief of congestion without causing systemic side effects. Topical decongestants may be used safely for up to 3 consecutive days. Prolonged use of topical decongestants will lead to rebound congestion. Analgesics such as acetaminophen (Tylenol), aspirin, and ibuprofen (Motrin) can be given for malaise.

Due to concerns about the use of pseudoephedrine to manufacture methamphetamine, a number of states have decreased access to OTC pseudoephedrine. Some states have declared pseudoephedrine a prescription medication; Oregon made it a Schedule III drug. In 2006, the Combat Methamphetamine Epidemic Act was incorporated into the USA Patriot Act, requiring special handling of pseudoephedrine, ephedrine, and phenylpropanolamine, all precursors to methamphetamine. The law requires precursors to methamphetamine to be placed behind the pharmacy counter nationwide to restrict access. Retailers must ask for purchaser identification and limit the amount of drug purchased to a 30-day supply. Providers need to be aware of the changing laws in their state or province of practice and provide a prescription for pseudoephedrine as needed. Many manufacturers have begun to create new products that replace the pseudoephedrine with phenylephrine (Sudafed PE), a decongestant that cannot be used to manufacture methamphetamine (see Table 46-1).

The use of cough and cold medications in young children, specifically children under age 5 years, has become an area of significant debate. The safety of cough and cold medications, specifically those containing decongestants, has been questioned after reports of deaths in infants taking cold medications (Taverner & Latte, 2007). Decongestants also have questionable efficacy in children. A *Cochrane Review* of the use of decongestants to treat nasal congestion associated with the common cold found a small (6%) but statistically significant improvement in congestion in adults but insufficient evidence regarding effectiveness in children (Taverner & Latte, 2007). A second *Cochrane Review* found no evidence supporting the efficacy of systemic decongestants or antihistamine-decongestant combinations in the treatment of URI in children younger than age 5 years (DeSutter, van Driel, Kumar, Lesslar, & Skrt, 2012).

In October 2007, a U.S. Food and Drug Administration (FDA) panel recommended that all pediatric cough and cold medications be relabeled as not indicated for use in children under age 4 years. This led to a voluntary withdrawal of infant drop formulations of cough and cold medications from the market in October 2007. This withdrawal of infant formulations of OTC cough and cold medications has resulted in a reduction (1,248 visits versus 2,790 visits) in emergency department visits related to adverse events in children younger than age 2 years (Shehab, Schaefer, Kegler, & Budnitz, 2010).

Nonpharmacological Therapy

Nonpharmacological therapy or lifestyle management includes increasing fluid intake, using nonmedicated cough drops, using nasal saline spray or drops to decrease the viscosity of nasal secretions, and rest. Patients and parents or other family members need to be reminded that anorexia is often associated with the common cold and that fluids often need to be forced on the ill person to maintain adequate hydration. Infants who are congested often cannot breathe and drink liquids from the bottle or breast at the same time; therefore, their fluid intake may be inadequate. Parents need to be encouraged to suction the infant's nose with a nasal bulb syringe to clear secretions before the infant eats or drinks. Nasal saline spray is also beneficial in thinning secretions at all ages to make blowing or bulbing secretions more effective. Patients can make their own saline solution by adding a quarter tsp salt to 8 oz warm water. If a dropper is not available, patients can use a cotton ball saturated with saline solution to squeeze three or four drops into each nasal passage. Many patients are overcommitted and overworked and must be reminded of the restorative powers of rest. Encouraging patients to take a day or two off from work is much more effective than prescribing an unnecessary antibiotic.

Monitoring

The patient with a viral URI should be monitored for signs of secondary bacterial infection. Monitor decongestant use in cardiac patients, who may have increased hypertension from the added vasoconstriction caused by oral decongestants. Older adults are more likely to have adverse reactions from decongestants.

Outcome Evaluation

Secondary bacterial infections may complicate the common cold. The most common complication in adults is sinusitis, which occurs in approximately 0.5% to 2.5% of colds (Friedman & Sexton, 2009). In children, sinusitis is a common secondary infection in 6% to 7% of colds (Wald et al, 2013), as is OM, which occurs in about 10% to 50% of children with colds (Pelton & Leibovitz, 2009). Some children appear more apt to get OM as a secondary infection, possibly because differences in middle ear and eustachian tube anatomy predispose them to ear infections or because of the number of bacterial otopathogens present in the nasopharynx. Children in day care tend to have more otopathogens present in the nasopharynx and therefore may be more likely to develop otitis media when they have a URI (Pelton & Leibovitz, 2009). Adults may not get acute otitis media as often as do children, but 50% to 80% of adults will develop eustachian tube dysfunction after a rhinovirus or influenza infection (Friedman & Sexton, 2009).

This chapter discusses sinusitis and otitis media, common complications of URI. Another complication of viral URIs is exacerbation of asthma symptoms, occurring in 30% to 50% of the colds acquired by people with asthma. See Chapter 30 for asthma management.

Patient Education

Patient education for a viral URI is centered on symptomatic treatment and proper dosing of decongestants. Parents should be educated about avoiding the use of cough and cold

medications in children, especially those age 4 years and younger. Patients need to be assured that most URIs resolve in 7 to 10 days and that very little can be done to shorten the course of the disease. Antibiotics are not necessary for viral infections, and education regarding the signs and symptoms of a secondary bacterial infection needs to be provided.

SINUSITIS

Diagnosis of sinusitis is based on clinical symptoms and the course of the illness. Any persistent URI lasting longer than 10 days without any clinical improvement is likely to be bacterial sinusitis (Chow et al, 2012). Severe symptoms such as high fever (greater than or equal to 39°F), facial pain, or purulent nasal discharge that last 3 to 4 consecutive days may be bacterial sinusitis (Chow et al, 2012; Wald et al, 2013). Likewise, patients may experience "double-sickening," that is, a worsening of symptoms such as new onset of fever, headache, or an increase in purulent nasal discharge that was previously improving (Chow et al, 2012; Wald et al, 2013).

In adults, three symptoms have high specificity and sensitivity for diagnosing acute sinusitis: purulent rhinorrhea, facial pain or pressure, and nasal obstruction (Chan & Kuhn, 2009). Patients may have a headache that worsens when they bend over, and they may have a cough that is worse at night. A sudden worsening of symptoms after improvement is also suggestive of sinusitis (Chan & Kuhn).

Children have subtler symptoms. Because their frontal sinuses are not completely developed until they are 10 years old, children often do not have the classic frontal headache of sinusitis. Children may vomit due to gagging on mucus. Children have colds more frequently than do adults. Therefore, a careful history of whether the symptoms have actually been prolonged or whether the patient has a new viral URI is essential.

Children and adults alike may have puffy eyes and a cough that worsens when they lie down. Radiological studies are of questionable validity because sinus images look the same for a viral URI as for a sinus infection (Wald et al, 2013). A contrast-enhanced CT should be obtained if orbital or intracranial extension of sinusitis is suspected (Chow et al, 2012). In children, a contrast-enhanced MRI or CT is ordered to rule out orbital or intracranial extension (Wald et al, 2013).

Sinus infections can be either acute or chronic. Chronic sinusitis is defined as signs and symptoms consistent with sinusitis that last 8 to 12 weeks and is confirmed via endoscopy or CT imaging (Chan & Kuhn, 2009; Desrosiers et al, 2011). Multiple (3 or 4) episodes of acute bacterial sinusitis per year suggest chronic sinusitis and require referral to a specialist for confirmation (Chow et al, 2012).

Pathophysiology

The most common bacterial organisms found in acute sinusitis are *Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis,* and, more rarely, *Staphylococcus. Staphylococcus,* gram-negative enteric organisms

---

> ### ⬤ CLINICAL PEARL ⬤
>
> **Nutritional or herbal therapy**
> Nutritional or herbal therapy is often thought to decrease symptoms of the common cold. In the 1970s, Linus Pauling first brought forward the idea that vitamin C prevents and alleviates episodes of the common cold. Although this has still not been scientifically proven, many patients continue to take vitamin C at the first sign of a cold.
>
> Zinc lozenges have also been proposed as a treatment for the common cold. It is thought that zinc ions inhibit rhinovirus replication in vitro. In a systematic review of seven randomized controlled trials (RCTs) (754 patients total), two of the studies suggested reduced duration and severity of upper respiratory infection (URI) symptoms (Marshall, 2000). Another review of 14 placebo-controlled trials published from 1966 to 2000 found that one well-designed study showed improvement with the use of zinc nasal gel (Caruso, Prober, & Gwaltney, 2007). In a more recent RCT, a group of patients took a 13.3 mg zinc lozenge every 2 to 3 hours while awake and had a significantly shorter duration of cold symptoms (4.0 days versus 7.1 days; *P* less than 0.0001), shorter duration of cough (2.1 days versus 5.0 days), and nasal discharge (3.0 versus 4.5 days) than did the placebo control group (Prasad, Beck, Bao, Snell, & Fitzgerald, 2008). In light of these studies, zinc lozenges may decrease URI symptoms in some patients. Zinc nasal gels (Zicam) should be avoided after reports of permanent anosmia and an FDA warning to avoid their use.
>
> Another common herbal therapy that patients may be using for their cold symptoms is echinacea. Echinacea is widely used in Europe for the prevention and treatment of colds and flu. Its use is increasing in the United States. A number of European studies have demonstrated the immune-enhancing properties of echinacea, specifically increasing T-cell activity and interferon. Among European providers, echinacea is the leading herbal recommendation for the prevention of colds and flu. It is available in tablet, liquid, and tea bag form. The correct dosage is 900 mg daily divided into two or three doses, or 40 drops of the juice 3 times a day. Length of therapy should not exceed 8 weeks. There are no reported side effects at the recommended dosages. It appears to be safe during pregnancy and lactation. The only true contraindication is having a progressive systemic disease such as tuberculosis or multiple sclerosis or an autoimmune illness. Echinacea is a relative of the daisy; therefore, patients who are allergic to daisies should also avoid any form of echinacea.

---

and anaerobic bacteria, are more common in chronic sinusitis. Rarely, the causative organism in chronic sinusitis is fungal, with *Aspergillus* the most common fungus found. Patients who are immunocompromised develop severe infection, even invasive infections with eye, mouth, and brain extensions. Culture of the nasal mucosa is not helpful in determining the causative agent in sinusitis. If the patient

is not responding to therapy, sinus aspiration or endoscopic aspiration is the only accurate way to determine the organism involved; both procedures require referral to an otolaryngologist.

Goals of Treatment

The overall goal for the treatment of sinusitis is absence of infection, demonstrated by the patient's freedom from all symptoms of a sinus infection.

Rational Drug Selection

Given the most likely organisms to be found in both children and adults, the first choice for antibiotic therapy in acute sinusitis is amoxicillin with or without clavulanate (Chow et al, 2012; Wald et al, 2013). The Infectious Disease Society of America recommends prescribing standard-dose amoxicillin-clavulanate for bacterial sinusitis and high-dose amoxicillin-clavulanate (2 g orally twice daily or 90 mg/kg/d orally twice daily) in patient at risk for resistance (age younger than 2 years or older than 65 years, recent hospitalization or antimicrobial use, day care attendance) (Chow et al, 2012). The AAP guidelines recommend standard-dose amoxicillin (45 mg/kg/d) as first-line therapy unless the local resistance pattern for *S. pneumonia* is greater than 10%; then high-dose amoxicillin is prescribed (Wald et al, 2013). Amoxicillin is inexpensive and well tolerated (Table 46-2). For adults, the dose is 500 mg given 3 times a day, and in children, the daily dose is 45 mg/kg/d for standard dose and 80 to 90 mg/kg/d for high dose, divided in two to three doses. The usual length of treatment is 5 to 7 days in adults and 10 to 14 days in children (Chow et al, 2012).

Table 46–2 ❋ Drugs Commonly Used: Sinusitis and Otitis Media

Drug	Dose	Length of Treatment	Strengths Available	Comments
Amoxicillin (Amoxil, Trimox)	*Adults and children >20 kg*: 500 mg q8h *Children*: 80–90 mg/kg/d divided in 3 doses	Sinusitis: 10–14 days or until 7 d after symptom-free (may need 21 d of treatment) Otitis media: 7–10 d; children <2 yr: 10 d	Capsules: 250, 500 mg Chewable tablets: 125, 200, 250, 400 mg Powder for suspension: 50, 125, 200, 250, 400 mg/5 mL	First choice for non–penicillin allergic patients. Higher doses may be used for children who have recently been on antibiotics or in day care, up to 90 mg/kg/d.
Amoxicillin and clavulanate (Augmentin)	*Adults*: 500 mg q12h or 250 mg q8h *Children <3 mo*: 30 mg/kg/d of amoxicillin divided q12h *Children >3 mo, <40 kg*: 25–45 mg/kg/d of amoxicillin divided q12h (use 200 mg/5 mL or 400 mg/5 mL suspension) *or* 20–45 mg/kg/d of amoxicillin if using 125 mg/5 mL or 250/5 mL suspension dosed every 8 h. Drug-resistance dosing: 80–90 mg/kg/d divided every 12 h. Use Augmentin ES or a 7:1 bid formulation.	5–14 d for all patients	Tablets: 250 mg amoxicillin & 125 mg clavulanate; 500 mg amoxicillin & 125 mg clavulanate; 875 mg amoxicillin & 125 mg clavulanate Chewable tablets: 125 mg amoxicillin & 31.25 mg clavulanate; 200 mg amoxicillin & 28.5 mg clavulanate; 250 mg amoxicillin & 62.5 mg clavulanate; 400 mg amoxicillin & 57 mg clavulanate Suspension: 125 mg amoxicillin & 31.25 mg clavulanate/5 mL; 200 mg amoxicillin & 28.5 mg clavulanate/5 mL; 250 mg amoxicillin & 62.5 mg clavulanate/5 mL; 400 mg amoxicillin & 57 mg clavulanate/5 mL; 400 mg amoxicillin & 57 mg clavulanate (Augmentin ES = 600) amoxicillin 600 mg/5 mL and 42.9 mg clavulanate/5 mL (Augmentin ES = 600) amoxicillin 600 mg/5 mL & 42.9 mg clavulanate/5 mL	Children's dose is based on amoxicillin content. Because of the clavulanate content, two 250 mg tablets are *not* the same as one 500 mg tablet. Because of the different clavulanate levels in the suspensions, it is not appropriate to dose the 125 mg/5 mL or the 250 mg/5 mL suspensions bid. Children should not be given the 250 mg tablet until they are >40 kg. High-dose amoxicillin/clavulanate requires use of a formula of 600 mg amoxicillin/42.9 mg clavulanate per 5 mL.
Cefdinir (Omnicef)	*Adults ≥13 yr*: 300 mg q12h or 600 mg q24h *Children*: 14 mg/kg/d in 1 or 2 doses	AOM: 5–10 d Sinusitis: 10 d	Capsules: 300 mg Suspension: 125 mg/5 mL 250 mg/5 mL	Do not use for type 1 Penicillin = allergic patients (urticaria of anaphylaxis). Adjust dosing for renal insufficiency.
Cefpodoxime (Vantin)	*Adults*: 200 mg q12h *Children*: 10 mg/kg/d divided q12h (max dose 400 mg)	5–14 d	Tablets: 100 mg, 200 mg Suspension: 50 mg/5 mL, 100 mg/5 mL	Broad spectrum

Continued

Table 46–2 ❖ **Drugs Commonly Used: Sinusitis and Otitis Media—cont'd**

Drug	Dose	Length of Treatment	Strengths Available	Comments
Cefprozil (Cefzil)	*Adults and children >12 yr:* 500 mg q12h *Children:* 30 mg/kg/d divided into 2 doses 12 h apart	10–14 d	Tablets: 250 mg, 500 mg Suspension: 125 mg/5 mL, 250 mg/5 mL	Broad-spectrum coverage
Ceftibuten (Cedax)	*Adults:* 400 mg once daily *Children:* 9 mg/kg/d in 1 daily dose	10 d	Tablets: 400 mg Suspension: 90 mg/5 mL, 180 mg/5 mL	Must be given on an empty stomach.
Ceftriaxone (Rocephin)	*Children:* 50 mg/kg given as 1 IM dose (maximum of 1 g/dose)	One dose only	Powder for injection: 250 mg, 500 mg, 1 g	May be used as 1-time dose for otitis media in children. Very expensive compared with amoxicillin. Broad spectrum
Cefuroxime (Ceftin)	*Adults and children >12 yr:* 250 mg or 500 mg q12h *Children:* 30 mg/kg/d given q12h up to 1,000 mg/d	10 d	Tablets: 125, 250, 500 mg Suspension: 125 mg/5 mL Note: Tablets and suspension are *not* bio-equivalent and are *not* substitutable on a mg-for-mg basis	Prolonged half-life in patients with renal failure. Suspension must be given with food. Broad spectrum Expensive

The AAP guidelines include the option of observing the patient for 3 days before starting antibiotics (Wald et al, 2013). Antibiotics are started if there is no improvement in symptoms or if the patient worsens during the observation period.

If the adult patient is allergic to penicillin, doxycycline (100 mg PO bid or 200 mg daily) or a respiratory fluoroquinolone, such as levofloxacin (500 mg daily) or moxifloxacin (400 mg daily) may be prescribed. Children with penicillin allergy may be treated with a third-generation cephalosporin, including cefdinir (14 mg/kg/d), cefuroxime (30 mg/kg/d), or cefpodoxime (10 mg/kg/d).

If the patient is worsening or not improving after 72 hours, bacterial resistance needs to be considered. For sinusitis that fails to improve after a week of first-line therapy, the drugs of choice are high-dose amoxicillin-clavulanate (Augmentin) or in adults a respiratory fluoroquinolone (levofloxacin, moxifloxacin) (Chow et al, 2012; Wald et al, 2013). Fluoroquinolones should not be prescribed for children or adolescents because of the potential for adverse reactions, which is discussed further in Chapter 24. Children treated with amoxicillin who fail to improve are treated with high-dose amoxicillin-clavulanate (80 to 90 mg/kg/d of amoxicillin component), cefdinir (14 mg/kg/d), cefuroxime (30 mg/kg/d), or cefpodoxime (10 mg/kg/d) (Wald et al, 2013). Failure to respond indicates either misdiagnosis of sinusitis or resistance. Although radiological evaluation is not indicated in patients initially diagnosed with sinusitis, failure to improve warrants either computed tomography (CT) or MRI to confirm diagnosis. Consultation with an otolaryngologist may also be warranted to determine the need for sinus aspiration to guide antimicrobial choice (Chow et al, 2012; Wald et al, 2013).

Chronic sinusitis is defined by 8 to 12 weeks of symptoms and the documentation of inflammation either by examination or radiographic findings (Desrosiers et al, 2011; Rosenfeld et al, 2014). Amoxicillin-clavulanate is the drug of choice in chronic sinusitis; adults may also be treated with a respiratory fluoroquinolone. Patients with chronic sinusitis may also need a short course of inhaled or oral corticosteroids, both of which have no proven efficacy in acute sinusitis (Chan & Kuhn, 2009; Desrosiers et al, 2011). Hypertonic or isotonic saline washes are a critical part of chronic sinusitis treatment. Patients who fail to respond to antibiotics may need referral to an otolaryngologist. Other causes for chronic sinusitis need to be considered, including allergies and immunodeficiency (Rosenfeld et al, 2014). Figure 46-1 provides an algorithm for the treatment of sinusitis.

Monitoring

Patients who are being treated with antibiotics for sinusitis need to be monitored for adverse reactions to the antibiotics and for their response to treatment. They should begin to respond in 3 to 4 days. If there is no improvement in clinical symptoms, then bacterial resistance must be considered.

Outcome Evaluation

Sinusitis symptoms should resolve after 7 days of treatment. Chronic or recurrent sinusitis requires a referral to an otolaryngologist. Often, surgical intervention is needed to provide adequate drainage from the sinuses. Untreated sinusitis can lead to invasive disease such as orbital cellulitis or brain involvement. These are both medical emergencies and fortunately rare, usually seen only in immunocompromised patients. As with viral URIs, acute or chronic sinusitis may exacerbate asthma.

Patient Education

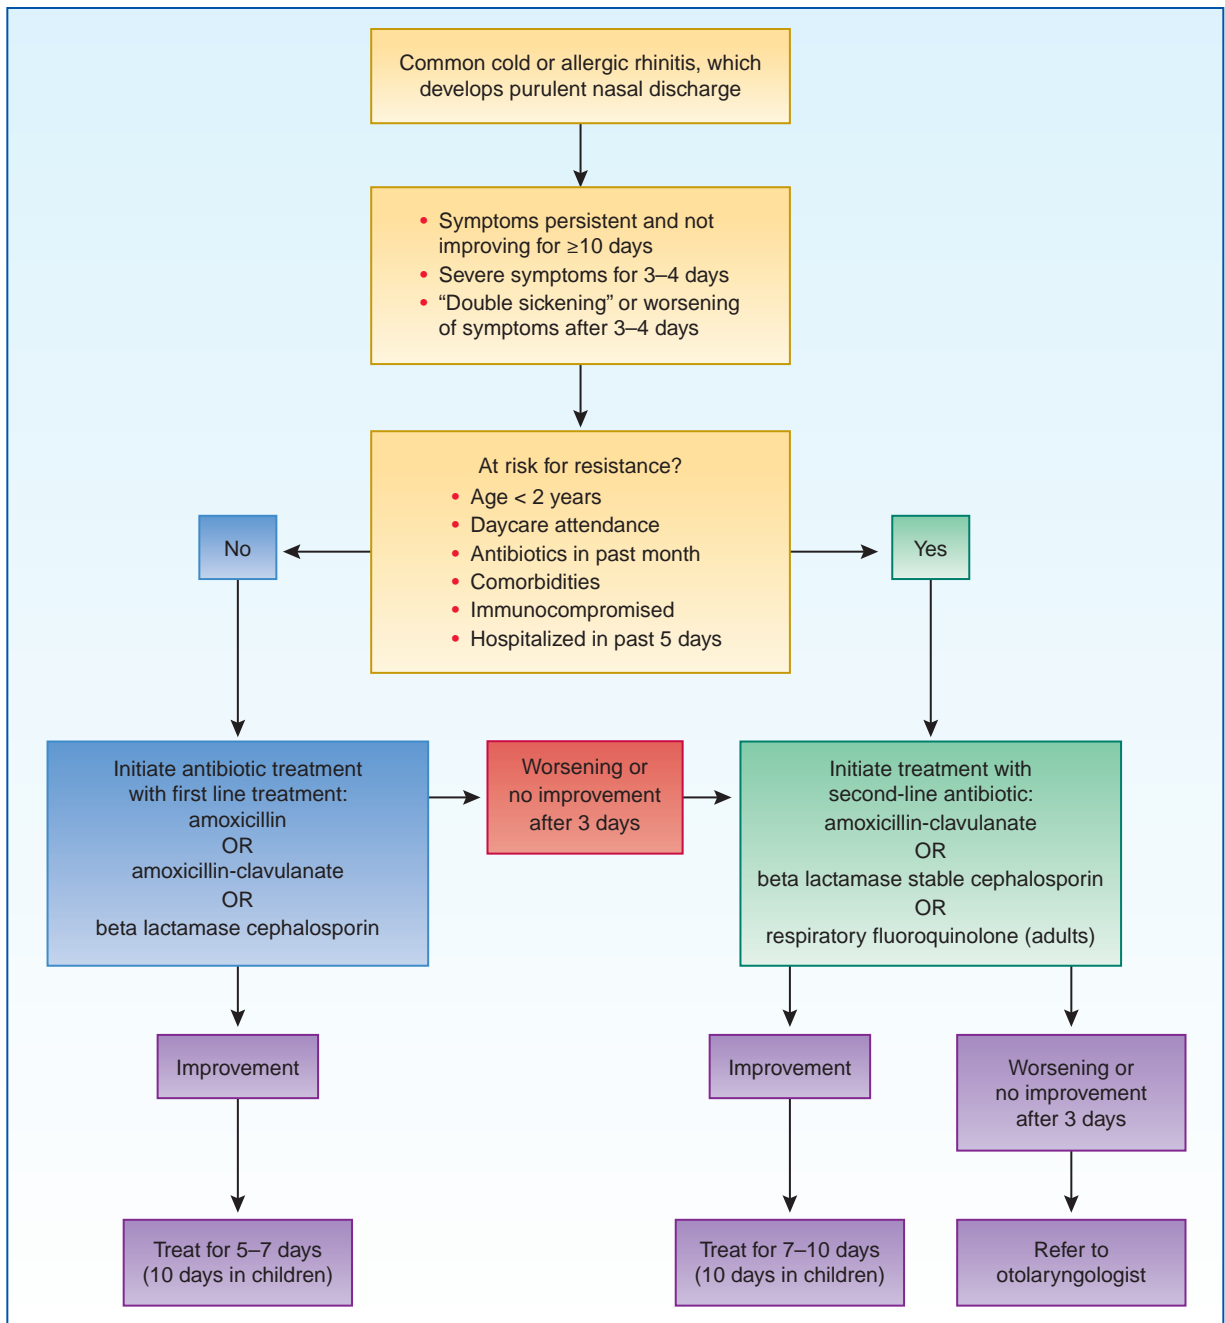
Nonprescription management includes decongestants, either topical or systemic, to improve nasal obstruction. Patients


Figure 46–1. Algorithm for treatment of sinusitis.

should be warned against long-term use of topical decongestants, but they can be very helpful in providing symptomatic relief during the few days it takes to respond to antibiotics. Saline nasal spray or wash prevents crusting of secretions in the nasal cavity, facilitating removal of secretions. Adequate hydration is essential in liquefying secretions. The facial pain and headache associated with sinusitis can be severe, and the patient should be encouraged to take acetaminophen or ibuprofen for pain. A warm pack to the frontal and maxillary sinuses often provides pain relief. Running a humidifier at night can alleviate the dry mouth caused by mouth breathing during sleep. Breathing in hot steam often helps clear nasal passages, but caution patients about burns.

Sinusitis causes the air passages in the sinuses to become swollen and blocked and to trap air. Therefore, sinusitis poses a hazard to patients who dive because of the changing air pressures in the sinuses, and diving is contraindicated. Patients who are planning to fly or to drive over mountain ranges can use topical decongestants prior to the trip to prevent the pain associated with the changing air pressures in the air trapped in the sinuses.

OTITIS MEDIA

The most common reason for which children in the United States receive antibiotics is acute otitis media (AOM); an

estimated 10.3 million visits annually are coded AOM (Coco, Vernacchio, Horst, & Anderson, 2010). Office visits for otitis media in children younger than age 18 years as measured by the U.S. National Ambulatory Medical Care Survey declined from 34.47 per 100 children in 1997 to 24.66 per 100 children in 2007 (National Institute on Deafness and Other Communication Disorders, 2012). The cost of treating AOM in the United States, including office visits and antibiotics, is $2.88 billion, based on the 2009 Medical Expenditure Panel Survey (Ahmed, Shapiro, & Bhattacharyya, 2013). OM may occur at any age, but the most common presentation is in children under age 10 years. The prevalence of OM in children younger than age 3 years in 2007 was 724 per 1,000 children, a drop of 38% since 1997 (Hoffman et al, 2013). The introduction of the 7-valent pneumococcal vaccine (PCV7) decreased the number of medical visits and subsequent antibiotic prescriptions for AOM by 40% (Falup-Pecurariu, 2012).

Every practitioner encounters OM, and those who work with children see OM daily. Defining AOM and otitis media with effusion (OME) would seem to be a simple task, yet there is great diversity in the criteria for diagnosis and management among primary care providers. Criteria for the diagnosis and management of AOM and OME, based on the AAP guidelines, are discussed in this section of the chapter.

The hallmark symptom of OM is ear pain, often unilateral. Patients may also complain of hearing loss in the affected ear. Preverbal children may tug or poke at the affected ear, be irritable, and sleep poorly. Fever often accompanies AOM. Patients may also report tinnitus, dizziness, an unsteady gait, or balance problems. In children, vomiting and diarrhea may be associated with OM.

According to the AAP guidelines, the diagnosis of AOM is a clinical one based on a spectrum of signs and symptoms (Lieberthal et al, 2013). The AAP guidelines recommend diagnosing AOM in children with (1) moderate to severe bulging of the TM or new onset of otorrhea not due to acute otitis externa or (2) mild bulging of the TM and recent (less than 48 hours) onset of ear pain or intense erythema of the TM; and (3) no diagnosis of AOM in children who do not have middle ear effusion (MEE) (Lieberthal et al, 2013). OME is fluid in the middle ear without any signs or symptoms of acute illness. Erythema is nonspecific, and AOM should never be diagnosed on the basis of tympanic membrane (TM) color alone, as the TM can redden from crying or a fever. Fluid in the middle ear (MEE) is assessed by observing white or yellow fluid, observing the air/fluid level, observing air bubbles, or noting decreased TM movement via pneumatic otoscopy. A thin-walled bulla is seen with bullous myringitis, a very painful form of AOM.

Pathophysiology

AOM occurs when there is a combination of eustachian tube dysfunction, which blocks the flow of secretions from the middle ear to the pharynx, and negative pressure developing in the middle ear, which causes reflux of bacteria into the middle ear space. This combination results in an MEE that becomes infected with nasopharyngeal bacteria.

A predisposing factor in young children (younger than 5 years) is that they have shorter, more horizontal, and more flaccid eustachian tubes, and bacteria are more easily drawn into the middle ear space. Certain risk factors predispose children to AOM: URIs, Down syndrome, cleft palate, HIV infection, and Eskimo or Native American heritage. Children who are bottle-fed formula have a higher incidence of AOM than do breast-fed infants, as do children who live with one or more tobacco smokers (Hoffman et al, 2013). Day-care attendance can double the odds of developing AOM (Hoffman et al, 2013). Immunocompromised patients and patients with indwelling nasogastric tubes have an increased incidence of OM, regardless of age.

The pathogens found in AOM may be bacterial or viral in origin. *S. pneumoniae*, *H. influenzae,* and *M. catarrhalis* are the pathogens found most frequently in AOM in both children and adults. Since the introduction of PCV7 and subsequently PCV13, the frequency of the three pathogens has shifted from predominately *S. pneumoniae* to *H. influenzae* becoming the most common pathogen (Leiberthal et al, 2013). The conjugate Hib vaccine has not affected AOM caused by *H. influenzae* because approximately 90% of *H. influenzae* in AOM is nontypeable. Viruses (respiratory syncytial virus, rhinovirus, coronavirus, adenovirus, and parainfluenza virus) are found alone (4%) or as a copathogen (66%) in AOM cases (Lieberthal et al, 2013).

Goals of Treatment

The goal for the treatment of AOM is to clear infection from the middle ear fluid with the use of antibiotics. If the antibiotic chosen is effective against the pathogen, then the infection clears. Because the treatment of AOM is empiric based on the most commonly found pathogens, a change of antibiotic is necessary at times to treat the infection. The goal remains the same: clearing infection from the middle ear fluid.

Rational Drug Selection

Guidelines

There is much controversy regarding the treatment of OM. In 2004, the AAP and the AAFP issued a joint clinical practice guideline for the diagnosis and treatment of AOM, which provides an evidence-based approach to caring for the child aged 2 months to 12 years with uncomplicated AOM. The guideline was updated by the AAP in 2013 (Leiberthal et al, 2013).

The AAP recommendations are the following:

1. Diagnosis of AOM includes the following criteria: spectrum of symptoms: (1) moderate to severe bulging of the TM or new onset of otorrhea not due to acute otitis externa; (2) mild bulging of the TM and recent (less than 48 hours) onset of ear pain or intense erythema of the TM; and (3) no diagnosis of AOM in children who do not have middle ear effusion (MEE).

2. Pain must be assessed and adequate pain management provided.

3a. Antibiotic therapy should be prescribed for severe AOM in children aged 6 months or older. Symptoms of severe AOM include: moderate or severe otalgia, otalgia for at least 48 hours, or temperature great than 39°C (102.2°F).

3b. Antibiotics should be prescribed for nonsevere bilateral AOM in young children (6 months to 23 months).

3c. For nonsevere unilateral AOM in children 6 to 23 months of age, an antibiotic or initial observation may be prescribed with close follow-up within 48 to 72 hours, based on a joint decision with the parent(s) or caregiver. Antibiotic therapy is started if the child worsens or fails to improve in 48 to 72 hours.

3d. An antibiotic or observation should be offered for nonsevere AOM (unilateral or bilateral) in children age 24 months or older based on joint decision making with the parent(s) or caregiver. Antibiotic therapy is started if the child worsens or fails to improve in 48 to 72 hours.

4a. If treating with an antibiotic, amoxicillin is the first choice for most children if they have not received amoxicillin in the last 30 days. Amoxicillin should be dosed at 80 to 90 mg/kg/d. Patients with penicillin allergy may be treated with cefdinir (14 mg/kg/d), cefuroxime (30 mg/kg/d divided bid), cefpodoxime (10 mg/kg/d divided bid), or ceftriaxone (50 mg/d IM or IV for 1 to 3 days).

4b. Patients who have had amoxicillin in the past 30 days, those with concurrent conjunctivitis, or those who warrant coverage for beta lactamase–positive *H. influenzae* and *M. catarrhalis*, should be prescribed amoxicillin-clavulanate (90 mg/kg/d of amoxicillin and 6.4 mg/kg/d of clavulanate in two divided doses) as the drug of choice.

4c. If the patient fails to respond to an initial management option (3a, 3b, or 3c) within 48 to 72 hours, the clinician must reassess the patient to confirm AOM and exclude other causes of illness. If initially managed with observation, then antibiotics should be started. If an antibiotic was initially prescribed, then the antibiotic should be changed.

5. Clinicians should encourage prevention of AOM according to the Advisory Committee on Immunization Practices (ACIP) through the reduction of risk factors such as recommending pneumococcal conjugate vaccine and annual influenza vaccine to all children, breastfeeding for the first 6 months of life, and reducing exposure to tobacco smoke.

Figure 46-2 provides an algorithm for treating OM.

Antimicrobial Resistance

The emergence of antimicrobial resistance among respiratory pathogens has caused primary care providers to reevaluate their routine use of antibiotics for all illnesses, especially OM.

Almost 100% of *M. catarrhalis* produces beta lactamase, which can be resistant to amoxicillin and other penicillins (AAP, 2012b). *H. influenzae,* another beta lactamase producer, is 30% to 40% resistant to amoxicillin (AAP, 2012c). At one point in the early 2000s, up to 20% of *S. pneumoniae* was resistant and 20% was intermediately resistant to penicillin, but more recent studies indicate 92% of pneumococci is susceptible to penicillin (Centers for Disease Control and Prevention, 2008). The decrease in resistance is the reason amoxicillin remains the first-line treatment for acute otitis media.

S. pneumoniae is also resistant to the common macrolides erythromycin (35.3% resistance), azithromycin (35.3% resistance), and clarithromycin (35.2% resistance) (Jenkins & Ferrell, 2009). Resistant *S. pneumoniae* is more common among children who are in day care, have recurrent AOM, are younger than 2 years, or have been recently treated with beta lactamase antibiotics (Leiberthal et al, 2013). In light of this increasing resistance among common OM pathogens, the provider needs to decide carefully whether an antibiotic is necessary and, in the case of treatment failure, consider the possibility of resistant bacterial strains. The common antibiotics and their dosages used for OM are listed in Table 46-2.

Dosing Regimen

Amoxicillin remains the first-line drug of choice for AOM in spite of resistance per the AAP guidelines for the management of AOM (Lieberthal, et al, 2013). Amoxicillin is dosed at 80 to 90 mg/kg/d, which raises the concentration in the middle ear fluid to be effective against intermediate and resistant strains of *S. pneumoniae*. Conversely, patients who have had repeated episodes of AOM or have been on antibiotics in the past 30 days should be treated with beta lactamase–stable amoxicillin/clavulanate or beta lactamase–stable cephalosporin if allergic to penicillin. Table 46-3 discusses antibiotic treatment options for AOM in patients who have been on antibiotics recently.

Length of Treatment

Length of treatment has also been investigated in recent years. In the United States, AOM has traditionally been treated for 10 days with antibiotics. There are few controlled studies to support the practice. Compliance and completion of the 10-day regimen have also been an issue. A number of studies have compared outcomes after 5 or 7 days of antibiotics versus 10 days. For patients over age 5 years, a shortened 5-day course of treatment is probably adequate (Lieberthal et al, 2013). Children age 2 to 5 years may be treated for 7 days, and children under age 2 years or with severe symptoms are treated for 10 days (Leiberthal et al, 2013).

Watchful Waiting (No Antibiotics)

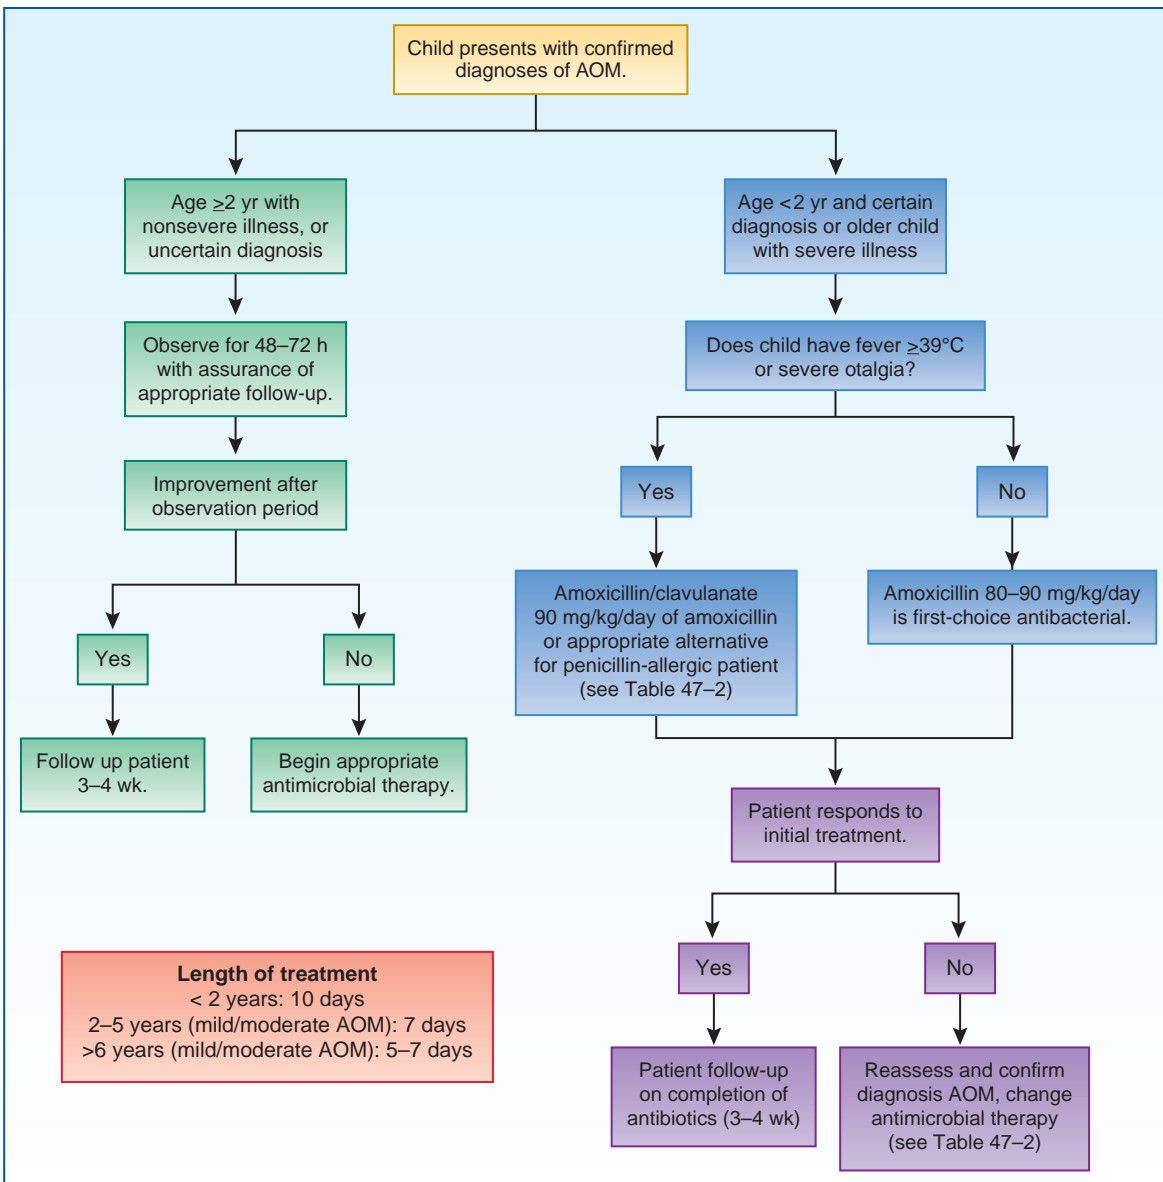
With the guidelines recommending a period of "watchful waiting" for 48 to 72 hours in low-risk patients, providers must have confidence in their decision to not treat with antibiotics. Providers are concerned not only about the prudence


Figure 46–2. Algorithm for treatment of AOM.

of the treatment but also about the acceptance of watchful waiting by parents of children with OM.

Acceptance of watchful waiting among parents of children with AOM has been evaluated. A *Cochrane Review* of 10 studies examining delayed antibiotics for respiratory infections including AOM indicates delayed antibiotic prescription slightly reduces parent satisfaction compared to immediate antibiotics (87% versus 92%) (Spurling, Del Mar, Dooley, & Foxlee, 2007). A study examining the AAP recommendation of watchful waiting indicates that although antibiotic prescribing in children under age 2 years decreased 21% to 26%, parental sick days increased 13% to 14% (Meropol, Glick, & Asch, 2008). The increase in parental sick days may be a reason for decreased parental satisfaction with watchful waiting.

Providing a "safety-net" prescription for parents to fill after an initial period of observation or watchful waiting is an option for the treatment of AOM. Initial observation of

AOM for 48 to 72 hours has been a recommendation of the Dutch College of General Practitioners for almost 30 years (Culpepper & Froom, 1997). Using these guidelines, Dutch children have outcomes at 2 months similar to those of children from other countries treated with antibiotics. Meropol and colleagues (2008) found that using the watchful waiting approach reduced antibiotic use 67% in children aged 2 to 12 years. The pediatric provider needs to educate parents about the rationale for initial observation of AOM and provide adequate pain relief during the observation period to ensure success with this approach.

Pain Relief

Regardless of whether the patient receives antibiotics, all children require pain relief for the first 24 to 72 hours of treatment. Adequate dosing of acetaminophen (15 mg/kg per dose) or ibuprofen (5 to 10 mg/kg per dose) is necessary.

Table 46–3 Treatment Options for Otitis Media

Temperature >39°C (102.2°F) and Severe Otalgia; or <age 2 years	Initial Treatment	Alternative Treatment (if Penicillin Allergy)	Antibiotic Treatment After 48–72 h of Failure of Initial Antibiotic Treatment
No	High-dose amoxicillin (80–90 mg/kg/d in 2 divided doses)		Amoxicillin-clavulanatea (90 mg/kg/d of amoxicillin, with 6.4 mg/kg/dof clavulanate [amoxicillin to clavulanate ratio, 14:1] in 2 divided doses)
		Cefuroxime, Cefdinir	
		Cefpodoxime	
		Cefriaxone (IM)	
		Cefixime	
Yes	High-dose amoxicillin/ clavulanate (80–90 mg/kg/d)	IM ceftriaxone OR Clindamycin (30–40 mg/kg per day in 3 divided doses) plus third-generation cephalosporin	IM ceftriaxone × 3 d or tympanocentesis

Source: From Lieberthal et al, 2013.

It is the provider's responsibility to determine the dose of analgesic that ensures adequate pain relief. Topical analgesia (Auralgan otic solution, a combination of antipyrine, benzocaine, and u-polycosanol 410 otic solution) can be applied. In a study of children aged 5 years or older who were being adequately dosed with acetaminophen (15 mg/kg), the study patients who received Auralgan reported lower ear pain scores than did the control group who received the placebo (olive oil). A number of the study patients reported dramatic and immediate reductions in pain (Hoberman, Paradise, Reynolds, & Urkin, 1997). Some providers stock Auralgan in the clinic to provide immediate pain relief for their OM patients. Auralgan should never be used before the provider observes an intact TM.

Monitoring

Monitoring the effectiveness of the treatment chosen, either to prescribe antibiotics or to provide symptomatic care for the first 2 to 3 days, is essential to the optimal outcome for the patient. Patients may still experience pain with OME, even if the appearance of the TM improves. Patients with persistent symptoms or failure to improve in 48 to 72 hours should be reexamined to determine whether the initial plan (whether antibiotics were prescribed or not) needs to be reevaluated (Leiberthal et al, 2013).

If symptoms resolve, patients younger than 2 years of age should be reexamined in 8 to 12 weeks after beginning antibiotics, with the understanding that, at 4 weeks, there is a 40% chance that fluid is still present in the middle ear and that effusions can last up to 3 months (Leiberthal et al, 2013). Older children (older than 2 years) without language or learning problems can be followed at their next scheduled well-child exam, or sooner if there are concerns (Klein & Pelton, 2009). Older children with known language or learning problems should be examined 8 to 12 weeks after the AOM.

Antibiotics are not appropriate for the initial treatment of OME, and there is controversy regarding their use at all for this indication, even after 3 months of persistent effusion. Persistent effusion beyond 3 months is an indication for a referral to an otolaryngologist.

Outcome Evaluation

The patient should be evaluated 8 to 12 weeks from the beginning of treatment to determine if the infection is completely resolved. The provider may choose to evaluate the patient sooner, with the understanding that some MEE may remain.

Patient Education

Two areas have to be covered in educating patients and families about the use of antibiotics for AOM: the proper use of the prescribed antibiotic and the predicted course of the infection once antibiotics are started. The instructions regarding the antibiotic dosage and timing of doses must be clear, and any questions regarding the medication answered. Expected adverse reactions, such as the mild diarrhea that may accompany many of the antibiotics, must be discussed. Patients and family members should be aware that the expected course of the ear infection, once antibiotics are started, is some symptomatic relief in 24 to 48 hours. Use of acetaminophen or ibuprofen for pain relief is necessary during this initial period to provide comfort. Parents should be encouraged to give their children a dose of ibuprofen or acetaminophen just before bedtime because children seem to complain of greater ear pain at night during the healing stages. Patients who are still having significant pain after 48 hours should be reexamined for the possibility of a resistant organism. Bacterial resistance ought to be mentioned, and the patient should be encouraged to complete the course of medication to prevent the development of antibacterial resistance to a partially treated organism.

OTITIS EXTERNA

OE (external OM) is an acute infection that causes an inflammatory reaction in the external auditory canal. It is also known as swimmer's ear.

The patient generally presents with severe ear pain, which may have begun as itching and irritation. The pain is generally unilateral and localized to the ear. Manipulation of the pinna or tragus causes moderate to severe pain, a finding that is usually absent in OM. The TM is normal in OE, but the external auditory canal may be swollen such that the TM is difficult to visualize. Malignant OE is found in patients with diabetes and presents as severe cellulitis due to *Pseudomonas aeruginosa.*

Pathophysiology

Trauma or prolonged exposure to moisture predisposes to infection. The chlorine in swimming pools kills the normal flora in the external ear canal, which allows growth of pathogens. The most common organism found is *P. aeruginosa,* followed by *Staphylococcus aureus.*

Goals of Treatment

The goal of treatment of OE is resolution of the infection, pain control, and prevention of recurrence.

Rational Drug Selection

Topical therapy delivers a high concentration of the antimicrobial to the infected tissue, significantly more than can be delivered via systemic antimicrobial treatment (Rosenfeld et al, 2014). The medications used in the treatment of OE include combination products (Cortisporin, Cipro HC) that contain a corticosteroid (hydrocortisone) and antibiotic(s) (neomycin, polymyxin B, ciprofloxacin), antibiotic alone (gentamicin, ofloxacin), and acetic acid or alcohol drops (Otic Domeboro, Burow's Otic, Vosol, Vosol HC).

The medication of choice is antibiotic/steroid eardrops, which combine an antibiotic(s) and an anti-inflammatory such as neomycin sulfate, polymyxin B, and hydrocortisone (Cortisporin Otic); ciprofloxacin and hydrocortisone (Cipro HC Otic); or ciprofloxacin and dexamethasone (Ciprodex). Eyedrops can be used for external otitis, including tobramycin and dexamethasone (Tobradex eyedrops), gentamicin and prednisolone (Pred-G), and sulfacetamide and prednisolone (Vasocidin solution).

Acid and alcohol solutions may also be used. Common products are Otic Domeboro and Burow's Otic, which contain 2% acetic acid in aluminum acetate solution. Another acid solution, Vosol Otic, contains 2% acetic acid solution and 3% propylene glycol. These solutions reduce inflammation and are antibacterial and antifungal.

Treatment consists of irrigation and antibiotic eardrops. The medication of choice is antibiotic/steroid eardrops, with cost and convenient dosing factored into decision making because all are equally effective (Rosenfeld et al, 2014). The routine dosing is three to four drops administered 4 times a day. Suspension formulations are less ototoxic than solution preparations of eardrops. A cotton wick may be necessary if the ear canal is extremely swollen. For severe cellulitis, parenteral antistaphylococcal and antipseudomonal antibiotics are necessary. Pain can be severe but patients should have relief with topical therapy and should only need NSAIDs for pain. Some patients with severe pain may need a combination product that contains an opioid (oxycodone or hydrocodone) in the short term to provide relief of pain while undergoing treatment (Rosenfeld et al, 2014).

Monitoring

The patient should begin to experience relief from pain in 3 or 4 days. Reevaluation in 1 week determines if the patient is clinically improving. Referral to a dermatologist or otolaryngologist may be necessary if there is no improvement or if symptoms worsen in spite of treatment.

Outcome Evaluation

To evaluate the effectiveness of OE treatment, the provider determines if the infection is resolved after treatment with antibiotic/steroid eardrops.

Patient Education

Educate the patient to prevent OE by avoiding pooling of water in the ears and by using a mildly acidic solution after swimming. Patients can instill three to four drops of a 1:1 solution of water and white vinegar or 70% ethyl alcohol. Commercially available products (EarSol, Swim-Ear) can also be used. Earplugs may be helpful for avoiding developing external otitis.

Explain proper irrigation of debris prior to instillation of eardrops to ensure that the medication contacts the affected area. Swimming should be avoided until external otitis has cleared, ideally for 7 to 10 days (Rosenfeld et al, 2014). Monitoring for increasing severity is essential to detect cellulitis early in the diabetic patient. The patient may take ibuprofen or another analgesic for the first 24 to 48 hours of treatment to provide pain relief.

URINARY TRACT INFECTIONS

Erin Anderson

U rinary tract infections (UTIs) are responsible for 8.27 million office visits per year (1.41 million men; 6.86 million women) (Litwin & Saigal, 2007). UTIs are more common in women because the short female urethra provides easy access to the bladder for bacteria (Griebling, 2007a). The lifetime risk of a woman developing a UTI is 60.4%, with one-third of women diagnosed with a UTI by age 18 years (Griebling, 2007a). UTIs also occur in men, who have a 13.6% lifetime risk, with most UTIs related to urinary tract obstructions, such as benign prostatic hypertrophy, which is reflected in the increased incidence of UTI as men age (Griebling, 2007b). UTIs affect 2.6% to 3.4% of children annually, with a childhood risk of developing a UTI 2% for boys and 8% for girls (Freedman, 2007). In infant males, circumcision decreases the risk of developing a UTI, with the rate in the first 6 months of life in uncircumcised boys 12 times higher than in circumcised boys (Freedman, 2007). Vesicoureteral reflux, constipation, and dysfunctional voiding all increase the risk for UTI in children (Freedman, 2007).

Most patients with UTIs do not experience long-term complications from these disorders. Those who do usually have a comorbid condition such as vesicoureteral reflux, renal stones, neurogenic bladder, diabetes, or obstruction. This chapter discusses the management of uncomplicated UTIs in otherwise healthy patients who do not have these comorbid conditions and who do not have retention catheters inserted.

PATHOPHYSIOLOGY

A complex interaction between host and microbial factors leads to UTIs. The anatomy and physiology of the genitourinary tract offer protective defenses against UTIs, although certain factors may increase risk for developing a UTI in certain populations. Likewise, behavioral factors may contribute to developing UTIs.

Host Factors

Anatomy and Physiology of the Genitourinary Tract

The bladder has unique intrinsic defenses against infection. Periodic washout, by voiding, of the bacteria that perpetually colonize the urethra is one of the main defense mechanisms. The bladder also deters microbial adherence to the mucosa through the antibacterial properties of the urinary bladder epithelium. Patients who have repeated UTIs appear to have altered bladder epithelial cells that facilitate adherence of bacteria to the mucosa rather than deter it. The low pH and high osmolality of urea and secretions from the uroepithelium and a competent urethral valve that prevents backflow also decrease UTIs. The longer urethra and prostatic secretions decrease the risk of infection in men.

