Preface to the Fifth Edition

It has been 17 years since the release of the last edition—an inordinately long interval in view of the dizzying pace of discovery in the biomedical sciences. That lengthy interval presented certain challenges in deciding