These defense mechanisms are severely limited if residual urine is regularly present after voiding. Pregnancy increases

the risk for UTIs because of pressure on the bladder from the enlarging fetus, increased incidence of residual urine, and changes in estrogen levels. Genetic factors, including expression of HLA-A3 and Lewis blood group Le(a−b−) or Le(a+b−), may put women at higher risk for developing UTIs (Griebling, 2007a). Estrogen deficiency and concomitant decreased acidification of the vagina, with increased vaginal colonization by *Enterobacteriaceae,* also contribute to increased risk in postmenopausal women. Men who develop benign prostatic hypertrophy (BPH) are at increased risk of developing a UTI due to bladder outlet obstruction (Griebling, 2007b). Fecal and urinary incontinence, lack of estrogen, immunocompromised states—including diabetes mellitus and taking antibiotics for other infections—have been associated with increased risk in the older adult. Any instrumentation of the urinary tract—including catheter placement or cystoscopy—places patients at risk of developing a UTI (Griebling, 2007b).

Behavioral Factors

Sexually active women are at higher risk than sexually inactive women for developing UTIs. Frequency of sexual intercourse, diaphragm or spermicide use, and failure to void within 10 to 15 minutes of coitus have all been associated with a risk for UTIs in women (Griebling, 2007a). Reasons for the increased risk may be urethral trauma, decreased urge to void, and residual urine. Diaphragm or spermicide use also appears to compromise host defense mechanisms to the extent necessary for virulent strains of bacteria to become capable of causing an infection.

Other behavioral factors have been inconsistently associated with UTI and are subject to some controversy. Purposely resisting the urge to void has been associated with UTIs in some studies and not in others. Increased fluid intake has also had an inconsistent association, although it is difficult to find a reason not to suggest adequate fluid intake for a variety of reasons, including increasing bacterial washout through more frequent voiding. Cranberry juice has an "on-again, off-again" history of association with prevention of UTI (Berger, 2005). A recent *Cochrane Review* states new studies show cranberry products are less effective than previously thought (Jepson, Williams, & Craig, 2012). Little evidence indicates that the direction of wiping after bowel movements, the use of oral contraceptives or tampons, or the habit of taking bubble baths or douching contributes to UTIs.

Microbial Factors

Ability of the Bacteria to Adhere to Epithelial Cells

Escherichia coli is responsible for 85% of community-acquired UTIs and 50% of hospital-acquired UTIs. This organism is successful in part because it contains fimbriae that allow attachment to host cell receptor sites on the bladder mucosa. Some women are thought to be genetically susceptible to certain strains of *E. coli* attachment. Other organisms that

commonly infect the urinary tract include *Klebsiella, Proteus* (more common in men), *Pseudomonas,* Enterobacter, and *Staphylococcus saprophyticus.*

Virulence of the Organism

Coliforms cultured from women with recurrent UTIs were more virulent than those cultured from patients with first-time infections or from the fecal flora of patients who had no history of UTIs.

Ability of the Organism to Survive the Urinary Tract Environment

Some bacteria are more tolerant of the low pH of urine. Table 47-1 lists the factors shown by research to be associated with the occurrence of UTIs. It also lists those factors that have been inconsistently related to UTIs or not demonstrated by research to be associated with UTIs.

Inflammatory Reaction to Bacteria

Infection with any organism initiates an inflammatory response and the symptoms of cystitis. The inflammatory edema in the bladder wall stimulates stretch receptors, which discharge with even small volumes of urine, producing the urgency and frequency or urination association with UTIs. Prostaglandins released from the mast cell as part of the inflammatory response produce pain. They also increase vascular permeability, which may be exhibited as hematuria.

Diagnosis of UTI is based on symptoms and laboratory data. Presenting symptoms of UTI vary with age, as shown in Table 47-2. Symptom presentation is similar for both men and women. All ages often exhibit dark, cloudy, and malodorous urine. Urethral discharge in men is more commonly associated with sexually transmitted infections (STIs) than with UTIs. STIs are discussed in Chapter 44.

Laboratory data for diagnosis include urinalysis (UA) and urine culture and sensitivity. The most common findings from a clean-catch urine specimen are (1) a positive leukocyte esterase or pyuria (usually greater than five white blood cells [WBCs] per high-power field), which has a sensitivity range of 90% to 100% and a specificity range of 58% to 91%; (2) the presence of bacteria, which has a sensitivity of approximately 81% and a specificity of approximately 83%; (3) and/or a positive dipstick for nitrates. When all are positive, the sensitivity is 99% to 100% and the specificity is up to 92%. The presence of casts or hematuria suggests an upper UTI.

Quantitative urine cultures are the most reliable method for diagnosing UTIs; however, they require trained personnel, are more expensive, and take time to complete, which might lead to postponing treatment of symptomatic patients. Cultures are usually reserved for children and men and for recurrent UTIs in women. Pregnant women should be screened for bacteriuria by urine culture at least once in early pregnancy because this population is at risk for asymptomatic UTI (Institute for Clinical Systems Improvement [ICSI], 2004; Nicolle et al, 2005). Nicolle and

Table 47–1   **Factors Associated With Urinary Tract Infections**

Host Factors	Microbial Factors	Inconsistent or Not Associated Factors
Anatomical and Physiological		
• Periodic washout with voiding* • Bladder epithelial cells that prevent adherence of bacteria*	• Ability of the organism to adhere to epithelial cells	• Ingestion of cranberry juice* • Purposely resisting the urge to void • Increased fluid intake* • Wiping from front to back after defecation* • Oral contraceptive use • Tampon use • Bubble baths • Douching
• Acid pH of urine* • Osmolality of urine*	• Virulence of the organism	
• Competent urethral valves to prevent backflow of urine* • Pregnancy • Estrogen deficiency • Residual urine • Lack of circumcision in males • Benign prostate hyperplasia	• Ability of the organism to survive the urinary tract environment	
Behavioral		
• Frequent sexual intercourse • Diaphragm use • Spermicide use • Failure to void 10–15 min after coitus • Multiple sexual partners • Anal intercourse • Fecal and urinary incontinence		

*These factors are negatively associated with UTIs and may prevent them.

Table 47–2   **Urinary Tract Infection Symptoms by Age**

Neonate	Failure to thrive, irritability, fever, hypothermia, sepsis, jaundice, vomiting, acidosis
Infant	Failure to thrive, irritability, fever, hypothermia, sepsis, jaundice, vomiting, acidosis, hematuria, urinary frequency, dysuria
Preschool- or school-age child	Abdominal or suprapubic pain, dysuria, frequency, urgency, enuresis, urinary incontinence
Adult	• Dysuria, frequency, urgency, burning on urination, incontinence, urethral pain, suprapubic pain, low back pain, hematuria • Significant fever is unusual in bladder infections but may occur, along with severe flank pain and costovertebral tenderness, in upper UTIs • Patients with upper UTIs may also demonstrate headache, malaise, nausea, and vomiting • Symptoms are similar for women and men
Older adult	• Same symptoms as adult, but also mental status changes from patient's norm • Urinary incontinence

colleagues (2005) do not recommend screening for or treatment of asymptomatic bacteriuria for premenopausal, nonpregnant women; diabetic women; older persons living in the community; older adults who are institutionalized; or catheterized patients while the catheter is still in place. Older institutionalized adults who exhibit altered mental status from their norm should be screened for UTI, because this symptom may indicate UTI in the absence of other reported symptoms.

PHARMACODYNAMICS

There is a wide range of antimicrobial agents available for treatment of UTIs. They include trimethoprim/sulfamethoxazole

(Bactrim, Septra), nitrofurantoin (Furadantin, Macrodantin), fluoroquinolones (cipro-floxacin [Cipro], gatifloxacin [Tequin], levofloxacin [Lavaquin], ofloxacin [Floxin]), cephalosporins (cephalexin [Keflex], cefixime [Suprax]), and penicillins (amoxicillin [Amoxil], amoxicillin/clavulanate [Augmentin]). The spectrum of antimicrobial activity varies among these agents. Recent studies have shown a slight but generalized decrease in bacterial susceptibility to some of these agents. Each of these is discussed in Chapter 24.

A *Cochrane Review* of the use of cranberries in the treatment of UTIs concluded that cranberry juice is less effective in decreasing the incidence of symptomatic UTIs than previously thought and cannot be recommended at this time to help decrease UTIs over a 12 month period (Jepson et al, 2012). Although there is some evidence that cranberry juice can decrease UTIs, it was not statistically significant and many people quit drinking it (Jepson et al, 2012). These new recommendations were specifically for cranberry juice. Cranberry products (powder, tablets, capsules) have differing amounts of the "active" ingredient and further testing is needed (Jepson et al, 2012). Studies indicate that a substrate in cranberries may exert a bacteriostatic effect by inhibiting the adherence of organisms to the mucosal surface of the bladder. Cranberries also change the surface properties of *E. coli,* preventing it from adhering to the bladder wall (Jepson & Craig, 2008). Symptomatic relief is often provided by urinary analgesics. The primary ingredient in these products is phenazopyridine, an azo dye taken orally that exerts a topical analgesic effect on the urinary tract mucosa when it is excreted into the urine. This dye is available under several different brand names. Azo-Standard, Prodium, Pyridium, Uricalm, and Urogesic all contain phenazopyridine 95 mg.

GOALS OF TREATMENT

Eradication of the causative organism is the primary goal of therapy. Relief of symptoms and prevention of recurrent infections are also therapeutic goals.

RATIONAL DRUG SELECTION

The main focus of this section is appropriate selection and use of drugs to treat both upper and lower UTIs.

Algorithm

This chapter does not discuss the testing involved in the diagnosis of UTIs beyond that needed for treatment decisions. The treatment protocol here assumes accurate diagnosis of the UTI by means of the appropriate diagnostic tools, including laboratory data. Once the diagnosis has been made, treatment regimens are determined.

Treatment of UTIs is directed at the three goals of eradication of organisms, relief of symptoms, and prevention of recurrence. The infecting organism is eradicated with antimicrobial therapy. Treatment for symptom relief often includes urinary analgesics. Prevention of recurrence may involve prophylactic drug therapy but involves lifestyle management as well.

Drug Therapy

Drug therapy is aimed at eradicating the infecting organism. Appropriate antimicrobial selection is based on drug variables—spectrum of activity of the drug, potential adverse drug reactions, patterns of resistance to the antimicrobial, and cost—and patient variables—age, gender, pregnancy, and the underlying cause of the UTI.

Drug Variables

Spectrum of Activity

Lower-tract UTIs are most commonly caused by gram-negative bacteria (95% of UTIs), with *E. coli* the most prevalent organism (80% of all lower UTIs are caused by *E. coli*) (Wagenlehner, Weidner, & Naber, 2005). Among community-acquired infections, *S. saprophyticus*, *Klebsiella,* and gram-negative enteric bacilli cause almost all the UTIs not caused by *E. coli.* In children, additional organisms include *Klebsiella* in neonates and *Proteus* in boys. All of the antimicrobial agents mentioned have a spectrum of activity that covers these organisms.

Empirical treatment with trimethoprim/sulfamethoxazole (TMP/SMX, Septra, Bactrim) is the first-line treatment choice when no complicating factors are present and the rate of local resistance rates is less than 20% (Gupta et al, 2011). TMP/SMX has fallen out of favor in spite of its being the recommended first-line drug per guidelines, inexpensive, and effective (Griebling, 2007a; Grover et al, 2007). A 3-day treatment is cost-effective, increases compliance, and reduces risk of developing *Candida* vaginitis (Thomas & Porter, 2007). The recommended dose for treating uncomplicated UTIs in adults is one double-strength tablet bid for 3 days (Hooton & Gupta, 2014a). The dose of TMP/SMZ to treat UTIs in children older than 2 months of age is 6 to 12 mg trimethoprim and 30 to 60 mg sulfamethoxazole/kg/day (Septra or Bactrim) in two divided doses (1 mL suspension per kg/d). Children should be treated with a 10 day regimen. Resistance to TMP/SMZ is seen in patients who have had antibiotic therapy for any reason in the past 3 months or if they have been hospitalized recently.

Nitrofurantoin is an effective treatment for lower UTIs, with a low *E. coli* resistance rate of 2.1% compared to TMP/SMZ, ciprofloxacin, and levofloxacin (Kashanian et al, 2008). It is now being recommended as a first-line therapy for uncomplicated lower UTIs in adult women (Gupta et al, 2011). The Infectious Disease Society guidelines recommend 100 mg bid for 5 days (Gupta et al, 2011); however, ACOG (2008) recommends a 7-day course. The pediatric dose is 5 to 7 mg/kg/d divided every 6 hours for 7 to 10 days. Shortened therapy should not be used in children. Nitrofurantion can be used prophylactically in adults and children who have recurrent UTIs defined as more often than 3 times per year.

Nitrofurantoin is Pregnancy Category B but should be avoided in pregnancy near term, in labor, and during lactation when the infant is less than 1 month of age because of a risk for the infant to develop hemolytic anemia.

Fluoroquinolones, including ciprofloxacin, are highly effective in treating UTIs; however, resistance and overuse are hindering its effectiveness to treat other infections (Gupta, et al, 2011). The American College of Obstetricians and Gynecologists (ACOG) recommends against using fluoroquinolones if the local resistance pattern is sensitive to TMP/SMX (ACOG, 2008). From 2000 to 2010, ciprofloxacin resistance increased from 3% to 17.1% (Sanchez, Master, Karlowsky, & Bordon, 2012). The dose is 250 mg bid for 3 days or ciprofloxacin extended release (Cipro XR) 500 mg daily for 3 days. Note that generic ciprofloxacin is similar in cost to TMP/SMZ, but Cipro XR is significantly more expensive ($4 versus $28 for a 3-day supply). Other fluoroquinolones that may be used as second-line therapy include Gatifloxacin 200 to 400 mg daily and levofloxacin 250 mg daily. Moxifloxacin and gemifloxacin are not approved for use with UTIs because they have poor concentration in the urine. Fluoroquinolone resistance has been steadily increasing, with 24.2% of *E. coli* resistant to ciprofloxacin and 24% resistant to levofloxacin (Kashanian et al, 2008). Cross-resistance occurs with the fluoroquinolones. Fluoroquinolones are not prescribed to children or pregnant women because of concern for adverse effects on joints and cartilage in animal studies. The exception is ciprofloxacin, which has U.S. Food and Drug Administration (FDA) approval as second-line therapy in complicated UTI or pyelonephritis in children.

Beta-lactam antibiotics such as amoxicillin or the cephalosporins (cephalexin, cefpodoxime, cefixime) can be prescribed as second-line therapy to patients who are allergic to sulfa drugs or the fluoroquinolones or as first-line treatment for women who are pregnant. Because 25% to 70% of *E. coli* is resistant to amoxicillin, it should not be used as first-line therapy unless patient factors warrant its use.

Any of these treatments generally sterilizes the urine and produces symptom relief in 24 or fewer hours. Patients who are very symptomatic or have severe burning on urination can have phenazopyridine 200 mg 3 times a day added to their treatment regimen for 2 to 3 days as a urinary analgesic.

Complicating factors in which short-course (3-day) therapy is not appropriate (ICSI, 2002) include the following:

- Symptoms longer than 7 days' duration
- Shaking chills (rigors)
- Flank pain: midback, severe, new-occurring with onset of UTI symptoms
- History of diabetes, pregnancy, immunosuppressed status, renal calculi, renal insufficiency, discharge from hospital or nursing home within the past 2 weeks, four or more UTIs in past year, failure of this drug to treat UTI within the past 4 months, or resident of extended-care facility

For patients with complicating factors, longer treatment protocols are needed or referral may be appropriate. Urine culture should be used to guide therapy.

All of the drugs discussed so far may also be used for prophylaxis. The drug of choice for adults for prophylaxis or for recurrent infections (more than three infections in 1 year) is one single-strength tablet of trimethoprim/sulfamethoxazole daily at bedtime for a minimum of 6 months or a self-administered single dose of two double-strength tablets at symptom onset. For children, the recommended dose of trimethoprim/sulfamethoxazole is 2 mg trimethoprim/10 mg sulfamethoxazole per kg as a single bedtime dose (Craig, et al, 2009). The nitrofurantoin adult dose is 50 to 100 mg at bedtime and for children it is 1 to 2 mg/kg/d in a single dose (Gaylord & Starr, 2009).

Patients with risk factors for STIs, a positive dipstick for leukocyte esterase or hemoglobin, and a negative Gram's stain are likely to have a UTI complicated by *Chlamydia trachomatis.* The recommended drug for these patients is doxycycline (Doxy-Caps, Vibramycin) 100 mg bid for 7 days. The alternative drug is azithromycin (Zithromax) 1 g in a single dose. Azithromycin is the preferred drug if the patient's adherence to the 7-day regimen is questionable.

Upper UTIs (e.g., pyelonephritis) involve the same likely organisms because the infections are most often ascended from a bladder infection; *E. coli* is the identified organism in more than 80% of pyelonephritis cases. Failure of a 3-day course of antimicrobials generally indicates an upper UTI.

Uncomplicated pyelonephritis in adults can usually be treated with an oral antibiotic with a 90% success rate (Ramakrishnan & Scheid, 2005). A pyelonephritis is uncomplicated if it is caused by a typical pathogen in an immunocompetent person with a normal urinary tract (Ramakrishnan & Scheid, 2005). The ICSI recommends ciprofloxacin 500 mg twice a day for 7 to 14 days as the first-line drug for nonpregnant adults (2004). Other fluoroquinolones (gatifloxacin 400 mg daily, levofloxacin 250 mg daily, or ofloxacin 400 mg bid) may also be used. The alternative drugs recommended are amoxicillin/clavulanate or an oral cephalosporin with the treatment extending for 14 days. Pregnant patients should be treated with amoxicillin or amoxicillin/clavulanate and followed closely. Patients with acute pyelonephritis who are not acutely ill or in whom oral therapy can be assured (i.e., not vomiting) may benefit from 1 to 2 g ceftriaxone IM at the time of diagnosis and switched to oral therapy on day 2 of treatment. Acutely ill patients require initiating parenteral therapy in an inpatient observation unit or hospital admission for IV fluids and parenteral antibiotics.

Potential Adverse Drug Reactions

A significant number of patients have allergies to sulfonamides and penicillins. Approximately 15% of patients allergic to penicillin are also allergic to the other class of beta-lactam drugs, cephalosporins. Note: Patients with allergies to other substances such as pet dander and pollens are at high risk for drug allergies. Patients allergic to sulfonamides and penicillins can be treated with nitrofurantoin 50 to 100 mg bid.

Amoxicillin and cephalosporins have a negative effect on bowel flora and often result in diarrhea. This adverse reaction is much less common with trimethoprim, and nitrofurantoin

does not affect bowel flora. Patients with bowel disease should be given either of the latter two drugs.

The fluoroquinolones—including ciprofloxacin—that are usually well tolerated have a Black-Box Warning regarding the development of tendonitis and tendon rupture, even after therapy has been completed. The risk is greatest in patients over age 60 years, those on corticosteroid therapy, and patients with previous tendon disorders or who exercise strenuously. Fluoroquinolones may have central nervous system effects, including increased intracranial pressure, dizziness, confusion, tremors, hallucinations, depression, and rarely, suicidal thoughts (Bayer Healthcare Pharmaceuticals, 2009). Patients with a known seizure disorder or a disorder that may predispose them to seizures should not be prescribed fluoroquinolones, because the drugs may lower the seizure threshold. Fluoroquinolones should not be prescribed for pregnant women because of the risk of joint disorders in the fetus and green discoloration of primary teeth developing in newborns. Fluoroquinolones are not the drug of first choice in pediatric patients because of concerns for joint disorders. The only exception is ciprofloxacin, which can be prescribed as second-line therapy in complicated UTIs and pyelonephritis in children ages 1 year to 17 years.

Long-term therapy with nitrofurantoin has been associated with pulmonary fibrosis and peripheral neuropathy. Short-term therapy has not been associated with this problem. If this drug is chosen for prophylaxis, it should be used for no more than 3 months. Nitrofurantoin should not be prescribed to pregnant women at term or during labor because of the risk of hemolytic anemia in the newborn. The drug should also be avoided in lactating women whose infants are less than one month old for the same reason.

Resistance Patterns

Drug resistance to antimicrobial therapy is a major factor in drug selection. In the United States, the resistance of *E. coli* to trimethoprim/sulfamethoxazole is approximately 24% and ciprofloxacin has resistance of 17% (Sanchez et al, 2012). The resistance pattern for nitrofurantoin has remained steady at 1.6% (Sanchez et al, 2012). Resistance to fluoroquinolones among *E. coli* isolates has been increasing; and they should be thoughtfully prescribed.

Resistance patterns vary in other countries. Prais and colleagues (2003) report research data from Israel, the United Kingdom, the Netherlands, and South Africa that show a clear difference in resistance patterns. In all of these countries, however, resistance to trimethoprim/sulfamethoxazole is lower than it is to any other drugs. Nitrofurantoin resistance was less than 10% in all countries studied and only 2% in the United States. Prais and colleagues also found that cephalexin was inadequate to resolve UTI in approximately one-third of cases, but 95% of the organisms were susceptible to cefuroxime axetil and amoxicillin/clavulanate.

Amoxicillin is no longer recommended for empirical therapy in the United States because up to one-third of the UTI organisms are resistant. Providers should be aware of local resistance patterns in their community. Providers can consult with their reference laboratory regarding the antibiogram pattern of resistance. The resistance patterns seen in inpatients may be different from community patterns of resistance.

Cost

Trimethoprim/sulfamethoxazole is the least expensive of the antimicrobials, especially when it can be given for 1 to 3 days. Generic ciprofloxacin is comparable in cost with TMP/SMZ for a 3-day supply, but be aware that brand-name Cipro XR is significantly more expensive than generic ciprofloxacin. Nitrofurantoin is also relatively inexpensive, although the brand-name Macrodantin that has bid dosing is more expensive.

Table 47-3 summarizes antimicrobial recommendations for upper and lower UTIs. Recommendations are included for adults and children. Figure 47-1 depicts the treatment protocol for management of UTIs in adult women.

Table 47–3 ❖ Drugs Commonly Used: Upper and Lower Urinary Tract Infections

Indication	Primary Choices	Alternative Choices
Upper UTIs (Adults)		
Simple, uncomplicated upper UTI Mild to moderately ill	• Ciprofloxacin 500 mg bid for 14 d • Trimethoprim-sulfamethoxazole double-strength 1 tablet bid for 14 d *or* • Ofloxacin 400 mg bid for 14 d • If client status warrants: give 1 to 2 g ceftriaxone IV on day 1, switching to one of the oral medications above on day 2	• Amoxicillin-clavulanate 500 mg bid for 14 d • Cefixime 200 mg bid for 14 d
Lower UTIs		
Simple, uncomplicated lower UTI in adults Symptomatic or asymptomatic and reinfection (single event)	• Trimethoprim-sulfamethoxazole double-strength 1 tablet bid for 3 d *or* • Nitrofurantoin 100 mg bid for 5–7 d • Ciprofloxacin 250 mg bid for 3 d • Ciprofloxacin Extended Release 500 mg daily for 3 d	• Gatifloxacin 200–400 mg daily for 3 d • Levofloxacin 250 mg daily for 3 d

Table 47–3 ❂ **Drugs Commonly Used: Upper and Lower Urinary Tract Infections—cont'd**

Indication	Primary Choices	Alternative Choices
Simple, uncomplicated lower UTI Serial reinfections (more than 3/yr)	• Trimethoprim-sulfamethoxazole double-strength 1 tablet bid for 3 d with onset of symptoms	• Ciprofloxacin 250 mg bid for 3 d with onset of symptoms
Simple, uncomplicated lower UTI associated with intercourse prophylaxis	• Trimethoprim-sulfamethoxazole double-strength 1 tablet single dose after intercourse	• Ciprofloxacin 250 mg single dose after intercourse
Simple, uncomplicated lower UTI recurrence prophylaxis	• Trimethoprim-sulfamethoxazole double-strength 1 tablet daily at bedtime for at least 6 mo	• Nitrofurantoin 50 mg daily at bedtime for no more than 3 mo
Complicated lower UTI or symptomatic after 3 d of therapy	• Trimethoprim-sulfamethoxazole double-strength 1 tablet bid for 7–14 d • Ciprofloxacin 250 mg bid for 7–14 d	• Nitrofurantoin 100 mg bid for 7–14 d • Ofloxacin 200 mg bid for 7–14 d
Special Considerations		
Risk factors for STD	• Doxycycline 100 mg bid for 7 d	• Azithromycin 1 g single dose
Pregnancy	• Nitrofurantoin 100 mg bid for 7 d	• Amoxicillin 500 mg tid for 7 d • Cefixime 200 mg bid for 7 d
Afebrile children: >1 month	• Trimethoprim-sulfamethoxazole 6 to 12 mg/kg/d trimethoprim plus 30 to 60 mg/kg/d sulfamethoxazole given in 2 divided doses for 10 d in infants > 2 months of age	• Nitrofurantoin 5 to 7 mg/kg/d in 3 or 4 divided doses × 10 d • Amoxicillin 40 mg/kg/d in 2 or 3 divided doses × 10 d if no resistance in the community • Augmentin 40 mg/kg/d of amoxicillin component divided TID × 10 d • Cefixime 8 mg/kg/d • Cephalexin 25 to 50 mg/kg/d in 3 or 4 doses • Cefpodoxime 10 mg/kg/d in 2 divided doses

Febrile UTI in children >1 month of age	• Parenteral antibiotics for first 24 h or until afebrile
	  • Ceftriaxone 50 to 75 mg/kg every 12 to 24 h
	  • Cefotaxime 150 mg/kg/d divided every 6 to 8 h
	  • Ceftazidime 150 mg/kg/d divided every 6–8 h
	• Oral antibiotics are started once the child is afebrile and continued for 10 to 14 d, followed by prophylaxis until radiological workup is complete
	• Oral antibiotic choices are the same as for afebrile UTI	

Estrogen deficiency/postmenopausal female	• Vaginal estrogen cream 0.5–2 g intravaginally daily	
Advanced age	• No treatment if asymptomatic	

Patient Variables

Age

Infants and Children

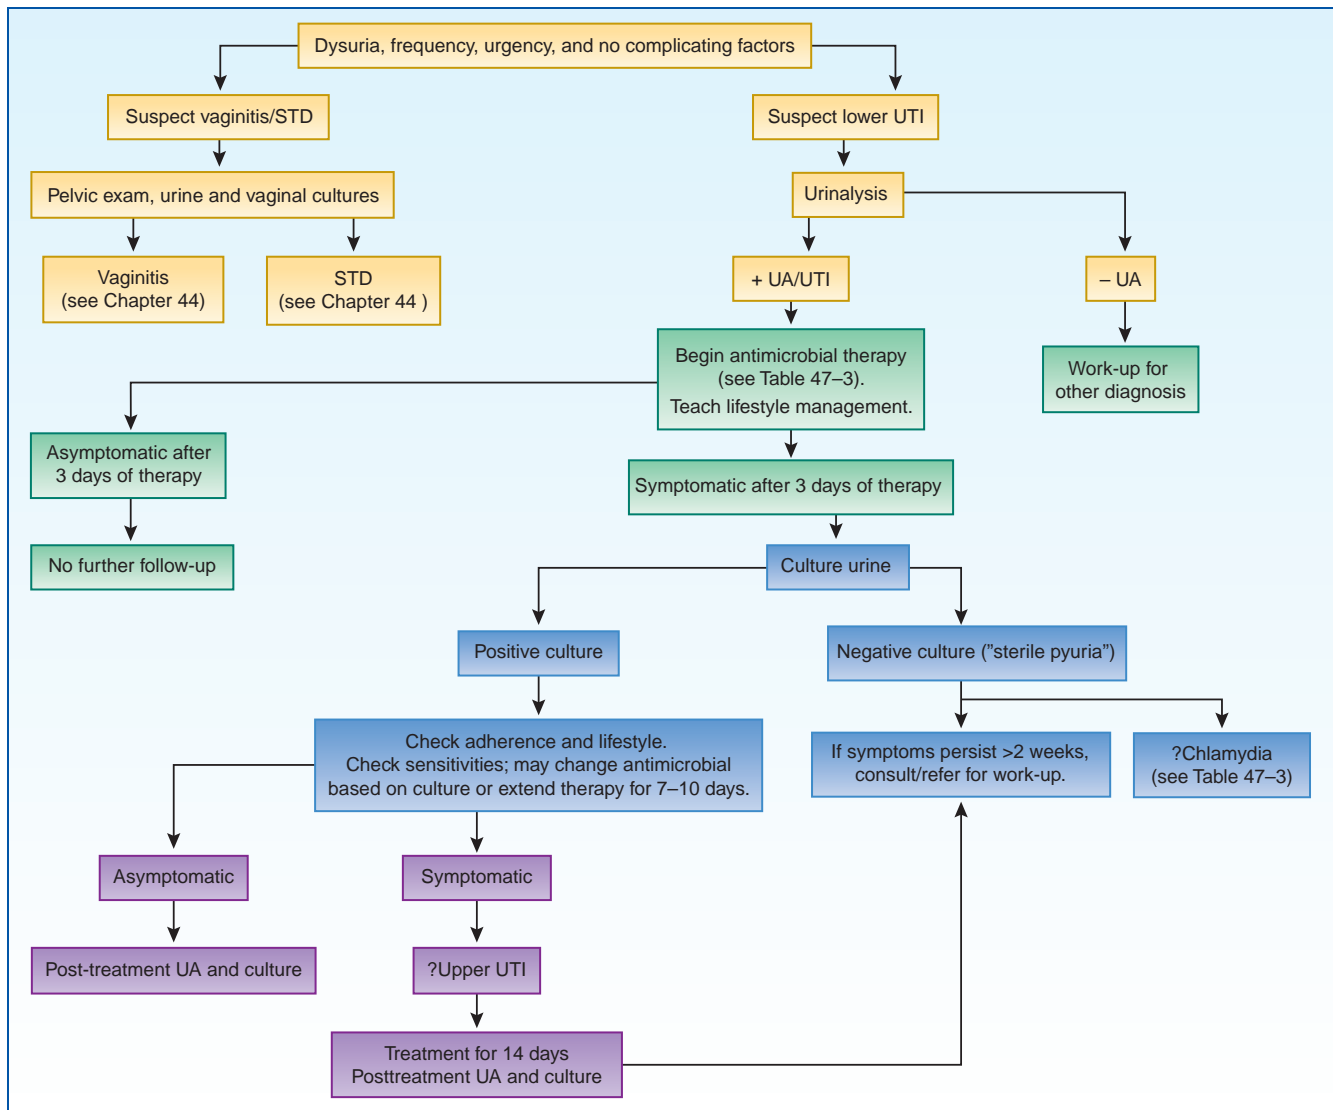
Signs and symptoms of UTI in infants and very young children are different from those in adults. The likelihood of UTI, especially with fever, increases in these circumstances: a history of crying on urination, foul-smelling urine, altered urination pattern, irritability, vomiting, diarrhea, and failure to thrive. All infants with fever of unknown origin should have a catheterized urine specimen obtained to rule out a UTI. The most accurate diagnosis of a UTI in a non–toilet-trained child is made with a catheterized urine sample. Bagged urine samples should not be used to diagnose a UTI (American Academy of Pediatrics [AAP], 2011). The common UTI symptoms of dysuria, urgency, frequency, and hesitancy may be present in preschool-age children, but are difficult to discern in this age group. The older the child is, the more likely


Figure 47–1. Treatment protocol: Urinary tract infections in women.

he or she is to have the "classic" UTI symptoms of dysuria and frequency.

Febrile UTI is treated aggressively in infants and children because fever is often an indication of pyelonephritis (Gaylord & Starr, 2009). Infants and children with febrile UTI should receive parenteral antibiotics for the first 24 hours or until afebrile. Ceftriaxone 50 to 75 mg/kg divided every 12 to 24 hours IV/IM is often used in children older than 3 months because of the convenience of 24-hour dosing. Other appropriate parenteral antibiotic choices are cefotaxime, ceftazidime, ampicillin, or gentamicin (see Table 47-3 for dosing).

All infants and children with febrile UTI are evaluated daily until afebrile. Complicated febrile UTI in children warrants inpatient treatment with IV antibiotics. Symptoms warranting inpatient treatment include high fever, toxic appearance, persistent vomiting, moderate to severe dehydration, and poor compliance (Gaylord & Starr, 2009). In addition, any patient younger than age 6 months who appears toxic should receive initial inpatient treatment for febrile UTI.

The goals for treatment of UTI in infants and children are the same as those for adults, with the exception that a search should be made for anatomical abnormalities of the bladder and kidneys. The AAP (2011) recently changed its guidelines for initial febrile UTI in children aged 2 to 24 months and now recommends a renal ultrasound (RUS) for the first infection and voiding cystourethrography (VCUG) after the *second* febrile UTI, provided the RUS is normal. The AAP recommends a RUS within the first two days of treatment. The rationale is that risk of renal scarring is low after one febrile UTI and the recommendation is meant to prevent unnecessary testing (AAP, 2011).

The new recommendation prompted a response from the section on Urology (Wan et al, 2012) expressing concerns about waiting until the second febrile UTI before obtaining VCUG. It remains to be seen if the AAP guidelines will be revised; however, the guidelines are only for children ages 2 to 24 months and are never a substitute for clinical judgment. In addition, the risk of renal damage increases as the number

of recurrences of UTI increases. Children with documented or suspected vesicoureteral reflux, renal scarring, or structural abnormalities of the urinary tract should be referred to a pediatric urologist. Children with an identified renal or bladder stone should also be referred to a pediatric urologist. Children should be on prophylactic antibiotics until the urological evaluation is complete.

Adolescents with pyelonephritis or a second UTI with documented positive urine cultures and no history of recent sexual activity require at least consultation (Gaylord & Starr, 2009). Older children (older than age 5) can be treated with the same drugs as adults, whether they are asymptomatic or symptomatic, but the extent of treatment may need to be 7 to 14 days. In a meta-analysis of published randomized controlled trials in children 0 to 18 years of age comparing long-course (7 to 14 days) with short-course (3 days or less) antibiotic treatment of UTI, long-course therapy was associated with fewer treatment failures with concomitant increase in reinfections, even when studies including subjects with evidence of pyelonephritis were excluded from the analysis. Based on this analysis, Keren and Chan (2002) recommend that clinicians continue to treat children with UTI for 7 to 14 days until more accurate methods of distinguishing upper from lower UTIs in children are available.

Consideration should be given to the effect of the agent chosen on bowel flora, which is highly correlated with diarrhea. Younger children are more likely to experience fluid volume deficits secondary to diarrhea. Among the available drugs, nitrofurantoin has the least effect on bowel flora and amoxicillin has the most effect. The effect of trimethoprim/sulfamethoxazole is only slightly more than that of nitrofurantoin. Figure 47-2 shows the treatment protocol for management of UTIs in children.

Older Adults

Elderly patients are at increased risk for UTIs and asymptomatic bacteriuria. In 1999, UTI was reported as the admitting or current diagnosis in 7.1% of female and 5.6% of male nursing home residents (Griebling, 2007b). Asymptomatic bacteriuria may be present in more than 20% of women over age 80 years and 6% to 15% of men over age 75 years living independently in the community (Fekete & Hooton, 2014). Asymptomatic bacteriuria is defined by the Infectious Diseases Society of America (IDSA) guidelines as two consecutive clean-catch voided urine specimens in women and one clean catch in men with isolation of a single organism in quantitative counts of greater than 10 ^{5} cfu/mL (Fekete & Hooton, 2014).

Asymptomatic bacteriuria is commonly associated with urinary incontinence, multiple medical illnesses, and impairment of mental status. Treatment with antimicrobial therapy is frequently unsuccessful in eradicating the infection and may be associated with the development of more resistant bacteria. Choice of antimicrobial should be based on culture and sensitivity tests rather than done empirically. No treatment is indicated in asymptomatic adults of advanced age unless in conjunction with surgery to correct obstructive

uropathy or after removal of an indwelling catheter (Fekete & Hooton, 2014; Nicolle et al, 2005). Changes in mental status, however, may indicate a symptomatic UTI that requires treatment.

Male Gender

Signs and symptoms of UTI are similar in males and females. Urethral discharge in men is more commonly associated with STDs than with a UTI. In children and young men, UTIs are more commonly associated with congenital obstructive disorders. The risk of infection with *E. coli* is increased in homosexual men and heterosexual men with a colonized partner. The rate of UTIs increases in men aged 50 to 65 and parallels the increase in hyperplasia of the prostate gland. Glandular enlargement leads to bladder outflow obstruction and increased residual urine. Older adult men (older than 65) have further prostate enlargement and increased urine residuals. Despite the high prevalence of UTIs in this age group, most remain asymptomatic and seem to be at low risk for serious complications. However, gram-negative sepsis from a UTI can occur and can be life-threatening.

Culture and sensitivity studies should be done in men with a history of UTI. In men, the organisms responsible for infection are slightly different. *E. coli* accounts for only about 25% of their infections. Gram-negative rods such as *Proteus* and *Pseudomonas* account for 50%, and enterococci and coagulase-negative staphylococci are responsible for the remaining 25%. Treatment should be based on culture results, and the treatment period should be for 10 to 14 days, with a follow-up culture drawn. Treatment for men of advanced age is similar to that for women of the same age. Figure 47-3 presents the treatment protocol for males with UTIs.

Pregnancy

Asymptomatic bacteriuria is relatively common, affecting 2% to 7% of pregnancies (Hooton & Gupta, 2014b). It should be treated because eradication of bacteriuria reduces the high incidence of symptomatic UTI that commonly occurs later; treatment may reduce the risk for preterm birth. All pregnant women should be screened for bacteriuria by urine culture at least once early in pregnancy, and they should be treated if the results are positive (Hooton & Gupta, 2014b; Nicolle, et al, 2005). Periodic screening for recurrent bacteriuria should be done following completion of therapy to ensure clearance of the infection and to monitor for any recurrence. Women who are culture negative at early screening do not require additional screening later in pregnancy. Symptoms of UTI should always result in urine testing and treatment if needed throughout pregnancy.

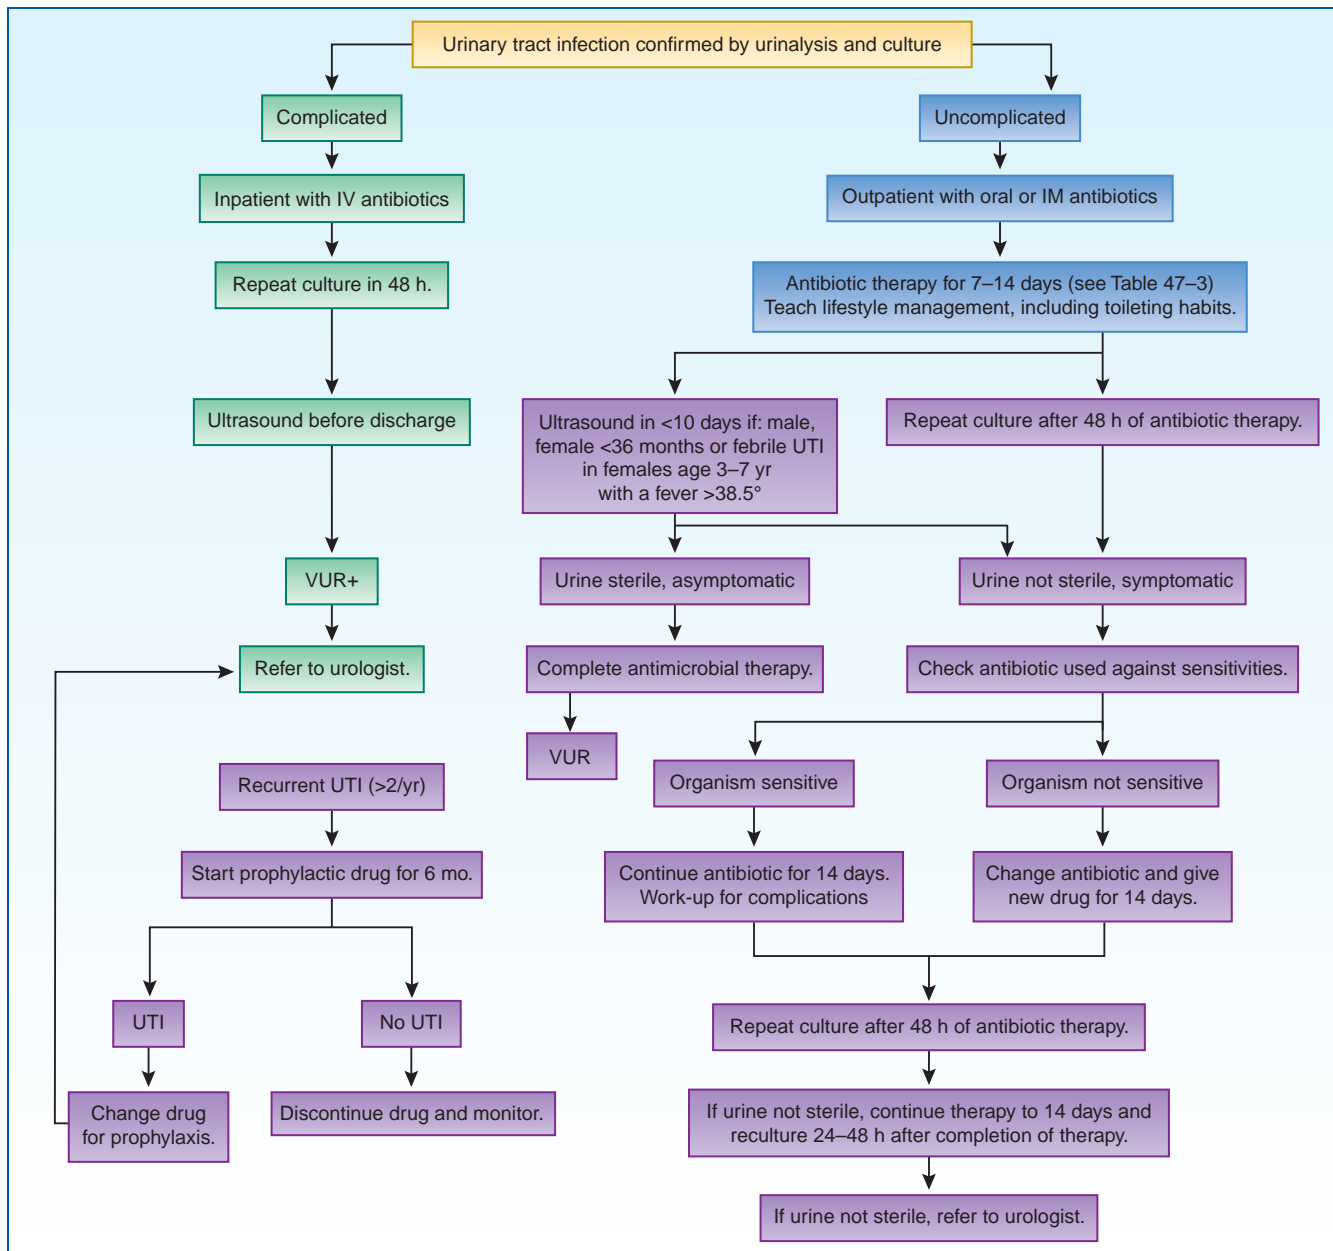
Nitrofurantoin 100 mg bid for 5 to 7 days, amoxicillin/clavulanate 500 mg bid for 3 to 5 days, and cephalosporins (cephalexin 500 mg every 12 hours for 3 to 7 days) are all acceptable during pregnancy (Hooton & Gupta, 2014b). Patients should have a repeat urine culture 1 week after completion of therapy to test for cure and then monthly until delivery.


Figure 47–2. Treatment protocol: Urinary tract infections in children.

Underlying Cause

If the UTI should develop in relation to intercourse, trimethoprim/sulfamethoxazole (double-strength, one tablet after coitus) may prevent the UTI. It is effective and inexpensive. A single dose of a fluoroquinolone (see earlier comments) is a second-line choice. It is also effective but more expensive. Patients should also void within 10 minutes after intercourse.

In postmenopausal women, UTIs associated with estrogen deficiency can be reduced by daily application of vaginal estrogen cream 0.5 to 2 g intravaginally.

MONITORING

For lower UTIs in women, a standard UA is cost-effective in diagnosing the disorder. Symptom resolution within 48 hours is considered sufficient monitoring of outcome. If symptoms persist, a urine culture is obtained and any necessary changes in antimicrobial therapy are instituted. For these patients, a follow-up office visit in 10 to 14 days should be scheduled.

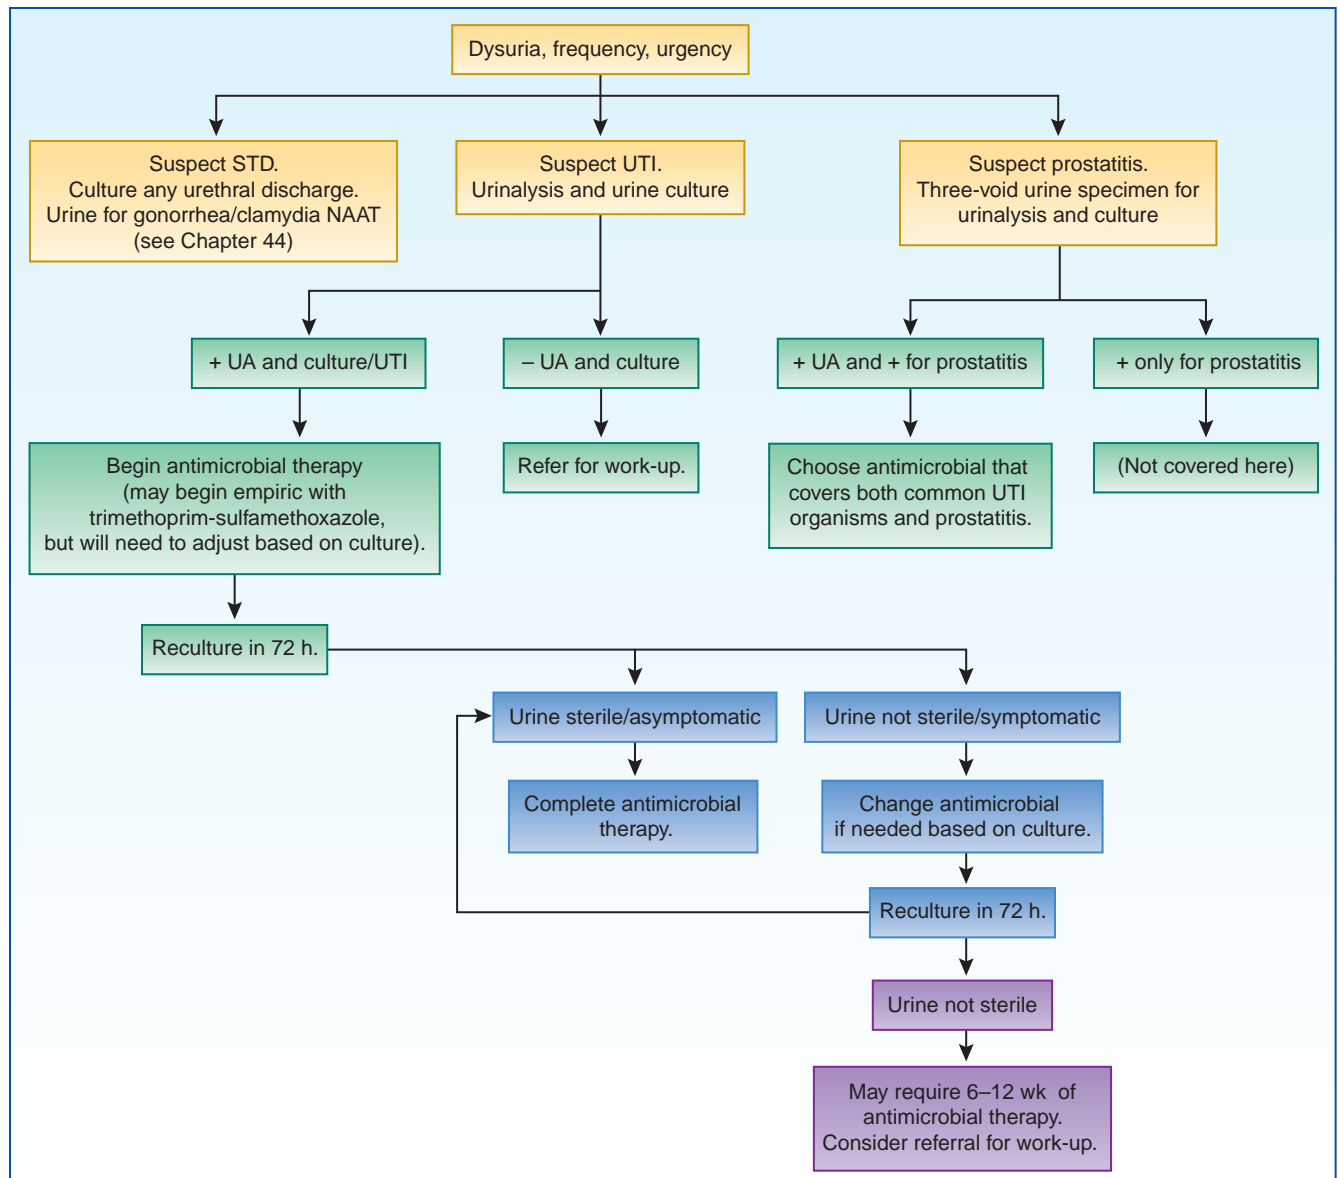
For patients with recurrent infections, obtaining and documenting one urine culture is worthwhile, although it is generally unnecessary for women with acute UTI. If the culture is negative despite a positive UA, investigation is needed for organisms that do not grow on standard laboratory media, such as those that cause gonorrhea, chlamydia, and renal tuberculosis. One post-treatment UA is useful to rule out persistent infection or hematuria. Routine UA to test for a cure is generally unnecessary in healthy adult women because all the main antimicrobials used to treat UTIs have 91% and


Figure 47–3. Treatment protocol: Urinary tract infections in men.

higher cure rates. Follow-up cultures are appropriate in children, pregnant, and elderly patients. If persistent as opposed to recurrent UTI is suspected, a follow-up UA may be helpful in making this diagnosis.

All children age 5 years and younger need radiological evaluation and appropriate referral to a pediatric urologist. Older children with a simple, uncomplicated UTI require urine culture for diagnosis of the offending organism and a culture after completion of therapy. Failure to produce sterile urine after 14 days of therapy suggests referral.

Pregnant patients with a positive urine culture should have a follow-up urine culture every 2 weeks until delivery and at their postpartum evaluation to validate sterile urine. Reinfections require prophylactic antimicrobial therapy. For upper UTIs, an initial telephone assessment of the patient's symptoms and response to therapy is important within 24 hours. A second assessment with an office visit should occur in 2 to 3 days. If

symptoms do not resolve or if they worsen, hospitalization may be required. A urine culture should be done 1 to 2 weeks after therapy in pregnant patients, children, patients who remain symptomatic, and those for whom suppression therapy is being considered. Follow-up cultures are optional for all other patients.

OUTCOME EVALUATION

Neonates, infants, and children under age 5 years who present with clinical and laboratory evidence of UTIs should be referred to a pediatric urologist. The cause is likely to be an anatomical obstructive problem, especially in boys. Although adults do not often have long-term complications from UTIs, 10% of children with reflux nephropathy go on to develop hypertension with bilateral scarring of the kidney within 10 years. Risk for development of end-stage renal disease after UTI is rare in adults but is 1:500 for children who later

---

URINARY TRACT INFECTIONS

PATIENT EDUCATION

Related to the Overall Treatment Plan or Disease Process

☐ Understanding the causes of UTIs and their prognoses.

☐ Role of lifestyle modifications in preventing UTIs, especially ingestion of cranberry juice or cranberry extract; avoidance of diaphragms and spermicides, especially those containing nonoxynol-9; voiding 10 to 15 minutes after sexual intercourse to wash out the bacteria from the urethra that may have entered the bladder during intercourse; maintaining fluid intake of at least 2,000 mL/d of noncaffeinated fluids; and not resisting the urge to void.

☐ Importance of adherence to the treatment regimen.

☐ Indications of relapse or complications that need to be reported.

☐ Need for a follow-up visit only if patient remains symptomatic.

Specific to the Drug Therapy

☐ Discussion of the reasons for taking the drug(s) and the anticipated action of the drug(s) on the disease process. The patient should be asymptomatic within 48 hours for simple, uncomplicated lower UTIs and within 7 days for upper UTIs. Urinary analgesics should relieve symptoms within 24 hours.

☐ Doses and schedules for taking the drug and the length of time the drug will need to be taken. Possible adverse reactions and what to do when they occur. For patients given phenazopyridine, warn them that the drug turns the urine bright orange and that this is not an indication of hematuria.

☐ Additional patient education specific to antimicrobials is provided in Chapter 24.

---

develop hypertension. Recurrent UTI in girls leads to increased risk for new infection in pregnancy.

Certain criteria in adults also suggest the need for an aggressive workup that requires referral to a urologist. Gross hematuria; persistent microscopic hematuria between episodes of infection; symptoms of obstruction; a clinical impression of persistent rather than recurrent UTI, or infection with urea-splitting bacteria, such as *Proteus mirabilis,* which are associated with staghorn calculi; and any symptomatic pregnant patients and patients who have a high fever or appear dehydrated or septic suggest referral. These patients may require hospitalization for IV therapy.

If patients remain symptomatic after 3 days of therapy for a simple, uncomplicated lower UTI or after completion of 10 to 14 days of therapy for an upper UTI, a culture should be done to determine the causative organism and a different antimicrobial may be needed.

PATIENT EDUCATION

Patient education should include a discussion of information related to the overall treatment plan as well as that specific to the drug therapy, reasons for taking the drug, drugs as part of the total treatment regimen, and adherence issues. Lifestyle changes to prevent UTIs should be addressed, especially with patients who have recurrent UTIs.

Lifestyle Management

Prevention is the key to management of UTIs. Although lifestyle management may not always prevent UTIs, studies confirm several practices that may help to prevent UTIs, especially in women. The following lifestyle modifications and behavioral strategies have research support for their role in prevention:

1. Avoiding spermicide and diaphragms. Use of these products may cause a change in vaginal pH and flora that increases the potential for vaginal colonization with organisms likely to produce UTIs. Nonoxynol-9 spermicides are especially associated with increased incidence of bacteriuria. The essential first step to UTIs in women is frequently thought to be the colonization of the vaginal introitus.

2. Voiding 10 to 15 minutes after sexual intercourse. Urination washes out the bacteria from the urethra that may have entered the bladder during intercourse.

Additional measures that have inconsistent support but would not be harmful and are likely to be helpful include the following:

1. Ingesting cranberry juice or cranberry extract. Cranberry substrates exert a bacteriostatic effect. Most studies have been done in elderly women, but the same mechanism may prove effective in younger women and in men. There is no evidence for the effectiveness of cranberry in preventing UTIs in children.

2. Maintaining fluid intake of at least 2,000 mL/d of non-caffeinated fluids. Sufficient fluid is necessary to ensure regular voiding throughout the day. Caffeinated fluids have a mild diuretic effect but are less likely to maintain fluid volume balance.

3. Not resisting the urge to void. "Holding" urine may stretch the bladder and cause small breaks in the bladder

mucosal layer that provide entrance for bacteria. Holding also increases the risk for growth of bacteria in residual urine.

4. Avoiding douche products that change the vaginal pH and flora. This practice may decrease the likelihood of vaginal canal colonization.

SPECIAL DRUG TREATMENT CONSIDERATIONS

WOMEN AS PATIENTS

Priscilla M. Nodine

Differences in patterns of health and illness between females and males have been well documented. Women tend to pay more attention to changes in health patterns, seeking health care earlier and more often than men. Even when diagnosed with similar medical conditions (such as cardiac disease or Alzheimer's disease), adult women have very different needs for care than do their male counterparts. Adherence to a prescribed medication regimen may be affected by gender, especially if the adverse effects have a particular impact on females (e.g., hirsutism or risk of thromboembolic disorders). This chapter will discuss treatment of common conditions experienced by women as a special population.

To review growth and development briefly, both sexes progress similarly until puberty, when increases in estrogen and progesterone prepare women for fertility and reproduction. Menopause signals the cessation of reproductive capability for females. During puberty, males respond to the influence of increased androgens, triggering a cascade of changes such as increased height, weight, and muscle mass and the genital changes that accompany the ability to reproduce. Whereas females are born with all of their gamete cells already present, sperm production in males begins at puberty and continues throughout their adult lives until levels of testosterone start to wane, usually in their sixth or seventh decade.

Prescribing for women in their childbearing years requires constant awareness of the possibility of pregnancy in order to avoid exposing the developing fetus to potential teratogens. Sexually active women who use birth control also become pregnant. In the United States, 48% of pregnancies are unintended (Finer & Zolna, 2011). Sexual activity (especially if begun early) can lead to lifelong viral infections or silent bacterial infections that scar delicate fallopian tubes and change cervical tissues, contributing to infertility. Early sexual activity in adolescents exposes them to risks of both infection and pregnancy, at a time when their bodies are still growing and their personalities are not yet mature.

Teenage pregnancy is associated with inconsistent prenatal care, smaller infants, and preterm labor. These infants are

at high risk for developmental disorders and other medical conditions associated with low birth weight. Neglect and abuse account for 2 deaths per 1,000 healthy infants born to adolescents 15 years or younger, and the risk from sudden infant death syndrome (SIDS) increases (Moos, 2005).

Breastfeeding is another time when prescribing for women requires special care and knowledge. For information on pharmacokinetics about breastfeeding to assist the practitioner in making safe decisions about prescribing, see Chapter 50.

Cultural attitudes, behaviors, and beliefs related to health can affect how a woman responds to and complies with health advice. Caring for women from different cultures requires knowledge of the treatments they will accept, of their personal values and beliefs, and of the customs of their identified cultural group. With the assistance of an interpreter, health-care providers should provide written and verbal instruction to women with language barriers (Davidson, London, Ladewig, & Davidson, 2011). Translation alone may not be an issue. The patients may not understand explanations if they lack basic education in their own country. Cultural influences are discussed in detail in Chapter 7.

During the 1980s, abuse of children and women was recognized as a significant public health problem. Although boys have also been abused, most abuse has been against girls and women. "Domestic violence against women is a major public health concern. Abuse often increases in frequency and severity over time and leads to significant social, psychological, and medical consequences" (Bohn, Tebben, & Campbell, 2004). Intimate partner violence (IPV), which can vary in frequency and severity, is a type of violence that occurs among heterosexual and same-sex couples. IPV is also a serious public health problem (Centers for Disease Control and Prevention, 2013b). Statistics about IPV vary because of differences in the way different data sources define IPV and collect data. In addition, most IPV incidents are not reported to the police; thus, available data underestimate the true extent of the problem (Centers for Disease Control and Prevention, 2013b).

Women are at high risk for violence during pregnancy, a complication that can lead to many other problems: miscarriage, placental abruption, low-birth-weight infants, premature labor or birth, substance abuse, late entry to prenatal care, intrauterine fetal death, and sexually transmitted and urinary tract infections (Bohn e t al, 2004; Schoening, Greenwood, McNichols, Heermann, & Agrawal, 2004).

The American Nurses Association (ANA), the Association of Women's Health, Obstetrics and Neonatal Nurses (AWHONN), the American College of Obstetricians and Gynecologists (ACOG), and the American Medical Association (AMA) recommend that practitioners screen all patients for IPV at every encounter with the health-care system, regardless of the reason for which health care is being sought. Routinely asking all women about physical and emotional abuse increases a practitioner's opportunity to uncover the underlying causes of women's physical symptoms or depression, conditions that may be related to some form of abuse

(Schoening et al, 2004). Women are 4 times more likely to report abuse if they are simply asked.

In most of the world, the majority of the older population is comprised of women. This demographic phenomenon has been called the feminization of later life (Ginn, Street, & Arber, 2001). Women's life expectancy in developed countries is an average of 7 years longer than that of men, with the gender gap narrowing to 3 years in developing countries (mostly due to high maternal mortality rates) (United Nations, 2012). The feminization of later life carries consequences that include a high incidence of widowhood, living alone, disability, and poverty. Women are more likely to live alone than are their male counterparts, who frequently marry again. In addition, an increase in chronic illness also accompanies women's longer life spans, including cardiovascular disorders, strokes, diabetes, arthritis, and Alzheimer's disease. Management of chronic illnesses in the face of economic concerns in this vulnerable population presents significant challenge for health-care providers.

In the United States, women are the most impoverished subgroup of society. At both ends of the demographic spectrum, single mothers with children and elderly women are the poorest of the poor (U.S. Department of Health and Human Services, 2005). Lack of health insurance coverage leads many women not to fill prescriptions or to take medications on an altered schedule. Prescribers must adequately assess a patient's financial status and be aware of the possibility that a woman's noncompliance may be primarily economically driven.

Practitioners often neglect the complex needs of older women, maintaining a symptom-specific focus. By age 65, half of all women have two or more chronic conditions (Agency of Healthcare Research and Quality, 2002). The need for polypharmacy that often results from multiple co-morbidities necessitates a more holistic approach to these patients' care.

Although defining disability can be a daunting task because of a multitude of components, practitioners need to be aware that about 27 million women in the United States have disabilities, about 1 in 5. Rates are higher in older women, with 50% of women older than 65 living with a disability, most commonly caused by arthritis or rheumatism (National Institute of Health, 2009). Because of their longer life expectancy, women are more likely than men to be disabled, with the most prevalence among women over age 85.

Disability refers to a chronic physical or mental health problem or an impairment that restricts an individual's ability to perform one or more activities (Davidson et al, 2011). Various categories of disabilities include developmental (present before the age of 22), neurological, psychiatric, and sensory. Autoimmune diseases are categorized as neurological disabilities, as is Alzheimer's disease (AD). Psychiatric disabilities include depression, anxiety, panic disorders, and phobias. Women have 50% higher rates than do men of all of these disabling conditions.

As women age, changes in cognitive functioning—learning, memory, concentration, and planning ability—often occur. Clinically apparent cognitive decline is called dementia (Davidson et al, 2011). In the United States, Alzheimer's disease (AD) is the most commonly occurring form of dementia (Plassman et al, 2011). About twice as many women suffer from Alzheimer's disease as men. This sex difference is due in large part to the fact that life expectancy is longer for women, but also women may survive longer than men after initial diagnosis (Plassman et al, 2011).

Acetylcholinesterase inhibitors are the only medications approved by the U.S. Food and Drug Administration (FDA) to treat cognitive dysfunction. Evidence has been conflicting about the effect of estrogen or hormone replacement therapy (HRT) in either prevention or the delay of AD onset in women. Studies have found impaired cognition in older women taking both estrogen and progesterone (Shumaker et al, 2003).

In 2010, the National Institutes of Health (NIH) published a six-goal agenda on women's health that included Goal 2: "Incorporate findings of sex/gender differences in the design and applications of new technologies, medical devices, and therapeutic drugs" (Wood, Blehar, & Mauery, 2011). Research continues to include more women as subjects, but work needs to persist in this area.

In this chapter, the biological and molecular basis for sex-related differences in pharmacokinetics, pharmacodynamics, drug effects, and safety will be discussed based on the current science.

PHARMACOKINETICS AND PHARMACODYNAMICS IN WOMEN

Pharmacokinetics

Gender differences occur in all phases of pharmacokinetics between men and women. Table 48-1 presents some gender differences in pharmacokinetic properties. Women have longer gastric emptying times, which influence the absorption and bioavailability of some drugs. The volume of distribution (Vd) of drugs is dramatically altered by body composition. The higher percentage of body fat means a larger Vd for lipophilic agents (Gandhi, Aweeka, Greenblatt, & Blaschke, 2004; *Women and trials*, 2005). The fat-soluble drug diazepam (Valium) has been observed to have a significantly larger Vd in women, and the water-soluble drug metronidazole (Flagyl) demonstrates a lower Vd, although increased clearance in women accounts for a lower area under the curve (AUC) for this drug in females. Water-soluble fluoroquinolones also have a smaller Vd in women. Both the oral clearance and Vd of prednisolone are significantly lower in women (Gandhi et al, 2004). Tricyclic antidepressants take longer to reach a steady state in women because of the drugs' lipophilic distribution. As a result, women experience more adverse reactions after the drug saturates all the sites in adipose tissues and more active drug remains in the bloodstream.

Gastric levels of alcohol dehydrogenase are lower in women, so a greater fraction of ingested alcohol would be oxidized

Table 48–1 Gender Differences in Pharmacokinetic Parameters

Pharmacokinetic Parameter	Sex-Based Difference
Absorption and bioavailability	• Gastric emptying time is slower in females, mainly related to the effects of estrogen. Drugs absorbed in the stomach will have longer exposure to absorption sites. • Gastric levels of alcohol dehydrogenase are lower in females. Plasma concentrations are greater in females than males after ingestion of similar amounts of alcohol. • Gastric acid secretion, pH, osmolality, electrolyte concentrations, and levels of bile acids and proteins do not vary significantly between sexes.
Distribution	• Females have lower body weights and BMI than males. • Females have a higher proportion of body fat. Lipophilic drugs are more readily absorbed and have relatively greater volumes of distribution than hydrophilic drugs. • Plasma volume is lower in females. Drugs with high volumes of distribution will be more concentrated in the plasma of females. • Organ blood flow is lower in females. • Estrogen is distributed attached to a serum-binding globulin. Exogenous estrogens increase levels of many serum-binding globulins such as corticosteroid-binding globulin and thyroxine-binding globulin resulting in less free drug.
Metabolism	• Studies have been inconsistent in showing differences in CYP450 substrates; the general trend is toward high rates of metabolism for CYP450 3A4 substrates and lower rates for 1A2 and 2D6 substrates. • Females have lower levels of p-glycoprotein and higher rates of drug clearance for drugs that are substrates of p-glycoprotein.
Excretion	• Gender differences in rates of renal excretion of most drugs are probably more related to simple weight differences. • Drugs that are actively secreted by the kidney may show gender differences, but further study is required to demonstrate this difference.

BMI = body mass index.

in men prior to absorption than in women. This is a significant factor behind why blood alcohol levels are disproportionately higher in women after ingestion of similar amounts of alcohol.

Gender-based differences in drug metabolism play a larger role in inter-gender pharmacokinetic differences than any of the other parameters. While hepatic blood flow is lower in women, differences in hepatic enzymes seem to be the major factor in variability. The frequency of variant alleles for the CYP450 system (a major group of enzymes involved in drug metabolism and bioactivation) has been shown to exist both between races and sexes. Studies have shown that CYP 3A4 activity is 24% higher in women (Gandhi et al, 2004) and CYP 1A2 is lower (Davis, 1998). It is acknowledged that some studies demonstrated that the mean amounts of these isoenzymes did not differ (Gandhi et al, 2004), but specific drugs have shown differences. For example, erythromycin is more rapidly cleared in women than it is in men, which is thought to be related to its CYP450 3A4–mediated effect. Orally administered verapamil (Isoptin, Calan) clears more quickly in men than it does in women based in part on its CYP 3A4 metabolism. Higher absolute bioavailability of this drug in women may explain the greater pharmacodynamic effects on blood pressure and heart rate in women. The CYP 2D6 isoenzyme is important in the metabolism of many psychotropic drugs. One study showed that tardive dyskinesia develops more frequently in female Chinese schizophrenics secondary to increased frequency of a defective CYP 2D6 allele in Chinese women (Gandhi et al, 2004).

Propranolol (Inderal) was one of the earliest drugs to show a clear gender difference in metabolic clearance of a drug. Oral doses of this drug had a significantly higher (63%) rate of clearance in men than it did in women (*Women and trials*, 2005). IV doses demonstrated no differences, indicating that this was a hepatic first-pass metabolism issue. Women might be expected, therefore, to show a significantly greater clinical response to oral doses of this drug than men.

The difference in clearance rates among the benzodiazepines can be explained in part by CP450 (oxidative) versus conjugative activity for drug metabolism. Those that undergo oxidative metabolism (alprazolam, diazepam, and midazolam), which is higher in women, are more rapidly metabolized than those that undergo conjugation (chlordiazepoxide, temazepam, and oxazepam), which is lower in women. The gender-related difference in CYP 2D6 activity and p-glycoprotein expression may be an important reason for different responses to antidepressants such as serotonin reuptake inhibitors (*Women and trials*, 2005). Finally, oral contraceptives have been demonstrated to significantly inhibit CYP 2C19 activity, which accounts for many drug interactions with other drugs using this substrate.

Studies aimed at showing differences in drug metabolism based on menopausal status have been inconsistent. Conflicting data exist on whether menopausal status or estrogen and progesterone level in HRT significantly affects drug metabolism and, therefore, no recommendations can be made at this time.

Kleist (2005) reminds us that many of these effects have been subtle and their overall clinical relevance remains to be demonstrated. With the exception of propranolol and verapamil, in which differences in outcome have been clearly significant, and erythromycin, which appears to be more effective in women, the provider should use these data to alter individual drug regimens cautiously.

Excretion of drugs by the kidney depends on weight, body surface area, age, and gender. Renal clearance of drugs that are not actively secreted or reabsorbed is dependent on the glomerular filtration rate, which is directly proportional to weight and consequently higher (on average) in men. Gender differences in excretion, therefore, are thought to be largely related to weight differences. Drugs that are actively secreted by the kidney may show gender-based differences, but further study in humans is necessary to clearly demonstrate this difference (Gandhi et al, 2004).

Pharmacodynamics

Pharmacodynamic differences in drug response based on gender have not been studied to the same extent as pharmacokinetic differences. Pharmacodynamic differences are demonstrated only when the same plasma concentration of a drug in both males and females yields a different pharmacological outcome. The clinical relevance of gender-related differences in pharmacodynamics appears with greater risk for adverse drug responses (1.5% to 1.7% higher) in women (Rademaker, 2001). However, not all drugs that have pharmacokinetic differences have pharmacodynamic differences.

The pharmacokinetic differences seen in prednisolone correlate with increased cortisol and T-helper lymphocyte suppression in women. This difference may be mediated by endogenous estrogen, because increased sensitivity has been found at higher estradiol concentrations, which may translate into clinical differences in postmenopausal women. The pharmacokinetic differences seen in verapamil lead to pharmacological effects of greater reductions in blood pressure and heart rate in women.

Gender differences in response to various analgesics have been well studied. Opiates seem to have a greater analgesic effect in women (Gandhi et al, 2004; *Women and trials*, 2005), but this difference is accompanied by an increase in adverse effects, especially nausea and vomiting. These differences in pharmacological response appear to be due to pharmacodynamic differences, including gender differences in drug-receptor affinity, receptor density, or signal transduction pathways (Gandhi et al, 2004). The effects of several cardiovascular drugs on women are different from their effects on men. Women aged 15 to 50 years have longer QT intervals, making them more vulnerable to cardiac arrhythmias. Macrolide antibiotics cause a woman's heart to repolarize more slowly. Pharmacokinetic differences in females may explain the increased incidence of life-threatening ventricular arrhythmias, which are twice as common in women who are taking erythromycin (*Women and trials,* 2005). Women taking oral anticoagulants (warfarin) or thrombolytic agents

(e.g., after myocardial infarction [MI]) have less benefit with respect to mortality but more bleeding episodes (Gandhi et al, 2004; *Women and trials,* 2005). Aspirin is often prescribed for MI and stroke prevention. Randomized trials have shown that although aspirin lowers the risk for ischemic stroke in women, it has little effect on their risk for MI; the opposite is true in men (*Women and trials,* 2005). The exact mechanism for this gender-related difference in outcome has yet to be elucidated.

Many psychotropic drugs appear to exhibit gender-mediated differences in pharmacodynamics. In general, women show both greater improvement in symptoms and more severe adverse reactions with antipsychotics (Gandhi et al, 2004). These effects appear to be related to the anti-dopaminergic actions of estrogens, duplicating the major mechanism of action of typical antipsychotics. These findings have resulted in a trend toward prescribing lower doses for women. Tricyclic antidepressants exhibit both pharmacokinetic and pharmacodynamic differences between genders. Studies have shown that premenopausal women respond better to selective serotonin reuptake inhibitors (SSRIs), and men respond better to tricyclic antidepressants (Anderson, 2005; Davis, 1998). Another example is lithium and its increased bioavailability because of renal excretion. This pharmacokinetic difference can result in levels of this drug that are higher in women. The narrow therapeutic range for this drug means the risk for toxicity is increased in women, though no studies have confirmed this (Grandjean & Aubry, 2009). Drug levels drawn early in therapy may prevent toxicity in drugs, such as lithium, digoxin, and theophylline, which have narrow margins of safety.

Infection with HIV and the development of AIDS are increasing in females, as is the use of antiretroviral drugs. Multiple studies have shown differences in treatment efficacy, toxicity profile, and drug pharmacokinetics between women and men (Gandhi et al, 2004). Women experience more frequent and severe adverse effects with various protease inhibitors, including higher rates of gastrointestinal and neurological adverse effects, with ritonavir secondary to higher plasma concentrations of this drug. They also demonstrate higher rates of allergic reactions and nephrolithiasis with protease inhibitors. Related problems (neuropathy, pancreatitis, and toxicity-driven regimen changes) also occur more often in women (Gandhi et al, 2004). A few studies have shown increased efficacy of antiretrovirals in women compared to men, including slower rates of disease progression and hospital admissions related to HIV disease in women on highly active antiretroviral therapy (HAART) (Hermes et al, 2012; Moore, Sabin, Johnson, & Phillips, 2002). Further discussion of HIV infection and AIDS is found in Chapter 37.

In summary, an increasing number of gender-related differences in pharmacokinetics and pharmacodynamics are emerging. Kleist (*Women and trials, 2005*) warns, however, that these differences generally have not had an impact on drug dosing and most drugs on the market have a wide enough therapeutic index that minor differences usually do not reach clinical significance. Clinical significance can be seen in drugs that have marked gender-specific pharmacokinetic differences and those with narrow therapeutic indices, a steep dose-concentration curve, or both. As more clinical trials include both women and men, more pharmacodynamic and pharmacotherapeutic differences may appear.

FACTORS THAT INFLUENCE MEDICATION ADMINISTRATION

Puberty

Adolescent female athletes may display a combination of symptoms, including amenorrhea, disordered eating, and osteoporosis, called the "female athlete triad" (Gibbs, Williams, & De Souza, 2012). This syndrome is a disruption in normal growth and development caused by inadequate nutrition (caloric intake lower than expenditure) and over exercising (strenuous athletic training). These two behaviors lead to suppression of the hypothalamic-pituitary-ovarian axis, which in turn leads to reduced estrogen levels, amenorrhea, and decreased bone mineralization. Incidence of secondary amenorrhea (defined as absence of menses for 6 months in a girl who has had at least one menstrual period) runs between 10% and 50% in highly trained female athletes. Many young athletes present with primary amenorrhea (absence of menses by age 13 with secondary sex characteristics or absence of menses by age 15 with secondary sex characteristics). Hormonal therapy is not successful with this type of hypogonadism; however, other strategies that decrease the risk for osteoporosis should be incorporated into the routine health care of adolescent females in order to promote positive lifetime habits. Strategies include increasing daily calcium intake and assessing the amount of vitamin D exposure, which can help decrease the risk of osteoporosis. Decreasing the level of physical activity, increasing dietary intake, and increased body mass index (BMI) have been associated with the return of normal menstruation (Arends, Cheung, Barrack, & Nattiv, 2012).

Persistent low levels of estrogen in adolescent women are of concern regarding bone mineralization. Forty percent of bone accrual occurs during adolescence with bone formation continuing up to age 30 years, after which a gradual bone loss begins (Moos, 2005), so building bone during this developmental stage is crucial. Because adolescents have not yet reached peak bone mass, interpreting adolescent bone density measurements should be done appropriately with pediatric/adolescent-specific software that calculates Z scores, rather than T scores. Without appropriate intervention, girls with low bone density may never achieve adequate bone mass and run the risk of fractures and osteoporosis. Bisphosphonates (used to treat osteoporosis in postmenopausal women) are not FDA-approved for use in the teen population and do not appear effective in treating osteoporosis in teens (Dominguez-Bartmess, Tandberg, Cheema, & Szalay, 2012). Adequate calcium intake along with vitamin D can help build bone mass. Successful management of the female athlete triad must be multidisciplinary, requiring the support of coaches, family, trainers, nutritionists, physicians, and counselors (Arends et al, 2012).

Because adolescent diets are often not healthy, strategies that decrease the risk for osteoporosis should be incorporated into the routine health care of adolescent females in order to promote lifetime wellness habits. A daily intake of 1,300 mg of calcium daily is recommended for females aged 9 through 18 years, an amount that can be obtained by drinking three cups of low-fat or skim milk and consuming 8 ounces of low-fat yogurt. If a young woman consistently is unable to meet the recommended daily amount of calcium through diet alone, calcium carbonate (Tums, Caltrate, or Viactiv) should be consumed with food to maximize absorption. Because vitamin D is required for optimal calcium absorption, a daily multivitamin that includes at least 400 IU vitamin D should also be taken (Moos, 2005). Adolescents should also be discouraged from smoking, because smoking has been associated with poor uptake of the nutrients needed to build healthy bone.

Another concern related to bone mineral density (BMD) is long-term use of medroxyprogesterone acetate (Depo-Provera), an injectable form of birth control used by approximately 10% of adolescents. In 2004, the FDA announced a Black-Box Warning for this drug when studies demonstrated an association between long-term Depo-Provera use and significant BMD loss. Because adolescent females have not yet reached their peak BMD, prolonged use of Depo-Provera may put these girls at increased risk for osteoporosis. Mounting evidence suggests bone mass recovery occurs when the drug is discontinued; however, the long-term impact of this drug on BMD throughout a woman's life remains unknown (Harel et al, 2010). The FDA warning indicates that Depo-Provera should not be used as a birth control method for longer than 2 years (Isley & Kaunitz, 2011). Treatment of osteoporosis, including nutrition, is discussed in Chapter 38.

Another concern common in adolescent girls and young women is iron-deficiency anemia (IDA), a condition often related to heavy menstruation. Oral iron supplementation is recommended to replenish iron loss during menstruation. Girls going through puberty may also be avoiding red meat, a good source of iron, in favor of lower-calorie salads and vegetables. Although green, leafy vegetables contain iron, plant sources are not as fully absorbed as the iron found in meats. IDA is discussed in more detail in Chapter 27.

Pregnancy

Extraordinary anatomical and physiological changes occur in a woman's body during pregnancy. Her body changes shape and size, and every organ system modifies its function to create a protective and nurturing environment for the developing fetus (Cunningham & Williams, 2010). Drug absorption through the lungs, skin, and mucous membranes is increased because of increased cardiac output, which peaks at 20 to 24 weeks' gestation. Increases in cardiac output may be 30% to 50% above prepregnancy levels. Plasma volume is 50% higher by the third trimester; most of the volume is in the products of conception.

Clearance of some drugs is altered by these changes. Phenytoin clearance, for example, is increased during the second and third trimesters. The risks/benefits of continuation of anticonvulsants during pregnancy need to be weighed against the real potential risk of seizure activity during pregnancy on the mother and the fetus. Valproate is not recommended in pregnancy because its teratogenicity is higher than other anticonvulsants, in part due to higher levels found in fetal cord blood. Another example of changed metabolism is theophylline, which has increased half-life and volume distribution in the third trimester because of decreased renal clearance (Isoherranen & Thummel, 2013). Other drugs with effects similar to theophylline for asthma are preferred during pregnancy. In general, serum levels of phenytoin, the - ophylline, and other medications with altered metabolism, if used in pregnancy, need to be monitored.

Iron deficiency anemia (IDA) is one of the most common complications of pregnancy and is primarily due to expansion of plasma volume without equivalent expansion of maternal hemoglobin mass. This condition is called physiologic anemia (Friedman et al, 2012). IDA puts a pregnant woman at risk for susceptibility to infections, fatigue, and an increased chance of pre-eclampsia and postpartum hemorrhage. In addition, a pregnant woman with IDA tolerates even minimal blood loss during birth poorly and may experience delayed healing of an episiotomy, laceration, or cesarean birth incision (Cunningham & Williams, 2010).

Dietary iron is necessary for hemoglobin production, and during pregnancy hemoglobin is vital for transport of oxygen to the growing fetus. Daily iron intake of 30 mg is necessary during pregnancy, with the greatest need for iron intake in the last 20 weeks (Friedman et al, 2012). Stinging nettle *(Urtica dioica)* and chlorophyll are good sources of iron for pregnant women who find it difficult to consume adequate amounts of iron-containing foods. Stinging nettle can be consumed as a cooked green leafy vegetable, added to soups, or drunk as a tea. The tea is prepared by adding boiling water to two teaspoons of the dried or fresh herb and then steeping for several minutes. A woman should drink two cups of tea per day with cinnamon and honey added to improve the taste (Davidson et al, 2011). Table 48-2 lists herbs to avoid in pregnancy.

> ### ● CLINICAL PEARL ●
>
> **Prescribing for adolescents**
> State laws vary regarding consent for treatment of sexually transmitted infections, contraception, and medical record confidentiality in minor patients. Nurse practitioners should become familiar with what health-care services can be provided to minors without parental consent.

The physiologic anemia of pregnancy is commonly treated with ferrous sulfate. This oral preparation should be taken with vitamin C for increased absorption and should be taken after meals to reduce gastrointestinal irritation. Because

Table 48–2   Use of Selected Herbs During Pregnancy

Common Name	Comments
Selected Herbs to Avoid in Pregnancy	
Alder buckthorn	Very potent stimulators of bowel peristalsis known to irritate the uterus in sensitive women that may cause premature labor.
Almond oil	External application to abdomen has been associated with preterm birth.[*]
Angelica, dong quai	Uterine stimulant or may induce abortion/preterm labor. Dong quai is also an anticoagulant.
Arbor vitae and aloe	Oil-containing plants and essential oils that should not be taken internally during pregnancy.
Autumn crocus	Alkaloid-containing herbs that can be very potent and are best avoided in pregnancy.
Barberry	Uterine stimulant.
Black cohosh	Uterine stimulant.
Blessed thistle	Powerful laxative; may overstimulate digestion and metabolism, causing fluid and electrolyte imbalances.
Blue cohosh	Uterine stimulant.
Cascara sagrada	Powerful laxative; may overstimulate digestion and metabolism, causing fluid and electrolyte imbalance.
Ephedra	Cardiovascular stimulant.
Feverfew	Uterine stimulant.
Ginseng	Thought to affect the hormonal system.
Goldenseal	Uterine stimulant.
Gotu kola	Potential teratogen.
Juniper	Potential teratogen.
Licorice root	Powerful laxative; may overstimulate digestion and metabolism, causing fluid and electrolyte imbalances.
Mugwort	Uterine stimulant.
Pennyroyal	Uterine stimulant.
Senna	Powerful laxative; may overstimulate digestion and metabolism, causing fluid and electrolyte imbalances.
Yarrow root	Uterine stimulant.
Selected Herbs That Appear to Be Safe in Pregnancy[†]	
Chamomile flowers	May be taken in capsule form or used as a tea or infusion for nausea.
Black haw/cramp bark	Uterine relaxant; used for cramping.
Dandelion greens and root	For anemia.
False unicorn root	Uterine tonic; used with black haw/cramp bark to prevent miscarriage.
Ginger root	For nausea.
Jasmine	Essential oils that can be safely used in aromatherapy during pregnancy. Do not ingest or use internally.
Nettle leaf	Allergy prevention.
Peppermint leaf	For nausea.
Red raspberry leaf	Uterine toner.
Slippery elm bark	Uterine relaxant; used for cramping.

[*]Facchinetti, F., Pedrielli, G., Benoni, G., Joppi, M., Verlato, G., Dante, G., et al. (2012). Herbal supplements in pregnancy: Unexpected results from a multicentre study. *Human Reproduction, 27*(11), 3161–3167.

   [†]Effectiveness for most of these herbs has not been proven.

women with IDA may be asymptomatic, and because not all pregnant women need large quantities of supplemental iron, monitoring hemoglobin and hematocrit is necessary. To prevent IDA, a prenatal vitamin with an iron supplement of 30 mg/d should be initiated at the first prenatal visit, and pregnant women should be advised to eat an iron-rich diet (Friedman et al, 2012).

Pregnancy may present an opportune time for women to modify unhealthy or high-risk lifestyle behaviors. For example, illicit drug use may be corrected or reduced when patients are motivated by the birth of a child. Although legal, nicotine and alcohol are harmful to the developing fetus.

The use of caffeine during pregnancy remains controversial. At this time, no conclusive evidence links caffeine consumption to birth defects, spontaneous abortion (Davidson et al, 2011), pregnancy duration, condition of newborn (Jarosz, Wierzejska, & Siuba, 2012), or offspring behavior problems at age 5 to 6 (Loomans et al, 2012). Caffeine is found in beverages such as coffee, teas, colas, and some other sodas, in foods such as chocolate, and some over-the-counter (OTC) pain relievers. Caffeine, a central nervous system stimulant, causes mood swings and diuresis and readily crosses the placenta to the fetus, who is unable to metabolize it effectively. Caffeine may cause fetal or newborn cardiac arrhythmias. Some women may choose to avoid caffeine intake during pregnancy altogether. Until more information is available, pregnant women should be counseled about sources of caffeine and advised to limit their consumption to 150 to 300 mg a day or less (ACOG, 2010; Davidson et al, 2011).

Smoking has been linked to higher infertility rates in both men and women. Women who smoke have a higher risk for spontaneous abortion, preterm birth, placenta previa, abruptio placentae, and premature rupture of membranes. The risk is directly related to the number of cigarettes smoked, so any decrease in smoking will improve fetal outcomes. Two main ingredients in cigarette smoke affect the fetus: carbon monoxide and nicotine. Carbon monoxide competes for oxygen binding sites on fetal hemoglobin and nicotine causes vasoconstriction in both the mother and the fetus. The compound effect of these two ingredients is decreased availability and delivery of oxygen to maternal and fetal tissues, including the uterus and placenta (Cunningham & Williams, 2010).

Alcohol causes decreased folic acid and thiamine absorption. Mothers who drink alcohol while pregnant frequently deliver low-birth-weight infants, and they risk their infants' having problems of growth and development associated with fetal alcohol syndrome. To date, no safe level of alcohol consumption during pregnancy has been identified; therefore, women should be counseled to abstain from alcohol during pregnancy (Cunningham & Williams, 2010).

Complementary and alternative therapies, such as the use of medicinal herbs, are currently being evaluated with randomized methodologies to evaluate their efficacy. Many herbs can be useful for treating pregnancy-associated discomforts. Examples include ginger for nausea and vomiting, horse chestnut for varicose veins, and meadowsweet for heartburn (Blumenthal, Goldberg, & Brinckman, 2000; Gottlieb, 2008; Hardy, 2000). Women interested in taking herbs during pregnancy should be advised: (1) to avoid most herbs during the first trimester (except up to 1 g of ginger per day), (2) to avoid standardized or highly concentrated extracts, and (3) not to ingest essential oils (Davidson et al, 2011; Hardy, 2000). Table 48-2 presents selected herbs that are contraindicated during pregnancy and some that may be beneficial.

Menopause

Menopause, a natural passage in a woman's life, is a time of transition that marks the end of a woman's reproductive abilities. Women experience changes in their reproductive, musculoskeletal, and cardiovascular systems as well as vasomotor and cognitive function changes. Despite the significance of these changes, few women going through menopause have engaged in discussion with their health-care provider about menopausal symptoms, risk for chronic disease, or hormone use (Davidson et al, 2011; Smith, 2005).

Many options for managing menopausal symptoms are available, such as the use of exercise, relaxation techniques, massage therapy, acupuncture, herbs, or pharmaceuticals such as HRT (Roush, 2012). Some women are unable or choose not to take HRT and have turned to phytoestrogens, substances with estrogen-like properties found in certain herbs—such as ginseng, black cohosh, dong quai, fenugreek, and licorice—and certain foods—especially carrots, yams, and soy products—with varying efficacy (Roush, 2012). Another menopause treatment option the practitioner should consider is nutritional supplements for a diet rich in calcium and vitamins E, D, and B complex. In addition, menopausal women should avoid foods such as caffeine, alcohol, and spicy foods that can trigger vasomotor symptoms (Davidson et al, 2011). Alternative therapies for symptoms of menopause are presented in Table 48-3; herbal therapies are discussed in Chapter 10, and HRT is discussed in detail in Chapter 38.

Although managing menopausal symptoms is important, it is also vital at this time of life for a woman to achieve and/or maintain good health. Emphasis in the care of women in their 50s should be on health promotion and prevention of the diseases of older age. Classically, after menopause the lipid profile of women changes. The decline in endogenous estrogen removes a protective physiological mechanism that supports higher levels of high-density lipoprotein (HDL) and lowers low-density lipoproteins (LDL). Loss of estrogen places a woman at increased risk for coronary artery disease, hypertension, and stroke (Davidson et al, 2011). In fact, menopausal women "catch up" to men in relation to risks for these diseases and may experience "silent" coronary artery disease, which can become their greatest risk factor for death. Studies show that fewer women than men survive their first heart attack (Davidson et al, 2011). Providers need to educate themselves and their female patients about the signs and symptoms of cardiac disease in women and how the symptoms differ from

Table 48–3 **Alternative Therapies for Menopause Symptoms**

Symptom	Alternative Therapy and Its Effects
Hot flashes	• **Suggest taking vitamin E 400 bid:** affects blood vessel walls; some women have blood pressure changes; monitor patients with hypertension. • **Suggest taking soy 2 oz:** contains 45 mg phytoestrogens (genistein); may protect from cancer. • **Suggest taking evening primrose 3 oz:** eliminate breast tenderness: stabilizes hormone fluctuations. • **Suggest taking remifemin (black cohosh) 1 tablet bid:** suppresses LH but not FSH; progesterone precursor; reduces hot flashes; used in Germany. • **Suggest taking dong quai:** estrogen precursor. • **Suggest taking bioidentical hormones:** contain equivalent hormones but from plant sources.
Reduced libido (or lack of sex drive)	• **Talk with the patient, sexual counseling/therapy:** ensure that spousal issues are not a hidden factor; if the intimate relationship is not good, menopause may not be the primary problem. • **Investigate sleep issues:** sleep disturbances can cause depression. • **Screen for depression:** depression often associated with altered libido. • **Suggest using alternative therapies listed for weight fluctuation:** improves self-image, which weight gain may hinder; increases energy after minimal weight loss (5 to 10 lb). • **Suggest using alternative therapies for vaginal dryness or soreness:** reduces vaginal dryness and pain; allows for anticipation of positive sensations.
Mood changes (irritability, depression)	• **Take vitamin B$_6$ (pyridoxine) 1.3 mg daily:** turns amino acids into serotonin, which affects mood. • **Practice meditation, yoga, or prayer:** calms nervous system; stimulates immunity; enhances personal control. • **Obtain adequate sleep:** aids relaxation. • **Improvise stress management techniques:** improves relaxation.
Sleep disturbances	• **Suggest taking valerian root, chamomile, melatonin:** aids relaxation. • **Exercise:** stimulates serotonin production after 40 min; affects mood. • **Decrease intake of or avoid stimulants (caffeine, nicotine, large protein-rich meals):** allows relaxation of nervous system. • **Avoid alcohol:** negatively affects all stages of sleep. • **Meditate, pray:** calms nervous system; stimulates immunity; enhances personal control.
Stress incontinence (urinary)	• **Decrease intake of caffeine beverages and diuretics:** reduces irritated detrusor muscle; results in less urgency. • **Perform Kegel exercises:** strengthens pelvic floor muscles. • **Treat/reduce constipation:** relieves pressure on urethra and bladder. • **Participate in bladder training programs:** reduces incidence of incontinence.
Vaginal dryness or soreness	• **Reduce or avoid use of medications such as antihistamines, decongestants, anticholinergics, and diuretics:** improves tissue moisture. • **Suggest using alternative therapies listed for hot flashes:** increases epithelial lining of vaginal tissues. • **Use water-soluble lubricants daily (e.g., Replens, Astroglide, Lubrin):** facilitates penetration; enhances foreplay (ensure that the patient knows areas to apply for maximum stimulation).
Weight fluctuations	• **Exercise 30 to 60 min daily:** reduces weight gain; stabilizes mood; strengthens muscles; improves balance; stimulates good bone metabolism.

LH = luteinizing hormone; FSH = follicle-stimulating hormone.

those in men, with particular emphasis on the need to seek early treatment. Angina and ischemic heart disease are discussed in Chapter 28. Hypertension is discussed in Chapter 40, and hyperlipidemia in Chapter 39.

Genetics play a role in the diseases that afflict women at midlife, including heart disease, but preventive measures can be taught as well as prescribed. Primary prevention studies demonstrate that diets high in complex carbohydrates, fiber, and protein and low in animal fat are best. Balanced diets such as those recommended in *My Pyramid* (Guenther, Reedy, & Krebs-Smith, 2008) can lead to a lower body mass index (BMI). Normal BMI is considered between 18.5 and 24.9; 25 to 29.9 is considered overweight, and 30 or more is obese. Persons with a BMI greater than 30 are associated with morbidity and shortened life expectancy.

Exercise is a nonpharmacological health promotion strategy. The exercise does not have to be strenuous, just consistent. Walking, yard work, bicycling, and swimming are all good forms of exercise. Thirty minutes of moderate physical activity for at least 6 days per week is recommended for best health (Leitzmann et al, 2007). Other alternative therapies for menopausal symptoms are listed in Table 48-3.

Other postmenopausal physical changes seen in women are the results of normal human aging and are shared by both sexes. These changes include thinning and graying of the hair, weight gain, drying skin, vision changes associated

with presbyopia, and increased healing time for musculoskeletal injuries. Female genitourinary tract changes, affecting the vagina and urinary system, are the result of the cessation of ovarian function and decreased estrogen levels. Loss of the ureterovesicular angle and detrusor muscle instability result in urinary frequency and leakage, with increased residual bladder volume. Breast composition changes from dense glandular tissue to fatty replacement.

Older Age

In this millennium, many women are living as long after menopause as they did before it. Women in every culture live longer than men (Austad, 2006). Race is a major determinant of women's life spans. In the United States, white women have a life expectancy of 80.5 years, in contrast to African Americans, whose life expectancy is 76.1 years (Hoyert, Mathews, Menacker, Strobino, & Guyer, 2006). Cardiovascular disease causes the greatest morbidity and mortality for the aging woman, followed by cancer and cerebrovascular disease (Bertoia, et al, 2012).

Aging women experience more frequent autoimmune disease, which manifests itself in joint and soft tissue pain and deformity. Although the risks for cancer increase with age and an estimated 250,000 new cases of breast cancer are diagnosed in the United States every year, many women never have mammograms because of lack of information, poor access to health care, or insufficient insurance coverage (Peipins et al, 2012). Smoking by women increased during the post–World War II years until the 1970s, which is hypothesized as the reason for increased lung cancer rates for older women. More recently, smoking rates have declined such that 17.9% of U.S. women smoke (Moolgavkar et al, 2012).

FACTORS THAT INFLUENCE POSITIVE OUTCOMES

Factors that produce positive outcomes are discussed in detail in Chapter 6. This section will discuss only those specific to women.

Number of Drugs Taken

Adult women receive more prescription drugs than men of the same age. Women are more apt to take medications for their skin, muscles, urinary tract, ophthalmological and otological problems, fatigue, extremity pain, weight, hypertension, and emotional complaints. Depression and connective tissue diseases are much more common in women. The risk for adverse reactions and drug interactions increases proportionately with the number of drugs being taken concurrently. The overall treatment regimen of each female patient should be regularly reviewed to eliminate any drugs that have "outlived" their usefulness or are duplicates.

Duration of Medication Therapy

Most patients can remember to take medications for a few days, especially if they are feeling ill, but drugs that must be taken daily and for many years are subject to poor adherence rates. Women may find themselves responsible for taking oral contraceptive pills (OCPs) for 10 to 40 years, with other drugs added in from time to time. Adherence with OCP use varies over time, but generally averages between 47% to 74% (Zapata, Steenland, Brahmi, Marchbanks, & Curtis, 2012). Providers who care for women of childbearing age need to be ever cognizant of the risk of pregnancy, even in women who are using contraception.

Strategies to improve compliance, such as taking medications along with other routine activities of daily living, have been shown to work well. Women are frequently the primary caregivers of children and may also care for other family members (spouses, elderly parents, and relatives). The busyness of women's lives can complicate medication administration and decrease adherence.

Fear That Medications Cause Disease

Social networking is frequently the way that women access health information. Through social media they hear about drugs (such as hormones) causing cancer or other disease from the media (e.g., television, newspapers) and from friends and relatives. This information is often sensational and can be inflammatory while being nonspecific. Concerns about exogenous hormones being carcinogenic can drive patient behavior, and it behooves providers to take time to explore them with patients. Education is needed to help women understand the results of studies done when much higher levels of potent estrogen were used in OCP and HRT formulations. Recent studies on the risk of gynecological cancers have shown a large hereditary component in breast cancer, especially when it occurs in women who are premenopausal. Genetic testing is now available for breast and ovarian cancers. Women may have a hard time deciding if they should use hormonal therapies because it is difficult to calculate their own absolute risk. What they hear in the media are relative risks, which refer to populations of women in certain age brackets. The results of the Women's Health Initiative (WHI) continue to be evaluated and clarified. Providers need to read current research and be accurate in their knowledge in this area and share updated data with patients (Nelson, Walker, Zakher, & Mitchell, 2012).

Nutritional Status

Appropriate diet and good nutritional status are necessary for facilitating optimal growth in adolescents and for promoting health and wellness in women of all ages.

Obesity is a growing problem in all segments of the U.S. population. Women are at higher risk than men for eating disorders, which can lead to both overweight and underweight conditions. Many women have weight retention after pregnancy and then start their next pregnancy overweight. Obesity carries with it increased risks of pregnancy complications, infertility, cardiovascular and organ disease, hypertension, and diabetes. Anorexia nervosa and bulimia are complicated disorders with mental, emotional, and physical

components that can lead to underweight as well as dental problems, infertility, osteopenia/osteoporosis, organ failure, and death. Of note, depression—more women than men suffer from this chronic mental illness—is the most common comorbidity with both obesity and anorexia (Ward & Hisley, 2009). Treatment for both overweight and underweight women can be challenging, with the best results involving an interdisciplinary team of providers. Polypharmacy can be a hazard in these patients, and prescriber vigilance in monitoring both drugs and changing doses, as weight and other body parameters change, is needed.

Safety of Medications While Breastfeeding

The benefits conferred to infants by breastfeeding, especially in the first year of life, are well described in the literature. Points to be considered in prescribing to lactating mothers are the acidity of breast milk in relation to the pH of plasma, the protein-binding effects of the drug prescribed, the liposolubility of the drug prescribed, and the molecular weight of the drug prescribed. All prescribed medications in the United States have labeling delineating breastfeeding risks. The National Library of Medicine maintains an evidence-based database of the effects of drugs and other chemicals to which breastfeeding mothers might be exposed Called LactMed (http://toxnet.nlm.nih.gov/). The LactMed database provides information on the level of substances in breast milk, effects on the breastfeeding infant, as well as suggested therapeutic alternatives.

Ethnic, Cultural, and Religious Differences

Although women from diverse cultures commonly seek health care more often than do men (this is true in most cultures), many cultures are patriarchies. In patriarchal societies, men make the decisions about birth control, whether women work outside the home, and how much money women receive to run the household. Women may not have the choice to refuse sexual relations. The lack of power and control over their own bodies can generate many somatic complaints. These women patients often present on multiple occasions with what may appear to be nonspecific and unrelated symptoms (Crissman, Adanu, & Harlow, 2012). Pelvic pain and genital pain are frequent complaints, and unplanned pregnancies are not unusual. Adherence to prescribed contraceptive regimens is difficult, if not impossible, for women in many of these situations.

Religion can also raise issues related to the prescribing of medications. If a patient's belief system does not support a treatment that the provider is prescribing, adherence may become a problem. Cultural issues are discussed in detail in Chapter 7.

COMMON PROBLEMS THAT REQUIRE MEDICATIONS

In addition to the array of medical problems shared by both genders—hypertension, cardiovascular disease, diabetes,

---

CLINICAL PEARL

Prescribing in pregnancy and lactation
The pregnancy risk categories (A, B, C, D, X) should be used as a guide only. Category X (known teratogenic effects on the fetus) must be avoided in pregnancy. Category D drugs should be used only in a life-threatening situation (i.e., chemotherapy drugs), as known fetal risks exist. Categories A, B, and C may have some risks. Every prescription drug now provides "Pregnancy Implications" and "Lactation" labeling and these should be read and understood before prescribing.

In 2014 the Food and Drug Administration passed The Pregnancy and Lactation Labeling Rule that will affect all prescription drugs and biological products. The pregnancy risk categories (A, B, C, D, X) will be eliminated and replaced with a summary of risks of using the drug during pregnancy and while breastfeeding. There will be a new section on drug labels titled "Female and Male of Reproductive Potential" that will include information about the need for pregnancy testing, contraceptive recommendations, and drug effects on fertility. All new drugs approved after June 30, 2015, will have the new labeling format (with no A, B, C, D, or X). The new format will be phased in gradually for previously approved drugs.

---

cancer, glaucoma, organ disease, arthritis, mental illnesses, autoimmune disorders, and pain management—specific problems in women that require medications include urinary tract infection and urinary incontinence, sexually transmitted infections and vaginitis, premenstrual disorders, endometriosis, polycystic ovarian syndrome (PCOS), contraception, infertility, menopause, gynecological cancers, osteoporosis, depression, and hypothyroidism. Many of these problems are discussed in the appropriate chapters in Unit III. Problems not discussed in Unit III chapters are included here: menopause, premenstrual syndrome and premenstrual dysphoric disorder, endometriosis, PCOS, HIV/AIDS in pregnancy, and infertility.

CLINICAL PEARL

Prescribing in a diverse culture
Be aware of the common ethnic groups in your patient population. Get to know the cultures. Frequently, community programs that teach cultural awareness and some simple ethnic phrases are available for health-care personnel. Bookstores carry pocket-sized books to facilitate a simple medical interview in different languages.

Menopause

Menopause is a normal physiological process in women, with the mean age of menopause in the United States at 51.3 years (Davidson et al, 2011; Smith, 2005). Several years of gradual decline or erratic levels of endogenous estrogen precede cessation of ovarian function. All women experience changes in

their secondary sexual characteristics. Some women barely notice vasomotor instability, whereas hot flashes and insomnia incapacitate others. Estrogen and progesterone may interact at more than 200 receptor sites in a woman's body, so exogenous treatment may affect women in many different ways. Alternative therapies for symptoms of menopause are presented in Table 48-3. When women are postmenopausal and choose to use drug therapy (HRT), absolute risks versus benefits for the individual should be assessed and discussed. Present recommendations are for the lowest amount of drug to be used for the shortest period of time to alleviate problematic symptoms (The North American Menopause Society, 2012). It is recommended that treatment with estrogen and progesterone, for women with a uterus, be for no more than 3 to 5 years due to earlier increased risk of breast cancer, but that estrogen therapy alone, for those without a uterus, can safely be continued longer when the balance of potential benefits and risks is favorable for the individual woman (North American Menopause Society, 2012).

Dysmenorrhea, Premenstrual Syndrome, and Premenstrual Dysphoric Disorder

Women typically have menstrual cycles for about 40 years. Cyclic perimenstrual pain and discomfort (CPPD) is the name of a concept developed by a team of American Women's Health, Obstetric and Neonatal Nurses (AWHONN) nurse-researchers (Collins Sharp, Taylor, Thomas, Killeen, & Dawood, 2002). This concept includes dysmenorrhea, premenstrual syndrome (PMS), and premenstrual dysphoric disorder (PMDD). CPPD can have a significant impact on a woman's quality of life. Nurse practitioners play a vital role in identifying and diagnosing dysmenorrhea, PMS, and the more disabling PMDD and in managing the symptoms of these disorders. Bhati and Bhati (2002) report that as many as 20% to 40% of menstruating women experience one of the disorders.

Dysmenorrhea

Dysmenorrhea, pain shortly before or during menstruation, is one of the most common gynecological complaints. Young adult women (under 20 years old) present most frequently with this complaint, but the condition affects women of all ages. Between 41% to 93% of adolescents experience symptoms; this incidence decreases with age (Zahradnik, Hanjalic-Beck, & Groth, 2010). Primary dysmenorrhea is due to increased myometrial activity, with contractions induced by prostaglandins in the second half of the menstrual cycle. NSAIDS are the first line of drug treatment for women not desiring contraception (Zahradnik et al, 2010) and are particularly effective if begun 2 to 3 days before menses or at the first sign of bleeding. OTC NSAIDs have the same active ingredients (e.g., ibuprofen, naproxen sodium) as prescription drugs; however, the labeled recommended dose for general discomfort may be subtherapeutic for dysmenorrhea. Preparations containing acetaminophen, which is not an NSAID, are ineffective because of the absence of antiprostaglandin

properties. For women who want contraception, oral contraceptive pills (OCPs) are a good therapeutic choice. Decreased prostaglandin synthesis results from an atrophic endometrium (Zahradnik et al, 2010). No single brand of OCP has been shown to be superior for this indication.

> ### ● CLINICAL PEARL ●
>
> **Progesterone-only therapies**
> Women who have contraindications to estrogen use need to be counseled that there are several easy-to-use progesterone methods, without estrogen, that offer effective contraception and treatment for dysmenorrhea.

Many nonpharmacological measures can be used to relieve primary dysmenorrhea, and often the best treatment strategies involve using medications and comfort measures along with lifestyle modifications. Complementary and alternative medicines (CAMs) shown to improve symptoms of dysmenorrhea include thiamine (vitamin B_1), magnesium, vitamin E, and omega-3 fatty acids (Zahradnik et al, 2010). Comfort measures, including heat (poultices or heating pads), massage/effleurage, guided imagery, progressive relaxation, yoga, exercise, and meditation, have been successful in managing menstrual discomfort. Decreasing dietary intake of salt, sugar, and red meat in the luteal phase and increasing water intake may reduce edema (Lowdermilk & Perry, 2007).

If dysmenorrheal discomfort is not relieved by one of the NSAIDS, further investigation into the cause of symptoms is required. Secondary dysmenorrhea usually develops later in a woman's life (after age 25) with a prevalence of about 5% (Zahradnik et al, 2010). Pelvic pathology—such as adenomyosis, endometriosis, pelvic inflammatory disease (PID), endometrial polyps, and myomas (fibroids)—is associated with secondary dysmenorrhea (Lowdermilk & Perry, 2007). Many of the relief measures for primary dysmenorrhea are also helpful for women with secondary dysmenorrhea, but treatment is aimed at removal of the underlying pathology.

Premenstrual Syndrome (PMS)

The diagnostic criteria for PMS were written by the ACOG (Davis & Johnson, 2000). Symptoms include irritability, depression, angry outbursts, anxiety, confusion, social withdrawal, and mood swings. Somatic symptoms include fatigue, insomnia, dizziness, headaches, breast tenderness, weight gain, abdominal bloating, edema secondary to water retention, and muscle and joint pain (*Premenstrual syndrome*, 2003). Women often respond to exercising aerobically, decreasing caffeine, reducing salt intake, and taking ibuprofen 500 to 1,000 mg/d during the luteal phase: days 17 to 28 of the menstrual cycle (Frackiewicz & Shiovitz, 2001). Pritham (2002) recommends eating smaller, more frequent meals that are high in complex carbohydrates and fiber; reducing intake of salty foods, sugar, caffeine, chocolate, red meat, dairy products, and alcohol; and increasing the dose of

calcium supplementation. She also recommends relaxation techniques, yoga, stress management, and good sleep hygiene. CAM that has been shown to be helpful include calcium, magnesium, vitamin B$_6$, evening primrose, and chasteberry (Zahradnik et al, 2010).

Premenstrual Dysphoric Disorder

A small subgroup of CPPD patients (2% to 10%) has a more severe form of the disorder: premenstrual dysphoric disorder (PMDD) (Epperson et al, 2012; Qiao et al, 2012). Diagnosis of PMDD is based on criteria established by the American Psychiatric Association (APA, 2013). To meet diagnostic criteria, patients must exhibit five or more symptoms, including at least one "core" symptom. Severely affected women typically have symptoms for 6 to 7 days each cycle. Symptoms of PMDD include the core symptoms of markedly depressed moods, heightened anxiety/tension/edginess/nervousness, affective lability, persistent and marked anger and irritability; plus other symptoms, such as decreased interest in usual activities, marked lack of energy (fatigue, lethargy), hypersomnia or insomnia, difficulty concentrating, appetite changes or cravings, and a subjective sense of being overwhelmed or "out of control," *plus* any of the physical symptoms already described in the PMS section of this chapter (Halbreich, et al, 2012). Symptoms are cyclical, occurring during the luteal phase of the menstrual cycle and are significantly reduced or disappear completely during menstruation. The morbidity of this condition is staggering when one considers that an average woman might have more than 400 cycles between the ages of 14 and 51, depending on the number of pregnancies and how long she breastfeeds. Some women can experience approximately *8 cumulative years* of severe PMDD during their reproductive years!

Pathophysiology

The exact cause of PMS and PMDD is unknown, but clearly multifaceted interactions among the central nervous system, hormones, and other chemical modulators occur. Genetic influences mediated phenotypically through neurotransmitters and neuroreceptors seem to play a large role. Seventy percent of women whose mothers have PMS will have PMS themselves, and a 93% concordance rate occurs in monozygotic twins compared to 44% in dizygotic twins (*Diagnosis and treatment of premenstrual dysphoric disorder,* 2002).

Theories about the pathophysiological cause that are supported in research suggest that PMDD may be caused by altered sensitivity in the serotonergic system to phasic fluctuation in female gonadal hormones. Some of the nutritional interventions are based in studies of the effectiveness of L-tryptophan, a precursor of serotonin, and of pyridoxine, a cofactor in the conversion of tryptophan into serotonin, in relieving PMDD symptoms. The success of SSRIs, which are considered first-line therapy in this disorder (*Diagnosis and treatment of premenstrual dysphoric disorder* , 2002; Frackiewicz & Shiovitz, 2001; Kaur, Gonsalves, & Thacker, 2004), also supports this hypothesis. Prostaglandins appear to play a role in some of the symptoms, and NSAIDs seem to be effective through their action on prostaglandins. Continuous combined oral contraceptive pills with 20 mcg estrogen and 90 mcg of levonorgestrel have been successful at treating symptoms of PMDD (Halbreich et al, 2012).

Treatments

The same lifestyle modifications used with PMS are also useful with PMDD. The outcome most suited to pharmacological therapy in PMDD is symptom reduction. Nutritional, herbal, and drug therapies play a role in this complex disorder. The dosing of selected nutritional, herbal, and drug therapies is presented in Table 48-4.

Nutritional Supplements

Randomized, placebo-controlled trials have shown vitamin B$_6$ in dosages up to 100 mg per day to benefit patients with premenstrual symptoms and premenstrual depression. Calcium

Table 48–4 Treatment Options for PMDD

Therapy	Dosing	Symptom Improvement
Nutritional Supplements		
Calcium carbonate	1,200–1,600 mg/d	Core symptoms
Magnesium	Up to 500 mg/d	Bloating
Tryptophan	Up to 6 g/d	Insomnia; affective symptoms
Vitamin B$_6$	Up to 100 mg/d	Core symptoms; depression
Vitamin E	200–400 mg/d	Stabilizes hormonal fluctuations
Herbals		
Evening primrose oil	500 mg daily to 1,000 mg tid	Anti-inflammatory; breast tenderness
Chaste tree berry	30–40 mg/d	Breast engorgement
Drugs (SSRIs)		
Citalopram (off-label)[*]	10–30 mg/d	All symptoms; fewer side effects than other SRIs

Continued

Table 48–4 Treatment Options for PMDD—cont'd

Therapy	Dosing	Symptom Improvement
Fluoxetine (indication)	20 mg/d	All symptoms; sexual side effects
Paroxetine (indication)	10–30 mg/d	All symptoms; GI and sexual side effects
Sertraline (indication)	50–150 mg/d	All symptoms; GI and sexual side effects
Drugs (Other)		
Alprazolam	0.375–1.5 mg/d	Anxiety and other affective symptoms
Bromocriptine	Up to 2.5 mg tid	Breast engorgement
Clomipramine	25–75 mg/d	All symptoms; anticholinergic effects
Ibuprofen	500–1,000 mg/d	Pain; breast engorgement
Spironolactone	100 mg/d	Water retention

PMDD = premenstrual dysphoric disorder.

carbonate in dosages of 1,200 to 1,600 mg per day reduced core premenstrual symptoms by 48% for 466 patients in one study (*Diagnosis and treatment of premenstrual dysphoric disorder,* 2002). Vitamin E, an antioxidant, reduces affective and physical symptoms in some patients. Finally, magnesium and tryptophan may also benefit PMS/PMDD patients. Nutritional supplements are generally considered second-line therapies, though they may be tried initially by women who are reluctant to take pharmaceuticals.

Herbals

Data on the efficacy and safety of herbal supplements marketed for women with PMS/PMDD have been inconsistent for many products. In addition, manufacturing standards for herbal products are not uniform. Given these caveats, two products based on research are recommended by Bhati and Bhati (*Diagnosis and treatment of premenstrual dysphoric disorder,* 2002). The most studied is evening primrose oil, which may be a precursor for prostaglandin synthesis and so may benefit symptoms associated with prostaglandins. Doses are 500 mg daily to 1,000 mg tid. Chaste tree berry has also been studied, although less so. Doses of 30 to 40 mg per day may benefit breast symptoms because it inhibits prolactin production (Pearlstein, 2012). Studies of vitamin A do not support its use. Other studies do not support the use of other herbals, such as black cohosh.

Drug Therapies

First-line therapy for PMDD is SSRIs. Three of them have been FDA-approved for PMDD: fluoxetine, paroxetine, and sertraline (*Diagnosis and treatment of premenstrual dysphoric disorder,* 2002). Both luteal phase and continuous use are beneficial, but continuous use may be better when cycles are not predictable, such as during peri-menopause (Pearlstein, 2012). Steiner and colleagues (Steiner et al, 2003) looked at fluoxetine efficacy related to affective and occupational functioning rather than physical symptoms. They found it reduced these symptoms relatively quickly at a low dose of 20 mg per day. Although they have been used for PMDD, the anxiolytics, citalopram and alprazolam, are off-labeled for this indication.

Second-line drug therapy includes tricyclic clomipramine and benzodiazepine. Although they are often helpful, tricyclic clomipramine has anticholinergic side effects and benzodiazepine is associated with tolerance if used long term.

Ibuprofen, spironolactone, and bromocriptine are focused on specific PMS/PMDD symptoms and are useful for patients with those symptoms. Table 48-4 gives doses for these drugs and the types of symptoms they are most effective in relieving.

Gonadotropin-releasing hormone (GnRH) agonists, and danazol, a weak androgen, have been used to treat PMDD (Epperson et al, 2012). GnRH agonists inhibit follicle-stimulating hormone (FSH) and luteinizing hormone (LH), suppressing ovarian steroid hormone production and preventing ovulation. As the effect is equivalent to a medically induced oophorectomy and often requires add-back estrogen and/or progesterone (Epperson et al, 2012), these drugs are best prescribed by a specialist.

Psychotherapeutics

A comprehensive treatment meta-analysis of 22 studies (6 psychotherapeutic; 16 SSRI) found that psychotherapeutics, such as cognitive-behavioral therapy, are as effective as SSRIs and yet both had a small to moderate effect. The authors suggest that a combination of psychotropic and psychotherapeutic treatments may offer improved outcomes, but this has not been studied (Kleinstauber, Witthoft, & Hiller, 2012).

Endometriosis

Endometriosis is primarily a disorder of young women. The incidence is hard to determine in asymptomatic adolescents and fertile women, but it has been estimated that 10% to 15% of reproductive-age women and 2% to 4% of menopausal women have endometriosis. As many as 50% of women evaluated for pelvic pain, infertility, or a pelvic mass are diagnosed with this disorder (McCance & Huether, 2014). The frequency and severity of symptoms do not correlate with the

extent or site of the lesions, and as many as 31% of asymptomatic fertile women are found to have endometriosis when undergoing laparoscopy.

Pathophysiology

Endometriosis is the presence of functioning endometrial tissue (called implants) outside the uterus. The cause is unknown, but theories include retrograde menstruation, depressed cytotoxic T-cell response to endometrial cells in ectopic locations, and a genetic hypothesis that proposes abnormal development of epithelial cells of the reproductive organs (McCance & Huether, 2014). Endometriosis appears to have a genetic predisposition; the condition is 6 to 7 times more prevalent in women who have a first-degree relative with endometriosis as compared to the general population (Layman, 2013). Women with early menarche, late menopause, low body mass index, nulliparity, mullerian anomalies, and shorter menstrual cycles are also at higher risk for endometriosis (Schrager, Falleroni, & Edgoose, 2013).

Endometrial implants can occur throughout the body but are most often found on the ovaries, uterine ligaments, rectovaginal septum, and pelvic peritoneum. Other common sites include the surface of the intestines, bladder, vulva and vagina, and the pleural cavity and lungs (McCance & Huether, 2014). Cyclical changes in gonadal hormones result in proliferation of the ectopic endometrium with the subsequent breakdown and bleeding that is part of the normal menstrual cycle. The bleeding produces inflammation with the usual release of inflammatory mediators and macrophage involvement (Capobianco & Rovere-Querini, 2013). Pain occurs in the surrounding tissues and the inflammatory process can lead to fibrosis, scarring, and adhesions, which are the lesions often held responsible for infertility in these women. Symptoms relate to the inflammatory process caused by the bleeding and include pelvic pain, dysmenorrhea, dyspareunia, and, less commonly, constipation and abnormal vaginal bleeding (*Endometriosis—Start with a natural approach*, 2011; McCance & Huether, 2014).

Drug Therapies

The ACOG (1999) issued the following recommendations based on reliable scientific evidence:

- For pain relief, GnRH agonists for at least 3 months or danazol for at least 6 months. Treatment with danazol is about one-third less costly than GnRH agonist treatment.
- When GnRH agonist treatment must continue for some time, "add-back" regimens with progestin, bisphosphonates, or pulsatile parathyroid hormone should be considered to reduce GnRH-induced bone mineral loss.

Pick and Holmes (*Endometriosis—Start with a natural approach*, 2011) recommend less dramatic treatments first. They report a high rate of success with a combination of dietary changes, nutrient support, emotional healing, and alternative therapies such as acupuncture. Their dietary recommendations remove xenoestrogen exposure by eliminating nonorganic dairy products, beef, and chicken; increase nutrient-rich food such as cruciferous vegetables, soy, cold water fish, and fiber; and suggest a lower carbohydrate diet to support healthy insulin metabolism. Supplementation with calcium and magnesium (see PMDD) and omega-3, an essential fatty acid, reduces inflammation. Resveratrol (found in the skin of grapes and other fruit) and epigallocatechin gallate (an antioxidant) have had success in rodent studies (Ricci et al, 2013).

When drugs are chosen, ibuprofen, naprosyn, and other NSAIDs are used to decrease pain and inflammation. Ovulation suppression therapies, such as oral contraceptives, are effective in treating endometriosis pain but do not improve pregnancy rates. To improve pregnancy rates, surgical treatment is recommended (Schrager et al, 2013).

HIV/AIDS in Pregnancy

Women are now the fastest-growing population with HIV infection and AIDS; an estimated 20% of new infections occur in women, and young women aged 25 to 44 accounted for the majority of new HIV infections among women in 2010 (CDC, 2013a). Pregnant women who are HIV-positive face many challenges, such as unpredictable symptoms and prognosis, the potential for maternal to infant transmission, and problematic life circumstances that have the potential to compromise parenting, such as poverty, substance abuse, and the stigma associated with this disease. Despite these challenges, HIV-infected women are no less likely to become pregnant, nor are they more likely to terminate a pregnancy (Kirshenbaum et al, 2004).

Other viral infections, such as herpes and cytomegalovirus, seem to be more prevalent in women infected with HIV than in men (Cunningham & Williams, 2010). HIV-positive women also may have more severe pelvic inflammatory disease than other women, and rates of cervical dysplasia and human papillomavirus (HPV) may be higher in HIV-positive women, with the clinical course accelerated and more frequent recurrence (Lowdermilk & Perry, 2007).

An infected woman can pass the HIV virus to her baby during pregnancy, delivery, or breastfeeding. Triple combined antiretroviral (ARV) therapy during pregnancy greatly reduces the risk of passing the HIV virus to the fetus. Reported rates of mother-to-child transmission are 2% when women begin ARV medication treatment early in pregnancy (Stephenson, 2005). This rate increases to 12% to 13% if treatment is not initiated until labor, delivery, or after birth and shoots up to 25% should women receive no preventive treatment (National Institute of Health, 2013).

Effective counseling, screening, and the use of zidovudine or another highly active antiretroviral therapy (HAART) for infected pregnant women has contributed to the decline in the number of new pediatric AIDS cases. Therefore, the Centers for Disease Control (CDC) recommends universal prenatal counseling and testing for pregnant women (National Institute of Health, 2014). Breastfeeding is not recommended in countries where other good alternatives exist (National Institute of Health). Further discussion of the management of HIV/AIDS is found in Chapter 37.

Infertility

Infertility, defined as the absence of conception despite unprotected sexual intercourse for at least 1 year, has a profound emotional, psychological, and economic impact on the affected couple and society. Women with infertility experience greater psychological symptoms, including depression, anxiety, and poor self-esteem (El Kissi et al, 2013). A serious medical concern, the condition affects the quality of life for about 6% to 10% of reproductive-age couples (CDC, 2012). About 35% of infertility problems are due to a male factor, 45% to a female factor, and the remaining 20% are due to problems with both partners or are unexplained. Incidence of infertility increases with a woman's age, particularly in women older than age 40 (Lobo, Lentz, Gershenson, & Katz, 2012).

Determination of hormone levels, such as prolactin, FSH, LH, estradiol (E2), progesterone, and thyroid, may be necessary to diagnose the cause of absent or irregular menstrual cycles. The clomiphene citrate challenge test (CCCT) can be given to assess ovarian reserves. Couples should undergo an infertility evaluation by a specialist if after 1 year of trying they have been unable to conceive. A woman older than 35 years may be referred earlier, for example, after only 6 to 9 months of unprotected intercourse without achieving conception (Davidson et al, 2011).

Polycystic Ovarian Syndrome

An endocrine imbalance that results in high levels of estrogen, testosterone, and LH with decreased levels of FSH, polycystic ovarian syndrome (PCOS) is associated with a number of problems in the hypothalamic-pituitary-ovarian axis. The ovaries can double in size with multiple follicular cysts, producing excess estrogen. Impaired glucose occurs in about 45% of women with PCOS (Huang & Coviello, 2012), and affected women are at high risk of developing type 2 diabetes and cardiovascular diseases (Huang & Coviello, 2012).

Analgesics may be prescribed for pain management, and regular examination is needed to monitor the symptoms. OCPs may be indicated to suppress functional cysts, if pregnancy is not desired. GnRH analogues may be used to treat hirsutism if OCPs do not improve this distressing symptom. If pregnancy is desired, medications for ovulation induction are usually given (Misso et al, 2013). Insulin and metformin are prescribed to manage the type 2 diabetes, lowering blood glucose and testosterone, which, in turn, can reduce acne, hirsutism, abdominal obesity, and amenorrhea in some women with PCOS (ACOG, 2003; Lord & Wilkin, 2004).

HEALTH PROMOTION, DISEASE PREVENTION, AND SCREENING

Preventive screening and testing save lives by identifying previously undiagnosed conditions and by allowing for early intervention and treatments so that health outcomes are improved. Many simple, preventive measures can be taken by women to reduce morbidity and mortality. These measures include immunizations for pneumonia and influenza and screening for high blood pressure, cholesterol, and blood sugar. Screening tests to identify heart disease, cancers, and diabetes are recommended by the American Cancer Society, the American Diabetes Association, the American Heart Association, the American Academy of Family Physicians, and the U.S. Preventive Services Task Force.

Some preventive health-care screening recommendations for adult women without symptoms of disease should begin at age 18 years and include an eye examination, blood pressure check, and gynecology visits as indicated. PAP testing is recommended at age 21 (National Institute of Health, 2013). Studies on self-breast exams failed to show a benefit and have reported a higher rate of breast biopsies for benign disease (Baxter, 2001; Hackshaw & Paul, 2003), although self-breast exams may prevent mortality from breast cancer (Harvey, Miller, Baines, & Corey, 1997).

Tetanus with pertussis (Tdap) immunizations should be updated, with a pregnant women needing a Tdap with every pregnancy. Anyone in a risk category should complete immunization series for hepatitis A and B. In 2006, the CDC recommended routine vaccination of girls aged 12 to 24 years against HPV (CDC, 2012). Other screening tests should be implemented beginning at age 40 years, such as a breast examination performed by a health-care provider and mammograms (American Cancer Society, 2006). There is no consensus on the frequency of mammograms for women between 40 and 49 years of age; recommendations vary from annually over age 40 (American Cancer Society) to annually over age 50 (Squiers et al, 2011). Providers are urged to individualize recommendations for their patients. Since lung and colon cancers have increased in the past century, patients need to begin screening procedures, such as colonoscopy at age 50 years. Skin examination for cancer should be done every 3 years between ages 20 and 40 and at least annually afterward. Bone mineral density (BMD) testing is recommended for all women aged 65 and older and younger women at risk for osteoporosis. A complete list of preventive health-care screening tests can be found at http://www.womenshealth.gov/.

GAY AND LESBIAN HEALTH

Membership in a sexual minority group is not in and of itself hazardous; however, risk factors may be conferred through the social stress of being different. Homophobia is the socialization of heterosexuals against members of the lesbian, gay, bisexual, and transgendered (LGBT) community. The strain of societal homophobia has been linked to increased rates in smoking, alcohol use, depression, HIV/AIDS, physical violence, and attempted suicide rates among LGBT individuals and occurs at a great cost to society (Goldberg, 2005).

Heterosexist attitudes permeate health-care environments and are manifested through avoidance, inappropriateness, and distance, which create an atmosphere of nondisclosure

of important health-related information to health-care providers. The assumption by health-care providers that heterosexuality is the relationship norm and any other variation is deviant makes it difficult and embarrassing for individuals to open up about their sexuality (Schuklenk & Smalling, 2013). Ignorance resulting from heterosexist assumptions has resulted in practitioners erroneously advising lesbians they cannot contract a sexually transmitted infection (STI) from a female partner or that screening for cervical cancer is not required. Evidence has demonstrated that lesbians who have had no history of sexual intercourse with males can have abnormal Pap smears (Goldberg, 2005).

Lesbian health is not completely the same as women's health because their lived experiences in the world are different (Goldberg, 2005). As a group, lesbian and bisexual women are less likely to have health-care insurance or access to health-care services. Those with access to care are less likely than heterosexual women to adequately use preventive health-care services because of fear of discrimination.

Providers have a professional and moral responsibility to treat all people with respect and dignity, regardless of their sexual orientation or preference. Providers working with the gay and lesbian community can use several helpful strategies to promote a positive environment. First and foremost, the provider must be aware of his or her own biases and be open, knowledgeable, and comfortable with sexual differences. This "gay positive" posture creates a safe atmosphere for disclosure of information so that appropriate diagnosis, treatment, and information can be provided to the patient. The provider should also reconsider how health histories are obtained. For example, consider creating a space for the client to document nonheterosexual relationships on written documents and modifying questions used to obtain information regarding sexuality. One method for acknowledging a current relationship status is to ask questions such as, "Are you at present in a relationship?" or "Who is your partner in your relationship?" In addition, an accepting physical environment can be achieved by having pamphlets about lesbian and bisexual health readily available. Finally, providers and others should avoid using euphemisms such as "special friend" when asking about the patient's partner (Goldberg, 2005).

Providers can obtain additional facts and information about gay and lesbian health-care issues from the Lesbian Health and Research Center at http://www.lesbianhealthinfo .org/ or the Gay and Lesbian Medical Association at http:// www.glma.org.

MEN AS PATIENTS

James Raper

Gender-related health disparity across the life span is significant for men. The Men's Health Network (2008) reports a number of disparities between males and females across their life spans. The male fetus is at greater risk for miscarriage and stillbirth, and male newborns have a 25% greater risk of mortality than do female newborns. Three-fifths of sudden infant death syndrome (SIDS) victims are boys. Men are 100% less likely to receive annual examinations and disease prevention services than are women. Men die at higher rates from the top 10 causes of death than do women. Men are 4 times more likely to commit suicide than women are. A total of 33% of men do not have health-care insurance, compared to 28% of women. Men account for 92% of deaths in the workplace. Men have fewer infection-fighting T cells and are thought to have weaker immune systems than women. Testosterone is linked to elevations of low-density lipids (LDLs) and declines in high-density lipids (HDLs). Men suffer hearing loss at twice the rate of women. Life expectancy of men is 5 years less than that of women; women

outnumber men 8 to 1 by age 100 years. Clearly, there is a need to address health specific to men.

Some government agencies, such as the Agency for Healthcare Research and Quality (AHRQ), address the need for greater dissemination of information about men's health issues. AHRQ's campaign Real Men Wear Gowns (www.ahrq.gov/realmen/) is an example of how to increase public awareness of the importance of men's health issues. These issues do not fare as well when compared to efforts to promote awareness of disease conditions affecting women. It is common to see diseases affecting women grouped under the identifier of women's health (www.qualityforum.org/Topics/Disparities.aspx). The paucity of literature pertaining to men's health, the glaring absence of health-care policies addressing men's health, and the lack of health-care options available for men underscore the need for a greater focus on men's health.

Even with age-adjusted mortality rates, men have higher death rates compared with women for the 15 leading causes

of death in the United States, except for Alzheimer's disease (Williams, 2003). The leading causes of death in men are heart disease, cancer, and unintentional accidents, whereas the leading causes of death in women are heart disease, breast cancer, and stroke (Centers for Disease Control and Prevention [CDC], 2007). According to the U.S. Department of Health and Human Services (2007), men are 2 1/2 times less likely to have seen a doctor than are women. The determinants of men's poorer health status arise from cultural and social beliefs about men, manhood, and masculinity. Although socioeconomic status (SES) is considered the strongest determinant of men's health (Williams, 2003), men from all SES groups are considered disadvantaged as compared with women. Other determinants of men's health are absence of work, marginality, poor emotional processing ability, cumulative adversity over a life span, and access to and use of health services. Little is known about men's perception of health and the influences of masculinity on health-care–seeking behaviors by men (Liburd, Namageyo-Funa, & Jack, 2007).

The cultural concept of masculinity begins with socialization at a young age. Edley and Wetherell (1996) define masculinity as a "shared understanding of what it means to be a man: what one looks like, how one should behave and so forth" (p 185). Masculinity directly affects health care and health-care choices. The socialization of men helps determine to what degree men respond to pain (Braithwaite, 2001), make health-care selections, engage in risk-taking behaviors, achieve effective self-care in the management of type 2 diabetes (Liburd et al, 2007), and adhere to medical plans of care (Brooks, 2001).

Although culture plays a significant role in masculinity, steroid hormones known as androgens affect the development of male-specific phenotype during embryogenesis; in the establishment of sexual maturation at puberty; and in the maintenance of the male reproductive function, spermatogenesis, and sexual behavior during adult life. These steroid hormones also affect a wide variety of functions in nonreproductive tissues, such as bone and skeletal muscle (Matsumoto, Shiina, Kawano, Sato, & Kato, 2008). Testosterone and its active metabolite dihydrotestosterone (DHT) exert most of their effects by binding to the androgen receptor (AR), a ligand-activated transcription factor that results in the control of gene transcription by the interaction of AR with coregulators and specific DNA sequences of androgen-responsive genes of the target cells. Because of the involvement of androgens in a large number of pathological processes, several synthetic steroidal and nonsteroidal AR ligands have been developed and are widely used in clinical applications, including the treatment of male hypogonadism (AR agonists), prostate diseases (AR antagonists), and others.

In this chapter, the basic effects of androgen deficiency on various organ systems; reported improvement of features of metabolic syndrome, bone mineral density, mood and sexual function; and the potential complications of testosterone treatment are presented. Symptoms related to androgen deficiency are presented as psychosomatic complaints, metabolic disorders, and sexual health problems. Patients suffering from one of these three constellations of symptoms may exhibit distinct features in terms of androgen levels, age, and body mass index. In addition to discussing testosterone-related health conditions of men as patients, the chapter discusses other common conditions requiring medication along with racial and cultural differences affecting men's health.

A number of health issues in men respond to pharmacological treatment. The natural decline in testosterone levels as men age or in adolescents with hypogonadism may respond to testosterone therapy. Erectile dysfunction may respond to phosphodiesterase type 5 (PDE-5) inhibitors. Benign prostatic hypertrophy, prostatitis, and male pattern hair loss may also respond to pharmacological intervention.

HYPOGONADISM

Hypogonadism, thought to be one of the main causes of male fertility problems, occurs in an estimated 13 million men in the United States. The exact prevalence is uncertain, because less than 10% of those affected by hypogonadism seek treatment. Hypogonadism refers to the failure of the testes to produce androgen, sperm, or both. Hypogonadism affects a man's fertility because the lack of testosterone makes it difficult for men to properly produce sperm. Furthermore, a low testosterone level can contribute to a low sex drive as well as erectile dysfunction.

Pathophysiology

Circulating testosterone is largely protein bound. The major protein is sex hormone–binding globulin (SHBG) with only 2% present as the biologically active or free fraction. The bioavailable fraction, representing testosterone loosely bound predominantly to serum albumin, is probably more meaningful. Hepatic SHBG production rises with aging and thyroid hormone excess and declines in hyperinsulinemic states (obesity and type 2 diabetes) so that free values may not always be concordant with total testosterone values. The biological effects of testosterone may be mediated directly by testosterone or by its metabolites, 5a-dihydrotestosterone or estradiol (Fig. 49-1).

Classifications

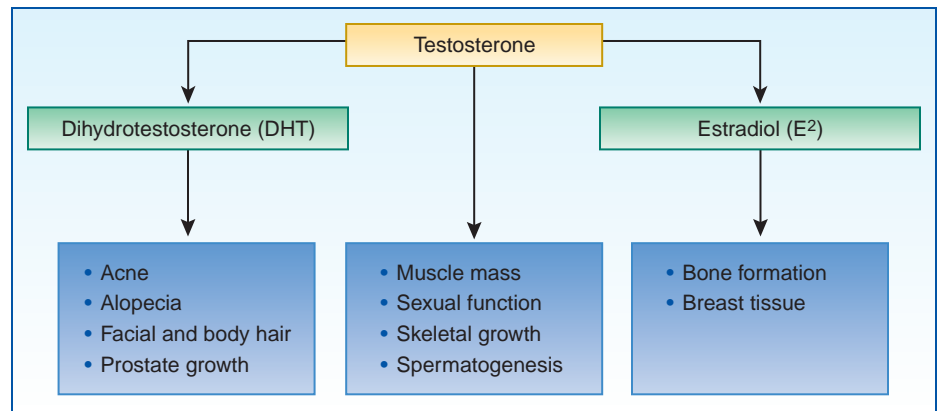
Men with classical hypogonadism are routinely classified into two categories: (1) those with primary hypogonadism (testicular failure) characterized by low testosterone and elevated gonadotropins and (2) those with secondary hypogonadism (hypothalamic-pituitary failure) with low testosterone and low or normal gonadotropins. Interestingly, a third category represents a significant proportion of older men who do not fit into either of the classical categories. These men are typically older and have high gonadotropins and testosterone within the normal range (Harkonen et al, 2003; van den Beld et al, 1999; Wu et al, 2008). This may represent a state of


Figure 49–1. Effects of testosterone and its metabolites in men.

compensated, or subclinical, hypogonadism that could eventually develop into overt primary hypogonadism. A similar, well-recognized situation occurs in the pituitary-thyroid axis when high TSH is observed in the face of normal thyroid hormone levels, a hallmark of subclinical hypothyroidism.

Deficient testosterone production can happen at any point during a man's life. Common causes of hypogonadism are displayed in Box 49-1. In some men, hypogonadism is a congenital abnormality, as the deficiency has been present from birth. For other men, the deficiency does not present itself until the onset of puberty. In some cases, a man may not develop the testosterone disorder until well into adulthood.

Testosterone production declines with advancing age; 20% of men older than 60 years and 30% to 40% of men older than 80 years have serum testosterone levels that would be subnormal in their younger adult male counterparts. This physiological decline in circulating testosterone levels is compounded in frequency by permanent disorders of the hypothalamic-pituitary-gonadal axis, including transient deficiency states associated with acute stressful illnesses, such as surgery and myocardial infarction, and the more chronic deficiency states associated with wasting illnesses, such as cancer and AIDS.

The underlying etiologies and clinical management of secondary and primary hypogonadism are different. It may be informative to differentiate older men who are candidates for the diagnosis of late-onset hypogonadism (LOH) into different categories of hypogonadism by coupling testosterone with luteinizing hormone (LH) levels. Specific risk factors or clinical features can differentiate between secondary, primary, and the new subclinical form of compensated hypo - gonadism (Lee et al, 2009). Age-related symptoms of LOH, such as decreased bone density, energy, muscle mass and strength, erectile function, mood, and libido, are reminiscent of typical androgen deficiency in symptomatic hypogonadism due to pituitary or testicular disease in young men (Snyder, 2004). Other common terms used to describe LOH are andropause, male menopause, and androgen deficiency syndrome of the aging male (ADAM).

Perhaps the minor contribution of adrenal androgens (or androgenic precursors) may substitute for testicular deficiency once the target tissues have been fully developed. Moreover, ingrained behavior patterns may be resistant to androgenic hormone deficiency. Certainly, prolactin excess, testosterone deficiency, or both in men may result in decreased libido and erectile dysfunction. The yield of finding hyperprolactinemia or testosterone deficiency, or both, in patients presenting with these symptoms is generally less than 5%. However, a large survey of patients with erectile dysfunction presenting to a Veterans Affairs center suggested that the prevalence of these abnormalities is substantial, with 18.7% of patients having low testosterone levels and 4.6% with elevated prolactin levels (Bodie, Lewis, Schow, & Monga, 2003).

Signs and Symptoms of Hypogonadism Across the Life Span

In instances of congenital hypogonadism, insufficient amounts of testosterone are produced by the gonads. This causes the developing fetus to have improperly formed external genitals and internal reproductive organs, resulting in the birth of a child whose sex is not entirely clear. Beginning at birth and through infancy, the persistent failure of the testes to descend may be an early manifestation of testicular dysfunction. In addition, a normally formed but hypotrophic penis may provide a clue to an abnormality of the hypothalamic-pituitary-gonadal axis. Later, during puberty, delayed, arrested, or absent testicular growth and secondary sexual characteristic development are hallmarks of pubertal disorders. Males starting puberty with a testosterone deficiency suffer from a variety of symptoms affecting almost every part of their normal growth and development. Because the body does not produce enough testosterone, the voice does not deepen and little muscle mass increase occurs, although there may be some development of the breasts. The penis and testicles also do not develop and mature, the growth of facial hair is inhibited, and arms and legs grow out of proportion to the trunk of the body. Skeletal proportions may be abnormal (eunuchoid) with more than a 5 cm difference between span and height and between pubis-floor and pubis-vertex dimensions. During adulthood, manifestations are generally more subtle.

When hypogonadism presents itself in adulthood, the physical appearance of the man can be significantly altered.

BOX 49–1   COMMON CAUSES OF PRIMARY AND SECONDARY HYPOGONADISM

Primary Hypogonadism

Cancer treatment. Chemotherapy or radiation therapy for the treatment of cancer can interfere with testosterone and sperm production. The effects of both treatments are often temporary, but permanent infertility may occur. Although many men regain their fertility within a few months after treatment ends, preserving sperm before starting cancer therapy is a consideration.

Hemochromatosis. Excess iron in the blood can cause testicular failure or pituitary gland dysfunction, affecting testosterone production.

Klinefelter syndrome. In this congenital abnormality of the sex chromosomes, X and Y, a male has two or more X chromosomes in addition to one Y chromosome. The Y chromosome contains the genetic material that determines the sex of a child and related development. In addition to other defects, the extra X chromosome causes abnormal development of the testicles, which in turn results in underproduction of testosterone.

Mumps orchitis. If a mumps infection involving the testicles (mumps orchitis) occurs during adolescence or adulthood, long-term testicular damage may occur. This may affect normal testicular function and testosterone production.

Normal aging. As men age, testosterone production slowly and continuously decreases. The rate of decline varies greatly among men. As many as 30% of men older than 75 years have a low testosterone level, according to the American Association of Clinical Endocrinologists. The value of treatment is controversial.

Trauma to the testicles. The testicles are prone to injury. Damage to normally developed testicles can cause hypogonadism. Damage to one testicle may not impair testosterone production.

Undescended testicles. Before birth, the testicles develop inside the abdomen and normally move down into their permanent place in the scrotum. Sometimes, one or both of the testicles do not descend at birth. This condition often corrects itself within the first few years of life without treatment. If not corrected in early childhood, it may lead to malfunction of the testicles and reduced production of testosterone.

Secondary Hypogonadism

HIV/AIDS. This virus can cause low levels of testosterone by affecting the hypothalamus, the pituitary, and the testes.

Inflammatory disease. Certain inflammatory diseases, such as sarcoidosis, histiocytosis, and tuberculosis, involve the hypothalamus and pituitary gland and can decrease testosterone production.

Kallmann syndrome. Abnormal development of the hypothalamus can cause hypogonadism. This abnormality is also associated with impaired development of the ability to smell (anosmia).

Medications. Certain drugs and some hormones can affect testosterone production.

Obesity. Being significantly overweight at any age may be linked to hypogonadism.

Opioid users. Commonly prescribed opioids in sustained-action dosage forms usually produce subnormal sex hormone levels, which may contribute to a diminished quality of life for many patients with painful chronic illness.

Pituitary disorders. An abnormality in the pituitary gland can impair the release of hormones from the pituitary gland to the testicles, affecting normal testosterone production. A pituitary tumor or other type of brain tumor located near the pituitary gland may cause testosterone or other hormone deficiencies. Surgery or radiation therapy for the treatment of brain tumor may impair pituitary function and cause hypogonadism.

Normal reproductive functioning may cease, while emotionally a man can exhibit changes similar to those of menopausal women. Symptoms of this type of hypogonadism may include depression, development of male breasts, erectile dysfunction, failure of facial and body hair to grow, increase in body fat, loss of energy, inhibited sexual desire, loss of muscle mass; menopausal emotions including hot flashes, irritability and mood swings; onset of osteoporosis; and shrinking and softening of the testicles.

Hypogonadism affects a man's fertility because the lack of testosterone makes it difficult for men to properly produce sperm. Male factor infertility is likely to be responsible for one-third of the 10% to 15% of couples who are unable to conceive within 1 year of unprotected intercourse. Most of these male-associated cases result from diminished, absent, or faulty spermatogenesis. In addition to abnormal sperm production, other associated conditions causing infertility include obstructive ductal disease, epididymal hostility, immunological disorders, and erectile or ejaculatory dysfunction. Furthermore, a low testosterone level can contribute to a low sex drive as well as erectile dysfunctions.

Older Men

The aging man represents a special case. There is a well-known decline in testosterone production with age in otherwise healthy men. This decline in mean testosterone values can be seen in free testosterone levels, beginning in the

mid-40s (some clinicians suggest even earlier), as a consequence of increasing sex hormone–binding globulin levels. The physiological mechanism for this is unknown. Total testosterone levels decline on average beyond 70 years. The diurnal rhythm is lost beyond 60 years. Although testicular size also declines in this age group, spermatogenesis may be well maintained into the 80s or even beyond. Gonadotropin levels tend to rise after 70 years, indicating that the testosterone deficiency is usually primary. Using the criterion of a low testosterone value, and remembering that commercially available tests have considerable variability regarding normal young-adult ranges, an estimated 7% of 40- to 60-year-olds, 22% of 60- to 80-year-olds, and 36% of 80- to 100-year-olds are hypogonadal (Vermeulen & Kaufman, 1995).

Increased longevity and population aging will increase the number of older men with LOH. The condition is common but often underdiagnosed and undertreated. Although controversy remains regarding indications for testosterone supplementation in aging men because of lack of large-scale, long-term studies assessing the benefits and risks of testosterone replacement therapy (TRT), reports indicate that TRT may produce a wide range of benefits for men with hypogonadism that include improvement in body composition, bone density, cardiovascular (CV) disease, cognition, erythropoiesis, libido and sexual function, mood, muscle mass, and quality of life. The ultimate issue as to whether these changes are normal and physiological or should be considered pathological, thus demanding therapy, remains unresolved. Indeed, it is a situation analogous to the ongoing dilemma of hormone replacement therapy for postmenopausal women, although in women the hormonal deficiency state is usually more abrupt and symptomatic.

In the largest double-blind, placebo-controlled interventional study of testosterone replacement in elderly men to date, Srinivas-Shankar and colleagues (2010) report that for intermediate-frail and frail elderly community-dwelling hypogonadal men at least 65 years of age, TRT prevents deterioration in muscle strength and improves body composition and symptom-related quality of life. Furthermore, TRT was associated with improved physical function in older and frailer men, highlighting possible functional consequences of small changes in physical performance.

Diagnosis

A biochemical diagnosis of low testosterone is dependent on accurate measurement. Serum testosterone has a well-known diurnal rhythm that appears to be lost when a man reaches age 60 years. Because testosterone values are 30% or so higher near 8 a.m. versus the later day trough, a testosterone value should be determined first thing in the morning. Although normal testosterone ranges vary among reference laboratories, the usually quoted range for young men is 300 to 1,000 ng/dL. In general, values below 220 to 250 ng/dL are clearly low in most laboratories; values between 250 and 350 ng/dL should be considered borderline low. Because the acute effect of stressful illness may result in a transient lowering of testosterone levels, a

confirmatory early morning specimen should be obtained. Measurement of free testosterone levels or bioavailable testosterone levels, determined adequately in some reference laboratories, may provide additional information. Free testosterone levels may be lower than expected from the total testosterone level as a result of aging and higher than expected in insulin-resistant individuals, such as in the case of obesity. In addition, serum follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin levels should be used to help determine the cause of hypogonadism.

If gonadotropin levels are not elevated, despite clearly subnormal testosterone values, anterior pituitary (thyroid-adrenal) function should be determined by measuring free thyroxine and thyroid-stimulating hormone levels, as well as an early morning cortisol level. A magnetic resonance imaging (MRI) scan of the brain and sella should be considered. An exception to this recommendation is the condition of morbid obesity, in which both total and free testosterone levels are typically low and gonadotropin values not elevated. Hyperprolactinemia, even of a small degree, may also warrant ordering an MRI, because interference of hypothalamic-pituitary vascular flow by space-occupying, stalk-compressing lesions will lead to disruption of the tonic inhibitory influence of hypothalamic dopamine and result in modest hyperprolactinemia (20 to 50 ng/mL range). Semen analysis should be performed when fertility is in question.

TESTOSTERONE REPLACEMENT THERAPY

Pharmacodynamics

Restoring testosterone levels to within the normal range by using testosterone replacement therapy (TRT) can improve many of the effects of hypogonadism (Table 49-1). Gooren (2010) presents a review of clinically based evidence from the past decade that denotes the benefits of TRT on multiple target organs of hypogonadal men. The review provides a comprehensive appraisal of the well-substantiated benefits of clinically indicated TRT and areas that need additional investigation.

Anemia

Endogenous androgens are known to stimulate erythropoiesis; increase reticulocyte count, blood hemoglobin levels, and bone marrow erythropoietic activity in mammals, whereas castration has opposite effects. Hypogonadism results in a 10% to 20% decrease in the blood hemoglobin (Hgb) concentration that can result in anemia. Young hypogonadal men usually have fewer red blood cells and lower Hgb levels than do age-matched controls.

Bone Mineral Density

Osteopenia, osteoporosis, and fracture prevalence rates are higher in hypogonadal men because testosterone plays a major role in bone density (BMD). The prevalence of osteoporosis in hypogonadal males is twice that of those of eugonadal men.

Table 49–1 Postpubertal Hypogonadal-Related Problems and Effectiveness of Testosterone Replacement

Postpubertal Problems Associated With Hypogonadism	Evidence of Improvement With Administration of Testosterone
Decreased bone mineral density	Increased bone mineral density
Decreased cognitive function	Increased cognitive function
Decreased energy, mood, and quality of life	Increased energy, mood, and quality of life
Erectile dysfunction	Increased sexual function
Decreased hematocrit and hemoglobin concentrations	Increased hematocrit and hemoglobin concentrations
Decreased muscle mass	Increased muscle mass
Decreased prostate glands	Increased prostate gland size—prostate symptom score, urine flow rate, and postvoiding residual urine in the bladder after voiding did not change significantly*
Decreased sexual desire	Increased libido

*Snyder et al, 2000.

Bone density in hypogonadal men of all ages increases under appropriately dosed TRT, although normal adult bone mass is not achieved. Testosterone produces this effect by increasing osteoblastic activity and through aromatization to estrogen-reducing osteoclastic activity. Part of testosterone's effect on bone is at least partially indirect, mediated via its aromatization product estradiol. Patients with prostate cancer treated with androgen deprivation therapy have an increased risk of osteoporotic fracture. The role of LOH in bone fracture rate in aging males is not known.

The long-term benefit of TRT requires further investigation. Trials of the effects of TRT on BMD yield mixed results. The pooled results of a meta-analysis suggest a beneficial effect on lumbar spine bone density and equivocal findings on femoral neck BMD. Trials of intramuscular testosterone reported significantly larger effects on lumbar bone density than trials of transdermal testosterone, particularly among patients receiving chronic glucocorticoids. No studies have been powerful enough to show a reduction in fracture risk with TRT.

Cognitive Function

Age-related decreases in testosterone predict an age-related decline in visual and verbal memory. Evidence exists for a correlation between testosterone levels and cognitive performance, such as spatial abilities or mathematical reasoning. Higher free testosterone concentrations are associated with better performance in specific aspects of memory and cognitive function, optimally in men ranging from 35 to 90 years of age, even after adjustment for age, educational attainment, and CV morbidity. Total testosterone does not consistently have the same associations. Suppression of endogenous testosterone synthesis and blockade of the androgen receptor in men undergoing hormonal therapy for prostate cancer result in a beneficial effect on verbal memory but an adverse effect on spatial ability and slowed reaction time. There is no definitive proof of the beneficial effects of restoring testosterone levels to normal in elderly men.

Trials of TRT in men to evaluate its effects on measures of cognitive function and memory are relatively small, are of a short duration, and show mixed results (Beauchet, 2006; Hogervorst, Bandelow, Combrinck, & Smith, 2004). Testosterone treatment in men aged 34 to 70 years improved verbal memory, spatial memory, and constructional abilities in nonhypogonadal men with mild cognitive impairment and Alzheimer's disease (Cherrier, Craft, & Mastsumoto, 2003; Cherrier et al, 2005). In one study of healthy men aged 50 to 90 years, testosterone alone or in combination with the aromatase inhibitor anastrozole improved spatial memory, but verbal memory only improved in testosterone-treated men in the absence of anastrozole (Cherrier et al, 2005). This raises the possibility that part of the effect of exogenous testosterone is mediated by its aromatization to estradiol. Whereas the results from these observational studies are not uniform, it appears that lower free testosterone is associated with poorer outcomes on measures of cognitive function, particularly in older men, and that testosterone therapy in hypogonadal men may have some benefit in cognitive performance.

Lower Urinary Tract Symptoms

In addition to improvement in sexual function, TRT may also improve lower urinary tract symptomatology and bladder functions by increasing bladder capacity and compliance and decreasing detrusor pressure at maximal flow in men with LOH.

Metabolic Syndrome and Type 2 Diabetes

Dyslipidemia-impaired glucose regulation, hypertension, insulin resistance, and obesity (all components of the metabolic syndrome) are also present in hypogonadal men. Lower testosterone levels are associated with surrogate markers for CV disease, including less favorable carotid intimal medial thickness, ankle/brachial index as a measure of peripheral arterial disease, and calcific aortic atheroma. There is a positive correlation between serum testosterone levels and insulin sensitivity in men across the full spectrum of glucose tolerance.

Improvement of insulin sensitivity is noted after TRT. The effects of TRT, diet, and exercise on glycemic control of men with diabetes mellitus indicate a favorable effect. By increasing lean body mass and reducing fat mass, testosterone therapy modulates insulin resistance and risk of metabolic syndrome. The mechanism of the fall in lipids may be related to the decrease in the visceral abdominal fat mass under the influence of testosterone, which inhibit lipoprotein lipase activity and increase lipolysis, with improvement of insulin sensitivity and mobilization of triglycerides from abdominal fat tissue. Hypogonadism is associated with an increased risk of CV disease in men (Muller et al, 2004). However, data are lacking as to whether higher testosterone levels predict reduced incidence of combined nonfatal and fatal major CV events. The inverse correlation between testosterone levels and the severity of coronary artery disease may be related to the fact that low testosterone levels are accompanied by an accumulation of abdominal visceral fat associated with increased CV risk factors, impaired glucose tolerance, and non-insulin-dependent diabetes mellitus (Caminiti et al, 2009).

Cardiovascular Disease

TRT does not increase the incidence of CV disease, myocardial infarction, stroke, or angina. The evidence supports no association between TRT and cardiac events. However, trials of TRT generally have not been designed or adequately powered to detect effects on clinically significant CV events. The outcome of most studies in men report either a favorable or neutral effect of normal testosterone levels on CV disease in men (Caminiti et al, 2009). TRT at physiological concentration increases coronary blood flow in patients with coronary heart disease. Beneficial effects on endothelial function and myocardial ischemia have been demonstrated, but not on CV mortality. Thus, although lower testosterone levels are associated with higher CV risk and mortality in aging men, adequately powered, randomized controlled clinical trials are needed to determine whether TRT will reduce morbidity and mortality from CV disease in hypogonadal or eugonadal men.

Mood and Energy and Quality of Life

Hypogonadal men older than 50 years report decreased quality of life, including common complaints of dysphoria, fatigue, loss of libido, and irritability (Wang et al, 2004; Wang et al, 2000). These symptoms coincide with signs and symptoms of major depression. There is significant inverse correlation between free testosterone levels (but not with total testosterone) and a depression score in elderly men, regardless of age and weight. There are reduced libido and reduced feelings of well-being with hypogonadism; the depressive symptoms during the hypogonadal state are reversed by TRT. Men who received TRT report variable effects on mood, energy, and sense of well-being.

TRT at physiological doses to nondepressed eugonadal men does not result in significant effects on mood (Haren, Wittert, Chapman, Coates, & Morley, 2005; Tricker et al, 1996). In hypogonadal men, testosterone replacement was associated with improved mood and well-being and reduced fatigue and irritability. Randomized controlled trials of TRT in men without or with underlying chronic illness report equivocal improvements in quality-of-life measures, including fatigue and general well-being (Gruenewald & Matsumoto, 2003; Livermann & Blazer, 2004).

For patients with major depression and/or dysthymia, improvement was equal to that achieved with standard antidepressants with significant improvement in the depression inventory score. This effect may be a direct effect of testosterone or related to positive effects of testosterone on weight and/or other anthropometric measures. Additional research is needed to assess the effects of TRT on clinical depression in patients with human immunodeficiency virus. No relationship between testosterone level and depressive symptoms was found in the Massachusetts Male Aging Study (Harkonen et al, 2003; Seidman, Araujo, Roose, & McKinlay, 2001). Gooren (2010) postulates that the discrepancy in the results of the effects of TRT on mood is the result of a genetic polymorphism in the androgen receptor that defines a vulnerable group in whom depression is expressed when testosterone levels fall below a particular threshold.

Muscle Mass and Strength

Aging is accompanied by significant changes in body composition as evidenced by decreased fat-free mass and increased and redistributed fat mass. These changes may impose functional limitations and increase morbidity. Maximal muscle strength correlates with muscle mass independently of age. In men, declining testosterone levels that occur with aging can contribute to these changes by direct effect on muscle cells or by stimulating IGF-1 expression directly and indirectly, leading to increased muscle protein synthesis and growth. There is a correlation between free testosterone concentrations and fat-free mass; however, the correlation with grip strength is not clear.

TRT may reverse age-dependent body composition changes and associated morbidity. TRT improves body composition: a decrease of fat mass and an increase of lean body mass. In many studies, body weight change did not differ significantly (Morley et al, 1993; Page et al, 2005; Sih et al, 1997). TRT was associated with a greater improvement in grip strength than a placebo. Research supports the benefits of TRT on skeletal muscle performance in elderly men with chronic heart failure and its positive effects on the prevention of loss of muscle strength of the lower limbs (Caminiti et al, 2009; Srinivas-Shankar et al, 2010). Although TRT is promising for improving muscle mass in some patients, changes in lower-extremity muscle strength and measures of physical function are inconsistent.

In aging men, positive correlations between testosterone and muscle strength parameters of upper and lower extremities also exist, as measured by leg extensor strength and isometric hand-grip strength (Srinivas-Shankar et al, 2010). Testosterone replacement is positively associated with functional parameters, including the doors test as well as the "get up and go" test and the 5-chair sit/stand test. Although increase in lean body mass has been observed, there is no proof

of increase in physical function or in strength of knee extension or flexion. Although a potential role for TRT in the management of frailty exists, whether testosterone replacement improves physical function and other health-related outcomes or reduces the risk of disability, falls, or fractures in older men with low testosterone levels is unknown.

Sexual Desire, Function, and Performance

The prevalence of erectile dysfunction (ED) increases with age. Free testosterone is correlated with erectile and orgasmic function. Compared with younger men, elderly men require higher levels of circulating testosterone for libido and erectile function. Decreased libido, with or without hypogonadism, might be related to other comorbidities or medications.

Men with ED or decreased libido and documented hypogonadism may benefit from TRT. Adequate TRT can restore venous leakage in the corpus cavernosum, a condition that is a frequent factor in ED in elderly men. Research indicates some benefit of TRT on sexual health-related outcomes (Krause, Mueller, & Mazur, 2005). Long-term follow-up of TRT in hypogonadal males indicates that self-assessment of libido is higher with TRT (Bhasin et al, 2010). TRT also enhances libido and the frequency of sexual acts and sleep-related erections (Bhasin et al, 2010). Transdermal TRT is linked to positive effects on fatigue, mood, sexual function, and increases in sexual activity. In the presence of a clinical picture of hypogonadism and borderline testosterone levels, a short therapeutic trial may be reasonable. Evidence indicates that the combined use of testosterone and PDE-5 inhibitors in hypogonadal or borderline eugonadal men have a synergetic effect (Shabsigh, Kaufman, Steidle, & Padma-Nathan, 2004). The combination treatment should be considered in hypogonadal patients with ED failing to respond to either single treatment. Testosterone produces this effect by enhancing the production of nitric oxide synthase.

Testosterone Clinical Use and Dosing

Testosterone replacement therapy is relatively straightforward. See Table 49-2 for testosterone preparations available in the United States. Typically, the depot esters are administered parenterally by an intramuscular (IM) or subcutaneous (SQ) route. Testosterone cipionate (Depo-Testosterone) is the only IM form available in the United States. It is administered once every 2 weeks at a dose of 200 mg in adult men. An SQ slow-release pellet (Testopel) is the other parenteral option. The pellets have 75 mg of testosterone. Usually 8 to 14 pellets are inserted SQ in the buttock area, which then provides coverage for 3 to 6 months (Cavender & Fairall, 2009). A usual dosage for the transdermal or the buccal preparations results in the systemic absorption of 2.5 to 10 mg daily.

If the parenteral IM route is chosen, patients should and can be taught to self-inject. The major disadvantage with the IM parenteral route is that testosterone levels exhibit a saw-toothed pattern, with high-normal or supranormal levels on days 2 to 4 and low-normal or borderline-low trough values before the next injection. Mood, sense of well-being, and libido may vary accordingly in some individuals. Dosages may be adjusted by aiming for midnormal (400 to 600 ng/dL) testosterone levels after 1 week or at the low end (250 to 350 ng/dL) just before the next injection is due at 2 weeks. The insertion procedure for the testosterone pellets is simple with a short learning curve. Limited compliance issues and the elimination of risk of transdermal transmission of drug to others are distinct benefits for the use of pellets. However, disadvantages include wound infection and pellet extrusion, seen in 0.3% to 12% of patients in various studies (Cavender & Fairall, 2009).

Patches are applied daily and are rotated to different sites with minimal risk for skin transmission to others, although use may be limited by site dermatitis. Three hydro-alcoholic gel formulations are currently available in the United States: Androgel (1% or 1.62%), which is applied to the chest or the shoulders; Fortesta (2%), which is applied to the thighs; and

Table 49–2 ❖ **Testosterone Preparations Available in the United States for Replacement in the Hypogonadal Male**

Drug	Dose
Buccal (Striant)	30 mg to the gum region twice daily (q12h)
Intramuscular Depot esters—testosterone cypionate (Depo-Testosterone), enanthate (Delatestryl), propionate, phenylpropionate, isocaproate, decanoate, acetate	50–400 mg administered every 2–4 weeks
Subcutaneous pellets (Testopel)	10–15 pellets every 3–6 months
Topical gel (AndroGel 1% or 1.62% , Testim)	5–10 mg (1–2 packets/tubes or 1–8 pumps depending on concentration) once a day to clean, dry, intact skin of shoulders and/or upper arms or abdomen
Topical gel (Fortesta 2%)	40 mg (4 pump actuations) applied once daily to the inner and anterior thighs
Topical genital skin patch (Testoderm)	6 mg/d applied to scrotal area and worn for 22–24 h
Topical liquid (Axiron)	30–90 mg (2–4 pumps) once daily to axillae
Topical nongenital skin patch (Androderm)	5 mg/d applied once daily to clean, dry, intact skin of the shoulders, upper arm, or abdomen

Testim 1%, which is applied to the shoulders. A new liquid preparation, Axiron, is applied to the axillae. Because secondary transfer to women and children is possible, it is important to thoroughly wash hands after application and to cover the treated skin with clothing. In 3 to 4 hours, all the medication is absorbed, and the area should then be washed before direct skin contact with others.

Testosterone values become stable within a few days or weeks after initiation of the buccal, liquid, gel, or patch preparation. It should be ascertained whether the preparation was actually used on the day that the sample was drawn. A testosterone value in the midnormal range (400 to 600 ng/dL) is the goal. Although comparable testosterone levels are reached via the patch and the gels, skin reactions at the application site are much more common with patch use. Because of the very high cost associated with transdermal preparations, many insurance plans do not include them on their formularies or require prior authorization. The buccal preparation is difficult for some patients to use because of gum irritation, pain, tenderness, and/or swelling. Alkylated oral androgens should be viewed as potentially hepatotoxic and should not be used. Criteria for the selection of testosterone preparations are summarized in Table 49-3.

Risks and Contraindications

The most controversial issue related to TRT is associated risk (Bassil, Alkaade, & Morley, 2009; Bhasin et al, 2010). Erythrocytosis is a recognized risk of TRT; therefore, hemoglobin (Hgb) and hematocrit (Hct) levels should be checked periodically. Incremental increases are to be expected in the first 6 months of treatment, but an Hgb level higher than 17.5 g/dL, Hct higher than 54%, or both suggests overtreatment or occasionally abuse. Greater increments tend to occur more frequently with the IM preparations than with the transdermal. If the Hct is greater than 54%, therapy is stopped until the Hct decreases to a safe level. The patient should also be evaluated for hypoxia and sleep apnea (Bhasin et al, 2010). Restarting therapy at a reduced dose usually solves problems.

There is a risk of prostate cancer with the use of testosterone replacement. The Endocrine Society lists detection of subclinical prostate cancer and growth of metastatic prostate cancer as known risks of TRT (Bhasin et al, 2010). The Endocrine Society advises avoiding TRT in patients with

metastatic prostate cancer or breast cancer (Bhasin et al, 2010). A digital rectal examination and PSA should be monitored throughout therapy. A urological consultation should be obtained if indicated by prostate symptom score, decreased urine flow rate, or postvoiding residual urine.

Additional risks of TRT have been identified. There is evidence of decreased sperm production and infertility reported by the Endocrine Society among men receiving TRT (Bhasin et al, 2010). Boys receiving TRT may experience acne and gynecomastia. The most serious risks of TRT in adolescents are aggressive behavior and premature closure of the epiphyses, leading to permanent short stature (Snyder, 2010).

Consideration of a number of clinical situations makes the risk of TRT an absolute or relative contraindication. Potential risks and contraindications are presented in Table 49-4. Clinical studies in large numbers of patients (either young or old) are limited, so potential risks and benefits should be individualized. Pierorazio and colleagues (2009) report that higher levels of serum-free testosterone are associated with an increased risk of aggressive prostate cancer among older men. Their data highlight the importance of prospective trials to ensure the safety of TRT in men older than age 65.

Drug-Drug Interactions

A total of 111 drugs (467 brand names and generics) are known to interact with testosterone (Drug Information Online, 2012). Of these, five medications have major interactions. The five high-risk medications are anisindione, dicumarol, leflunomide, teriflunomide, and warfarin. Using testosterone with any of these medicines is usually not recommended but may be required in some cases. Dose adjustment may be required for one or both of the interacting medicines. See Chapter 22 for further discussion of drug interactions with reproductive drugs, including testosterone.

Monitoring

The Endocrine Society recommends monitoring the following in men receiving testosterone replacement therapy (Bhasin, et al, 2010):

1. Evaluate the patient 3 to 6 months after treatment is started to determine efficacy in treating symptoms and if there are any adverse effects.

Table 49–3 Comparison of Testosterone Replacement Therapies

	Buccal	Intramuscular	Subcutaneous	Topical Gels & Liquids	Topical Patch
Convenience	Yes	No	Yes, but requires surgical intervention	Yes	Yes
Cost	High	Low	High	Very high	High
Physiological	Yes	No (sawtooth)	Yes	Yes	Yes
Side effects	Local, moderate	Systemic and local	Local, risk of pellet migration or extrusion	Local, minimal	Local, moderate
Stigma	No	No	No	No	Yes

Alkylated oral androgens should be viewed as potentially hepatotoxic and should not be used.

Table 49–4 **Contraindications and Associated Potential Risk for Testosterone Replacement Therapy**

Parameter	Contraindication vs. Potential Risk
Abnormal digital rectal examination	Contraindication
Breast carcinoma (history or presence)	Contraindication
Elevated levels of prostate-specific antigen	Contraindication
Erythrocytosis	Risk
Exacerbation of sleep apnea	Risk
Gynecomastia	Risk
Hypercoagulable states	Contraindication
Liver toxicity and liver tumor	Risk
Polycythemia (hematocrit >51%)	Contraindication
Prostate carcinoma (history or presence)	Contraindication
Psychopathology	Contraindication
Severe benign prostatic hyperplasia	Contraindication
Severe coronary heart failure (class III or IV)	Contraindication
Skin diseases	Risk
Stimulate growth of prostate cancer and breast cancer	Risk
Testicular atrophy and infertility	Risk
Untreated sleep apnea	Contraindication
Worsen symptoms of benign prostatic hypertrophy	Risk

2. Evaluate the patient's testosterone level 3 to 6 months after starting therapy. The goal is the midnormal range.
   a. Injectable testosterone: measure levels midway between injections.
   b. Transdermal patches: measure levels 3 to 12 hours after applying patch.
   c. Buccal testosterone: measure immediately after applying a new dose.
   d. Testosterone pellets: measure at the end of therapy.
   e. Oral testosterone: measure 3 to 5 hours after ingestion.
3. Evaluate hematocrit at baseline, at 3 and 6 months, then annually.
4. Evaluate bone mineral density after 1 to 2 years of therapy.
5. Evaluate PSA levels and perform a digital rectal exam prior to beginning therapy, at 3 and 6 months, then per age-related guidelines for prostate cancer screening.

Obtain a urological consultation if there are concerns about response to therapy, an increase in PSA levels of greater than 1.4 ng/mL in a 12 month period, or if any prostatic abnormality is palpated on rectal exam (Bhasin et al, 2010).

Patient Education

TRT should not replace healthy lifestyle changes. There has been a significant increase in the initiation of TRT for nonspecific symptoms of LOH in aging, androgen-deficient men. With this increase in TRT, there is a risk of overtreating. While there are many encouraging associations between treatment of androgen deficiency and improvement in rates of morbidity and mortality, much remains unknown about the overall long-term risks and benefits of TRT. It is important to remember that TRT should not replace healthy lifestyle changes, including smoking cessation, regular exercise, weight loss, and diet modifications that may provide the patient symptom resolution. It is important to have a thoughtful dialogue with the patient before the initiation of TRT. This conversation should include thorough disclosure of the risks and benefits of treatment and the limitations of the data as it evolves.

COMMON PROBLEMS THAT REQUIRE MEDICATIONS

Erectile Dysfunction

Erectile dysfunction (ED) is a common sexual problem in men. The incidence increases with age and affects up to one-third of men at some time during their lives. ED causes a substantial negative impact on intimate relationships, quality of life, and self-esteem. Treatment includes phosphodiesterase type 5 (PDE-5) inhibitors or TRT, if appropriate. Penile self-injection and vacuum-assisted erection devices are not discussed in this chapter, as these are usually prescribed by urological specialists. Cognitive behavior therapy and therapy aimed at improving relationships may also help to improve ED (Heidelbaugh, 2010).

Pathophysiology

Normal erections require a complex interaction between hormonal, vascular, neurological, and psychological systems (Spark, 2011). Any disruption in any of these systems may cause ED. Risk factors for ED include chronic illnesses such as diabetes mellitus, hypertension, obesity, dyslipidemia, and cardiovascular disease (Spark, 2011). Smoking and medication use may also contribute to development of ED. Because there is no preferred first-line diagnostic test, in most cases history and physical examination are sufficient to make a diagnosis. Initial diagnostics are usually limited to a fasting serum glucose level and lipid panel, morning total testosterone level, and thyroid-stimulating hormone test. Screening for CV risk factors should be considered in men with ED because symptoms of ED present on average 3 years earlier than symptoms of coronary artery disease (Heidelbaugh, 2010).

Phosphodiesterase Type 5 (PDE-5) Inhibitors

Pharmacodynamics

First-line therapy for ED consists of lifestyle changes, modifying drug therapy that may cause ED, and pharmacotherapy with PDE-5 inhibitors. PDE-5 inhibitors are the most effective oral drugs for treatment of ED, including ED associated

with antidepressants, diabetes mellitus, and spinal cord injury. There are three PDE-5 inhibitors available: sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis). One aspect of a normal erection is the release of nitric oxide in the corpus cavernosum during sexual stimulation. Catabolism of cyclic GMP (guanosine monophosphate) is responsible for detumescence. The PDE-5 inhibitors work by blocking the catabolism of cyclic GMP. Blocking cyclic GMP results in an increased number and duration of erections in men with ED.

PDE-5 inhibitors are indicated for the treatment of ED. They vary in onset and duration of action (see Table 49-5 for dosing). Sildenafil and vardenafil have a 4-hour duration of effectiveness. Tadalafil may assist men with ED to have an erection in response to sexual stimulation for up to 36 hours after a single dose. Sildenafil and vardenafil should be taken on an empty stomach, as high-fat meals or alcohol will delay absorption. Tadalafil absorption is not affected by food or alcohol. Sildenafil has the longest safety record of the three (Spark, 2010).

Risks and Contraindications

PDE-5 inhibitors are contraindicated in patients sensitive to any component of the medication.

There is a potential for fatal hypotension if PDE-5 inhibitors are taken concurrently with nitrates (nitroglycerine).

Patients with cardiovascular disease, including acute myocardial infarction, stroke, or life-threatening arrhythmia within the past 6 months should not be prescribed PDE-5 inhibitors. Unstable angina, severe heart failure or prolonged QT, hypotension (systolic blood pressure less than 90 mg Hg), or hypertension (blood pressure greater than 170/110) requires caution in prescribing PDE-5 inhibitors.

Priapism is a rare occurrence. If the patient has an erection lasting longer than 4 hours, he should seek medical care.

Although PDE-5 inhibitors are specific for PDE-5, there have been reports of visual disturbances in some users of PDE-5 inhibitors most likely related to type 6 phosphodiesterase, which is required for the transformation of light into electrical signals.

PDE-5 inhibitors have been associated with rare reports of sudden hearing loss of unknown etiology. The hearing loss is temporary in one-third of patients and ongoing for the remaining patients (Spark, 2010). The U.S. Food and Drug Administration (FDA) is monitoring reports of hearing problems and any new hearing loss in patients who experience hearing problems while taking PDE-5 inhibitors; these cases should be reported to MedWatch (www.fda.gov/safety/medwatch).

Drug-Drug Interactions

The most concerning drug interactions with the PDE-5 inhibitors are the vasodilators, specifically the nitrates or nitroprusside.

Coadministration with alpha blockers may lead to additive hypotension. If coadministration is being considered, the patient should be stable on his dose of alpha blocker before considering PDE-5 inhibitors. The lowest dose of a PDE-5 inhibitor should be used and the patient monitored closely for hypotension.

PDE-5 inhibitors may interact with any of the antihypertensives and cause additive hypotension.

PDE-5 inhibitors should not be given concurrently with class 1A or III antiarrhythmics or drugs that cause prolonged QT interval.

Plasma levels of PDE-5 inhibitors may be increased by CYP3A4 inhibitors.

Monitoring

There is no specific laboratory monitoring for PDE-5 inhibitors. Patients should report symptoms of hypotension and any changes in self-monitored blood pressure readings.

Patient Education

Patients should be educated regarding the proper use of PDE-5 inhibitors. Drug interactions, specifically nitrates and other antihypertensives, should be discussed. Adverse drug reactions including priapism and visual and hearing disturbances should be explained and the patient advised to seek care if these occur.

Table 49–5 ❀ Dosing Schedule of PDE-5 Inhibitors

Drug Name	How Supplied	Dose
Sildenafil (Viagra)	25, 50, 100 mg tablets	Initial dose 50 mg Take 1 dose as needed 1–4 hours before sexual activity, up to once daily. Decrease dose to 25 mg in patients with hepatic or renal impairment, or coadministration with CYP3A4 inhibitors.
Tadalafil (Cialis)	2.5, 5, 10, 20 mg tablets	As needed dosing: Initial dose 10 mg Take 1 dose as needed before sexual activity. May increase dose to 20 mg. May last up to 36 hours. Higher dose should not be used daily. Daily dosing: 2.5 mg taken at the same time each day. May increase dose to 5 mg daily.
Vardenafil (Levitra)	2.5, 5, 10, 20 mg tablets	Initial dose 10 mg Take 1 dose as needed 1–4 hours before sexual activity, up to once daily. Decrease dose to 5 mg in patients with hepatic or renal impairment, or coadministration with CYP3A4 inhibitors.

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia affects the prostate, a male sex gland beneath the urinary bladder. A donut-shaped gland, the prostate encircles the urinary outlet, or urethra. Contraction of the muscles in the prostate squeezes fluids into the urethral tract during ejaculation. An enlarged prostate is not cancerous but can cause disability and even serious illness if left untreated. When the prostate becomes too large, it presses against the urethral canal and interferes with normal urination. As a result, urine may back up in the kidneys, subsequently damaging them by excessive pressure and contaminated urine. Bladder infections such as cystitis commonly occur as well.

These lower urinary tract symptoms (LUTS) are a common complaint among aging men: 8% of men aged 31 to 40 years, 50% in those aged 51 to 60 years, 70% in those aged 61 to 70 years, and 90% in those aged 81 to 90 years (Laborde & McVary, 2009). The symptoms are often caused by benign prostatic hyperplasia (BPH) and include nocturia, burning, decreased urine flow rates, difficulty in starting and stopping urination, hesitancy, incomplete bladder emptying, pain, progressive urinary frequency, urgency, and urinary frequency. A number of medical treatments for LUTS/BPH exist, such as alpha blockers (discussed in Chapter 14), 5-alpha-reductase inhibitors (discussed in Chapter 22), anticholinergics (discussed in Chapter 14), PDE-5 inhibitors, and combination therapies.

The science of how tadalafil treats ED may explain how it also treats the symptoms of BPH. Whereas tadalafil belongs to a group of medicines called PDE-5 inhibitors, phosphodiesterase type 5 is an enzyme found in many tissues in the body; it helps prevent blood vessels from relaxing and filling up with blood. Blood flow to the penis is necessary to get and keep an erection. Tadalafil blocks PDE-5 and causes smooth muscle and blood vessels in the penis to relax. This relaxation leads to the increased blood flow that is necessary for getting and maintaining an erection. PDE-5 enzymes are also found in the prostate and bladder. Tadalafil inhibits PDE-5 in these tissues as well, but the mechanism of how tadalafil reduces BPH symptoms is not completely understood.

Prostatitis and Male Pelvic Pain Syndrome

Prostatitis and male pelvic pain syndrome combine to form a multifactorial syndrome of largely unknown etiology. Prostatitis can partially or totally block the flow of urine from the bladder, resulting in urine retention. This causes the bladder to become distended, weak, tender, and susceptible to infection due to the increased amount of bacteria in the retained urine.

Prostatitis is classified into a number of subtypes: acute bacterial prostatitis, chronic bacterial prostatitis, inflammatory and noninflammatory chronic pelvic pain syndrome, and asymptomatic prostatitis. Some symptoms of acute prostatitis include fever, chills, frequent urination accompanied by a burning sensation, pain between the scrotum and rectum, fatigue, blood or pus in the urine, lower back pain, and ED. It usually results from a bacterial infection and is common among males between the ages of 20 and 50. Pathogenic organisms can be cultured only in acute and chronic bacterial prostatitis. It is important for men who suffer from any of the symptoms associated with prostatitis to see a health-care provider because the condition may progress to more severe complications, including kidney infection, orchitis (painful swelling of the testicles), and epididymitis (inflammation of the epididymis, a tube along the backside of the testicles). Acute prostatitis is treated with antibiotics, usually fluoroquinolones, for an adequate period of time. Treatment of prostatitis is covered in Chapter 44.

Premature ejaculation (PE) is a common sexual problem, and chronic prostatitis is an important cause of PE. Antimicrobial therapy is useful in the treatment of PE associated with inflammatory prostatitis (Zohdy, 2009).

Ninety percent of patients with prostatitis syndrome, however, suffer not from bacterial prostatitis but from chronic (abacterial) prostatitis/chronic pelvic pain syndrome (CP/CPPS). It remains unclear whether CP/CPPS is of infectious origin, and therefore the utility of a trial of antimicrobial treatment is debatable (Wagenlehner, Naber, Schleipfer, Brähler, & Weidner, 2009). Noninfective forms of prostatitis may be associated with autoimmune disorders. Bladder outlet obstruction and prostate stones may also occur if chronic prostatitis remains untreated.

Hair Loss

Rogers and Avram (2008) provide a comprehensive review discussing the current medications available to treat hair loss and medications currently under investigation. There has been extensive use of minoxidil (2% and 5%) topical solutions. Minoxidil maintains and thickens existing hair and, in some patients, it regrows hair follicles. Minoxidil is also available in a foam preparation. Finasteride is a type II 5-alpha-reductase inhibitor that is used to treat BPH and androgenetic alopecia. Finasteride is an effective inhibitor of type II 5-alpha-reductase, the enzyme responsible for the reduction of testosterone to dihydrotestosterone (see Fig. 49-1). Its effects include increasing the hair growth rate, thickness, and hair count. Clinical use and dosing of minoxidil and finasteride are discussed in depth in Chapter 32.

Medications currently under investigation but not approved for the treatment of hair loss include dutasteride, ketoconazole, and latanoprost. Dutasteride is a potent type I and type II 5-alpha-reductase inhibitor that has shown superior hair count number and growth rate. Ketoconazole is an antifungal medication that has also been shown to promote hair growth. Its exact mechanism in hair loss treatment is poorly understood. In a clinical trial, Inui and Itami (2007) found that ketoconazole topical cream (2%) showed increased vertex hair growth in two of the five patients. Latanoprost is a prostaglandin analogue used for glaucoma and ocular hypertension that was found to encourage eyebrow and eyelash hair regrowth. Although no formal clinical studies exist using latanoprost, it appears to be a promising agent for further investigations.

In addition to the current medications and those under investigation, the field of hair transplantation has evolved considerably. The cosmetic results of contemporary hair transplantation are virtually undetectable. Large, pluggy "punch grafts" have been replaced with natural-appearing follicular unit grafts, which maintain their existing anatomy and with proper technique can match the orientation of surrounding hair follicles. Some of the important factors to consider include age of the patient, pattern of hair loss, and expected future hair loss (Lee & Minton, 2009).

HEALTH PROMOTION, DISEASE PREVENTION, AND SCREENING IN MEN

The top 10 threats to the health of men in the United States include heart disease, cancer, injuries, stroke, chronic obstructive pulmonary disease (COPD), type 2 diabetes, influenza, suicide, kidney disease, and Alzheimer's disease (Mayo Clinic, 2010). Health promotion through preventive screening and testing is very important to preventing mortality and morbidity associated with these threats. Health promotion is about keeping healthy, living a healthy lifestyle, preventing illness, and preventing any existing illness from becoming worse. Immunizations also play an important role in health promotion. A schedule of recommended screening tests and guidelines for men by age is presented in Table 49-6. Immunizations recommended for men of all ages are found in Chapter 19.

ETHNIC AND RACIAL ISSUES

Compared with African American women and white men in the United States, African American men have more health risks and a shorter life span. The U.S. Department of Health and Human Services (2000) reported that African American men live an average 6 years less than African American women and 7 years less than white men. Reducing

Table 49–6 Screening Tests and Immunization Guidelines for Men by Age

Screening Tests	Ages 18–39	Ages 40–49	Ages 50–64	Ages 65 and Older
Blood pressure test	At least every 2 years	At least every 2 years	At least every 2 years	At least every 2 years
Cholesterol test	Start at age 20	Health-care provider to discuss with patient	Health-care provider to discuss with patient	Health-care provider to discuss with patient
Colorectal health (use 1 of these 3 methods): 1. Fecal occult blood test 2. Flexible sigmoidoscopy (with fecal occult blood test) 3. Colonoscopy			Yearly Every 5 years Every 10 years	Yearly; older than age 75, discuss with patients Every 5 years. Older than age 75, discuss with patient Every 10 years. Older than age 75, discuss with patients
Diabetes: blood sugar test	Health-care provider to discuss with patient	Start at age 45, then every 3 years	Every 3 years	Every 3 years
Eye and ear health: complete eye exam	At least once between the ages 20–29 and at least twice between the ages 30–39, or any time there is an eye problem	Get an exam at age 40, then every 2–4 years or as health-care provider advises	Every 2–4 years or as health-care provider advises	Every 1–2 years
Hearing test	Starting at age 18, then every 10 years	Every 10 years	Every 3 years	Every 3 years
General health: full checkup, including weight and height	Patient specific	Patient specific	Patient specific	Patient specific
HIV test	Test once for basic screening and then risk-based screening thereafter	Test once for basic screening and then risk-based screening thereafter	Test once for basic screening and then risk-based screening thereafter	Discuss with patient
Mental health screening	Patient specific	Patient specific	Patient specific	Patient specific
Oral health: dental exam	One or two times every year	One or two times every year	One or two times every year	One or two times every year
Prostate health: digital rectal exam (DRE)		Discuss with patient	Discuss with patient	Discuss with patient
Prostate-specific antigen (PSA) test		Discuss with patient	Discuss with patient	Discuss with patient

Continued

Table 49–6   Screening Tests and Immunization Guidelines for Men by Age—cont'd

Screening Tests	Ages 18–39	Ages 40–49	Ages 50–64	Ages 65 and Older
Reproductive health: testicular exam	Discuss with patient	Discuss with patient	Discuss with patient	Discuss with patient
Sexually transmitted infection (STI) tests	Both partners should be tested for STIs, including HIV, before initiating sexual intercourse	Both partners should be tested for STIs, including HIV, before initiating sexual intercourse	Both partners should be tested for STIs, including HIV, before initiating sexual intercourse	Both partners should be tested for STIs, including HIV, before initiating sexual intercourse
Skin health: mole exam	Monthly mole self-exam; by a health-care provider as part of a routine full checkup starting at age 20	Monthly mole self-exam; by a health-care provider as part of routine full checkup	Monthly mole self-exam; by a health-care provider as part of routine full checkup	Monthly mole self-exam; by a health-care provider as part of routine full checkup
Immunizations				
HPV vaccine	All males 13 through 21 years of age, up to 26 years of age for men who have sex with men.			
Influenza vaccine	Yearly	Yearly	Yearly	Yearly
Meningococcal vaccine	One dose between age 16 years and 21 years.			
Pneumococcal vaccine	High risk patients	High risk patients	High risk patients	One time only
Tetanus-diphtheria booster vaccine	Every 10 years	Every 10 years	Every 10 years	Every 10 years
Zoster (Shingles)			Discuss with patient	Discuss with patient

Source: Adapted from http://www.everydayhealth.com/family-health/mens-health/screening-tests-and-immunizations-guidelines-for-men.aspx.

the life expectancy disparity between African American men and other ethnic groups requires efforts to improve the overall health of these men with an emphasis on factors that influence their health-related behaviors, the role of their health perceptions in perpetuating their behaviors, and strategies to overcome the disadvantages.

Factors such as socialization, structural barriers, and practitioner bias can adversely affect health behaviors and health outcomes in African American men. Young African American males are socialized to accept masculine behavior through strength, dominance, autonomy, and physical aggression into adulthood. Difficulty expressing feelings leads to inner stress and adverse health consequences such as high rates of anxiety disorders and depression. Structural barriers such as poverty and lack of health insurance impede the delivery of health care to African American men. These men hold a disproportional share of part-time, contract, or temporary jobs. Many of these jobs have no associated health-care benefits. Practitioner bias and patronizing attitudes, especially by those who are non-African American, can have a negative impact on African American men's health and heighten perceptions of mistrust. Some providers may inadvertently engage in negative racial stereotyping when caring for African American men and thereby contribute to their patients' negative health perceptions and underuse or delayed use of health-care services.

HEALTH ISSUES FOR MEN WHO HAVE SEX WITH MEN

Health care for gay men and other men who have sex with men (MSM) is a complicated mix of physical, psychosocial, and cultural phenomena that requires provider awareness of the issues. Gay men's health issues are unique and need to be incorporated into clinical practice to provide comprehensive and culturally appropriate care.

HIV Infection and Sexually Transmitted Infections

Although HIV infection and sexually transmitted infections (STIs) are potential major health issues for all people, those issues remain of significant importance to gay men. The continued high rate of newly diagnosed HIV and STI cases signals that many gay men and other MSM are not taking the threat to their health seriously. Additionally, MSM are much more likely to become infected with HIV than their heterosexual counterparts. African American and Latino American MSM have twice the risk for acquiring HIV infection when compared to whites (CDC, 2006b).

Rates of three sexually transmitted infections (STIs)—chlamydia, gonorrhea, and syphilis—remain high in the United States (CDC, 2009). These infections can be cured but

can cause serious complications if untreated and can increase the risk of HIV acquisition and transmission. High STI rates among African Americans and teens are particularly alarming, and MSM account for the greatest prevalence of syphilis (CDC, 2009).

Additionally, recreational drug use with substances such as cocaine, ecstasy, inhalants, and methamphetamines influence unsafe sexual behavior in gay men and MSM (CDC, 2009). Many of these recreational drugs are used during "white" or "circuit" party activities in which gay men from various geographical locales gather in one large metropolitan gay community over an extended 2 or 3 day period for the purpose of intense recreation and sexual activity.

Anal Cancer

Anal cancer is increasing in MSM and particularly in HIV-infected MSM. From 1973 to 2000, the incidence of anal cancer (2.1 per 100,000) in the United States increased in the general population for both men (160%) and women (78%). The incidence is substantially higher in MSM, HIV-infected men and women, transplant recipients, and women with cervical squamous intraepithelial lesions. Data collected before the height of the HIV epidemic revealed the incidence of anal cancer in U.S. MSMs to be 35 per 100,000 (Daling, Weiss, & Hislop, 1987; Daling, Weiss, & Klopfenstein, 1982). Estimates now put the incidence among HIV-infected MSM at least twice as high; 70 to 100 per 100,000. The incidence of anal cancer is 17 times higher in gay and bisexual men than it is in heterosexual men (CDC, 2008b).

In view of this increased incidence, there has been considerable discussion about whether regular anal screening using an anal PAP test should be implemented in the MSM population and specifically in the HIV-infected MSM population (CDC, 2008b). In 2011, the Advisory Committee on Immunization Practices (ACIP) recommended routine use of quadrivalent human papillomavirus (HPV) vaccine (HPV4; Gardasil, Merck & Co. Inc.) in boys aged 11 or 12 years. ACIP also recommended vaccination with HPV4 for young men aged 13 through 21 years who have not been vaccinated previously or who have not completed the three-dose series; males aged 22 through 26 years may be vaccinated. These recommendations replaced the 2009 ACIP guidance that HPV4 may be given to males aged 9 through 26 years. For these recommendations, ACIP considered information on vaccine efficacy (including data available since October 2009, on prevention of grade 2 or 3 anal intraepithelial neoplasia [AIN2/3], a precursor of anal cancer), vaccine safety, estimates of disease and cancer resulting from HPV, cost-effectiveness, and programmatic considerations.

Tobacco Abuse

Tobacco abuse continues to plague the gay community. Smoking among gay men occurs in nearly 33% of the population, whereas it remains at around 24% for the general public (CDC, 2006a). There is a paucity of interventions designed to target gay men with tobacco-abuse problems. Because HIV-infected individuals develop significant CV disease, a concerted effort must be taken to curtail smoking in this population. In addition, smokers who survive into later life may be at risk for significant cognitive decline. People who smoked 20 or more cigarettes daily have demonstrated faster declines in their verbal memory and slower visual search skills (Richards, Jarvis, Thompson, & Wadsworth, 2003). Smoking cessation programs designed to target gay men are being implemented slowly, but the need remains great. Smoking cessation is discussed in Chapter 43.

CONCLUSION

Most of the published studies addressing gender influence on health care focus on women's health or low-income and minority groups (Galdas, Cheater, & Marshall, 2005). There is a gap in research pertaining to men's health and an absence of health-care policies addressing men's health. Although men are usually research subjects, they are rarely the subjects of research.

Limited health-care resources; inequitable options available to men in seeking health care; and the absence of policies addressing gender-specific issues such as learning styles, masculinity, influences of testosterone on health, and stereotypical male traits—such as risk-taking behaviors—underscore the need for further studies and better understanding of men's health (Perls, Salzman, & Schaefer, 2006).

PEDIATRIC PATIENTS

Teri Moser Woo

Pediatric patients present a special challenge to the primary care practitioner; they are constantly changing, both physiologically and developmentally. The practitioner who is making a treatment decision must consider the parent and the family situation, as well as the patient, in determining if the treatment will be appropriate. In addition, information on use of medications in children is evolving as new studies regarding efficacy and safety of medications in children are published. This chapter presents the factors that the prescriber will need to consider to safely prescribe to children.

HISTORICAL PERSPECTIVE ON PEDIATRIC PRESCRIBING

Federal Drug Regulation

Drug regulation in the United States has often been moved forward after tragedies have occurred that directly involved children. Regulation began with the passage of the Federal Food and Drug Act of 1906, which was enacted because children had died from ingesting tainted food products and soldiers had died from ingesting adulterated quinine. This law, known as the Wiley Act, prohibited the manufacture and interstate shipment of adulterated and misbranded foods and drugs. In 1938, the next major legislation, the federal Food, Drug, and Cosmetic Act, was enacted. It was passed as the result of continued adulteration of products, including sulfanilamide, which had caused more than 100 deaths in children because of the diethylene glycol used in the elixir. For the first time, documentation of drug safety was mandated. This act also mandated truthful labeling and established the new drug application process that required toxicology testing prior to drugs being promoted and distributed. In 1962, the Harris-Kefauver Amendment was passed, prompted by the births of thousands of deformed infants whose mothers had taken the sedative thalidomide. This amendment mandated preclinical animal trials before testing drugs in humans. It also established three phases of clinical testing: phase I establishes safety and pharmacokinetics; phase II establishes initial effectiveness and dose range; phase III conducts comparative clinical trials.

Although the Harris-Kefauver Amendment increased the safety of new drugs coming onto the market, it also slowed new drug development, increasing the time from investigational new drug to new drug approval to 8 or 9 years. In 1972, an over-the-counter (OTC) drug review process was begun

to enhance the safety and labeling of nonprescription medications. In 1986, the Child Vaccine Act was passed requiring patients/parents be informed regarding the vaccines they are being given. In spite of all of these laws, as late as the 1990s the percentage of approved drugs that contained no labeling information for children was approximately 70%.

The next major legislation that affected children was the U.S. Food and Drug Administration (FDA) Modernization Act of 1997. The act had two main components pertaining to pediatrics. First, the FDA could require in writing that the manufacturer submit data on pediatric patients for drugs that appeared to have a pediatric use. Previously, drugs were approved for use in adults and the pediatric prescribing information happened later. This law mandated that the FDA require the pediatric data up front. Second, pharmaceutical companies were rewarded by a 6-month extension on any patent if they voluntarily tested the medications for safety in children. The FDA Modernization Act was challenged by the drug companies and overturned in 2002, a setback for pediatric drug safety.

Best Pharmaceuticals for Children Act

Fortunately, the American Academy of Pediatrics and other groups concerned with pediatric drug safety went before Congress and the result was the passage in 2003 of the Best Pharmaceuticals for Children Act (BPCA). This reinstated the pediatric exclusivity rule, giving a 6-month extension on patents if a manufacturer studies a given drug in children. It also established a mandate for an annual list of drugs requested to be studied. Experts in pediatrics are consulted and a list is developed for priority testing. In addition, the Pediatric Research Equity Act (PREA) was signed into law in December 2003. It requires that all applications for new active ingredients, new indications, new dosage forms, new dosing regimens, and new routes of administration must contain a pediatric assessment unless the sponsor has obtained a waiver or deferral of pediatric studies. The BPCA was renewed in 2007 and became permanent in 2012 under the Food and Drug Administration Safety and Innovation Act. The outcome so far of these major moves toward pediatric drug safety has been 469 studies completed between September 2007 and November 2013.

As of June 2014, 512 drugs have been relabeled or newly labeled for pediatric use (FDA, 2014). As more studies are completed, we will have a clearer picture of the safety and efficacy of the drug prescribed, and pediatric providers will have to do less off-label prescribing of medications. When a relabeled drug contains the statement "Safety and effectiveness have not been established," it really means that the drug is either not safe or not effective in children as determined by pediatric studies. Providers can find current information regarding drug label changes at the FDA Web site: http://www.fda.gov in the Pediatric Product Development section.

Pediatric exclusivity, which grants a 6-month extension on the patent if drugs are studied in children, has been successful in ensuring most new drugs are at least evaluated for use in children. Wharton and colleagues (2014) examined 401 pediatric exclusivity requests and found that from 1998 to 2012 there were 189 studies completed and 173 drugs received new pediatric labeling. Of note is that Wharton and colleagues found efficacy was not established for 78 of the drugs studied. The economic benefit of the 6-month market exclusivity is weighed not only in additional profits for the manufacturer of the drug but in improved outcomes for pediatric patients (Vernon, Shortenhaus, Mayer, Allen, & Golec, 2012). Another exciting development in pediatrics is an international movement toward improving pediatric drug safety. The World Health Organization (WHO) launched the "make medicines child size" campaign in December 2007 to raise awareness and encourage medication development for children younger than age 12 years (WHO, 2010). A global alliance in pediatric pharmacology has been formed and pediatric pharmacologists from more than 30 countries have met to share information from pharmacokinetic and pharmacodynamic studies and avoid unnecessary duplication of studies (Koren, Reider, & MacLeod, 2009). The WHO publishes a *Model List of Essential Medicines for Children* with over 200 medicines to be used as a reference for countries to develop their own national pediatric essential medications lists (WHO, 2013).

> The Pediatric Trials Network is funded by the Best Pharmaceuticals for Children Act via the Eunice Shriver National Institute of Child Health and Human Development (NICHD). The purpose of the Pediatric Trials Network (PTN) is to create an infrastructure to study critical drugs and diagnostic devices in children to improve labeling for pediatric use. The PTN will conduct 16 trials over the next 5 years, adding to critical information on pediatric drug safety and efficacy. For more information see PTN's website, www.pediatrictrials.org.

PHARMACOKINETIC AND PHARMACODYNAMIC DIFFERENCES IN CHILDREN

Pharmacokinetics

Drug absorption, metabolism, and excretion can vary throughout infancy and early childhood. Even at puberty, there are differences in drug clearance between girls and boys as drug clearance rates reach adult levels. As more is learned about the metabolic pathways in the adult liver, more knowledge is gained about how to study the differences in children. Past disasters caused by lack of understanding about the physiology of newborn metabolism have led to caution regarding the use of medications in infants. Gray baby syndrome caused by inadequate glucuronidation of chloramphenicol, which led to dangerous drug accumulation, and sulfonamide-induced kernicterus (caused by displacement of bilirubin from plasma proteins by sulfonamides) are two such disasters that have been hard lessons

in the use of medication in newborns. Well-designed pharmacokinetics studies in the newborn and careful therapeutic drug monitoring have improved our knowledge of neonatal pharmacology, yet care is essential when any new therapy is tried.

Drug Absorption

Drug absorption can be affected in children more than it is in adults by three factors: (1) the blood flow at the site of administration (intramuscular [IM] or subcutaneous [SC] administration), (2) gastrointestinal (GI) function, and (3) thin stratum corneum.

Neonates have more variability in the blood flow to the muscles, especially ill newborns, and poor blood flow can lead to delayed or variable absorption of medications. If perfusion suddenly improves, there can be a rapid absorption of the medication from the muscle, leading to possible toxic levels. Care should be taken when administering potentially toxic drugs such as cardiac glycosides, aminoglycoside antibiotics, and anticonvulsants IM to ill infants.

GI function is variable in neonates and young infants. Gastric acid function begins soon after birth and gradually increases over several hours. In premature infants, gastric acid secretion occurs more slowly and takes up to 4 days to reach normal levels. Gastric pH does not reach adult values until 20 to 30 months. Gastric emptying time is prolonged, reaching adult values by 6 to 8 months, meaning medications absorbed from the stomach may therefore have increased absorption. The neonate also has slow and irregular peristalsis, and medications absorbed primarily from the small intestine should be monitored for potentially toxic levels. It is known that the neonate has decreased oral absorption of acetaminophen, phenobarbital, and phenytoin, whereas ampicillin and penicillin G have increased bioavailability when taken orally. Diarrhea, a common ailment in young children, lessens the extent of absorption from the intestine, causing decreased drug levels.

The developmental changes in gastric function alter drug absorption in a fairly predictable manner. The oral bioavailability of acid labile compounds (beta-lactams) is increased and the oral bioavailability of weak organic acids (phenobarbital and phenytoin) is decreased. Basic drugs, such as diazepam and theophylline, have increased absorption. Gastric motility greatly alters the absorption of drugs with limited water solubility (phenytoin and carbamazepine) (Kearns, 2000; Kearns et al, 2003; Rakhmanina & van den Anker, 2006).

It is well known that infants and young children have a thin stratum and larger body surface area in relation to size and this affects topical absorption of medication. Children absorb topical medications more readily than do adults, leading to the systemic toxicity seen with topical medication use, for example, lidocaine or diphenhydramine. Most providers are familiar with the concern for systemic absorption of topical corticosteroids in children, with systemic Cushingoid symptoms or HPA (hypothalamic-pituitary-adrenal-axis) suppression developing with topical use.

Due to BPCA and pharmacokinetic studies that indicated HPA-axis suppression or adrenal suppression in children, a number of topical corticosteroids have been relabeled. Diprolene (diprosone) cream, ointment, and lotion are not recommended for use in children younger than 12 years due to HPA-axis suppression. In addition, Diprolene AF and Elocon (mometasone) lotion are not recommended, although Elocon cream and ointment may be used in children as young as 2 years. In an open-label study of Lotrisone (clotrimazole and betamethasone dipropionate) cream for the treatment of tinea pedis, 17 of 43 (39.5%) patients (12 to 16 years) demonstrated adrenal suppression as determined by cosyntropin testing. In an open-label study of Lotrisone cream for the treatment of tinea cruris, 8 of 17 (47.1%) patients (12 to 16 years) demonstrated adrenal suppression by cosyntropin testing. Lotrisone has been relabeled and is not recommended for children younger than 17 years and not recommended for diaper dermatitis; previously it was not recommended for children younger than 12 years. Cutivate (fluticasone) ointment has been similarly relabeled to be used only in adults (U.S. Food and Drug Administration, 2010).

Distribution

There are clear changes in body composition in neonates, infants, children, and adolescents. Newborns have total body water (TBW) of 80%, which drops over the first few months to TBW of 60% at 6 months; therefore, infants require higher doses of hydrophilic drugs. Infants also have a decreased volume of distribution for lipid-soluble drugs. Infants younger than 6 months have decreased plasma proteins available for drug binding, which will cause elevated levels of unbound medication. Providers need to monitor for drug toxicity even if there is normal or low plasma concentration of total drug. Phenytoin is one example of this, as it is only 80% to 85% bound in infants and 94% to 98% bound in adults (Kearns, 2000; Kearns et al, 2003).

The ratio of fat to lean muscle also shifts throughout childhood with a shift toward decreased total body fat in adolescence, a shift of approximately 50% in males between ages 10 and 20 years. Consequently, lean body mass increases more in males. The shift in females is less dramatic, shifting from 28% to 25% from ages 10 to 20 years (Kearns, 2000; Rakhmanina & van den Anker, 2006). Due to these changes. it may be difficult to predict pharmacokinetics of some drugs during pubertal growth. Medications that the patient takes chronically, such as seizure medications, need to be monitored closely during pubertal growth.

Metabolism

Phase I Enzymes

The pathways of drug metabolism develop variably over the first year of life and may be influenced by medications that induce drug-metabolizing enzymes (e.g., phenobarbital). In adults, much has been learned about the cytochrome P450 (CYP450) enzymes, and much is still unknown. The exact developmental pattern is not known for all of the CYP450 isoenzymes although our knowledge is increasing rapidly. It

is known that CYP 3A7 is active during gestation and is the most active isoenzyme at birth. CYP 3A7 disappears at a few weeks of life but may remain active in 5% of people (Kearns, 2000; van den Anker, 2010).

Studies of CYP450 1A2 using caffeine as the test substrate demonstrate limited metabolic clearance in the newborn. CYP 1A2 reaches adult levels at 4 months and then exceeds adult levels at 1 to 2 years throughout childhood. At puberty (Tanner stage II), clearance begins to decline to adult levels, in girls sooner than in boys. Diseases such as cystic fibrosis (CF) can affect CYP1A2 activity and CF patients may need higher doses of medications metabolized via the CYP1A2 pathway. There are many medications that are metabolized via the CYP1A2 enzymes, including theophylline, erythromycin, cimetadine, phenobarbitol, phenytoin, carbamazepine, clarithromycin, and others. Foods that are affected by the CYP1A2 pathway are grapefruit juice, cruciferous vegetables, and charbroiled foods—foods not commonly eaten by children, but the provider should be aware of these food interactions. Cigarette smoking also affects CYP1A2 enzymes and providers should inquire if patients taking medications are smoking because it may affect therapeutic levels of medication, including a number of seizure medications. In practice, this implies that drug dosages need to be adjusted as a child goes through phases of CYP1A2 maturation; higher dosages may be needed from 1 year until puberty and therapeutic drug levels will need to be monitored as a child goes through puberty.

CYP 2D6 is absent in the fetal liver and 0% to 5% active at birth. At 1 month of age CYP 2D6 has 20% adult activity and reaches adult activity at age 3 to 5 years of age (Kearns, 2000; van den Anker, 2010). There is significant genetic variability in CYP 2D6 activity. Up to 20% of Africans of Ethiopian descent are 2D6 ultrametabolizers, whereas 3.4% to 6.5% of African Americans are ultrametabolizers (FDA, 2012). Among Caucasians 3.6% to 6.5% are ultrametabolizers. CYP 2D6 ultrametabolizers may be at risk for respiratory depression after taking codeine because they metabolize codeine to morphine at a greater than predicted rate, leading to elevated morphine levels. In 2012, the FDA issued an advisory regarding prescribing codeine to children.

Additionally, 5% to 10% of Caucasians and 1% to 2% of Asians are poor CYP 2D6 metabolizers. Many psychotropics, including SSRIs, are inhibitors of CYP 2D6, leading to prolonged half-life, and even small doses may not be tolerated by poor metabolizers. Antiseizure medications such as carbamazepine, topiramate, and lamotrigine will require careful monitoring in poor metabolizers.

The isoenzyme CYP3A4 is the most abundant CYP isoform and undergoes a maturational process similar to CYP1A2. CYP3A4 has low activity at birth and reaches 30% to 40% of adult levels by 1 month. By 6 months, it is at full adult levels and exceeds adult levels at 1 to 4 years. At puberty it decreases to adult levels. The CYP3A4 enzymes are used to metabolize more than 20 commonly used pediatric medications, including carbamazepine, prednisone, oral contraceptives, macrolides, NSAIDS, antihistamines, and others. The implications for pediatric practice include monitoring when prescribing more than one drug metabolized by CYP3A4 enzyme and monitoring during developmental changes.

Recent studies recognize that the small intestine is a major site of drug metabolism because it contains enterocytes in the bowel mucosa, which have CYP450 drug metabolism enzymes. This information enhances our knowledge of drug metabolism, but there may be large interindividual variation in the capacity of the small bowel to metabolize drugs.

Phase II Enzymes

Phase II enzymes are responsible for synthesis of water-soluble compounds. There is less information available on phase II activity in children. UDP glucuronosyltransferase (UGT) is responsible for the glucuronidation of hundreds of hydrophobic compounds. It is known that morphine is metabolized by UGT 2B7. It is known from morphine studies in neonates that premature infants (gestational age 24 to 37 weeks) have a much lower plasma clearance of morphine than children 1 to 16 years. It is thought that morphine clearance reaches adult levels at 2 to 6 months, although some children do not reach adult levels until 3 years (Blake, Castro, Leeder, & Kearns, 2005; Kearns, 2000; Rakhmanina & van den Anker, 2006). There appear to be ethnic variations in thiopurine methyltransferase (TPMT) activity; Koreans, for example, do not reach adult activity levels until 7 to 9 years. Little is known about the phase II enzymes in children, but the knowledge base is growing. Commonly used medications such as acetaminophen, morphine, propofol, and caffeine are metabolized via the phase II enzymes, and providers need to be aware of developmental as well as possible ethnic variations.

One essential consideration from our knowledge thus far is that, during times of great physiological change (the premature, the neonate, puberty), there are likely to be major changes in pharmacokinetics. More variability among individuals and within the individual is likely during these periods. Careful monitoring of therapeutic drug levels is critical to safe outcomes. In the neonatal period, frequent adjustments may be necessary because of the rapid changes the neonate is undergoing. A drug dosage that is at a therapeutic level in a 9-year-old girl has to be carefully monitored as she proceeds through puberty to ensure that she will not develop toxic levels as her drug clearance reaches adult levels.

Drug metabolism is an area in which the BPCA and Pediatric Research Equity Act (PREA) studies have expanded our knowledge. For example, females aged 8 to 11 years have higher therapeutic levels of fluvoxamine (Luvox) compared to boys the same age. The studies indicate that girls need lower doses of fluvoxamine (FDA, 2014). Likewise, pharmacokinetic studies of oxcarbazepine (Trileptal) in children have determined clearance decreases with age, to the point that children aged 2 to younger than 4 years may require up to twice the dose per body weight compared to adults, and children aged 4 to 12 years may require a dose 50% higher per weight than adults (FDA, 2014). Pharmacokinetic studies

of levetriacetam (Keppra) found clearance increased with increased body weight; adults have a 40% higher clearance than do children. Hence, prescribers need to be aware of nonlinear pharmacokinetics seen with some pediatric medications and prescribe and monitor accordingly.

Excretion

Drug excretion rates are affected by the lower glomerular filtration rate in newborns, which is only 30% to 40% of adult values. By age 6 to 12 months, the glomerular filtration rate reaches adult values (per unit surface area). Drugs that depend on renal excretion are cleared more slowly in neonates. Drug dosages and dosing intervals in newborns are adjusted accordingly for medications such as ampicillin, aminoglycoside antibiotics, and digoxin. Renal blood flow is also reduced in neonates and reaches adult levels at approximately 9 months.

Pharmacodynamics

There are pharmacodynamic differences between children and adults that need to be taken into consideration in prescribing for children. Like much medical knowledge, information on the differences between children and adults has been gained from an unexpected outcome in children in response to a medication that is safe for adults. The classic examples are antihistamines and barbiturates, which may cause hyperactivity rather than sedation when given to children. Another classic example is tetracycline, which deposits in developing teeth and causes permanent stains. Systemic corticosteroids stunt linear growth if taken for long periods, as well as producing all of the same adverse reactions found in adults. Some medications, such as isoniazid, are less toxic in children than they are in adults.

Another concern in children is the vehicle in which the medication is administered or the formulation of the vehicle. Children have sometimes had toxic or unexpected results not from the medication, but from the additives or preservatives used. As recently as the 1980s, benzyl alcohol, a preservative used in drugs, was discovered to cause "gasping syndrome" when medications containing it were administered to newborns.

Topical ointments and creams are routinely prescribed to adults and children, yet there is a major difference between adults and children in the absorption rates from the skin. Infants and children have a thinner stratum corneum that allows medications to be more readily absorbed. Compared with older children and adults, infants have a larger skin surface area that is capable of greater weight-adjusted absorption of hydrophilic drugs. Occlusive dressings can increase the absorption of medications, which is of particular concern regarding corticosteroids in the diaper area. The plastic coating on the diaper can cause occlusion, thereby increasing absorption and producing systemic steroid effects.

DEVELOPMENTAL ASPECTS OF PEDIATRIC MEDICATION ADMINISTRATION

With adults, the provider can assume that, if reasonably clear instructions are given, the patient will take the medication as prescribed. With children, many added variables affect administration of the medication and compliance with the medication regimen. The first consideration is the developmental level of the child and the amount of parental control at each developmental level. This section addresses these differences and suggests strategies for improving compliance at each age level.

Breastfed Infants

Breastfeeding an infant the first year of life is beneficial both physically and emotionally to the infant. Therefore, when prescribing medications to a lactating woman, the practitioner needs to be aware of which medications can be used safely and which are contraindicated (Box 50-1). The most up-to-date, peer-reviewed, and easily accessible resource is the LactMed database at the National Library of Medicine TOXNET Web site (http://toxnet.nlm.nih.gov/index.html). LactMed is searchable by drug name and gives recommendations for prescribers with updated safety information.

BOX 50–1   PRESCRIBING TO LACTATING WOMEN

Prescribing medications for lactating women should be undertaken with the same caution as prescribing for pregnant women. Assume that any drug prescribed will, in some amount, be found in the breast milk. Therefore, knowledge regarding safety of medications for lactating women is essential for all primary care practitioners. When prescribing, take the following steps:

1. Review the safety of the drug during lactation.
2. If the drug is relatively safe, discuss the risks with the mother and explain the symptoms of drug toxicity.
3. Explain that the drug should be taken just after nursing or before infant's sleep.
4. Measure drug concentrations in milk or infant's serum when toxicity is likely.
5. Monitor the infant for signs of pharmacological action or drug toxicity.
6. Report any symptoms or signs of drug toxicity to the American Academy of Pediatrics, Committee on Drugs.

A few medications are absolutely contraindicated in lactating women (see Table 50-1). Contraindications include anti-neoplastic drugs because of immediate or delayed toxicity in the infant. Weekly use of methotrexate for rheumatic disease is acceptable during lactation, but the infant needs to be monitored closely, with routine laboratory analysis of complete blood count with differential, liver enzymes, and renal function essential to infant safety. Another contraindication to breastfeeding

is iodine-containing radioactive medications used in nuclear medicine studies. In this case, temporary cessation of breast-feeding ("pump and dump") is indicated. The length of time before resumption of breastfeeding is determined by the half-life of the radiopharmaceutical agent.

Drugs that should be avoided include lithium and oral contraceptives, yet both have been used in lactating women. Lithium is excreted in breast milk at about 40% of the concentration of maternal serum, and milk and infant serum levels are approximately equal. If, for maternal health reasons, lithium needs to be prescribed, the infant's serum lithium level needs to be monitored closely. The main contraindication to oral contraceptives containing estrogen is that they may decrease milk supply. An oral contraceptive with low estrogen levels can be prescribed once the milk supply is well established (more than 6 weeks' postpartum), but the first choice should be a progestin-only oral contraceptive. Decreased milk supply should be discussed with the mother as an adverse effect of estrogen-containing oral contraceptives prior to prescribing.

All illicit drugs are contraindicated in lactating women, specifically cocaine, heroin, and methamphetamine. Infants exposed to cocaine via breast milk may show signs of toxicity (irritability, tremors, increased startle response). Cocaine metabolites can be found in breast milk for up to 36 hours after the mother's last dose. Heroin enters breast milk and can cause neonatal depression. Amphetamines are excreted in breast milk and cause excitation in the infant. Methamphetamine poses an additional concern because some of the chemicals used to manufacture the illicit drug are toxic to both mother and infant, specifically lead, which is quite harmful to the infant. Any drug use during lactation should be explored and the mother encouraged to discontinue breastfeeding if illicit drug use is a concern.

Alcohol and **tobacco** are two commonly used legal drugs that can affect the breastfed infant. Alcohol passes freely into breast milk and reaches levels close to maternal serum levels. High levels of alcohol in the breast milk put the infant at risk for sedation and cause a reduction in the maternal milk-ejecting response. There is controversy regarding maternal alcohol use during lactation. It is probably safe for the mother to ingest small amounts of alcohol timed just after a feeding, when levels in the milk are the lowest possible. Tobacco is a concern because of both secondhand smoke exposure and the nicotine that passes into breast milk. Nicotine passes freely into breast milk, and therefore the breastfed infant is exposed to this toxin. If a nicotine replacement patch is used for maternal smoking cessation, then the nicotine blood levels and therefore breast milk levels are lower than with smoked tobacco.

Because drugs are almost never tested for use in lactating women prior to their release onto the market, questions regarding their safety during breastfeeding always exist. Understanding some basic principles regarding the transfer of drugs into breast milk and their pharmacokinetic actions helps the practitioner make decisions about safe prescribing. The practitioner should have ready reference to the most current information available about drugs during lactation, including *Drug Facts and Comparisons; Drugs in Pregnancy and Lactation* by Biggs, Freeman, and Yaffe; and *Teratogen Information Services,* available from your local Poison Control Center.

The National Library of Medicine TOXNET (Toxicology Data Network) maintains a peer-reviewed, searchable online database of drugs in lactation: LactMed (http://toxnet.nlm.nih.gov/index.html).

Drug Excretion in Breast Milk

The mammary gland can be viewed as an elimination organ in relation to maternal medication ingestion. Like other elimination organs, the properties of the medication determine how much of the medication will be in the breast milk. Because breast milk is more acidic than plasma, basic compounds (beta blockers) may be slightly more concentrated in the milk, and the concentration of acidic compounds (penicillins and NSAIDs) in the milk will be lower than plasma levels (Berlin & Briggs, 2005). Protein binding also affects the transfer of medications into breast milk. Highly plasma protein–bound drugs have a lower amount of drug available to transfer into milk because only the free drug is available for transfer. Liposolubility also affects the ability of drugs to cross the alveolar cells by diffusion and enter the milk. Another factor is the molecular weight of the drug: drugs with high molecular weight are transferred less easily into milk than drugs with lower molecular weight.

Factors Influencing an Infant's Exposure to Drugs in Breast Milk

A number of factors must be accounted for in determining the infant's exposure to a drug (Table 50-1). The following variables encompass physiological processes in both the infant and the mother that influence the effects of a drug on the infant:

1. Maternal pharmacokinetics has a great impact on the level of drug found in breast milk; the higher the drug concentration in the maternal plasma, the higher the concentration of that drug in the milk. Pregnant women have altered pharmacokinetics in the last trimester of gestation. Failure to monitor doses and decrease medication dosages appropriately after delivery may lead to toxic effects in both the mother and the breastfed infant. A higher maternal drug dose or decreased clearance leads to increased amounts of a drug in breast milk.

2. The infant suckling pattern can determine the level of drug found in breast milk. The time of the feeding in relation to the maternal dosing determines how much of the drug is in the breast milk. A drug with a short half-life, given to the mother right after feeding, decreases the amount of drug the infant is exposed to. Likewise, drugs with a long half-life increase the infant's exposure to the drug. Infant suckling time and the number of feedings also have an impact on drug exposure. Some infants nurse for long periods or very

Table 50–1   Effects of Commonly Prescribed Medications on Infants During Lactation

Drug	Effect on Infant	Comments
Acetaminophen	Minimal	Found in breast milk. No adverse reactions reported. Safer than aspirin when lactating.
Amoxicillin (all penicillins)	Minimal	Excreted in breast milk in low concentrations. May cause mild diarrhea in infant.
Amoxicillin-clavulanate (Augmentin)	Minimal	Excreted in breast milk. Infant may have diarrhea.
Amphetamine	Unknown	It is not known if levels prescribed for medical indications affect the neurological development of the infant.
Aripiprazole	Unknown	Maternal doses up to 15 mg daily produce low levels in milk. Avoid in nursing women until more information is available.
Asenapine	Unknown	Avoid until more information is available.
Aspirin	Minimal, rare complication of bleeding or metabolic acidosis	Excreted in breast milk. Low dose (75–162 mg daily) may be considered as antiplatelet therapy for breastfeeding women. Avoid breastfeeding for 1–2 h after a dose to minimize effects on the infant.
Atenolol	Moderate to significant	Excreted in breast milk in a milk to plasma (M:P) ratio of 1.5:6.8 (one patient had an estimated dose of 0.13 mg atenolol per feeding with a maternal dose of 100 mg/d). Cyanosis and bradycardia have been reported in breastfed infants with maternal intake of 100 mg/d. **Use with caution. Avoid in infants younger than 3 months of age.**
Caffeine	Minimal	Excreted in breast milk. If mother has one cup of coffee, the infant probably ingests 1.5–3.1 mg of caffeine. Caffeine has a long half-life in young infants (82 h in term newborn, 14.4 h in 3–4.5/2-mo-old infants, and 2.6 h in 6-mo-old infants). Probably safe in small amounts, with variable reaction based on individual infant.
Bromocriptine	Minimal	Used to suppress lactation.
Carbamazepine	Moderate	Infants have measurable carbamazepine levels. Monitor the infant for jaundice, drowsiness, adequate weight gain, and developmental milestones, especially in younger, exclusively breastfed infants (LactMed).
Chloramphenicol	Significant	**Avoid while lactating.** Possible bone marrow suppression.
Cascara	Moderate	Excreted in breast milk. Causes colic and diarrhea in the infant. **Avoid.**
Cephalosporin antibiotics	Minimal	Excreted in small amounts in milk. Probably safe.
Chlorpromazine	Probably minimal	Excreted in breast milk. Monitor infant for drowsiness and developmental milestones.
Citalopram	Minimal	Excreted in breast milk. Monitor infant for sedation or fussiness. OK if required by mother. Consider a trial of escitalopram, which appears safer.
Codeine	Minimal; infant may experience lethargy	Excreted in breast milk. Limit use to 4 d and keep dose low. Newborns particularly sensitive to effects of maternal codeine use (LactMed).
Diazepam (all benzodiazepines)	Significant; infant may experience lethargy; apnea reported	Infants metabolize benzodiazepines more slowly than adults; accumulation of toxic levels of drug is possible. **Avoid in nursing mothers** other than a single dose for procedures (LactMed).
Dicumarol	Minimal	Excreted in breast milk in **inactive** form. May want to monitor infant's prothrombin time.
Digoxin	Minimal	Small amounts excreted in breast milk. Probably safe.
Duloxetine	Minimal, not well studied	Dose in milk is low. Monitor infant for drowsiness, weight gain, and developmental milestones.

Continued

Table 50–1 **Effects of Commonly Prescribed Medications on Infants During Lactation—cont'd**

Drug	Effect on Infant	Comments
Ergot	Significant; infant may experience vomiting, diarrhea, peripheral vasoconstriction	**Contraindicated** in lactation. May suppress lactation.
Escitalopram	Minimal	Maternal doses up to 20 mg/d produce low levels in breast milk. Safer than citalopram.
Fluoroquinolones	Unknown	Small amounts in breast milk. Little information available. Use an alternate drug for which safety information is available (LactMed).
Fluoxetine	Moderate	Colic, irritability, feeding and sleep disorders, slow weight gain. If mother requires fluoxetine, lactation is not a reason to stop. Monitor the infant.
Fluconazole	Minimal	Fluconazole is excreted in breast milk at concentrations similar to plasma. Safe.
Fluvoxamine	Minimal	Maternal doses up to 300 mg/d produce low levels in milk.
Furosemide	Minimal or unknown	Excreted in breast milk. Use with close monitoring of the infant.
Gold salts	Significant hepatonephrotoxicity	**Contraindicated** in lactation. May be excreted in milk after therapy is discontinued.
Heparin, LMW heparin	Minimal	Not excreted in breast milk in significant amounts.
Iodine (radioactive)	Significant; may cause thyroid suppression in the infant	**Contraindicated.** Maternal testing requiring radioactive iodine requires breast milk to be discarded according to the half-life of the drug.
Isoniazid (INH)	Minimal; possibility of pyridoxine deficiency developing in the infant	Milk levels same as maternal plasma levels. Observe infant for adverse effects. Probably safe. Nursing mothers who are taking isoniazid should take 25 mg of oral pyridoxine daily.
Lithium	Moderate	Lithium may be used in full-term infants if monitored closely. Consider monitoring infant serum lithium levels, serum creatinine, BUN, and TSH every 4–12 wk during breastfeeding. Lithium toxicity may occur if elimination is impaired, as in infant dehydration, prematurity, or the immediate newborn period (LactMed).
Macrolide antibiotics	Minimal	All macrolides are minimally excreted in breast milk. Monitor infant for diarrhea and *Candida* infection.
Methadone	Significant	May be used under close medical supervision at doses of less than 100 mg/d. Infants receive 1%–3% of maternal dose. Infant may exhibit signs of withdrawal if methadone is discontinued abruptly or if breastfeeding is discontinued abruptly.
Metoprolol	Minimal	Excreted in very small amounts in breast milk. Infant consuming 1 L breast milk will get <1 mg metoprolol.
Metronidazole	Unknown	Milk levels similar to maternal plasma levels. Half-life in breast milk 8–10 h. Long-term systemic therapy produces measurable amounts of metronidazole in infant's serum and the effects are unknown. Nursing mothers should express and discard milk during and for 24–48 h after single-dose treatment. Topical and vaginal application is probably safe.
Olanzapine	Minimal	Doses up to 20 mg/d not detected in infant serum. Limited information available. Monitor the infant for drowsiness and developmental milestones, especially if other antipsychotics are used concurrently (LactMed).
Oral contraceptives	Minimal to moderate	Hormones are released into breast milk. May cause jaundice and breast enlargement in the infant. Estrogen compounds suppress lactation, decreasing the quantity and quality of breast milk. Use progestin-only preparations ("minipill") or wait until milk supply is well established (>6 wk postpartum) to use combined forms.
Paroxetine	Minimal	Minimal levels in breast milk. Preferred drug in lactating women (LactMed).

Table 50–1   **Effects of Commonly Prescribed Medications on Infants During Lactation—cont'd**

Drug	Effect on Infant	Comments
Phenobarbital	Moderate; lethargy in the infant	Excreted in breast milk. Monitor infant for lethargy and feeding problems.
Phenytoin	Minimal	Low levels in breast milk. Probably safe.
Prednisone	Moderate	Excreted in breast milk and may suppress growth and interfere with exogenous steroid production in the infant. Low maternal doses (<20 mg/d) probably safe. Larger doses for a short time may not harm the infant. It is best to time the medication dose just after a feeding and wait 3–4 h for next feeding.
Propranolol	Minimal	Excreted in breast milk in amounts too small to have any effect.
Propoxyphene (removed from U.S. market)	Minimal; possible lethargy	Excreted in small amounts in breast milk.
Propylthiouracil	Minimal	Little PTU passes into breast milk. Doses up to 450 mg/d may be safe. Take dose of PTU just after nursing and wait 3–4 h to minimize infant dose. Monitor CBC, T4, and TSH if any suspicion of adverse effects.
Risperidone	Unknown	Maternal doses up to 6 mg/d produce low levels in milk. Little information available. Other agents may be preferred especially in the newborn or preterm infant.
Radioactive material	Significant; carcinogenic	**Contraindicated**
Sertraline	Minimal	Low levels of sertraline in breast milk, so amounts ingested by infant are small. One of the preferred antidepressants during lactation.
Spironolactone	Minimal	Very small amounts (0.2%) of metabolite of mother's daily dose are excreted in breast milk. Safe for use with breastfeeding.
Tetracycline	Moderate; discolored teeth	Excreted in breast milk, M:P ratio of 0.6–0.8. **Avoid when lactating.** Use safer antibiotics.
Warfarin	Minimal	Excreted in breast milk in inactive form. Safe during breastfeeding.
Ziprasidone	Unknown	Avoid while breastfeeding until more information available.
Zolpidem	Minimal	Low levels excreted in breast milk. Short-acting.

frequently, which will increase the amount of drug that the infant ingests.

3. Infant pharmacokinetics also plays an important role in how maternal medication use affects the breastfed infant. As mentioned at the beginning of this chapter, gastric acid production and gastric emptying time are decreased and variable in neonates. The volume of distribution in infants is greater because of their greater total body water and their lower body fat. Infants also have significant differences in drug metabolism by the liver, as previously mentioned. Renal excretion, too, is altered in younger infants, which can affect their overall clearance rate of drugs. All of these factors need to be considered in prescribing to a lactating woman, especially if the breastfed infant is very young (less than 1 month old).

4. Susceptibility to a drug's effects can vary among infants. There is some dose-related predictability to a drug's effects that are related to the pharmacological properties of the drug. In some infants, however, there are unique effects that are not dose-related and instead are idiosyncratic and therefore unpredictable. This reaction is fortunately uncommon but must be considered if an infant is demonstrating some effects of maternal drug use.

5. The milk to plasma (M:P) drug ratio affects the infant's exposure to a medication because the infant's clearance of the drug affects the overall exposure. Even drugs with a low M:P ratio may produce a toxic level if the infant is unable to effectively excrete the drug.

Infants

Infants are totally dependent on their parents to administer their medication. Although the infant may balk at the taste of a medication, the parent is still in control of administering it. Intervention at this age is aimed at teaching parents or caregivers how to properly administer the medication. Parents need to be edified and encouraged as they take on the role of administering and monitoring a child's medication. Many parents are nervous the first time they give their child

medication. Thorough education ensures better medication compliance.

Medication dosing errors by parents are common; 39.4% of parents made a measurement error in a study of 287 parents enrolled in the emergency department after their child was prescribed liquid medication (Yin et al, 2014). Discussing the reason for the medication, the dose, how to draw up the medication in milliliters, the length of treatment, medication administration tips, and expected and unexpected adverse effects (e.g., the mild diarrhea that is expected with some antibiotics) should increase a parent's comfort with administering medications. Written instructions are essential at all ages but especially for the infant, because the parent is more likely to be fatigued and less likely to retain instructions given orally. Dosing medications for parental convenience increases compliance. Ask parents if they are working outside their home and who else may be administering the medication. A medication with fewer daily doses may be indicated if the child is in a day-care setting or has multiple caregivers.

CLINICAL PEARL

Infants

- Parents are often unsure how to administer medication to an infant. While the parents are in the clinic with the child, the practitioner should address this issue and demonstrate how to do it. For ease of administration, use a medication syringe and insert the syringe into the mouth along the inner cheek. To decrease choking, advise parents to squirt small amounts (1 mL) of medication at a time into the inner buccal space. Wait until the infant swallows, and then administer another small amount until all the medication is administered. Direct parents not to administer the medication directly over the tongue, which increases choking and allows the infant more easily to spit out the medication.
- Advise parents to check with the pharmacist before mixing any medication with formula or breast milk; some medications are bound with the calcium or other ingredients in the formula, causing them to be less effective.
- Breastfed infants often choke and sputter when medications are first administered because these infants are used to only the feel of the breast in their mouths. Warning parents of this response and teaching them proper technique will help them gain confidence in medication administration.
- Giving acetaminophen in suppository form is an option if administering oral medications to the infant is difficult. The practitioner can demonstrate this procedure, which works well in breastfed infants especially.

Toddlers and Preschoolers

Toddlers and preschoolers are beginning to exert their independence, and administering medications to this age group can be a challenge, even a battlefield. Even the most experienced parent can have difficulty administering oral medications to a toddler. The key to success with this age group is to discuss medication administration with the parent prior to prescribing and, if possible, choose a medication that poses the fewest problems with administration. Doses per day, palatability, and dosage forms should be taken into consideration. If the toddler is resistant to taking medication, prescribe a once- or twice-daily medication if possible. Using chewable formulations, if the child has molars, can increase compliance because the child can self-administer the medication. Using higher concentrations of medication, if possible, to decrease the volume administered can be helpful. By 2 or 3 years, children can often begin to self-administer oral medication by using a vertical medication spoon or medicine cup. Parents can help a child practice this skill with juice or another liquid before taking the medication. Discussing administration of the prescribed medication while the family is still in the clinic is essential. Ask the parent what has worked in the past to ease medication administration and what has not worked. Listen to parents; they know their child and can anticipate what will ease the medication administration.

School-Age Children

Giving medication to school-age children is often easier than it is in other age groups. Developmentally, they are industrious and eager to learn. It is essential to include the child in the decision-making process, if possible. Let the child choose the formulation. Does he or she want liquid, chewable tablets, or pills to swallow? Some liquid medication doses become large in volume as the child gets to school age (e.g., trimethoprim-sulfamethoxazole and prednisone), so advise parents and the child who chooses a liquid formulation of this fact. Be sure the child can swallow pills before prescribing them. Some medications can be crushed and mixed with highly viscous fluid (e.g., chocolate syrup). Check with the pharmacist prior to suggesting this if you are not familiar with a medication. Teaching with this age group should be aimed at both the parent and the child. Children need to know the rationale for prescribing a particular medication. They are being taught in school to avoid "drugs," and they need clarification about helpful medication and illicit drugs. Schools have varying regulations regarding administration of medication at school. If possible, avoid school-hour dosing to simplify the medication regimen.

Adolescents

Adolescent patients often administer their own medications. The compliance rates vary with this age group. Some teenagers are excellent at medication self-administration, and others are poorly compliant. The adolescent is developmentally entering the period of formal operational thinking, characterized by propositional thinking and abstract reasoning. Younger adolescents may still be in the concrete-thinking stage, and their interactions with the health-care provider may reflect this stage rather than the abstract thought process of older teenagers.

Although adolescents may be able to self-administer medication and appear to be capable of the task, they may vary in their sophistication regarding medication use. The practitioner needs to form an alliance with teenagers and ask their perspective regarding their medications. Do they have an opinion regarding the medication? What schedule will work best with their lifestyle? Teenagers appreciate having their opinions taken into consideration as treatment is planned. When a medication history is taken with the parent present, the teenager may not be completely truthful. Practitioners need to be aware of the laws of the state in which they practice and, when treating teenagers, maintain confidentiality if necessary. Teenagers, too, must understand the confidentiality laws of their state and at what age they are able to receive confidential treatment. Parents often struggle with letting teenagers self-administer medications. The practitioner needs to be skilled at assisting family members as they move from parent-controlled to child- or teen-controlled medication administration. This transition varies by family.

FACTORS THAT INFLUENCE POSITIVE OUTCOMES

Compliance or adherence with the medication regimen is an issue for all patients. Pediatric patients pose a unique dilemma because the practitioner has to address both the child's compliance and the parent's, plus possibly that of other caregivers. The many factors that influence adherence include length of medication regimen; number of medications prescribed; the medication interval, palatability, cost, and family issues. The practitioner needs to consider all of these issues when prescribing to ensure successful treatment.

There is little agreement over the definitions of *compliance* and *noncompliance.* Is anything less than full compliance considered noncompliance? If the therapeutic outcome is adequate, is less than full compliance with the treatment regimen acceptable? Dose omission and delay are the most common dosing errors, yet other forms of noncompliance may occur, including failure to fill the prescription, incorrect dosing or dosing intervals, and discontinuation of the medication prior to the recommended time.

A systematic review and meta-analysis of 46 studies of antibiotic misuse found a mean compliance rate of 62.2% (95% confidence level, 56.4% to 68.0%), although this study was not specific to pediatric patients (Kardas, Devine, Golembesky, & Roberts, 2005). In a review of the literature related to pediatric medication compliance, Winnock, Lucas, Hartman, and Toll (2005) found compliance ranged from 11% to 93% in the more than 250 articles they reviewed. Adherence to prescribed treatment regimen was measured in a retrospective cohort study of 24,438 Medicaid patients (89.39% under age 18 years) that found the overall adherence rate to be 11.74% (Tan et al, 2013). A study of adolescent females (aged 14 to 17 years) taking oral contraceptives pills (OCPs) found 45% of coital events were protected by OCPs (Woods et al, 2006). Clearly, medication adherence is less than ideal in children and adolescents.

Specific Factors That Influence Compliance

Long-Term Medication Regimens

Chronic illness, often including a daily medication regimen, presents a number of problems for the family. Adherence to daily preventive therapy for asthma is generally poor, with one large cohort study of 18,456 children enrolled in Medicaid reporting average adherence of 20% for inhaled corticosteroids and 28% for leukotriene inhibitors (Herndon, Mattke, Evans Cuellar, Hong, & Shenkman, 2012). Adherence to ADHD medication based on Medicaid prescription claims in Texas ($n = 62,789$) ranged from 9.8% (short-acting stimulants) to 25.8% (nonstimulants) (Barner, Khoza, & Oladapo, 2011). Even patients for whom noncompliance can be life-threatening are not taking their medications as prescribed. Children with sickle cell disease were found to have a refill rate for their daily medications of 58.4% (Patel, Lindsey, Strunk, & DeBaun, 2010). Of 104 adolescents prescribed antiretroviral treatment for HIV, 65.4% reported full adherence, with nonadherance associated with higher viral load (Chandwani et al, 2012). Risk factors for medication nonadherence after pediatric heart transplantation (median age 6 years) includes adolescent age at transplant, black race, Medicaid insurance, and ventilator or ventricular assist device support at transplant (Oliva et al, 2013).

Number of Medications Prescribed

The number of medications prescribed can have an impact on compliance with the regimen. The more medications that are prescribed, the lower the compliance rate is. Keeping medication schedules simple increases the likelihood of success for the treatment.

Medication Interval

Medication interval has a significant impact on the success of the treatment, especially given the number of families with both parents working and more children in day care. Children who are in school or have parents who are both working may not receive their medications as often as recommended if they are taking any medication that needs to be administered more than twice a day.

CLINICAL PEARL

Electrolyte solutions

- Pediatric electrolyte solutions are often not well accepted by children. One trick is to use electrolyte popsicles (Pedialyte) or freeze the bottled solution into homemade popsicles. The cold taste seems to be better accepted.

- Sugar-free Kool-Aid or another drink mix sweetened with Nutrasweet can be added to unflavored electrolyte solutions to make the taste of the electrolyte solution more acceptable to children.

Palatability

Palatability is often overlooked as a reason for noncompliance, yet in children it is a critical factor in medication compliance. Studies comparing the taste of a variety of antibiotics (Holas, Chiu, Notario, & Kapral, 2005; Powers, Gooch, & Oddo, 2000) determined that some antibiotics were ranked better tasting than others, with the cephalosporins (cefindir, cefixime, cephalexin, and cefaclor) ranked as the best tasting overall. Dicloxacillin ranked the worst for taste. Although no published reports studied taste differences between brandname and generic preparations, anecdotal reports from parents and patients suggest that brand-name preparations taste better. Of medications with the same efficacy profile, the best tasting is the easiest to administer to young children.

Cost

The cost of the medication needs to be addressed for patients who are not adequately insured for prescriptions. The cost of common antibiotics prescribed for otitis media range from $4 to more than $100 to treat a 15-kg child for 10 days. Prescribing an expensive antibiotic for a family who cannot afford to fill the prescription places the family in an uncomfortable position. Simply asking the family if they have insurance to cover the medication and then problem solving with them if they do not will increase the likelihood that the family will fill the prescription. For example, if an antibiotic is indicated, check the retail $4 list first to determine if the medication is available. If possible, give the family a few days of medication samples to defray the cost of the treatment if a less expensive medication is not available. Knowing which pharmacies in the local area are the least expensive or calling ahead for a price check before sending the family to the pharmacy is helpful. A family who knows the approximate amount that the medication will cost will not be surprised when the prescription is filled.

Family Issues

Family issues affect the family's ability to comply with the prescribed treatment regimen. Families in which both parents are working and therefore have limited time with their children have more problems with complex treatment regimens. Lack of social support can leave a parent isolated and make parenting more stressful. Parental fatigue is often overlooked as a factor in treatment outcomes. Parents who are fatigued can easily miss medication doses; even those who are usually well organized can miss medication doses when they are tired. Disruptive and dysfunctional families may have difficulty in following the plan of treatment because of the chaos present in the home. Another family situation that needs to be addressed when clinical improvement is less than satisfactory is parental use of the child's medications. For example, a child may be prescribed stimulants for attention deficit-hyperactivity disorder, and a parent or other family member may be abusing the child's medication. This is a situation no practitioner wants to encounter, yet there should always be some index of suspicion when the family history is not clear. All of these issues need to be accounted for when the practitioner is prescribing a medication and during follow-up on the patient's progress. They often present in an unclear fashion, and ferreting out the reason for noncompliance with the treatment regimen may take some time.

Improving Compliance in the Pediatric Patient

When poor compliance is identified, it is essential to address this issue and determine strategies with the patient and parent to improve the success of the treatment regimen. There are a variety of methods to improve the success of the treatment regimen, but first it is necessary to make sure that the diagnosis is accurate and that the drug therapy is beneficial.

Medication Concentration

Medication concentration can be adjusted in some of the liquid preparations. The practitioner can choose to prescribe a more concentrated form when a parent has difficulty administering medications to a patient. Many of the antibiotics come in different strengths, and giving one-half teaspoon is easier than administering a full teaspoon. Prednisone comes in two different strengths, as well as in tablets that can be crushed. By involving the parents in the decision to use a more concentrated form of a medication, you are allowing them some control over the treatment regimen, and they may therefore be more likely to administer the medication that is prescribed.

Written Versus Oral Instructions

Most practitioners should address the issue of written versus oral instructions in their own practice. Giving written instructions along with the oral directions will improve compliance. This is especially important for over-the-counter medications such as acetaminophen and ibuprofen. Parents need to understand the different formulations and dosing by weight, and every parent should have a weight-based dosing chart (Box 50-2).

Self-Monitoring Calendars

Self-monitoring calendars should be a standard in the treatment of preschool and school-age children. Children can apply a sticker or color in a box as each dose is taken. Parents should be involved in the process and set a reward for completion of the medication regimen. In acute illness such as otitis media, in which the patient will be returning to the clinic, the practitioner may offer a reward for a full calendar. Children with chronic illness, who are often on long-term medication, need to have a set reward for a certain number of days of successfully taking their medication. Parents need to take an active role in medication calendar usage, and they, too, should be praised for their participation in the medication regimen.

> ### BOX 50–2   PRESCRIBING OVER-THE-COUNTER PAIN MEDICATIONS FOR PEDIATRIC PATIENTS
>
> Pain in children can range from teething pain to pain associated with otitis media. Parents often ask the practitioner about using acetaminophen or ibuprofen for the treatment of pain in children. For the safety of their children and the efficacy of the medication, parents should be taught how to administer over-the-counter (OTC) pain medications properly.
>
> The two most commonly used analgesics in pediatric patients are acetaminophen and ibuprofen. Aspirin should never be given to children for acute pain management due to the risk of Reye syndrome, and the practitioner should teach parents this rule.
>
> Acetaminophen can be administered orally or rectally (suppository), and it peaks in 30–60 minutes. Dosage for children is 10–15 mg/kg/dose q4–6h.
>
> Ibuprofen is effective for pain control and has an additive anti-inflammatory effect, which appears to provide better pain control in acute otitis media than acetaminophen. The correct dosage is 5–10 mg/kg/dose q6–8h. Ibuprofen should not be administered by parents to children under age 6 months because immature kidneys are unable to excrete it, leading to increased risk of toxicity and renal damage. All children receiving ibuprofen should be well hydrated to prevent renal damage. Avoid ibuprofen if fluid intake is decreased.
>
> Although acetaminophen and ibuprofen provide good pain relief for mild to moderate pain and both have antipyretic effects, ibuprofen may be the drug of choice for night pain associated with otitis media because of its longer duration. Both drugs are equally easy to administer, although ibuprofen is not available in suppository form. Combining acetaminophen and ibuprofen in an alternating schedule for fever or pain is not recommended in the outpatient setting. One or the other, properly dosed, should be used. The goal of antipyretic therapy is not to reduce temperature to normal, but to decrease discomfort associated with fever.
>
> Give parents a dosing chart with their child's dose based on weight. The different strengths of acetaminophen must be dosed correctly.

Telephone/E-mail Reminders

Telephone or e-mail reminders are helpful in increasing compliance, especially if the parent is leaving the clinic with multiple prescriptions. A quick telephone call or e-mail allows the parent to clarify the treatment regimen and reinforces teaching that took place in the clinic.

Mobile Phone Medication Adherence Apps

There are a number of mobile phone apps available for reminding patients to take medications. In a review of 160 unique medication reminder apps, Dayer, Heldenbrand, Anderson, Gubbins, and Martin (2013) identified attributes to compare apps, including online data entry, cloud data storage, complex medication instructions (taper schedules, etc.), ability to export data, tracking missed doses, and the ability for the provider or pharmacist to input data. A medication regimen does not have to be complex in order to use a reminder app. For example, an app can be used to help remind adolescent females to take their daily oral contraceptive pill.

Contracts and Reinforcement Programs

Contracts or reinforcement programs may be necessary if compliance continues to be a problem. The practitioner, the patient, and the family need to be in agreement about the goals of the treatment contract and the consequences of non-compliance. A case conference may be necessary to involve other disciplines in the treatment. A home visit may provide information that leads to an altered treatment program that will be better tolerated by the family. The role of the practitioner is to attempt to simplify the medication treatment and

---

🟢 CLINICAL PEARL 🟢

Improving compliance with ophthalmic preparations

- Administration of ophthalmic preparations to toddlers and preschoolers is often difficult, and the incidence of noncompliance increases with each dose that is a battle to administer. Parents can safely restrain the child to administer eye medications as follows:

  1. Sit on the floor with the child sitting on the floor between the parent's legs.

  2. Place the child's feet near the parent's feet and the child's head between the parent's thighs.

  3. Slip the child's arms under the parent's thighs and, with the legs, hold the child's head and arms still.

  The parent then has both hands free to administer the eye medication. Although this procedure may sound drastic, it is a quick way for a parent to administer the medication when no other adult is around to assist with a squirming, resistant child.

- Older preschoolers and school-age children often cooperate with administration of eyedrops if they are told to lie back and close their eyes. Eyedrops can then be applied to the inner corner of the eyes (while the eyes are closed). Next, children are told to open their eyes, without any head movement. The medication rolls into the eye when the eye is opened. This is much easier than the bull's-eye approach of trying to get children to keep their eyes open for squeezing in drops.

still have an adequate therapeutic outcome. This goal should be shared with the patient and family.

Childhood Obesity Influences Outcomes

Over the past 30 years pediatric overweight and obesity have steadily increased. Approximately 17% of children and adolescents age 2 years to 19 years are obese (Centers for Disease Control and Prevention, 2013). Little is known about pharmacokinetic differences in obese children. Small studies on pediatric oncology patients indicate doxorubicinol, but not doxorubicin, clearance is decreased in patients with body fat greater than 30% (Thompson et al, 2009). Volume of distribution may be altered, particularly for lipid-soluble drugs. Obese children with nonalcoholic fatty liver disease may have altered metabolism of drugs, but large studies have not been conducted.

For the obese patient, the prescriber needs to decide whether to calculate the dose based on actual body weight or ideal body weight. When young children weigh as much as an adult, dosing quickly becomes a challenge. Although body weight may be consistent in an adult, liver and kidney functions are still at the chronological age of the child. Currently, no guidelines are available for dosing obese children, other than not to exceed adult doses of most medications. Studies are in progress and until guidelines are published, the nurse practitioner prescriber will need to use clinical judgment and monitor the patient closely for adverse effects if dosed by weight and efficacy if dosed by age.

GERIATRIC PATIENTS

Joan M. Nelson

P rescribing medications and predicting responses to these medications by older adults can be difficult because clinical drug trials often limit enrollment by age. Age-related changes in pharmacokinetics and pharmacodynamics can cause different responses to medications than those seen in the younger adult population. Older adults are at increased risk of adverse drug reactions as a result of the fact that they take more medications and due to the biological effects of aging and chronic diseases. Medication under- and overutilization by this population has been shown to increase the number of hospitalizations and emergency room visits, to worsen cognitive functioning, and to contribute to falls. Several large national initiatives geared toward reducing these catastrophic effects have been launched and will be discussed in this chapter.

DEMOGRAPHICS

The United States is rapidly aging. In 1900, only 2% of the U.S. population were age 65 and older, but by the year 2008 over 13% were older than 65. The U.S. Census Bureau anticipates that by the year 2030, older adults will comprise one-fifth of the U.S. population (The Federal Interagency Forum on Aging-Related Statistics, 2010). The rate of growth in the "old old" population of adults over the age of 85 is rising even faster. In the decade from 1990 to 2000, this population rose by over a million people, an increase of 25% of all people over 85 years of age in the United States (CensusScope, 2000). The dramatic rise in the older population results from both the increased birthrate during the time the baby boomers, who are now entering old age, were

born and because of increased life expectancy. In 1960, people who survived to age 65 could expect to live another 14.5 years, whereas currently, at age 65, the life expectancy is an additional 18.5 years. At age 85, a woman can expect an additional 6.8 years of life and a man is likely to survive another 5.7 years (Federal Interagency Forum on Aging-Related Statistics, 2010).

In adults over the age of 85, females outnumber males by a ratio of 3:1 and are, therefore, more likely to live alone than older males. Although only 10% of U.S. older adults live below the poverty level, members of ethnic minority populations are far more likely to live in poverty than Caucasians. Twenty-seven percent of older African American women and 20% of older Hispanic women live below the poverty level. Average prescription drug costs for older Americans were $2,107 in 2004, making it difficult for many older adults to purchase required medications (The Federal Interagency Forum on Aging-Related Statistics, 2010). Increased chronic illness, commonly seen with aging, is associated with higher prescription drug costs.

Diseases Associated With Aging

The most common chronic conditions among older adults are hypertension, arthritis, heart disease, cancer, and diabetes. Sixty percent of people over 85 have deficits in hearing and 28% have visual loss. These conditions cause functional losses; a staggering 47% of women over the age of 65 report some deficits in functional status (The Federal Interagency Forum on Aging-Related Statistics, 2010). These functional losses can make it difficult for older adults to manage their own medication administration due to an inability to read drug labels, see pill colors, and remember to take and order the medications in a timely manner.

Pharmacological Issues in Aging

Older adults comprise 13% of the population and use about one-third of all prescription and over-the-counter (OTC) drugs sold in the United States. One-third of older adults use three or more prescription drugs in conjunction with three or more dietary supplements (Nahin et al, 2009). This number is markedly higher for hospitalized patients or those living in nursing homes or assisted living facilities. Polypharmacy is not always inappropriate in this population of clients who have multiple chronic illnesses, but increased numbers of medications carry increasing risks. Budnitz, Lovegrove, Shehab, and Richards (2011) examined a large national database to discover that almost 100,000 Americans over the age of 65 were admitted to the emergency department (ED) annually, between 2007 and 2009 due to adverse drug events. Over half of these admissions were for patients over the age of 80 and four specific classes of medications accounted for over two-thirds of these ED visits: warfarin, insulin, oral hypoglycemic medications and oral antiplatelet medications.

PHYSICAL CHANGES ASSOCIATED WITH AGING

The physical changes associated with aging are responsible for some of the unique prescribing rules and drug effects seen with older adults. In this chapter, some of these physiological changes and their impact on pharmacokinetics and pharmacodynamics will be reviewed.

Mental Changes

Mental changes in the healthy older adult are minimal. Although white brain matter does begin to deteriorate at about 60 years, an inability of the older adult to function independently is not a normal part of the aging process. Disease processes are the culprits that rob older adults of the ability to think clearly and maintain independence. Both acute (hypoglycemia, infection, electrolyte imbalances, and many others) and chronic diseases, such as Alzheimer's disease and cerebrovascular accidents, may impair a person's mental status.

Cerebral blood flow, brain mass, and neurotransmitter concentrations are reduced as we age (Esiri, 2007), causing older adults to be more susceptible to the neurological side effects of drugs than younger people. These pharmacological effects can cause delirium, a reversible cognitive impairment. Younger people will likely respond to an infective process with fever, whereas older adults, who have reduced immunologic function and reduced ability to generate a fever, will often present with confusion.

Sensory Changes

Sight

Almost one-third of adults over the age of 65 have some impairment in their ability to see (Hartford Institute for Geriatric Nursing, 2005). Presbyopia results from a loss of elasticity in and thickening of the lens, which impairs near vision. Conditions that become increasingly prevalent with age, such as cataracts, glaucoma, and macular degeneration, can create difficulties for the patient in self-management of medications and can restrict the pharmacological choices available to treat the patient's medical condition in order to prevent worsening of the eye disease. Visual loss also makes it difficult for patients to manage their own medication or provide their own transportation and causes them to be increasingly dependent upon others.

Hearing

About one-third of adults over the age of 65 have some level of hearing loss, especially in the high-frequency range, and the incidence of hearing impairment increases with each decade (McCance & Huether, 2014). Cerumen impaction, seen in over one-third of older adults, further impairs hearing. Older adults have drier cerumen and are more likely to use hearing aids, which contribute to impaction (Roland et al, 2008).

Older adults may have lost their hearing gradually and be unaware that they are not fully hearing what is spoken. Missing

one or two words in the instructions for a prescribed drug could have devastating consequences.

Smell and Taste

The senses of smell and taste decline with aging and are further impaired with the use of medications (Hartford Institute for Geriatric Nursing, 2005). These sensory losses may impair appetite and nutritional status. Lack of dietary iron or the B vitamins can lead to atrophic changes of the oral mucosa, resulting in dry mouth and a change in taste.

Some older adults may complain of a burning mouth and tongue. Local trauma, poor nutrition, diabetes, or anemia can cause these symptoms. Chapter 50 discusses the role of taste and texture in the willingness of children to take certain drugs. Older adults also respond to taste and texture in taking oral suspensions.

Peripheral Sensation

Peripheral neuropathy, which can significantly increase fall risk, occurs in 28% of adults aged 70 to 79 and 35% of adults aged 80 and older (Vinik, Strotmeyer, Nakave, & Patel, 2008). Problems with circulation, vitamin deficiencies, and diabetes can aggravate an age-related loss of peripheral nerve function. Many classes of medications further contribute to fall risk, especially in the frail older adult. Prescribing requires a careful assessment of risk versus benefit of these agents.

Musculoskeletal Changes

Musculoskeletal changes associated with aging range from impaired manual dexterity, which can prevent older adults from opening medication containers, to mobility problems, which can keep them from getting to the pharmacy. These musculoskeletal changes can cause older adults to experience difficulty with drug administration and adherence. Mobility problems, including disorders affecting gait, limb function, manual dexterity, and driving, can threaten the independence and functioning of older adults, specifically their adherence to drug therapy.

Neurological diseases, such as cerebrovascular disease, Parkinson's disease, and motor neuron disease, can lead to increased difficulties in the practical application of drug treatments. Such problems may range from the inability to visit the health-care provider's office to the inability to open the childproof containers.

Immobility from joint deformity, pain, and impaired manual dexterity may make activating inhalers or nebulizers or applying eye drops difficult to perform. Some medications may dramatically improve patients' mobility (e.g., medications to treat Parkinson's disease), but others may dramatically exacerbate mobility problems (e.g., antihypertensives, tricyclic antidepressants).

PHARMACOKINETIC CHANGES

Absorption and Distribution

Older adults undergo normal age-related changes in the body that affect the action of bioactive substances. General absorption of drugs is not dramatically different in the older adult compared to the younger population for the vast majority of prescribed and OTC medications. Oral drugs are absorbed by the gastrointestinal (GI) tract. With aging, the GI tract produces less acid as fewer parietal cells are generated, but the change is too small to be clinically relevant. However, this small change does become clinically significant in the presence of drugs that compound this problem, such as proton pump inhibitors (Blume, Donath, Warnke, & Schug, 2006). There is decreased active transport of some drugs, causing decreased bioavailability.

Total body fat increases with age, whereas subcutaneous fat decreases (Hughes et al, 2004). Frail, older adults can have very little subcutaneous fat, which can reduce the absorption of transdermal drugs. This can be clinically important when managing pain with transdermal systems.

Distribution of drugs can be dramatically changed with age. Aging results in a reduction of lean muscle mass by about 20% and total body water by 10% to 15%, causing changes in the distribution of many drugs (Paddon-Jones, Short, Campbell, Volpi, & Wolfe, 2008). Pharmaceutical agents primarily distributed in lean body mass or body water may reach higher serum concentrations in older adults, resulting in magnified effects compared to similar doses in younger adults. Water-soluble drugs, such as lithium and digoxin, can have a smaller volume of distribution, resulting in a higher peak plasma concentration at normal dosages due to the lower ratio of water to fat in the body of the older adult. (Zagaria, 2005). This is especially important for drugs with narrow therapeutic ranges. Increased bioavailability is also apparent with drugs administered IM, which are often highly water soluble.

Lipid-soluble drugs, such as benzodiazepines, have a higher tendency to accumulate in adipose tissue, resulting in lowered serum concentrations. This accumulation in the adipose tissue can result in a prolonged duration of action due to an increased half-life. The result is a less intense immediate medication effect as well as a prolonged or unpredictable effect in the older adult.

Normal aging also results in a decrease, by as much as 20%, in serum albumin levels. Albumin is the primary drug-binding protein in the plasma. The consequence of these lowered serum albumin levels is fewer protein molecules available for binding to the drug and higher levels of free, unbound drug. It is free drug that exerts the physiological effect, so the result of decreased albumin is an increased potential for drug toxicity. This problem can be aggravated by poor nutrition, age-related liver changes, or the competition of multiple medications for protein-binding sites. With decreased binding ability, drug doses need to be reduced in order to prevent deleterious effects.

Metabolism and Excretion

Aging results in a decrease in both liver size and blood flow (Woodhouse & Wynne, 1988). Drug clearance by the liver depends on hepatic blood flow and enzyme activity. Acetylation and conjugation do not change appreciably with age. Oxidative

metabolism through the cytochrome P450 (CYP450) system does decrease with aging, resulting in a decreased clearance of some drugs.

The oxidative reactions of phase I metabolism decline secondary to these changes in the liver, resulting in decreased drug clearance and an increase in half-life for agents such as amitriptyline, morphine, and propranolol that rely on high rates of blood flow through the liver for extraction (Zagaria, 2005). In contrast, phase II metabolism is relatively unaffected by age, so that benzodiazepines such as temazepam and oxazepam, which are metabolized through phase II conjugation reactions, are better tolerated than diazepam, metabolized through phase I reactions. Reduction in metabolism is more pronounced in malnourished or frail elders.

First-pass metabolism is also decreased so that drugs like propranolol and verapamil, which undergo first-pass metabolism, have increased bioavailability in older adults. On the other hand, pro-drugs which rely on first-pass metabolism for activation, will act more slowly in older adults (Wilkinson, 1997).

Most drugs are eliminated through the kidney. The human kidney loses about 1% of its function every year, beginning at age 30, so that by age 80 there is generally a 50% decline in renal function. Dosing guidelines are available to help providers make appropriate adjustments for renal impairment. Examples of drug classes for which there is evidence of age-related reduction in clearance include antihypertensives, fibrates, sedative/hypnotic, and anxiolytic medications (Aronoff et al, 2007). Disease processes may be more of a factor in the reduction of renal function than normal aging. Diabetes and hypertension, for example, have been found to be powerful determinants of renal dysfunction in the very old (Wasen et al, 2004).

Determination of normal renal function is not easily established in the older adult. Although serum creatinine is the most reliable and easiest test to determine renal function in younger persons, it is an unreliable marker in older adults. Renal function tests are affected by poor nutrition and reduced lean muscle mass. Adequate protein ingestion is a requirement for evaluating accurate blood urea nitrogen levels, and adequate muscle mass is a requirement for determining accurate serum creatinine levels. Creatinine clearance evaluated with the Cockcroft-Gault equation (discussed in Chapter 2) is the best method for this evaluation (Zagaria, 2005). Although it is the most accurate method of evaluation, this equation still has limitations, especially in frail elders for whom it may overestimate creatinine clearance.

Table 51-1 presents common pharmacokinetic and pharmacodynamic age-related changes and the drug implications.

Table 51–1 Common Pharmacokinetic and Pharmacodynamic Changes in Older Adults

Pharmacokinetic Process	Changes in Older Adults	Implications
Absorption	Change not clinically significant	
	Oral drugs: Decreased acid production by parietal cells; delayed gastric emptying; reduced blood flow to GI tract. IM drugs: Decreased lean muscle mass.	Use of drugs that have same action as aging change may increase problem to level of clinical significance.
Distribution	Increased fat stores	Lipid-soluble drugs have greater Vd and longer half-lives.
	Decreased body water	Water-soluble drugs have smaller Vd and higher peak plasma levels.
	Decreased serum albumin levels	Decreased drug-protein binding; increased levels of free drug. Especially a problem for drugs with high protein-binding percentages. Changes onset and duration of action of highly tissue-bound drugs as well.
Metabolism	Decreased hepatic blood flow	Less first-pass effect so increased amount of drugs that have high first-pass breakdown and decreased amount of pro-drugs that require first-pass activation.
	Decreased CYP450 system function	Decreased metabolic clearance of drugs. Decreased metabolism of some drugs. Altered drug-drug interactions.
Excretion	Decreased renal mass and GFR Decreased tubular secretion	Decreased renal clearance of drugs. May require dosage adjustments. Treat older adults as if they had renal impairment.
Pharmacodynamic changes	Reduced thermoregulatory ability	Increased hypothermia risk. Direct effect on phenothiazines, BDZs, TCAs, and narcotics.
	Impaired baroreceptor function and altered fluid status	Postural hypotension with antihypertensives, TCAs, MAOIs, antihistamines.

BDZs = benzodiazepines; GI = gastrointestinal; MAOIs = monoamine oxidase inhibitors; TCAs = tricyclic antidepressants; Vd = volume of distribution.

PHARMACODYNAMIC CHANGES

Aside from the pharmacokinetic changes, one of the characteristics of old age is a progressive decline in counterregulatory (homeostatic) mechanisms and altered receptor sensitivity. Pharmacodynamic changes of aging involve increased sensitivity to drugs such as anticoagulants, and cardiovascular and psychotropic drugs due to common physiological changes in the cardiac and neurological systems. Decreased elasticity in the blood vessels and reduced heart rate responsiveness to the demands of exercise increase the risk for orthostatic hypotension in older adults. Reductions in cerebral blood flow and neurotransmitter concentrations enhance the neurological effects of pharmacological agents (Mangoni & Jackson, 2004). The results of this decline include less mitigation of drug effects, more intense drug reactions than those experienced by younger patients, and a higher rate and intensity of adverse effects (Zagaria, 2005).

Reflex tachycardia, commonly seen with vasodilator therapy, is often blunted, possibly due to dampened baroreceptor response. Caution must be exercised with the use of anticholinergic medications because older adults are very sensitive to adverse drug effects related to this class of medications. These adverse effects include cognitive impairment, hallucinations, dry mouth, blurred vision, glaucoma, constipation, nausea, urinary retention, and tachycardia.

Narcotic and psychoactive drugs can cause oversedation, confusion, and respiratory depression and distort the patient's sense of balance. Drugs that lower blood pressure may cause orthostatic hypotension. Some drugs used to treat diabetes are more likely to produce hypoglycemia. Diuretics carry an increased risk for fluid and electrolyte imbalances. Nonsteroidal anti-inflammatory drugs (NSAIDs) are more likely to produce GI bleeding, cognitive impairment, fluid overload, and hypertension. Coumarin anticoagulants have a greater effect on clotting factor synthesis such that required warfarin doses are generally lower in older adults compared to younger adults. Some over-the-counter (OTC) cold remedies with anticholinergic side effects may cause the patient with glaucoma to experience vision loss secondary to the increase of intraoptic pressure and commonly cause urinary retention and constipation.

Paradoxically, some older adults are less sensitive to certain drugs (Masoodi, 2008). For example, when compared to younger patients' reactions, older adults may have a decreased response to a beta blocker (propranolol), resulting in smaller reduction in heart rate or only a mild increase in heart rate in response to a beta agonist (epinephrine).

PHARMACOTHERAPEUTICS

The advanced practice nurse needs to consider the possibility of drug-disease interactions, drug-drug interactions, and drug-metabolism interactions when planning and monitoring drug therapy in the older adult. The onset of any new symptom in an older person should raise suspicion of an adverse drug reaction (ADR).

Older adults are at higher risk for drug interactions, not only because of physiological changes but also because of the medication practices of both health-care providers and patients. Nonadherence with drug therapy, either intentional or unintentional, is reported in up to 50% of older adults (Hughes et al, 2004). Health-care providers must be aware of the many compounding factors that create complexity in prescribing for the older adult population.

Polypharmacy

Polypharmacy is the concurrent use of several different drugs; the number of drugs constituting "polypharmacy" varies throughout the literature but is generally considered to be 5 to 10 medications, including OTC and herbal products. Polypharmacy alone does not necessarily create a problem. The problem begins when more drugs are prescribed than are clinically indicated or warranted. Polypharmacy becomes an issue for older adults when a medication regimen includes overlapping drugs for the same therapeutic effect. Another serious concern is the prescription of optional drugs for an effect that could be managed by nonpharmacological approaches. Other situations contributing to polypharmacy include the use of drugs prescribed to treat the adverse effects of other drugs rather than to treat the underlying problem, and drugs whose benefit is marginal at best. Failure to consider the patient's goals of care can also lead to overzealous use of medications in cases where limited life expectancy may make many medications inappropriate (Mitchell et al, 2009).

Polypharmacy contributes to ADRs, drug-drug interactions, decreased adherence to drug regimens, unnecessary drug expenses, and poor quality of life for the patient (Barat, Andreasen, & Damsgaard, 2001; Gray, Mahoney, & Blough, 2001; Gurwitz et al, 2003; Masoodi, 2008; Patel, 2003).

Multiple factors contribute to polypharmacy in the older adult. Older adults are more likely than younger patients to have multiple comorbidities managed by multiple providers. Disease-specific clinical practice guidelines often suggest multiple medications, which may interact with medications recommended by the guidelines for patients' other conditions.

Several steps can be taken to reduce polypharmacy (Bergman-Evans, 2004):

- Obtain a complete drug history and review current drugs (prescription and others) every 6 months. Look for drugs without indications and discontinue. (Many drugs must be tapered rather than abruptly discontinued to avoid serious withdrawal symptoms).

> ### CLINICAL PEARL
>
> **Start low, go slow**
> The Golden Rule of geriatrics: Start low, go slow, but go! Treat the problem, starting at lower dosages, and titrate up slowly over a longer period of time than for a younger person. Evaluate for ADRs before they become serious and costly.

- Avoid prescribing when the benefit is questionable. Consider the age of the patient and the stage of the disease when evaluating the benefit of prescription drug use.
- Evaluate for duplications in drug therapy. Simplify the regimen by using drug combinations or by prescribing single drugs that will provide multiple therapeutic effects whenever possible. The use of combination drugs improves adherence when compared to dual therapy.
- Review the medication list for drugs prescribed for an ADR. If these exist, explore whether the original drug can be withdrawn or changed to avoid this reaction. Avoid treating adverse reactions/side effects with more drugs. Treat the underlying condition, rather than the symptoms, if possible.
- Prescribe lifestyle changes and other nondrug therapies whenever possible. These may require support from family and other health-care providers.
- Clearly understand the difference between manifestations of the aging process and the disease state that must be treated.

CLINICAL PEARL

Avoiding ADRs
The first step in avoiding ADRs is to establish risk predictions. Polypharmacy is only part of the picture. Take into account age, gender, multiple comorbidities, body weight, renal and hepatic failure, and previous drug reactions. Avoid medications that create unnecessary risk for patients who are determined to be at high risk for ADR.

Adverse Drug Reactions

Because the prevalence of prescription medication use among older adults increases with advanced age, older adults are 2 to 3 times more at risk for ADRs. Older adults account for about one-quarter of emergency room visits and half of all hospitalizations due to ADRs (Budnitz et al, 2006). Risk of ADRs can be predicted based on the number of medications a patient takes and whether he or she has suffered a previous ADR (Onder et al, 2010).

Poor medication practices of older adults can also contribute to ADRs. Examples of poor practices include using another's medications, changing the medication regimen without notifying the provider, and neglecting to inform the provider about all therapies being utilized. Preventable ADRs are most commonly associated with the use of anticoagulants, atypical antipsychotics, loop diuretics, opioids, ACE inhibitors, antiplatelet agents, antidepressants, benzodiazepines, insulin, and laxatives (Gurwitz et al, 2005).

Providers can help to reduce ADRs with appropriate drug prescribing, monitoring, and dosing. Consistent use of the "start low, go slow" axiom will help reduce potential problems. Start with the lowest dose that will provide a therapeutic effect and titrate upward at a slower rate than is used with

younger adults. Monitoring older adult patients closely for deterioration in function (including physiological) and cognition is also necessary. Computerized order entry and electronic decision support tools with computer alerts may help to reduce ADRs.

Medications should be reconciled with the patient's pill bottles and drug list at each visit. Medication lists should be reviewed to see if there is an indication for each drug and if any can be discontinued. The advanced practice nurse should check to see if any medications can be substituted with nonpharmacological therapy or a safer drug. The dosing schedule should be made as simple as possible. Providers, on the other hand, need to ensure that all health conditions are being optimally treated and should not avoid the use of drugs with known benefit (Scott, Gray, Martin, & Mitchell, 2012).

Involving the patient in his or her care can also help to reduce ADRs. Some ways that patients who are competent to manage their own medications can play a role in reducing ADRs include:

- Maintaining a current and accurate drug record, including allergies and previous ADRs. This list should include generic and brand names of medications to avoid duplication.
- Bring a "brown bag" including all herbal and dietary supplements, OTC, and prescription medications to each clinic visit.
- Ask for a patient information sheet for each medication and review drug-drug interactions and contraindications.
- Use a medication organizer or "pill box."
- Make an appointment with the primary care provider as soon as possible after transitioning care from a hospital or rehabilitation center so that medications can be reconciled.

The Centers for Disease Control and Prevention (CDC) has developed a medication safety program with information for patients about high-risk medications and medication safety strategies that is available at www.cdc.gov/medicationsafety/. The Food and Drug Administration (2012) is spearheading a multiagency effort called the "Safe Use Initiative" that aims to coordinate efforts in order to improve the safe use of medications and to prevent harm caused from medication errors, abuse, and misuse. The American Pharmacists Association and the National Association of Chain Drugstores Foundation (2008) have created a service model to help with medication management.

Drug-Drug and Drug-Food Interactions

Empirical data about drug-drug interactions in community-living older adults are very likely underestimated. Pharmacological interventions contribute significantly to the treatment of diseases; however, ADRs also occur more frequently with the increased use of pharmacological treatments. Drug-drug interactions are a significant contributor to hospital and emergency room visits for ADRs (Juurlink, Mamdani, Kopp, Laupacis, & Redelmeier, 2003).

Interactions can also occur between prescription drugs and OTC medications and herbal remedies. These nonprescription remedies should also be included on the comprehensive medication list maintained by the older adult.

Drug-food interactions are also important, so a dietary assessment should be done. The patient is the best source of information about any ADRs he or she might have experienced. Ask about allergies and adverse reactions to both medications and foods. Drug-drug and drug-food interactions are presented throughout this book in each drug class.

During the drug history assessment, providers need to inquire directly regarding the use of OTC drugs, herbs, and vitamins. Specific questions should be asked in the review of systems that relate to the common ADRs that older adults experience (e.g., constipation). Providers should also instruct older adults to maintain a current medication list. This list should be kept accessible for use by emergency care providers.

Drug-disease interactions may also occur. Patients with Parkinson's disease have increased risk for drug-induced confusion. NSAIDs can exacerbate heart failure and reduce the effect of other drugs used to treat hypertension. Urinary retention may occur in older adults with benign prostatic hyperplasia if they take decongestants or anticholinergic drugs. Table 51-2 highlights some frequently occurring drug-drug interactions that can lead to adverse drug reactions.

Alternative Medicines

Utilization of alternative medicines is worth investigating, and knowledge about this area is valuable. Several reputable drug information sources now provide data about these drugs and these are discussed in Chapter 10. Diverse cultures, fads, and advertising have combined to make alternative medicines more prevalent now in the American culture. Use of complementary therapies is very common in older adults. Some common herbs and alternative therapies include the following:

- "Anti-aging" DHEA (dehydroepiandrosterone) and growth hormone
- Ginkgo biloba to prevent or treat dementia
- Saw palmetto to relieve the symptoms of benign prostatic hyperplasia
- Chondroitin sulfate and glucosamine sulfate for osteoarthritis
- St. John's wort and SAMe (S-Adenosyl-L-Methionine) to treat depression

Many practitioners utilize herbal medications, but the practice is very diverse and complicated. If the practitioner has only a limited knowledge of herbal medications or cultural practices, opening the dialogue with the older adult to understand the patient's practices will help in avoiding the adverse reactions of polypharmacy. Contact with a local person who is knowledgeable concerning these topics will help the practitioner prescribe and recommend appropriate treatment. Chapter 7 deals with cultural influences on pharmacotherapeutics.

Assessment

Assessing functional ability may be one of the most important steps in evaluating appropriate pharmaceutical interventions.

● CLINICAL PEARL ●

Medication review

Have the older adult bring all the drugs he or she is taking, including herbs, vitamins, and OTC drugs, in a brown bag to the annual visit. This will enable you to see all the drugs and to determine if there are overlapping drugs that could be eliminated, combinations that could reduce the total number of drugs, or drugs prescribed by other providers that the patient failed to mention. It also helps to evaluate the patient's knowledge of the drugs, including why the drug is being taken and if he or she understands the ADRs.

Using a thorough and quick checklist at each clinic visit with older adult patients provides an accurate evaluation of their understanding of the drugs and their ability to manage the regimen. Box 51-1 is a questionnaire that may be used for this assessment.

Table 51–2 Selected Common Drug-Drug Interactions in Older Adults

Drug	Drug	Interaction
Warfarin	Macrolides, trimethoprim-sulfamethoxazole, fluoroquinolones, metronidazole, acetaminophen	Changes in INR
Warfarin	NSAIDS, fish oil, garlic, ginseng, gingko, ginger, vitamin E	Increased bleeding risk
Potassium-sparing diuretics	ACE inhibitors	Hyperkalemia
Cholinesterase inhibitors	Anticholinergic medications	Antagonistic effects
Sinemet	Antipsychotic agent	Antagonistic effects
Clonidine	Beta-blockers	Bradycardia and heart block and antagonistic effects
Glyburide	Trimethoprim-sulfamethoxazole	Hypoglycemia
Digoxin	Clarithromycin	Digitalis toxicity

Older adults' abilities to manage activities of daily living and their cognitive status and social systems are strong indicators of their ability to manage pharmaceutical interventions. Several assessment tools developed specifically for use with older adults include the Katz Index of Independence in Activities of Daily Living (ADLs), the Lawton Instrumental Activities of Daily Living (IADLs), the Folstein Mini Mental Status Exam (MMSE), and the Geriatric Depression Scale (GDS). These tools are short, quick, and provide evidence-based assessment data for the evaluation of an older adult's overall functional ability (see Clinical Pearl, "Resources").

In addition, assessing older adults' sensory functions (sight, hearing, taste, touch) is important because of the possible impairments that occur with aging that may affect the patient's ability to manage a medication regimen. An accurate functional assessment helps assess risk behaviors, prevent catastrophic events triggered by ADRs or inadvertent misuse of medications, and improve a patient's quality of life.

Cognitive function must also be assessed. The MMSE or Mini-Cog (see "Try This" resource listing below) can be used to evaluate cognitive function. Several tools have been developed and tested in order to help assess a patient's ability to manage medications, but there is currently insufficient evidence to support the use of any one specific tool (Elliott & Marriott, 2009). The Medication Management Ability Assessment (MMAA) (Patterson et al, 2005) is a 1-hour assessment and the Medication Assessment Instrument (MAT)

(Schmidt & Lieto, 2005) takes about 15 minutes to administer. Both assessments require the patient to set up a day's supply of a simulated medication regimen. The Drug Regimen Unassisted Grading Scale (DRUGS) (Edelberg, Shallenberger, & Wei, 1999) and Medication Management Instrument for Deficiencies in the Elderly (MedMaIDE) (Orwig, Brandt, & Gruber-Baldini, 2006) assess the patient's ability to set up his or her own medications and take 15 and 30 minutes, respectively, to administer. These assessments can help to highlight barriers to optimal medication management and help to identify resources to combat these barriers.

- Helpful assessment tools: Try This and How to Try This Series—Resources for the care of older adults, including assessment tools and instructions for the proper use of those tools: http://consultgerirn.org/

Adherence

Adherence problems fall into two categories: intentional and unintentional. Intentional lack of adherence can occur because of doubt about the drug or its validity to treat the problem, lack of motivation, poor acceptability of the drug or the provider, poor tolerability of the drug and its effects, advice from others, dislike of the formulation, or financial concerns. Many older adults live on fixed incomes and have limited drug coverage in their health insurance plan. The Medicare Prescription Benefit (Medicare Part D) is a good first step, but it does not cover all drugs or the full cost of a drug. Some generic and OTC drugs are available on the $4.00 list, offered at many pharmacies, but this list is limited. Some older adults engage in "intelligent nonadherence" (Hindi-Alexander & Throm, 1987). They believe they are making an informed or valid decision to stop the drug or change the dose, but they fail to discuss it with their provider.

Unintentional nonadherence can occur because instruction about the drug and its use was poor or lacking altogether; the drug dosing regimen is complex and the older adult has some degree of cognitive, visual, or auditory impairment or dysphagia; the drug container is difficult to use; or the older adult has decreased mobility and may not be able to get to a pharmacy to fill the prescription. All of these are compounded if the person lives alone and has no family support.

Older adults often require small doses, but the dexterity needed to halve tablets may be a problem. Providers can help by prescribing the lower dose or by having the pharmacy halve the tablets for the patient and put them in blister packs. Pharmacies may change the company that supplies their generic drugs. The new generic may be a different color or shape. Whereas ordering generics can save the older adult

money—sometimes a great deal of money—older adults often use color and shape to keep track of their medications. If a change is required, special attention needs to be taken to assure that they know about the new drug and that it is the same medication as they were previously taking. Taping one old tablet and one new tablet on a paper together with the instructions may be helpful.

A variety of other methods can be used to improve adherence. Calendars, charts, medication boxes, measured-dose systems, and other memory aids are helpful. Planning drug administration around daily activities or at the beginning of the day can serve as a memory aid and increase adherence. Home delivery of drugs can be arranged. Regimens can be simplified. Caregivers and home-health visits can be supplied if needed. Chapter 6, "Factors That Foster Positive Outcomes," has other suggestions as well.

Exciting innovations to improve monitoring of adherence are on the horizon. The Food and Drug Administration has just approved a tiny ingestible sensor, made of silicon, which can be incorporated into the drug tablet or capsule and is able to relay information to a disposable patch that is applied to the patient's skin. Information about time of ingestion as well as physiological data such as temperature, heart rate, and respiratory rate are relayed to the patch, which communicates with a handheld mobile device for information display (Pullen, 2012).

Advice to Prescribers

Some practical guidelines that can be applied in most settings to facilitate drug therapy include the following:

1. While writing a prescription, assess potential problems that may create unintentional medication nonadherence. Can the patient open and remove the tablets from the childproof bottle or the prepackaged blister packs? Can the patient being asked to take half a tablet see the tablet well enough and have the manual dexterity to break or cut the tablet in half?

2. If an inhaler has been prescribed, does the older adult have the manual dexterity, cognitive function, and inhalation volume to activate the inhaler? Older adults require the use of a spacer (Aerochamber) in order to receive the fully inhaled dose from an MDI. Breath-activated inhalers (BAIs), which deliver the drug upon inhale without requiring the patient to push on the canister, have been developed to assist the patient with manual dexterity problems.

3. Home medication assessments of frail older adults may reveal drug administration problems, including incorrect dosages, incorrect frequency, use of expired drugs, and drug omission. Home visits could lead to improved pharmaceutical interventions and adherence. With the recent changes in Medicare reimbursement, the nurse practitioner can be reimbursed for such a home visit.

4. Utilize a pharmacist who has educational information and the ability to check for potential drug-drug interactions or duplications that can arise with medications from multiple prescribers.

Self-Medication Practices

The majority of minor, acute illnesses are treated independently, by patients, without consulting a primary care provider (World Health Organization [WHO], 2007). The current cohort of older adults grew up in a time when they went to the local druggist with their health/illness problems and together they decided on a drug/potion solution. They often also asked family members who were considered to be knowledgeable in the area of the problem or who had had similar symptoms. Health-care providers were considered "consultants" not "controllers" of their health/illness and its management.

In addition to use of prescribed drugs, older adults commonly use other products such as OTC drugs, herbal remedies, and dietary supplements. About half of community-dwelling, older American women use at least one dietary supplement (Qato, Alexander, Conti, Johnson, Schumm, & Lindau, 2008). There is a widespread misperception among the general public that OTC drugs and dietary supplements are generally safe.

Self-prescribing of potentially dangerous OTC medications, use of someone else's prescribed medication, over- or underuse of prescribed medications, and underreporting of drug side effects are common problems among older adults that contribute to adverse drug reactions (Neafsey et al, 2011). Box 51-2 presents poor medication practices commonly seen in older adults.

Inappropriate Prescribing: Drugs to Be Avoided in Older Adults

Medication toxic effects and drug-related problems can have profound medical and safety consequences for older adults and economically affect the health-care system. Beers, Ouslander, Rollingher, Reuben, and Beck (1991) first produced a list of explicit criteria for determining inappropriate medication use in the elderly. The list was updated in 1997 and again in 2003 and 2012 (American Geriatric Society [AGS], 2012; Beers, 1997; Fick et al, 2003).

Commonly referred to as the Beers Criteria, the authors have determined that medications found to be in conflict with these criteria should be discontinued, unless compelling evidence exists for their use in the older adult (AGS, 2012; Bergman-Evans, 2004; Fick et al, 2003). The decision to list

---

BOX 51–2 POOR DRUG PRACTICES COMMONLY SEEN IN OLDER ADULTS

- Using another's medications or remedies.
- Changing the prescribed medication regimen without informing the provider.
- Utilizing self-care practices based on no or poor information.
- Neglecting to inform the health-care provider about all therapies being utilized.
- Hoarding medications.

drugs and to rate them as "high concern" or "low concern" was made by a group of experts using the Delphi method. Drugs rated "high concern" included those that should be generally avoided in persons 65 years or older because they are ineffective or they pose unnecessarily high risk for older persons and a safer alternative is available. Drugs rated "low concern" included those that should not be used in older persons known to have specific medical conditions. These medications include long-acting benzodiazepines, sedatives, long-acting oral hypoglycemics, analgesics, antiemetics, and gastrointestinal antispasmodics. The comprehensive list of medication potentially inappropriate for use in older adults may be accessed at www.americangeriatrics.org/files/documents/beers/2012BeersCriteria_JAGS.pdf (AGS, 2012). It is imperative to seek out safer alternatives for those medications with a narrow therapeutic range, very slow elimination rates, or for which elimination is dependent on kidney function.

The Beers Criteria have been criticized over lack of evidence to support their effectiveness at reducing adverse drug events and reducing costs of care and because drugs known to cause adverse drug events are omitted from the list (O'Mahoney, et al, 2010). The Screening Tool of Older Persons' Prescriptions (STOPP) and the Screening Tool to Alert to Right Treatment (START) are new, validated tools for identification of inappropriate prescribing in the older adult that are suggested for use in conjunction with the Beer's Criteria (O'Mahoney et al, 2010). These criteria were developed by a consensus panel in the United Kingdom and Ireland, using the Delphi process, and have been shown to have good interrater reliability. Drugs to be avoided using the STOPP criteria and started using the START criteria are listed by body system.

About half of hospitalized older adults and one-fourth of community-dwelling older adults (Gallagher, Ryan, Byrne, Kennedy, & O'Mahoney, 2008) were found to lack one or more medicines that were known to be potentially beneficial, such as aspirin in patients with known coronary artery disease. The START criteria list these types of medications that should be used in older adults with specific conditions. In a study comparing hospital admissions of older adults in Europe due to the use of potentially inappropriate medications, violations of STOPP criteria were found to lead to these hospitalizations more often than violations of the Beers Criteria (Gallagher & O'Mahoney, 2008; Hamilton, Gallagher, Ryan, Byrne, & O'Mahoney, 2011). These results may differ geographically since medications on the Beers list include those more frequently used in the United States, whereas those on the STOPP list are biased toward those generally used in Europe. The American Geriatrics Society therefore recommends the use of both sets of criteria (AGS, 2012).

TRANSITIONS OF CARE AND CARE SETTINGS

According to the Institute of Medicine report (IOM), medication errors due to poor communication results in approximately 98,000 patient deaths per year (IOM, 2000). Of the 4,000 sentinel events from the last decade, the Joint Commission concluded that 60% were the direct result of ineffective communication, and of these, 70% resulted in patient death (Leonard, Graham, & Bonacum, 2004). Good communication is especially critical in the care of the older adult, who often has multiple specialists and frequently transitions from care setting to care setting. Frail older adults often live in independent living or assisted living facilities but may transition to emergency departments, hospitals, and skilled nursing facilities during periods of illness. Transitions between care settings represent periods of patient vulnerability, especially for older adults for whom comorbid illness, functional impairment, and multiple caregivers can compound complexity and compromise safety.

Each setting has its own unique challenges for the medical prescriber. A description of several of the living environments available for older adults and the personnel involved in each is critical to understanding these challenges.

- Private homes: Many older adults remain independent in their own homes and may require informal assistance from family, friends, and neighbors in order to pick up medications from the pharmacy, order medications, set up pill boxes, etc. After seeking the patient's permission, it may be as important to communicate the plan of care and information about medications ordered to the informal caregiver as it is to the patient. Investigation of limitations related to availability of care is important; for example, an adult child may only be available to help the patient acquire medications on his or her day off from work, so alternative plans may need to be made for medications needed more urgently.
- Home care is sometimes available as adjuvant care for the homebound older adult and can be provided as skilled or unskilled care. Skilled care, provided by a nurse or licensed physical or speech therapist, is reimbursed by Medicare for a limited period of time following a hospitalization, with the goal of restoring baseline functioning. Occasionally, the patient will be able to receive skilled services for a longer period of time as long as the "skilled need" continues to exist. Examples of skilled needs include wound care, IM injections, and catheter changes (Centers for Medicare and Medicaid Services [CMS], 2012).
- Many frail older adults have no "skilled needs" but do need help with instrumental activities of daily living. If the older person has no available family or friends to provide these services, they often utilize home caregivers and pay out of pocket for this care. These caregivers may change over time and have no nursing or medical training. The prescriber may need to communicate with these caregivers, who are charged with administering and organizing the patient's medications. It is important to remember that information should be provided in a manner appropriate for a lay audience. When soliciting information about the patient's health status from these caregivers, it is important to remember that they are not trained health-care providers.
- Patients who live independently and self-manage their medications will benefit from a simplified medication regimen, including the substitution of long-acting

medication for drugs requiring multiple daily doses and combination pills, when available. Medications that interfere with cognitive functioning should be avoided. Patients should be encouraged and taught to use pill boxes that are divided by days of the week and times of day. Coordinating medication administration with key daily activities like mealtimes, grooming routines, etc. can help patients remember to take medications appropriately.

- Independent living facilities provide individual apartments for seniors with no nursing or medical assistance. These facilities usually include an option for dining within the facility and provide transportation services to shopping and entertainment. The health-care provider will encounter the same limitations when providing care in these facilities as with patients who live in private homes. These apartments are, essentially, private homes with a few additional, nonmedical services.
- Assisted living facilities (ALF) exist as small group homes with 4 to 8 residents or as large facilities with over 100 residents that provide assistance with activities of daily living and 24-hour supervision. They generally share a philosophy toward providing a home-like, rather than a medical, environment and are not licensed as health-care facilities. ALFs are regulated by states, resulting in variable standards and admission criteria across the nation. Availability of nursing support in assisted living varies widely; some of the larger facilities have 24-hour nursing care, whereas most have a licensed practical nurse available for part of the day on weekdays only. Smaller facilities rarely have a nurse on staff.
- Residents of ALFs take an average of 9 to 10 medications (Young et al, 2008). Some patients self-administer medications, in which case provider concerns are similar to those associated with private homes or independent living facilities. Most patients living in ALFs require some help with medication management, however. Requirements for training of personnel who may administer medications in ALFs vary by state, but the majority of states allow nonlicensed personnel to administer some medications. Colorado, for example, allows medications to be administered by an unlicensed Qualified Medical Administration Person (QMAP), who records the administration on a medication administration record (MAR). QMAPs are not permitted to make any assessments or evaluations or exercise judgment related to these medications and may not administer injectable medications, including insulin. Written prescriptions for all medications, including OTC medications, dietary supplements, and herbal supplements must be provided in order for the QMAP to legally administer the drug or product. QMAPs receive one day of instruction related to medication administration and then take an exam that includes a practicum and a written portion (Department of Regulatory Agencies [DORA], 2008).
- Ninety percent of ALF residents have some level of cognitive impairment (Zimmerman et al, 2007), which is often the reason for moving into the ALF. In these cases, the prescriber is dependent upon the ALF staff to recognize and report symptoms that may signal disease. Since older adults often present with atypical signs and symptoms of disease, the untrained caregiver may miss and fail to report significant changes in health status. These caregivers may also call to insist upon treatment for a symptom expressed by a frail older adult when, at times, the risk of treatment for this vulnerable patient outweighs the benefit. Providers may have unrealistic expectations related to the caregivers' knowledge and ability to monitor for potential drug side effects. Specific orders for monitoring of vital signs related to drug effects will need to be provided to ALF staff. Careful communication and mutual understanding between prescribers and ALF staff is crucial to optimal care provision.

- Prescribers must remember to write prescriptions for all medications, including supplements and OTC medications, and to fax these prescriptions to the assisted living facility in order to ensure that patients living in this environment will actually be able to receive the drugs that are ordered. Any dose change or order for a new medication as substitute for another must be accompanied with an order to discontinue the initial dose or medication in order to avoid duplicative therapy. Prescribers must recognize the limited knowledge and experience of QMAPs and provide adequate additional instruction related to medications ordered. The provider must be knowledgeable about limits in the QMAPs' ability to administer injectable medications and monitor side effects of the drug.
- It is not uncommon to see patients leave their primary care provider's office with a prescription in hand for a given medication. The patient may pick up the medication from the pharmacy and return to the assisted living facility only to learn that the drug may not be administered, since there is no order for the ALF staff to administer it. Messages communicated to the patient related to dose or drug changes are insufficient to create this change if the medication is managed by the facility.
- Skilled nursing facilities (SNFs) are sometimes called "rehabilitation" because they provide short-term care after hospitalization in order to help the patient return to baseline functioning or learn to function with newly acquired deficits. They also provide professional staff for monitoring, treating, and evaluating a health condition. SNF care is not available when care needs are strictly custodial (ADL and IADL support) (CMS, 2012). SNF stays are reimbursable by Medicare with escalating co-pays for longer stays. SNFs are highly regulated by the Centers for Medicare and Medicaid Services as health-care facilities. CMS requires oversight of medication use by a licensed pharmacist and administration of medications only by nursing staff, who are also charged with monitoring for ADRs. CMS requires pharmacists and providers to collaborate to ensure that

each medication is associated with a diagnosis, dosages and duration of use of medications are consistent with manufacturer guidelines, nonpharmacological interventions are used as substitutions or adjuvants to pharmacological therapy, medication side effects are considered as potential causative agents for newly emerging symptoms, and that appropriate drug monitoring is performed (Long Term Care Professional Leadership Council, 2009).

- Prescribers working with patients in SNFs should be prepared to collaborate with pharmacists and to participate in quality improvement activities related to improving medication administration practices and patient safety. Queries by pharmacists related to drug substitutions, discontinuations, and monitoring are commonplace in this setting. As with ALFs, prescribers need to be sure to write discontinuation orders when substituting one drug for another or when changing medication dosages.

- Long-term care (LTC), or "nursing home" care, is utilized by people whose care needs exceed those that can be provided in the home or in assisted living facilities. Twenty-four-hour nursing care is provided and regulated by CMS in the same way that SNF care is regulated, but LTC costs are not covered by Medicare. Issues with prescribing are similar for LTCs and SNFs.

GENERAL PRINCIPLES FOR PRESCRIBING FOR OLDER ADULTS

Chapters 1 and 3 provide information about rational drug selection for the general population. All of these recommendations are valid for older adults but some are especially important for this population:

- Before prescribing, collect a complete drug history—including herbs, vitamins, and nonprescription drugs that the patient is taking. Ask specifically about the latter categories, because older adults may not consider these to be drugs.

- Evaluate if drug therapy is required. Determine if the problem can be treated with nonpharmacological interventions or if it can be resolved by removing unnecessary drugs from the patient's medication regimen. Discontinue drugs when possible if the benefit is unclear or the adverse effects of the drug result in nonadherence.

- Avoid a drug if the benefit is marginal or if a nonpharmacological alternative exists. This is especially true of high-cost newer drugs. Determine if the newer drug provides some unique benefit and if the benefit of adding an additional drug to the medication regimen is sufficient to justify the cost, the increased complexity of the regimen, and the risk of adverse reactions.

- When therapy is deemed appropriate, start low and go slow. However, do not fail to prescribe appropriate therapy in doses that are sufficient to resolve or treat the problem.

- Evaluate if the drug and its formulation are appropriate for older adults based on the normal physiological

changes associated with aging. Check the Beers and the STOPP criteria to ensure the drug is appropriate to use in this population.

- Use single daily-dose regimens or the simplest effective regimen. Avoid polypharmacy wherever possible.
- Limit the use of prn drugs.
- Consider all new drugs as a therapeutic trial; stop the drug if it is ineffective.
- Attempt to prescribe a drug that will treat more than one existing problem (e.g., an ACE-inhibitor to treat hypertension, heart failure, and/or as renal protection in diabetes).
- Provide legible written instructions and follow up on adherence to the treatment regimen.
- Consider the unique nature of individuals in terms of their diseases, comorbid conditions, and experiences with medications when prescribing.

PAIN MANAGEMENT: ACUTE AND CHRONIC PAIN

Ruth L. Schaffler

OVERVIEW OF PAIN CONCEPTS

Pain is the most common reason people seek health care (Centers for Disease Control [CDC], 2013; National Institutes of Health [NIH], 2013) not only in the United States but worldwide (Brennan, Carr, & Cousins, 2007; Scholten, Nygren-Krug, & Zucker, 2007); people expect pain relief when seeking treatment. Brennan and colleagues (2007) and Fishman (2007) declared pain management as a human right but also stated that a standard of care for pain management is neither an absolute science nor is it free of risk. Despite research that has increased the understanding of pain management and has broadened knowledge of effective methods to assess and manage pain, undertreatment of pain has been widely reported in the literature as a significant clinical problem (Wu & Raja, 2011). Failure to treat pain is unethical, poor clinical practice, and a violation of the human right to have pain appropriately managed. The Institute of Medicine (2011) called for examining pain as a national health problem and transforming the understanding, prevention, assessment, and treatment of pain.

Pain is defined by the International Association for the Study of Pain (IASP) as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage, or both"; however, pain is a subjective complaint. IASP (2012) updated a taxonomy of pain terms that have specific application to the perception of pain:

- Allodynia—pain from a stimulus that does not normally produce pain
- Analgesia—absence of pain in response to stimulation that would normally be painful
- Causalgia—a syndrome of sustained burning pain after a traumatic nerve lesion
- Dysesthesia—an unpleasant abnormal sensation, whether spontaneous or evoked
- Hyperalgesia—increased pain from a stimulus that normally provokes pain
- Hyperesthesia—increased sensitivity to stimulation
- Hyperpathia—a painful syndrome characterized by an abnormally painful reaction to a stimulus, especially a repetitive stimulus, as well as an increased threshold
- Hypoalgesia—diminished pain response to a normally painful stimulus
- Hypoesthesia—decreased sensitivity to stimulation

- Neuralgia—pain in the distribution of a nerve or nerves
- Neuritis—inflammation of a nerve or nerves
- Neuropathic pain—pain caused by a lesion or disease of the somatosensory nervous system
- Neuropathy—a disturbance of function or pathological change in a nerve: in one nerve, mononeuropathy; in several nerves, mononeuropathy multiplex; if diffuse and bilateral, polyneuropathy
- Nociception—the neural process of encoding noxious stimuli
- Nociceptive pain—pain that arises from actual or threatened damage to nonneural tissue and is due to the activation of nociceptors
- Nociceptor—a high-threshold sensory receptor of the peripheral somatosensory nervous systems that is capable of transducing and encoding noxious stimuli
- Paresthesia—an abnormal sensation, whether spontaneous or evoked
- Sensitization—increased responsiveness of nociceptive neurons to their normal input and/or recruitment of a response to normally subthreshold inputs

Suffering is an emotional reaction to pain and can be manifested by feelings of helplessness or hopelessness (Schaffler, 2007). Understanding of these terms can help the practitioner assess the pain symptoms, consider causality, and develop the best pain management plan for patients with specific presentations.

Pain can be either acute or chronic and is generally classified according to duration of symptoms and the presence or absence of sympathetic nervous system activity. Acute pain is associated with tissue injury and resolves when healing occurs and is subcategorized as physiological. Chronic pain lasts more than 6 months, well beyond the expected time of injury healing, and is subcategorized as pathological. Table 52-1 identifies the differences between the two pain categories. Each will be discussed in depth.

The Experience of Pain

Pain is a subjective experience with both sensory and emotional components, a uniquely personal experience that virtually a ll

people encounter at some point during their lifetime. The IASP definition of pain recognizes that pain is a perception and, as such, may or may not correlate to a source of injury that can be identified. Stimulation in the nociceptive system, the physiological mechanisms of pain, can occur with a disease process without a specific injury being present. In other cases, pain may not be related to a physical process, which indicates the influence of emotional and psychological factors that produce subjective reports of pain.

McCaffery (1972) defined pain as "Whatever the experiencing patient says it is and exists whenever he says it does" (p 8). It is important that the patient's statements about pain are believed by the practitioner as an initial step in pain management. A comprehensive assessment is imperative but the practitioner should also understand the nature of the patient's pain in terms of etiology, pathophysiology, relevant comorbid conditions, and the impact of the pain on activity and quality of life when making treatment decisions. Melzack and Casey (1968) developed a model for pain levels in terms of a hierarchy with three components:

- Sensory-Discriminative—the location, intensity, and quality of pain
- Motivation-Affective—depression or anxiety associated with the pain
- Cognitive-Evaluation—the patient's thoughts about the significance of the pain

These components influence the descriptions and importance of the pain experience that need to be acknowledged and explored.

Pain Threshold and Pain Tolerance

Pain threshold is the lowest point at which a nociceptive stimulus is perceived as pain. The perception of pain varies widely among patients and even within the individual at times. Perceptual dominance, the experience of intense pain in one location, is likely to increase the threshold in other areas. An example might be a trauma patient with multiple injuries who perceives only one injury as painful. The significance of pain as a threat to well-being may also influence the pain

Table 52–1 Comparisons of Acute and Chronic Pain

	Acute	**Chronic**
Etiology	Physiological	Pathological
Onset	Sudden	Gradual development
Localization	Generally well identified	Less easy to differentiate
Duration	Generally self-limiting with healing	Lasts beyond 6 months
Character	Varies, more overt signs	Varies, fewer overt signs
Temporal pattern	Varies, symptoms correctable	Varies, symptoms persistent
Associated symptoms	Physical and psychological (anxiety or irritability)	Physical and psychological (depression, insomnia, lethargy)
Prognosis	Complete relief in most cases	Complete relief generally not achieved

threshold. A patient experiencing chest pain may perceive pain as significant if the patient believes he or she is having a heart attack and is threatened with disability or death.

Pain tolerance is the amount of intensity or time a patient will endure before taking steps to relieve the pain. Past experience with pain is a factor in the patient's evaluation of the current pain experience. Tolerance to painful stimuli may decrease over time and can be influenced by anger, fear, lack of sleep, or other cognitive factors. Tolerance may increase with the use of medications, recreational drugs or alcohol, distraction, applications of heat and/or ice, herbs or alternative therapies such as acupuncture or hypnosis, cultural beliefs or expectations, or religious activities.

Neurological Basis of Pain

Anatomy and Physiology

The information in this section comes from Nelson-Marsh and Banasik (2010) and the American Medical Association's (2013a) online CME course entitled Pain Management.

The portions of the nervous system involved in the sensation and perception of pain can be divided into three areas:

- *Afferent pathways* are composed of nociceptors (pain receptors) in the peripheral tissues that respond to injury or inflammation. When cells are damaged, phospholipids in the cell membrane are broken down by the phospholipase A enzyme and converted to arachidonic acid. Further breakdown of arachidonic acid by another enzyme, cyclooxygenase (COX), forms prostaglandins. Nociceptors are sensitized by prostaglandins and lower the pain threshold. Other chemical mediators alter the membranes of the pain receptors—among them are bradykinins, histamine, cannabinoids, neurotensin, lactate, K^+, H^+ and others—to affect depolarization and transmission of the pain impulse. When depolarization of the nociceptors occurs, the impulse is sent along afferent neurons, A-delta fibers and C-fibers, to the spinal cord. A-delta fibers are myelinated, respond to mechanical and mechanico-thermal stimuli, have a fast conduction velocity, and have small reception fields, which allow for precise pain location. C-fibers represent approximately 70% of the fibers carrying thermal and chemical pain impulses, are unmyelinated, have a much slower conduction velocity, and less location-specific pain perception. The afferent pathway terminates in the dorsal horn of the spinal cord. Nociceptors that are stimulated transmit impulses through collateral branches to the central nervous system.
- *The central nervous system* is involved in interpretation of pain signals. Pain fibers bifurcate when they enter the spinal cord through the posterior nerve roots and ascend as well as descend several segments to form the tract of Lissauer, where interneurons carry the impulse across the cord to the contralateral ascending anterolateral tract to the brain. The substantia gelatinosa is a key anatomical region within the cord and has multiple synapses. Within this region pain impulses can be

intensified or blocked. Neurotransmitters such as Substance P, GABA, cholecystokinin, somatostatin, calcitonin-gene-related peptide, and excitatory amino acids (glutamate) bind to the neurons in the pathway in the spinal cord to transmit the impulses to the brain. Glutamate binding to *N*-methyl-D-aspartate (NMDA) receptors is thought to produce a kind of pain memory so that if repeated mild stimulation of C-fiber occurs, the stimulus can be perceived as painful and may be a mechanism that contributes to chronic pain syndromes. The synapses in the cord can become points of pain modulation through endogenous or exogenous means.

The anterolateral tract has two divisions, the neospinothalamic tract and the paleospinothalamic tract. The neospinothalamic tract transmits A-delta fibers quickly to the thalamus. Despite fewer synapses, the pain signal is received without the emotional component. C-fibers travel mainly through the paleospinothalamic tract, which has more synapses but the pain signal travels more slowly. The tract projects into the medulla and reticular activating systems, which alert, arouse, and elicit pain recognition and pain-related behaviors (Fig. 52-1).

Discrimination and localization of pain occur in a portion of the thalamus. Use of a dermatomal map may be helpful for isolating sources of neurological pain. The medulla and hypothalamus activate coping responses such as the release of catecholamines and cortico-steroids and physical responses such as increased heart rate and blood pressure. Complex modulations of pain transmission occur in other regions of the brain as well. Because the pain impulses arrive in the brain at two different speeds several seconds apart, the phenomenon of "double pain" sensation occurs.

- *Efferent pathways* are responsible for modulating the pain sensation. The pathway is composed of fibers that connect the reticular formation, midbrain, and substantia gelatinosa in the dorsal horn of the spinal cord. Neurons in these regions converge and interact to inhibit the transmission of pain signals through chemical mediation.

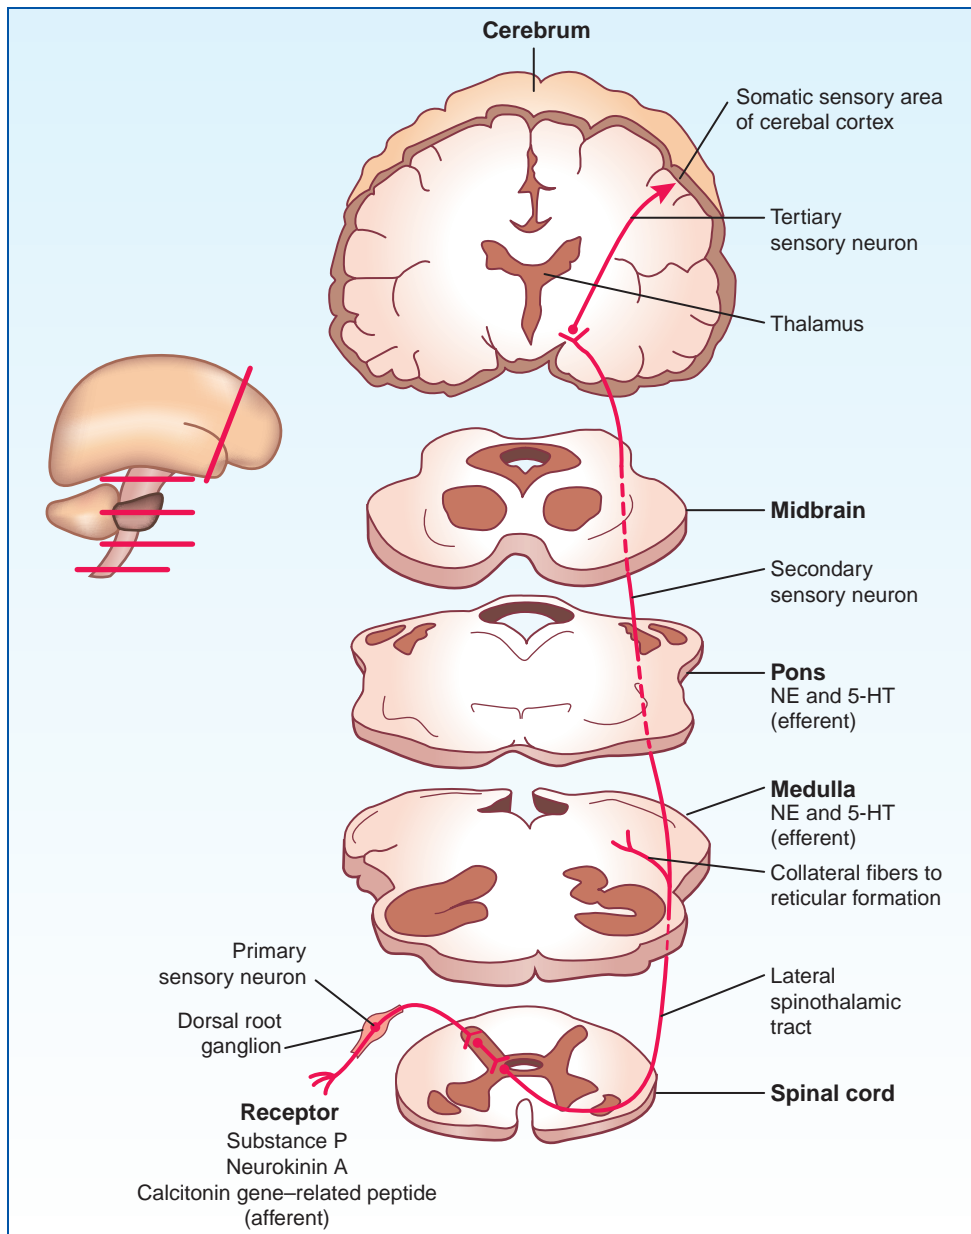
Within the brainstem nucleus is an area known as the raphe magnus that receives input from two other areas, the periaqueductal gray (PAG) area in the midbrain, which is rich in endogenous opioids (endorphins and enkephalins) considered the body's pain killers, and the rostral pons in the brainstem. Endorphins are neuropeptides that inhibit transmission of pain impulses within the spinal cord and brain. Enkephalins are found in the brain neurons; they are weaker than endorphins but more potent than morphine and last longer. Dynorphins found in the hypothalamus, PAG, and dorsal horn of the spinal cord are potent endorphins that impede pain signals but can also incite pain. Endomorphins are peptides formed in the brain that have high affinity for morphine receptors and cause vasodilation due to release of nitric acid from endothelial cells. When the PAG is stimulated, these opioids are released; concurrent serotonin release


Figure 52–1. Anatomy of pain transmission.

sends analgesic signals to the raphe magnus. Neurons projecting from the rostral pons to the raphe magnus secrete norepinephrine, which also has an analgesic effect.

Pain Modulation

The brain, spinal cord, and peripheral tissues contain opioid receptors— mu (μ), kappa (κ), and delta (δ)—to modulate pain perceptions. The μ and κ receptors have primary analgesic activity; other functions of the μ receptors are euphoria and respiratory depression, and the κ receptors produce sedative effects. The δ receptors have less analgesic activity but do have antidepressant effects. The μ and δ receptors are also responsible for physical dependence. Sigma (σ) receptors are no longer considered opioid receptors because they produce stress-related depression and dysphoria as well as other psychomimetic effects rather than analgesia; they are targets for drugs like phencyclidine (PCP) (Trescot, Datta, Lee, & Hansen, 2008).

In addition to CNS activity, the pituitary gland contains high levels of β-endorphins, which are believed to be released in times of pain or stress. The adrenal glands also release endogenous opioids as a stress response but these endorphins, which are released into the bloodstream, cannot effectively cross the blood–brain barrier, so the effects occur in the periphery. Endorphins are found in nerve endings, immune-related cells, and the CNS. Endorphins are released in times of stress, extreme physical exertion, acupuncture, or intercourse to raise the amount of endorphins circulating in the bloodstream. All endorphins attach to opiate receptors, so increased amounts raise the pain threshold.

Special Populations

The pain assessment should include a detailed history of the pain characteristics; symptom treatment prior to the visit; the

impact on function and well-being, sleep, medical and/or psychiatric conditions; and current medications. A complete physical examination should be conducted with a focus on the neurological and musculoskeletal systems to identify sensory and functional deficits. A review of the medical record will ascertain previous conditions and diagnostic test results that may contribute to the current pain complaint. Thorough data collection will help formulate a working diagnosis for the etiology of the pain and a plan for best treatment of the underlying cause and related symptoms.

The undertreatment of pain in the very young, the elderly, and in minority populations has been reported for decades. An inability to adequately report pain may contribute to lack of attention by the practitioner to evaluate the potential for pain. Understanding the multifactorial sources of pain is necessary to provide best practices in pain management.

Pediatric Patients

Neuroscientists have concluded that the nervous system is sufficiently developed before birth, which dispels the myth that infants are incapable of sensing pain. The inflammatory response is quite robust in infants and young children and can produce a greater neural response following noxious stimuli, yet enzyme systems that metabolize drugs are immature in preterm infants and neonates. Pain-producing events can have a significant impact on a young nervous system that can have lasting effects and produce a lower pain threshold for months (American Medical Association [AMA], 2013c). Older children tend to have higher pain thresholds, but responses are highly individualized.

Older Adults

Adults over age 65 can have multiple causes of pain that may not be adequately identified, which increases the risk for inadequate pain management. With aging come physiological changes in anatomy and the underlying neurophysiological mechanisms of pain along with comorbid conditions (Gibson & Helme, 2001), which can increase the pain threshold. Pain, particularly persistent pain, can be common in older adults, especially in those over age 85, most commonly due to arthritis. Older people are often reluctant to report pain for multiple reasons, and assessment can be a challenge especially in the presence of cognitive decline. The practitioner may need to clarify the words used by older adults to describe their discomfort as they are more apt to dismiss pain as part of the aging process or disease progression and may fear additional tests as well as costs.

Cognitive Impairment

Dementia and other cognitive impairments are more common in the elderly but can occur at any age. Mental capacity that is reduced does not mean physiological responses to pain are also reduced. Pain assessment becomes a challenge when patients are unable to clearly communicate their symptoms and needs. Pain that is poorly managed can result in behaviors that mimic psychological disorders, and misdiagnoses may lead to inappropriate treatment decisions.

Agitation, mood changes, withdrawal from activity, or other behavioral disturbances can be indicators of pain or distress but may not be recognized as such. The Mini Mental Status Examination (Folstein, Folstein, & McHugh, 1975) is an effective tool to screen for cognitive impairment and has been used extensively. Access to pain assessment tools for patients with dementia can be obtained through the Alzheimer's Disease Association at http://www.alz.org. The Checklist of Nonverbal Pain Indications (Feldt, 2000) is a more recent tool that specifically measures pain behaviors in cognitively impaired adults. Another useful tool, the Pain Assessment in Advanced Dementia (PAINAD) Scale, measures breathing, vocalization, facial expression, body language, and consolability in noncommunicative patients (Warden, Hurley, & Volicer, 2003). Additional pictorial pain scales used with young children can also be used to assess patients with communication limitations.

Comorbid Chronic Illnesses

Older adults are more prone to having comorbid conditions such as arthritis, cardiovascular disease, or diabetes requiring pharmacological therapy. NSAIDs used for the mild to moderate pain of arthritis have the potential for interaction with commonly prescribed drugs such as antihypertensive and antidiabetic medications. The risk of serious gastrointestinal (GI) side effects and renal toxicity are also contributors to complications. In addition, the aging process alters organ function important for the absorption, distribution, metabolism, and elimination of drugs. Patients should be carefully screened for GI disorders, hepatic and renal function, hypothyroidism, and adrenal function. NSAIDs are contraindicated in those with a history of GI bleeding. Patients with endocrine deficiencies are at risk for prolonged and exaggerated responses to opiates. Kidney dysfunction alters drug elimination, so dosing of analgesics is critical to avoid toxicity.

Pregnancy

In general, pregnant women should avoid the use of medications. The safe use of analgesics during pregnancy has not been well established and most are in Pregnancy Category C or D, indicating the practitioner should carefully weigh the benefits of therapy against the risk of fetal harm. Because research has demonstrated no fetal risk, acetaminophen, naproxen, oxycodone, and topical anesthetics are in Category B. If a pregnant woman is addicted to opiates, the newborn is subject to respiratory depression or excessive sedation in addition to drug withdrawal symptoms. The Food and Drug Administration (FDA) relabeled all extended-release and long-acting opioid analgesics in 2013 to add a boxed warning cautioning that maternal use may cause neonatal opioid withdrawal syndrome (FDA, 2013).

Substance Abuse

The overuse of alcohol or prescription or recreational drugs is a prevalent societal issue. Any practitioner who treats acute or chronic pain is likely to face the dilemma of selecting appropriate treatment for a known or suspected substance

abuser who presents with a complaint of pain. Chronic overuse of addictive substances alters the brain's neurochemistry, neurotransmission, and interactions within the reward structures in the frontal cortex that control motivation, memory, impulse, and craving. Problems in the frontal cortex lead to altered judgment, impulsivity, and a dysfunctional need for gratification. Development of these brain structures are still in process into adolescence and young adulthood, an important factor to consider when assessing the history and possible early exposure to addictive substances. Genetics also plays a significant role in the likelihood of addiction. Cultural factors can influence how a patient develops behaviors in a desire to be socially accepted within a group.

Addictive behaviors can be characterized as the inability to abstain from the drug of choice, impaired behavioral control, craving for drugs, inability to recognize significant problems with behaviors or relationships, or dysfunctional emotional responses (American Society of Addiction Medicine [ASAM], 2011). Pseudoaddiction is described as addiction-like behaviors such as "clock-watching" that occur when pain is undertreated. A distinction can be made between addiction and pseudoaddiction when eliciting history and pain assessment data because patients with pseudoaddiction no longer exhibit these drug-related behaviors when pain is effectively treated (AMA, 2013c, 2013d).

When considering prescribing potentially abusable drugs, the American Academy of Pain Medicine and the American Society of Addiction Medicine (2001) recommend using the following definitions to determine the degree of substance abuse disorder:

- *Addiction* is a primary, chronic, neurobiological disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.
- *Physical dependence* is a state of adaptation that is manifested by a drug class-specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.
- *Tolerance* is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time.

Patients with addiction are often extremely anxious about insufficient receipt of pain medications in association with trauma, disease, or surgery, which may influence how they express their pain. Practitioners should assure these patients that acute pain will be adequately treated despite the addiction (AMA, 2013d). Those who are opioid-dependent may require higher doses to reduce acute pain due to higher tolerance. Decision making about choice of drug, dosing, and scheduling should be shared to provide the patient with a sense of control and satisfaction that pain relief will be achieved.

ACUTE PAIN

Acute pain can be due to mechanical or thermal stimulation of nociceptive receptors in somatic or visceral tissues. Symptoms are of sudden onset and generally disappear when healing occurs.

Pathophysiology

Acute pain may be somatic, visceral, referred, neuropathic, or psychogenic in origin. A patient may experience single or multiple types of pain. Afferent neurons, A-delta fibers and C-fibers, are found in the skin, muscle, connective tissues, joints, and in some visceral tissues. A-delta fibers are myelinated and respond to thermal and mechanical sources; stimuli are fast-traveling and highly localized. C-fibers are unmyelinated and are activated by multiple sources; stimuli are poorly localized and impulses travel more slowly than through A-delta fibers.

Somatic pain involves skin, joints, bone, muscle, or connective tissue and is generally localized and described as aching, throbbing, stabbing, squeezing, stinging, pinching, or sharp. Examples might be burns, arthritis, or metastatic bone pain. Somatic pain responds well to NSAIDs, acetaminophen, corticosteroids, opiates, and topical applications of anesthetics, cold, or heat. *Visceral* pain arises from hollow organs and is often described as dull, aching, and burning, gnawing, or cramping sensations. Tissue damage to organs such as the heart produces complaints of sharp, stabbing, or throbbing pain and other descriptors similar to somatic pain. The use of opiates, NSAIDs, and corticosteroids are useful for this type of pain.

Referred pain can be perceived at a more distant site; some patterns are clinically relevant. Examples might be pain referred to the right shoulder from inflammation of the gallbladder or pain in the groin due to ureteral colic (Fig. 52-2).

Neuropathic pain is felt along dermatomes and can originate in central or peripheral nerves (Fig. 52-3). It is described as tingling, prickling, burning, or shock-like. Examples of this type of pain might be neuropathy due to herpes zoster or trigeminal neuralgia, or radiculopathy in an extremity from compression on a spinal nerve root.

More problematic is a report of pain that has no identifiable physiological etiology. The phenomenon of *psychogenic* pain is often seen in patients with psychiatric conditions or psychosocial disorders. Psychogenic pain can be a component of acute pain or caused by an array of reactive psychosocial disturbances. Assessment is complex and the practitioner should evaluate both the pain component and the psychiatric problem. The neurotransmitters norepinephrine and serotonin play a role in depression but also modulate sensitivity to pain in the efferent pathways. For psychologically based pain, traditional analgesics are not indicated (Agency for Healthcare Research and Quality [AHRQ], 2011).

Signs and Symptoms

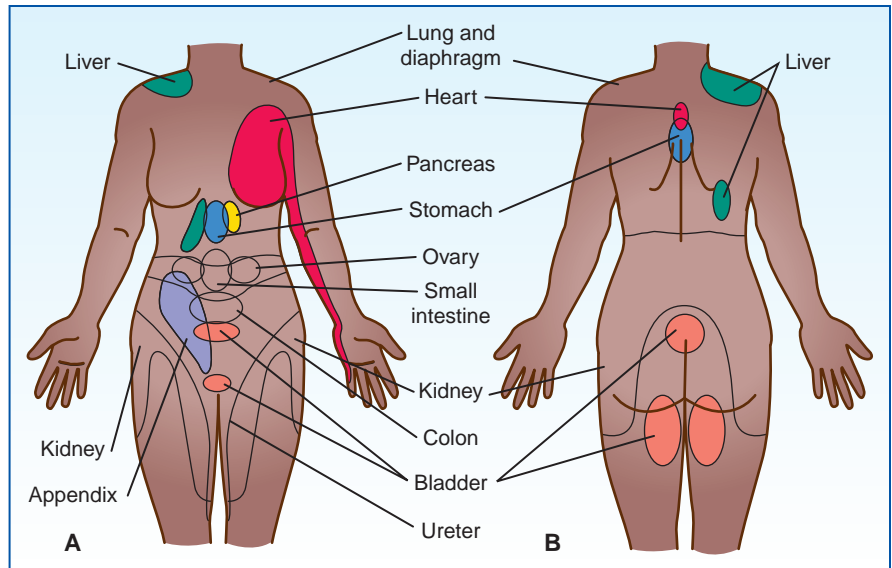
Acute pain is typically associated with stimulation of the nociceptors arising from tissue injury. Signs and symptoms


Figure 52–2. Referred pain sites.

include both physiological responses in the sympathetic nervous system and behaviors used to express pain. The practitioner should be alert to physiological responses, which include increased heart rate and blood pressure, increased respiratory rate, dilated pupils, diaphoresis, and pallor as blood flow to the skin decreases. Elevation of blood sugar can occur. Gastric motility and blood flow to the viscera decrease and can produce nausea and vomiting. Behavioral signs can range from stoicism and stillness to demonstrative expressions such as grimacing, moaning, crying, guarding, rocking, or pacing (Table 52-2).

Pain management is dependent on a detailed pain history and appropriate physical examination. Information about the onset, location, duration, characteristics, aggravating or relieving factors, and self-treatment is essential. Information regarding characteristics and intensity can be obtained through the use of pain scales. The numeric pain scale measures pain intensity on a 0 to 10 scale with 0 being no pain straight line with dichotomous endpoints. The patient marks a point on the line that correlates to the pain intensity and then the length of the line to the mark is measured in millimeters. The Brief Pain Inventory (BPI) is multidimensional and includes four pain intensity scales and seven scales that measure the pain impact on activity, mood, relationships, sleep, and quality of life (Daut, Cleeland, & Flanery, 1983). The McGill Pain Questionnaire (MPQ) is a tool that assesses three pain dimensions—sensory, affective, and evaluative—in sets of words the patient chooses that describe the pain, which, in turn, may suggest to the practitioner the underlying etiology (Melzack, 1975).

A review of past medical records and diagnostic studies should be included in the pain assessment. It is also important to obtain a history of potential substance abuse, which typically begins by asking about past or current smoking and use of alcohol and progresses to specific questions about recreational and prescription drug use. Other data may

include the patient's mood, coping strategies, and pain interference with activities of daily living. The practitioner should develop a working diagnosis for the pain etiology and a plan of care that may include additional diagnostic studies and treatments.

Pain assessment in infants and children younger than 18 months can be a challenge due to their inability to verbally express their discomfort. Validated pain scales for preterm and term infants can be used to monitor behaviors. The Premature Infant Pain Profile (Stevens, Johnston, Petryshen, & Taddio, 1996) and the CRIES Postoperative Pain Scale (Grunau, Johnston, & Craig, 1990) combine physiological measurements along with facial expressions to determine the degree of pain. The FLACC (Face, Legs, Activity, Cry and Consolability) Scale (Merkle, Shayvitz, Voelpel-Lewis, & Malviya, 1997) is a behavioral scale that can be used in children 2 months to 7 years in age. A pain score is calculated after observing the child for 5 minutes. Children as young as 18 months may be able to indicate their discomfort; children ages 3 to 4 years and older have acquired words they can use to report the pain location and describe its characteristics. They can generally use self-report pain scales such as the Wong-Baker Faces Scale (Hockenberry & Wilson, 2012), the Oucher Scale (Beyer, Denyes, & Villaruel, 1992), or the Poker Chip Scale (Hester, Foster, & Kristensen, 1990). School-age children may be able to use adult scales such as the Numeric Rating Scale or the Visual Analog Scale. Questionnaires have also been developed for children with chronic pain and include the Children's Comprehensive Pain Questionnaire (Ross & Ross, 1990) and the Varni-Thompson Pediatric Pain Questionnaire (Varni, Thompson, & Hanson, 1987).

Practitioners should take a thorough pain history and assess for pain as a routine part of the elderly patient's visit. The physical exam should focus on the musculoskeletal and neurological systems. Functional and range of motion testing
Levels of principal dermatomes

C5	Clavicles
C5, 6, 7	Lateral parts of upper limbs
C8, T1	Medial sides of upper limbs
C6	Thumb
C6, 7, 8	Hand
C8	Ring and little fingers
T4	Level of nipples

T10	Level of umbilicus
T12	Inguinal or groin regions
L1, 2, 3, 4	Anterior and inner surfaces of lower limbs
L4, 5, S1	Foot
L4	Medial side of great toe
S1, S2, L5	Posterior and outer surfaces of lower limbs
S1	Lateral margin of foot and little toe
S2, 3, 4	Perineum

Figure 52–3. Spinal dermatomes.

should be included in the pain assessment. Cognitive ability is also an important part of the assessment process; look for new or worsening symptoms along with evaluation for depression or anxiety, which can accompany persistent pain. Using common visual analog or numeric rating scales are useful but geriatric pain assessment tools may better assist in the overall assessment of pain in the elderly. Patients with cognitive deficits may do better with the Faces Scale or other pictures. Pain has a significant impact on quality of life in the older adult and should not be overlooked.

Table 52–2 Behavioral Responses to Pain

Age Group	Vocalizations	Facial Expressions	Body Movements	Coping Strategies

Infants	Crying
	Fussy
	Irritable
		Lowered brows
		Drawn together
		Eyes closed (young infant)
		Eyes open (older infant)
		Mouth open
			Generalized body
			  responses; rigid or
			  thrashing (young
			  infant)
			Localized body response;
			  withdraws stimulated
			  area (older infant)
				Oral stimulation (sucking)
				Crying
				Fetal position

Toddlers/
  Preschoolers
	Crying
	Screaming
	Asks to stop painful
	  stimulus
	Points to area of pain
		Eyes closed or open
		Furrowed brow
			Physical resistance
			Uncooperative
			Restless
			Clinging
				Oral stimulation
				Crying while sleeping (toddlers)
				Rocking
				Lying still or being active
				  (preschoolers)

School age	Crying
	Verbalizing pain
	Quality, location,
	  duration
		Withdrawn facial
		  expression
		Furrowed brow
			Muscle rigidity
			Gritted teeth
			Clenched fists
			Splinting/guarding
			Lying still
				Verbal stalling
				Being active or lying still
				Talking about the pain
				Using distraction techniques
				Sleeping
				Playing or watching television

Adolescents	Verbalizing pain
	Crying
		Withdrawn
		Eyes closed
		Furrowed brow
			Muscle tension and body
			  control
			Splinting/guarding
			Lying still
				Verbalizing pain
				Taking medication or initiating
				  actions to relieve pain
				Sleeping
				Lying still

Adults	Groaning Moaning Sobbing Grunting Shouting Praying Crying out for help	Frowning Staring Furrowed brow Teeth clenching	Thrashing Tossing Rocking Muscle rigidity	Protective behaviors Posturing Massaging
Elderly	Sighing Moaning Grunting Chanting Praying Crying for help	Eyes squeezed closed Withdrawn look Furrowed brow Staring	Rocking Clutching side rails Muscle rigidity	Wandering Rubbing Guarding

Pharmacodynamics

The use of nonopioid and opioid analgesics is the primary intervention to reduce or alleviate pain. Anti-inflammatory drugs and opiates are the two primary classes used to treat acute pain (Table 52-3). Corticosteroids also have value in reducing inflammation. In addition to analgesics, nonpharmacological strategies may also be used such as physical therapy, massage therapy, complementary and alternative medicine (CAM), and biofeedback or other behavioral or psychological interventions.

Anti-Inflammatory Drugs

Pain is commonly caused by inflammation at the cellular level. Anti-inflammatories are often the first-line drugs to manage acute pain symptoms and are generally administered orally.

This class of drugs interrupts the chemical mediators released from destruction of cell membranes at the site of injury. The COX enzyme discussed earlier is the target of these drugs, which include salicylates, acetaminophen, and non steroidal anti-inflammatory (NSAID) agents. Although the exact mechanism of NSAIDs is not known, it is believed they inhibit the action of the COX enzyme and the production and synthesis of prostaglandins, thus reducing inflammation and pain.

The COX enzyme consists of three currently identified isoenzymes. COX-1 is continuously present (constitutive) in all body cells and tissues with concentration in the endothelium; in platelets to cause aggregation; in the stomach to regulate acid and mucous production; and in the microvasculature, glomerulus, and collecting ducts in the kidney to regulate water excretion. COX-2 is not normally present in tissues but rapidly increases in concentration when inflammation is present

Table 52–3 Common Analgesics Used for Pain Relief

Classification	Drug	Indication	Contraindications	Side Effects	Route
Nonopioids	Acetaminophen (Tylenol, APAP and others)	Mild to moderate pain Mild to moderate pain	Hypersensitivity; active liver disease or severe dysfunction; alcoholism	Generally safe and well tolerated; unsafe with hepatic dysfunction or acute toxicity, gastric upset, bleeding, prolonged prothrombin time; CNS and metabolic toxicity at high dosages or with prolonged use	Oral, rectal
	Salicylates (aspirin products)		Hypersensitivity; bleeding disorders; vitamin K deficiency; peptic ulcer disease; do not administer to children with flu-like symptoms because of its risk of Reye's syndrome		Oral, rectal
	NSAIDs (ibuprofen, indomethacin, ketorolac, naproxyn, diclofenac, celecoxib)	Mild to moderate pain	Hypersensitivity to NSAIDs or aspirin; active GI bleeding or ulcer disease; severe hepatic or renal disease; not recommended during pregnancy	GI symptoms, bleeding; hepatitis; rash; headache	Oral, IM, IV
Selected Analgesic Adjuncts	Gabapentin (Neurontin) Pregabalin (Lyrica)	Neuropathic pain and fibromyalgia	Hypersensitivity; lactation	Confusion, depression, drowsiness; vertigo, ataxia; dry mouth	Oral Oral
	Tramadol (Ultram)	Moderate to moderately severe pain	Hypersensitivity; alcohol intoxication, CNS depression; opioid dependency; pregnancy, lactation	Seizures, dizziness, somnolence, GI symptoms, serotonin syndrome	Oral
Opioids	Codeine	Mild to moderate pain	Hypersensitivity; severe respiratory depression; severe renal, hepatic, or pulmonary disease; pregnancy; alcoholism; MAO inhibitor therapy within past 2–4 weeks; lactation; use cautiously in head trauma	Sedation, confusion; Respiratory depression, apnea; hypotension; nausea/vomiting; constipation; urinary retention; seizures	Oral, rectal
	Fentanyl (Sublimaze)	Moderate to severe pain; procedural sedation			IV, IM, transdermal, transmucosal
	Hydromophone (Dilaudid)	Moderate to severe pain			Oral, IM, IV, subcutaneous
	Morphine sulfate	Moderate to severe pain			Oral, rectal, IM, IV, subcutaneous, transdermal patch
	Oxycodone (Oxycontin, Percocet, Percodan, Tylox)	Moderate to severe pain			Oral, rectal
	Hydrocodone (Lortab, Vicodin, Ibudone)	Moderate to severe pain			Oral
	Oxymorphone (Opana)	Moderate to severe pain			Oral, IM, IV, subcutaneous
	Meperidine (Demerol)	Moderate to severe pain			Oral, IM, IV, SC
	Tapentadol (Nucynta)	Moderate to severe pain			Oral
	Methadone (Dolophine)	Severe pain; suppress withdrawal symptoms in opioid detoxification			Oral, IM, subcutaneous

Table 52–3 Common Analgesics Used for Pain Relief—cont'd

Classification	Drug	Indication	Contraindications	Side Effects	Route
Local Anesthetics/ Analgesics	Lidocaine (Xylocaine, Mepivacaine, Carbocaine) Procaine (Novocaine) Tetracaine (Pontocaine)	Infiltration, nerve blocks, topical, relief of pain of procedures or dermatological conditions	Hypersensitivity; use cautiously in severe hepatic disease, heart failure, respiratory depression, shock, or heart block; pregancy or lactation; geriatric or patients weighing less than 50 kg (110 lb)	Seizures, cardiovascular collapse; anaphylaxis; CNS toxicity, confusion, drowsiness Readily absorbed through mucous membranes Safety of patch not established in children	Topical, patch, infiltrate, mucosal
	LET (Lidocaine, epinephrine, tetracaine) EMLA cream (2.5 % lidocaine + 2.5% prilocaine)	Safer than TAC because it does not containe cocaine)			
	Capsaicin (Capzasin. Zostrix, Icy Hot, Salonpas)	Minor pain from arthritis sprains, herpes zoster, or diabetic neuropathy	Hypersensitivity to hot peppers Not for use near open skin or in eyes	BP increase, cough, transient burning sensation	Topical, transdermal patch

Adapted from Schaffler, R. (2007). Pain management. In K. Hoyt & J. Selfridge-Thomas (Eds.), *Emergency nursing core curriculum* (6th ed., pp 153–155). St. Louis, MO: Saunders.

(inducible). COX-3 has been more recently identified and is located only in the CNS within the blood–brain barrier. The properties of COX-3, also inducible, are to mediate central analgesia and to provide antipyretic activity.

Nonselective NSAIDs inhibit both COX-1 and COX-2 isoenzymes; the ratio varies by drug. COX-1 inhibition decreases the availability of gastroprotective prostaglandins, which is a primary factor in the development of adverse GI effects, particularly erosion and bleeding. Specific COX-2 inhibition is increased with celecoxib (Celebrex), currently the only drug on the market in this class, but which carries a Black-Box Warning of increased risk for cardiovascular events.

NSAIDS, as a class, bind to plasma proteins tightly, and interactions with other drugs commonly occur when they compete for binding sites. For example, platelet action is blocked by aspirin and other NSAIDs, which may have an effect on low-dose aspirin use associated with cardiovascular disease. The decision to initiate NSAID therapy must include consideration of the risk:benefit ratio.

Opioids

Opioids act on both central and peripheral pain receptors, most notably the μ and κ receptors, to inhibit the transmission and perception of pain impulses. Opioids are further classified according to their binding action at opioid receptor sites. Full agonists are the most widely prescribed and include morphine, codeine, hydrocodone, oxycodone, fentanyl, hydromorphone, methadone, and meperidine. Partial agonists (e.g., buprenorphine) have decreased activity at the μ sites, and mixed agonist-antagonists (e.g., butorphanol, nalbuphine) have action that can either bind or block opiates at receptor sites. Most have an analgesic ceiling that relates to

opioid-related side effects. Opioids have a high abuse potential and can cause withdrawal symptoms, especially in patients who are physically dependent on agonist opioids.

Agonist drugs can be further classified into categories based on duration of action. Short-acting opioids (4 to 6 hours), like morphine, require more frequent dosing to maintain a therapeutic effect. Long-acting opioids (8 hours or more) have long half-lives and release the drug more slowly. Examples include extended-release preparations of oxycodone, oxymorphone, morphine, and fentanyl and long-acting agents like methadone; these drugs may be preferred when managing chronic pain.

Adverse effects at the μ sites include euphoria, which is an incentive for abuse and contributes to dependence, as well as undesired effects of respiratory depression, constipation, and urinary retention. Tramadol is non-narcotic but acts on μ receptors to produce centrally acting analgesia. This drug also inhibits the reuptake of serotonin and norepinephrine, which provides dual-action pain relief. Sedation is produced at the κ sites without the other side effects. Naloxone is an antagonist for both μ and κ receptors and is the agent of choice for reversing the effects of opioids.

Goals of Treatment

The goal of treatment for acute pain is complete relief. In some cases, this may not be possible, so reduction may be a more realistic outcome. In either case, pain management with the least amount of adverse effects is desirable.

Addiction and Dependency

Opiates carry a high risk for tolerance, dependence, and abuse but are still appropriate to use for pain management with

monitoring. Practitioners should be aware of the red flags for addiction or dependency, which include the following:

- Concurrent use of alcohol or illicit drugs used for recreation
- Frequent need for dose escalations
- Multiple episodes of prescription loss
- Seeking prescriptions from multiple providers
- Prescription forgery
- Selling prescription drugs or buying from unauthorized sources
- Resisting change in therapy from pills to other modalities

Screening for substance abuse risk can be done with the use of questionnaires. Two popular tools are the CAGE-AID and the Drug Abuse Screening Test (DAST).

- CAGE-AID (Brown & Rounds, 1995) asks if the patient has ever
  - Felt you ought to cut down on your drinking or drug use?
  - Had people annoy you by criticizing your drinking or drug use?
  - Felt bad or guilty about the consequences of your drinking or drug use?
  - Had a drink or used drugs first thing in the morning to steady your nerves or to get rid of a hangover (eye-opener)?

Scoring for item responses are "0" for no and 1 for "yes." While the normal cutoff for this tool is two positive answers, it is recommended that primary care practitioners lower the threshold to one positive answer to identify more patients who may have a substance abuse disorder.

The DAST questionnaire (Gavin, Ross, & Skinner, 1989) has been found useful in screening for drugs of abuse other than alcohol. The tool consists of 28 questions:

- Have you used drugs other than those required for medical reasons?
- Have you abused prescription drugs?
- Do you abuse more than one drug at a time?
- Can you get through the week without using drugs?
- Are you always able to stop using drugs when you want to?
- Do you abuse drugs on a continuous basis?
- Do you try to limit your drug use to certain situations?
- Have you had "blackouts" or "flashbacks" as a result of drug use?
- Do you ever feel bad about your drug abuse?
- Does your spouse (or parents) ever complain about your involvement with drugs?
- Do your friends or relatives know or suspect you abuse drugs?
- Has drug abuse ever created problems between you and your spouse?
- Has any family member ever sought help for problems related to your drug use?
- Have you ever lost friends because of your use of drugs?
- Have you ever neglected your family or missed work because of your use of drugs?
- Have you ever been in trouble at work because of drug abuse?
- Have you ever lost a job because of drug abuse?
- Have you gotten into fights when under the influence of drugs?
- Have you ever been arrested because of unusual behavior while under the influence of drugs?
- Have you ever been arrested for driving while under the influence of drugs?
- Have you engaged in illegal activities in order to obtain drugs?
- Have you ever been arrested for possession of illegal drugs?
- Have you ever experienced withdrawal symptoms as a result of heavy drug intake?
- Have you had medical problems as a result of your drug use (e.g., memory loss, hepatitis, convulsions, bleeding, etc.)?
- Have you ever gone to anyone for help for a drug problem?
- Have you ever been in a hospital for medical problems related to your drug use?
- Have you ever been involved in a treatment program specifically related to drug use?
- Have you been treated as an outpatient for problems related to drug abuse?

A score of 1 is recorded for each "yes" answer except for items 4, 5, and 7, for which a score of 1 is given for a "no" answer. A total score of 12 or more is considered to be indicative of a substance abuse problem.

When substance abuse is suspected or detected, a pain contract may be appropriate. Opioids have been implicated in accidental death or even suicide due to overdose, particularly in combination with alcohol or other drugs. Setting clear expectations and responsibilities is critical to achieve mutually set treatment goals.

Rational Drug Selection

An algorithm for the management of acute pain is seen in Figure 52-4. Drug selection should be made based on the overall severity of the pain, side-effect profile, and the suspected source of pain. Nonopioids can provide effective relief for many types of acute pain and inflammation. Salicylates, acetaminophen, and NSAIDs are useful for somatic, dental, arthritic, traumatic, and post-operative pain of mild to moderate intensity. They differ from opioids in that they inhibit prostaglandin formation, have antipyretic properties, and are not associated with dependence or addiction. Regular use of nonopioids carries risks for bleeding and has potential for interaction with other drugs that may be taken on a regular basis (see Chapter 25).

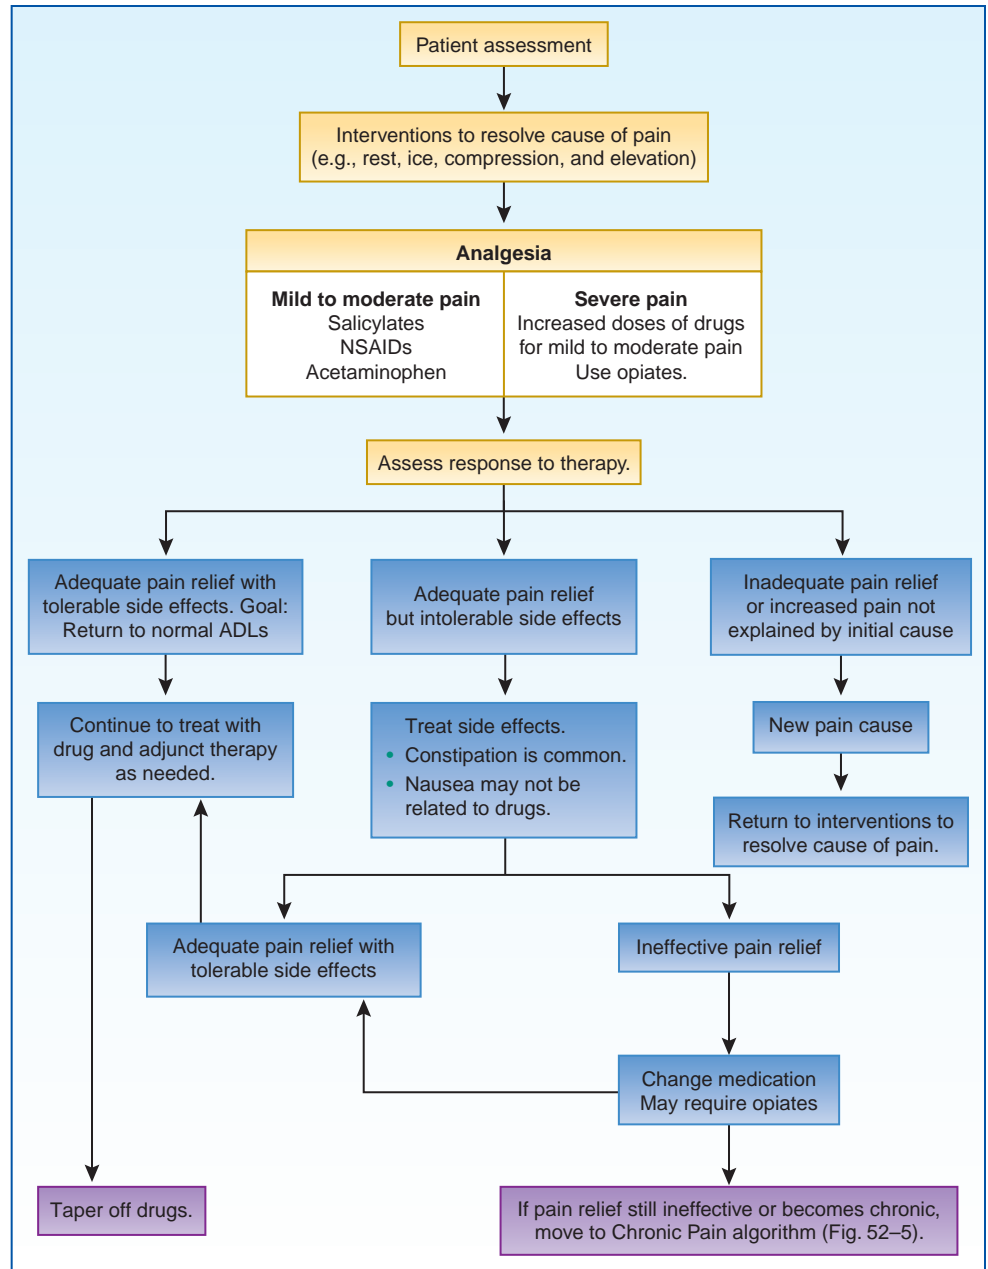
Researchers (Coxib and Traditional NSAID Trialists' Collaboration, 2013) recently conducted a meta-analysis of more than 600 studies showing the effects of long-term (1-year) use of NSAIDs. Findings included a significant increase in major vascular and coronary events, including death, occurring with long-term use of high-dose coxibs and


Figure 52–4. Acute pain management algorithm.

diclofenac; ibuprofen significantly increased coronary events but not vascular; and naproxen showed no increased risk for vascular or coronary events. The risk of heart failure was nearly doubled with all NSAIDs, and all NSAIDs increased GI complications. The practitioner should keep this information in mind when choosing to prescribe NSAIDs. Coxibs and diclofenac should be avoided in patients with known heart disease and cautiously in patients with high risk for coronary or vascular events.

Opioids are meant for short-term use and should be reserved for moderate to severe acute pain that is not well controlled with nonopioid analgesics. This therapeutic class of drugs carries risk for potential tolerance or abuse, and pain management should be monitored as to drug effect and pain reduction. The best choices for moderate pain are codeine,

oxycodone, and hydrocodone, usually in combination with acetaminophen or aspirin. Morphine, oxycodone, hydromorphone, oxymorphone, or fentanyl are better choices for severe pain. Hydromorphone in high doses is more potent than morphine and could be considered in special cases. Meperidine is no longer a favorable drug to use for pain management due to its degradation to neurotoxic metabolites and association with tremors, delirium, and seizures. Neuropathic pain can be effectively treated with anticonvulsants such as gabapentin and pregabalin, which are analgesic adjuncts that bind to calcium channels in CNS tissue and stabilize neuronal membranes, thus interfering with the transmission of pain impulses rather than binding to opioid receptors.

There is no single approach for the use of drugs to manage pain. Treatment requires skillful application of multimodal

therapies to include pharmacological and nonpharmacological interventions. While pharmacotherapy is a mainstay in the treatment of acute pain, other strategies such as psychological, rehabilitative, injections and/or blockades, behavioral therapies, or complementary medicine can be used alone or in combination with analgesics. The practitioner should consider the simplest approaches but recognize that other forms of treatment may also be valuable. In all cases, consider the patient variables discussed earlier.

Monitoring

Self-reporting is the most effective way of monitoring pain management. Use of pain rating scales or other assessment tools are instrumental when monitoring trends in pain intensity or patterns. For acute pain the intensity should diminish as healing occurs. If pain intensity is not abating, reevaluation of the drug or dose should occur and a new plan of care developed.

Outcome Evaluation

The acute pain treatment algorithm can be used as a guideline to develop and monitor the pain management plan and responses to treatment. For patients who have relief of symptoms and are pain free, no further treatment is indicated. For those who remain symptomatic, further changes in the treatment plan can be made based on a reassessment of the patient's needs. A specific drug could be continued, the dose changed, or a different combination of nonopioid and opioid drugs could be used. Nonpharmacological therapies could also be tried. Questions to consider at this phase of treatment could be:

- What pain relief measures are currently being used? Should additional or different measures be tried?
- When is the pain medication being used? Is it timely? Is the individual waiting until the pain becomes severe before taking the medication? Fixed intervals have been shown to be more effective in controlling pain than "as-needed" dosing.
- Does the individual believe the treatment plan is effective? There tends to be a placebo effect for pain treatment and if a patient believes a drug will be effective, it likely will be; and if he or she believes a drug will not be effective, the expected outcome will likely not occur.

If the response to initial or readjusted therapy is not successful, or if complications related to the pain source arise, the individual may need consultation with a specialist. If the complications are related to the pain medication, referral to a pain specialist may be prudent, especially in the case of dependency or addiction, even if pain relief is accomplished.

Patient Education

The practitioner should provide education about the drug, its side effects, dosing regimen, and the expected length of time

the drug should be taken. The patient should also be informed about follow-up visits, particularly if complications occur. See the box "Patient Education: Acute Pain Management."

CHRONIC PAIN

According to the IOM (2011) report, nearly 120 million people in the United States suffer from chronic pain. The effect of chronic pain is profound on ability to function and on quality of life. In addition, chronic pain leads to higher utilization of health care, lost productivity, and other societal costs.

Chronic pain is divided into categories of nonmalignant and malignant pain. Chronic pain, unlike acute pain, is less well defined in terms of its onset and duration. It usually lasts longer than 3 to 6 months. Pain can also be classified as chronic if it meets criteria of lasting a month beyond the usual

---

ACUTE PAIN MANAGEMENT | PATIENT EDUCATION

Related to the Overall Treatment Plan and Disease Process

☐ Pathophysiology of pain and its cause (where appropriate), at a level the patient can understand, to explain how the drugs work.

☐ Importance of adherence to the treatment regimen.

☐ Indications for contacting the health-care provider when pain relief is ineffective.

☐ Need for follow-up visit(s) with the primary care provider.

Specific to the Drug Therapy

☐ Reasons for taking the drug(s) and the anticipated action of these drug(s) in pain relief.

☐ Doses and schedules for taking the drug(s), including early round-the-clock dosing of drugs.

☐ Possible adverse reactions and what to do if they occur.

Reasons for Taking the Drug(s)

☐ Patient education about specific drugs is provided in Chapters 15 and 25. The explanations should be clear about what pain drugs can and cannot do.

Drugs as Part of the Total Treatment Regimen

☐ Role of both pharmacological and nonpharmacological treatments for pain and their interconnection.

Adherence Issues

☐ The fact that most acute pain can be resolved should be stressed. The importance of that resolution to avoid the development of chronic pain should be addressed.

☐ Adherence to the drug regimen is important to resolving acute pain.

course of an illness or injury, is associated with chronic pathological conditions, or if it is recurrent over weeks or months (AMA, 2013b). Recurrent pain can be a hallmark of certain disorders, such as headaches, inflammatory arthritis, dysmenorrhea, inflammatory bowel disease, musculoskeletal disorders, or sickle cell disease. Recurrent acute pain can also occur in patients with cancer or AIDS related to the disease processes, treatments, or both. When acute episodes occur in the presence of otherwise controlled underlying pain, it is known as breakthrough pain. The focus in this section will be on nonmalignant pain.

Pathophysiology

Pain experts have endorsed a key concept that when pain is persistent, it should be conceptualized as its own illness (AMA, 2013g). Pain that is present most of the time can be due to a variety of pain syndromes. The underlying cause is not always identifiable. Chronic pain is not generally associated with sympathetic activity seen in the presence of acute pain. The body has become accustomed to the pain and the nervous system has been desensitized to noxious stimuli. Changes occur over time in nerve terminals, dorsal root ganglion, afferent fibers, and the CNS, thus increasing stimulation of C-fibers and decreasing the production of endorphins. Persistent pain causes physiological adaptation over time so that blood pressure along with heart and respiratory rates remain normal. Responses to chronic pain vary and have fewer overt signs but tend to be more psychological than physical.

The origins of persistent, nonmalignant pain are often multifactorial. The etiology of chronic pain is described as nociceptive, neurogenic, or psychogenic. Chronic pain is difficult to assess in that there are often no overt signs of tissue injury, nerve damage, or inflammation.

Nociceptive Pain

Nociceptive pain infers some sort of tissue damage or inflammation to somatic or visceral tissues. In the case of chronic pain, the damage may be ongoing and insidious. Ongoing tissue injury or inflammation leads to neurochemical and neurophysiological changes that affect the nervous system, leading to persistent input along afferent neurons from a specific source as discussed earlier.

Neurogenic Pain

The underlying cause of neurogenic pain is damage to neural tissues in the central nervous system, the peripheral nervous system, or both. Characteristics of neurogenic pain are varied but are usually expressed as burning, tingling, or electric shock sensations. Neuropathic pain syndromes can also be accompanied by allodynia, hyperalgesia, hyperpathia, or referred pain. Neuralgia occurs as a result of injury to a peripheral nerve from infection or disease. Classic examples are post-herpetic neuralgia and diabetic neuropathy.

The origins of neurogenic pain are not as clear as somatic pain. Injury to a peripheral axon can result in altered nerve morphology where multiple nerve sprouts generate increased activity within weeks after the injury. These nerve sprouts can form neuromas. The areas of increased sensitivity also have changes in sodium receptor concentrations, which make them more sensitive to stimuli. Tinel's sign, a pain or tingling response to tapping over a nerve, is often positive. Over time, atypical cross-connections are developed between somatic and efferent nerves and nociceptors, which alter transmission of pain impulses. Nerve sprouts may also occur in the dorsal horn of the spinal cord following a peripheral injury. These changes also occur at sites of demyelinzation. Reports of pain may or may not be out of proportion to overt signs of injury. If peripheral injury is most likely, interventions such as release of entrapped nerves, anesthetic injection, or resection of a neuroma should be considered. In the case of a CNS injury, as seen with spinal cord trauma, there is little information about the processes that cause central pain syndromes.

Psychogenic Pain

The term *psychogenic pain* is generally used when there seems to be no physiological evidence of the source of pain, and the pain becomes predominantly unremitting due to psychological factors. There is a complex relationship between pain perception and psychological factors. Persistent pain can induce changes in mood, coping abilities, or behavior changes. Some patients develop these in the presence of chronic pain while others have underlying comorbid psychiatric disturbances that become exaggerated when pain is unrelieved. All patients who present with suspected psychogenic pain may be inappropriately labeled and stigmatized, so it is imperative to conduct both physical and psychological assessments before making a judgment.

Pharmacodynamics

NSAIDs and opioids are commonly prescribed for patients with chronic pain. Due to an added psychological factor associated with chronic pain, patients who exhibit signs of depression or anxiety may require medications such as SNRIs or TCAs to manage those symptoms. Patients with neurogenic pain may benefit from the use of anticonvulsants.

The transmission of pain impulses is inhibited by the presence of norepinephrine in the rostral pons and serotonin in the PAG. These neurotransmitters also play a role in mood stabilization. Decreased levels of norepinephrine and serotonin are common in depression. SNRIs inhibit the reuptake of serotonin and norepinephrine into nerve terminals thus making more of the transmitter available at the synapses.

Originally developed to treat depression, TCAs are now more commonly used to treat neuropathic pain syndromes and insomnia, which can accompany chronic pain. Full analgesic effect may take several weeks or months. TCAs

also block the reuptake of norepinephrine and serotonin but have a more significant side-effect profile due to their additional blockage of histaminergic, dopaminergic, adrenergic, and muscarinic receptors. Of particular note is the risk for dysrhythmias and suicidal thoughts.

Goals of Treatment

The goal of treatment for all pain is elimination. In cases of chronic pain this is less likely to occur and a more realistic goal might be to reduce the pain to a tolerable level to maximize function and quality of life. As with acute pain management, it is desirable to meet treatment goals with minimum side effects. A comprehensive approach is needed and multimodal forms of pain relief should be incorporated into the plan of care. Mutual decision making between the patient and practitioner should be employed when choosing the drug, dosing, pain relief goals, and follow-up. Spiritual and cultural factors should be incorporated into the plan to make pain management patient-centered.

Pawar and Garten (2010) concluded that children should have chronic pain managed in the same manner as adults. Treatment is aimed at the underlying cause and associated symptoms. Oral medication is preferred and on a scheduled rather than a prn basis. It is important to consider the neurodevelopmental age of the child as well as to know how to assess pain in different age groups so that the most effective treatment plan can be implemented. A young infant may have a central respiratory problem, so opioid use should be minimized. A toddler or older child may require less medication and use play or other distraction methods to cope with pain. No analgesia should be withheld from a child due to practitioner bias or insufficient assessment.

Rational Drug Selection

An algorithm for the management of chronic pain is depicted in Figure 52-5. Treatment is not solely based on the use of drugs. Multimodal interventions are available to attain the treatment goal of reducing chronic pain while maintaining maximum function.

Lifestyle Modifications

Chronic pain frequently requires lifestyle modifications. Weight loss can be helpful in those who are overweight. Achievement of ideal body weight may not be possible but even small, incremental weight losses can be of benefit to reduce stress on muscles and joints. An increase in physical activity can help with weight loss as well as maintenance of mobility. Exercise has also been shown to have a positive effect on mood and sleep. A progressive plan of exercise should be developed to improve flexibility, strength, balance, and endurance. Walking and resistance training are low-impact exercises that are suitable for patients with chronic pain; activity can be increased based on the patient's tolerance and allows the patient to have an active role in the treatment plan.

Rehabilitative methods can improve physical functioning. Physical therapy, occupational therapy, ice, heat, massage, and aquatic therapy are useful for many types of pain but particularly for fibromyalgia.

Cognitive-Behavioral Interventions

The Institute for Clinical Systems Improvement (2011) recommended several strategies for managing chronic pain. There are a number of independent activities that do not require a specialist, such as relaxation techniques, meditation, imagery, diaphragmatic breathing, and muscle relaxation exercises. Interventions that would likely require a therapist include biofeedback, hypnosis, guided imagery, and counseling. The patient's family members as well as the practitioner can be powerful reinforcers of wellness behaviors that are beneficial to overall well-being. The patient should be encouraged to make progress visits with the practitioner on a regularly scheduled basis rather than only when the pain is out of control.

Drug Therapy

In 1986, the World Health Organization (WHO) developed a conceptual analgesic ladder to help guide the management of pain. Initially developed for cancer pain, it has since been more broadly used in the treatment of all types of pain. The ladder consists of three steps: (1) nonopioids + adjuvants such as antidepressants or antiepileptics that do not have primary indications for pain management, (2) adding an opioid for mild to moderate pain, and (3) adding a stronger opioid for moderate to severe pain. Use of these principles can help the practitioner and patient select the best treatment plan based on the overall severity of the pain and the desired outcomes.

Anti-Inflammatories

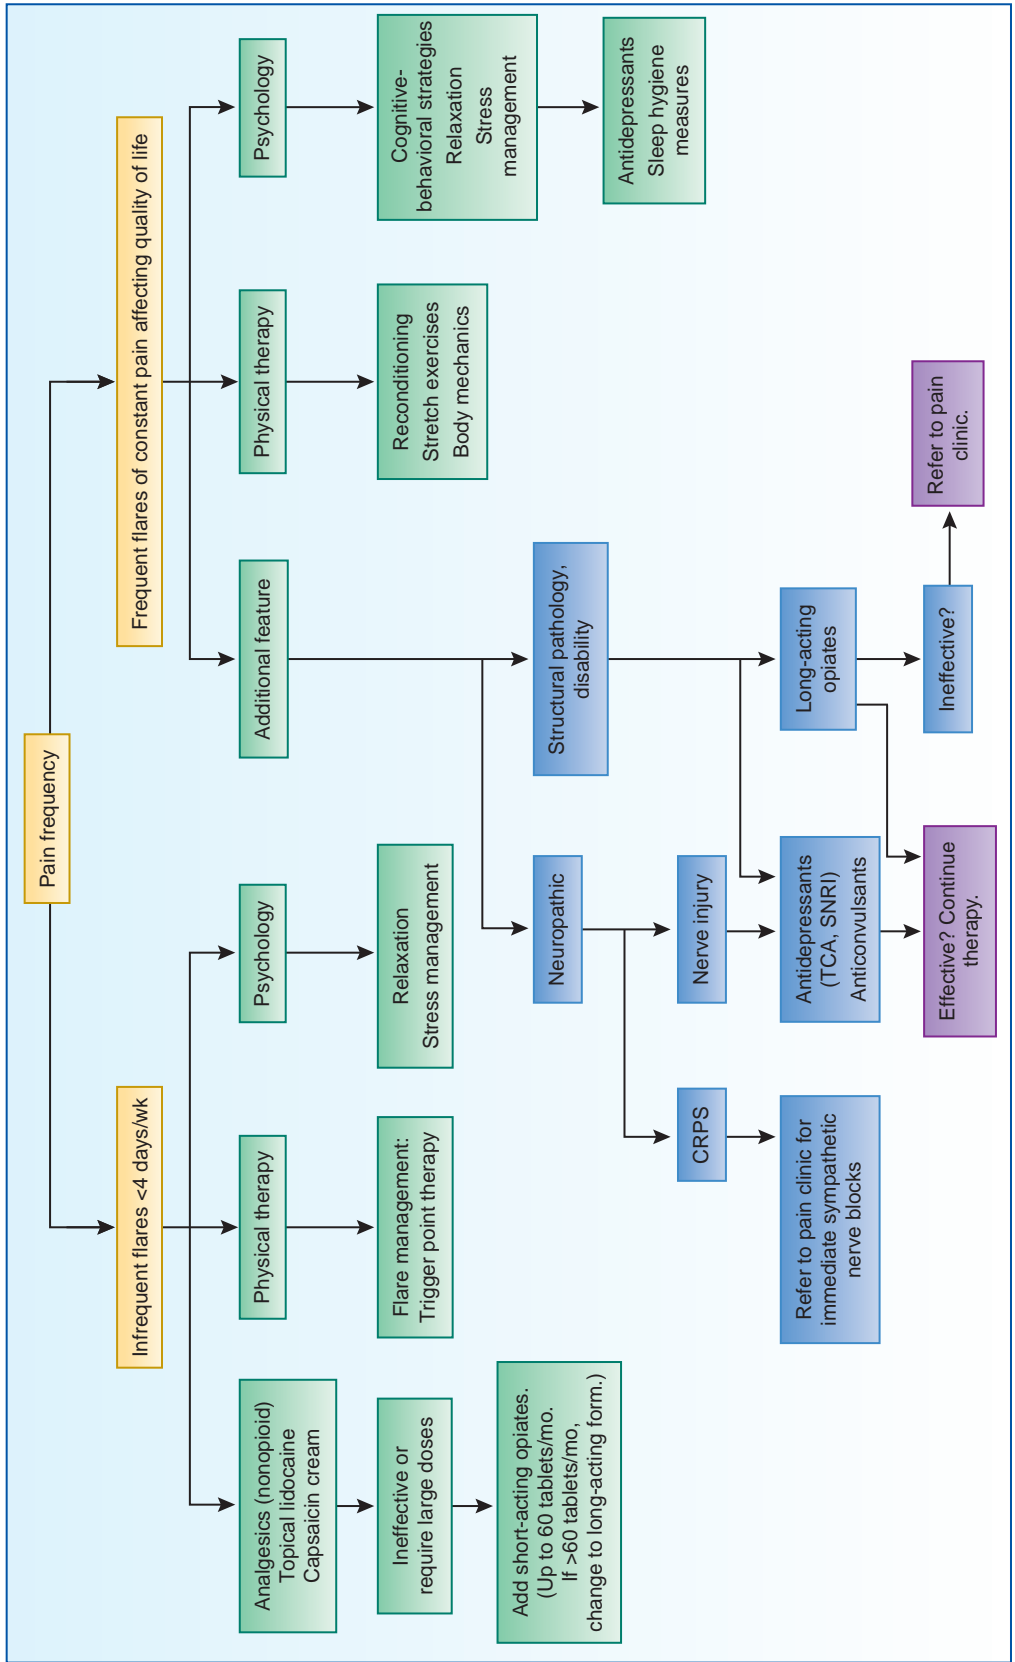
As discussed in the acute pain section, anti-inflammatory drugs can be quite useful to reduce mild to moderate pain and inflammation. NSAIDs are often the first-line drugs of choice in Step 1 of the analgesic ladder, but all carry risk of serious adverse effects, especially in the elderly who are more likely to have comorbid conditions. The patient's risk for cardiovascular disease, GI bleeding, and renal dysfunction should be assessed before recommending this class of drugs. The risk for renal insufficiency increases with chronic NSAID use, especially in diabetics. Piroxicam and indomethacin are of high risk in older adults due to CNS side effects, GI bleeding, and drug-induced hepatitis. Naproxen may be safer than diclofenac and ibuprofen when the risk of cardiovascular disease is high. Celecoxib also carries a Black-Box Warning about cardiovascular disease and should be used with caution. One specific drug should *not* be considered for chronic pain—ketorolac (Toradol)—which is meant only for short-term use that should not exceed 5 days. Acetaminophen may be a good choice for older adults but liver function should be monitored with long-term use. All patients should be cautioned to read labels for common OTC remedies also containing acetaminophen to avoid accidental overdosing.


Figure 52–5. Chronic pain management algorithm.

Adjuvant Analgesics

Adjuvant drugs are used for treating conditions other than pain. However, in combination with analgesics, they have a synergistic effect to reduce multiple types of pain. Corticosteroids such as prednisone and dexamethasone can be helpful in relieving the discomfort of inflammation but are generally used short-term for this purpose. Chronic use can cause adrenal suppression, GI bleeding, or thromboembolism.

Depression or anxiety can be managed with SNRIs or TCAs along with pain modulation. Of the SNRIs, duloxetine (Cymbalta) 30 mg daily (titrated to 60 mg daily) can be useful for diabetic peripheral neuropathy with results in approximately 1 week; venlaxafine (Effexor) has also shown to be effective at doses of 150 to 225 mg daily. TCAs are effective for several types of neuropathic pain but can take up to 6 weeks for full analgesic effect. Avoid amitriptyline in older adults due to its anticholinergic effects. TCAs are contraindicated in patients with heart disease because sudden death can occur. A baseline ECG for patients over the age of 40 should be obtained prior to treatment with any TCA.

Tramadol (Ultram) is a nonopioid analgesic that binds to the μ receptor and has weak opioid and serotonin-norepinephrine reuptake inhibitor (SNRI) activity. Because of its opioid-like activity, tramadol should not be used in patients recovering from narcotic addiction. Dosing of tramadol is usually 50 to 100 mg every 4 to 6 hours and should not exceed 400 mg/d; the maximum dose in patients older than 75 years is 300 mg/d. Seizures and serotonin syndrome are adverse effects. Safety has not been established in children.

Cyclobenzaprine or other skeletal muscle relaxants are useful for fibromyalgia. Muscle relaxants are also helpful in the short-term management of acute exacerbations of muscle spasms associated with chronic low back pain. They are not helpful for long-term use due to their sedating properties.

Topical applications of anesthetics or capsaicin can be useful for neuropathic pain at peripheral sites without significant systemic effects. Other drug classes for neuropathic pain include anticonvulsants; gabapentin (Neurontin) and pregabalin (Lyrica) are recommended for diabetic neuropathy, post-herpetic neuralgia, and fibromyalgia. Gabapentin is more efficacious than TCAs in treating post-herpetic neuralgia. It is initially dosed at 300 mg 3 times a day and titrated to 900 to 1,800 mg 3 times a day; it is a suitable drug for children over the age of 3 at initial doses of 10 to 15 mg/kg 3 times a day and titrated based on age and weight. Pregabalin also has anxiolytic effects, which are helpful for mood stabilization in patients with neuropathic pain. The starting dose of pregabalin for the pain of diabetic neuropathy is 50 mg 3 times a day, then titrated over the next 7 days to 100 mg 3 times a day. The dose for fibromyalgia is 75 mg twice a day initially, then may be increased over the next 7 days to 150 mg twice a day.

Patients may also wish to use complementary or alternative therapies for chronic pain relief. Herbal preparations are not regulated nor do they undergo the rigorous testing done on pharmaceuticals; however, they may play a role in treating chronic pain conditions. Internet consumers can find multiple Web sites that list "natural pain killers" such as turmeric (fibromyalgia), feverfew (rheumatoid arthritis), eucommia (connective tissue disorders), kava kava (arthritis and neuropathic pain), capsaicin (neurogenic pain), or Devil's claw (muscle and low back pain), to name a few. Practitioners should educate themselves about herbs and the possible interactions between herbs and pharmaceuticals. For instance, turmeric interacts with anticoagulants, antidiabetic agents, antihypertensives, and hepatotoxic agents, which would increase the risk of bleeding, hypoglycemia, higher blood pressure, and liver damage; feverfew interacts with antiplatelets and antidepressants, which would increase the risk of bleeding and may worsen depression (Ulbricht, 2011).

Opioids

Opioids are added in Step 2 of the analgesic ladder when pain is persistent or not well controlled with nonopioids. Step 2 opioids are indicated for mild to moderate pain; Step 3 opioids are used for moderate to severe pain. Opioids can be administered by a variety of routes and have a wide range of drug duration. An initial trial should be made and if the drug of first choice is not effective, a trial of a different opioid or route is warranted. For patients with episodic or breakthrough pain episodes, short-acting opioids (4 to 6 hr) are appropriate and can be taken as needed. Examples are codeine, hydrocodone, or oxycodone. For patients with persistent and unrelenting pain, long-acting opioids (8 to 12 hr or more) provide a more steady state of analgesia and should be taken on a regular schedule. Examples are OxyContin or MS Contin, which can provide relief for up to 12 hours. More recent preparations of morphine (Kadian and Avinza) and hydromorphone (Palladone) can last 12 to 24 hours. The fentanyl transdermal patch can provide relief for up to 72 hours (Hattori, n.d.).

It is necessary to start with lower doses of opioids and gradually titrate to the desired effect. If necessary to convert from a short-acting agent to a long-acting opioid, the transition should be done cautiously, especially in opioid-naïve patients and the elderly. Methadone should be used with extreme caution because of its unpredictable pharmacokinetics and accumulation from repeated doses. Treatment is best provided by a pain management expert.

Patients should be weaned from opioid therapy for the following reasons: (1) there is little clinical benefit despite multiple dosing adjustments and opioid rotation, (2) the patient has poor tolerance to the opioid at doses required for analgesia, (3) there are ongoing adherence issues (e.g., drug-seeking behaviors or diversion) despite the use of a pain contract or other treatment limits set with the patient, and (4) the patient has a comorbid condition that makes opioid therapy more harmful than helpful (Argoff, 2011). Downward tapering of drug doses should be done over time by decreasing the opioid dose by 10% of the original dose each week over several weeks. Abrupt cessation or rapid tapering can precipitate seizures or withdrawal symptoms. Switching

from a long-acting opioid to a short-acting one may also be helpful because some patients may do better with lower potency drugs.

To decrease the possibility of nonadherence to the treatment plan, limit the opioid supply to 7 days at the new dose during tapering. Monitor the patient during the withdrawal period for signs of abstinence syndrome, such as nausea, diarrhea, muscle pain, and myoclonus. These symptoms can be managed with clonidine (Catapres) 0.1 to 0.2 mg every 6 hours or a clonidine patch 0.1 mg over 24 hours weekly during the transition period (Washington State Agency Medical Directors' Group, 2007). Mild withdrawal symptoms may last up to 6 months after opioids have been discontinued; although the symptoms may be unpleasant, they are not serious. The patient should be monitored for behavioral changes during the tapering process and appropriate management strategies utilized.

In general, Schedule II controlled substance prescriptions are written for a 30-day supply (subject to state laws and insurance carriers) without refills, which would ordinarily require an office visit for renewal. The Drug Enforcement Administration (2006) revised its regulations to allow multiple prescriptions for Schedule II drugs in some cases, authorizing a total of a 90-day supply under the following conditions: the practice of writing multiple prescriptions is permissible under applicable state laws, the practitioner indicates on each prescription the earliest date the prescription can be filled, and the practitioner concludes there is no risk of aberrant behavior or drug abuse. Schedule III and IV controlled substances may be refilled if authorized on the prescription. These prescriptions may only be refilled up to 5 times within 6 months of the original issue date; after that time a new prescription is required.

RECLASSIFICATION OF HYDROCODONE AS SCHEDULE II

In 2013 the U.S. Food and Drug Administration (FDA) recommended that the U.S. Drug Enforcement Administration (DEA) reclassify hydrocodone from a Schedule III to a Schedule II drug due to the misuse and abuse of the drug. In October 2014 the DEA reclassified hydrocodone, the most prescribed opioid in the United States, as a Schedule II drug.

Monitoring

Periodic assessment should be made of patients treated for chronic pain. Assessment of progress toward goal attainment should include documentation of pain intensity, functional ability, and quality of life. The practitioner should observe mood, affect, and coping abilities along with a physical examination. If the patient's status is stable, these assessments can be brief; if worsening conditions or complications are encountered, a more in-depth assessment is necessary.

The practitioner should always assess for changing conditions and the risk of aberrant behaviors. For patients with a high risk of aberrant drug use, such as patients who are only interested in obtaining oral pills or who "run out" of medication before the 30-day period, other strategies should be utilized. For instance, urine drug screens or frequent follow-up visits with pill counts could be initiated. A pain contract that clearly identifies goals, expectations, and responsibilities of both patient and practitioner may be useful for patients who have a history of substance abuse or fall in the high-risk category. Comanagement with or referral to an addiction specialist could also be arranged.

Outcome Evaluation

Goals of treatment should be negotiated when therapy begins and a baseline of acceptable pain level should be established. The outcome may not be total pain relief but should aim to restore as much function as possible. Quality of life is also a mainstay of therapy. Since psychological effects of chronic pain are prevalent, assessing mood and coping skills is also important. It is difficult to use physiological measures but other indicators such as sleep, appetite, amount of physical activity, participation in work or hobbies, and social relationships can give insight into the success or failure of the treatment plan.

Patient Education

As with treatment of acute pain, the individual should be educated about the specific choice of drug or combination drug therapy to address chronic pain, dosing regimens, and realistic goals about pain management. Complete relief may be an unrealistic expectation, yet there are not only drugs but also adjunct and alternative therapies that can be helpful in reducing the pain to an acceptable level. Common side effects with long-term use of an opioid should be explained along with adverse effects. Differences between drug dependence, tolerance, and addiction should be reviewed because many patients are fearful that addiction will occur. The practitioner should assure the individual's report of pain is believed and that there are multiple modalities that can address the pain as well as the accompanying symptoms. Establishing a therapeutic partnership for the control of chronic persistent and recurrent pain is key. See "Patient Education, Chronic Pain Management."

CHRONIC PAIN MANAGEMENT

PATIENT EDUCATION

Related to the Overall Treatment Plan and Disease Process

☐ Pathophysiology of pain and its cause (where appropriate), at a level the patient can understand, to explain how the drugs work.

☐ Role of lifestyle modification in improving prognosis and keeping the number and cost of required drugs and other treatments down.

☐ Indications for contacting the health-care provider when pain relief is ineffective.

☐ Need for follow-up visit(s) with the primary care provider.

Specific to the Drug Therapy

☐ Reasons for taking the drug(s) and the anticipated action of these drug(s) in pain relief.

☐ Doses and schedules for taking the drug(s), including round-the-clock dosing of drugs.

☐ Possible adverse reactions and what to do if they occur.

☐ Coping mechanisms to deal with the complex and costly treatment regimens.

Reasons for Taking the Drug(s)

☐ Patient education about specific drugs is provided in Chapters 15 and 25. The explanations should be clear about what pain drugs can and cannot do.

☐ Patient should be made aware that the drug(s) may need to be taken over a long period of time, so interventions to reduce adverse reactions and reporting them when they occur are important.

Drugs as Part of the Total Treatment Regimen

☐ Role of both pharmacological and nonpharmacological treatments for pain and their interconnection.

Adherence Issues

☐ The fact that most chronic pain cannot be resolved should be addressed.

☐ Adherence to the drug regimen is important to improving chronic pain.

☐ Adherence to lifestyle issues is equally important.

☐ Discussion of ways to remove barriers to adherence should occur.
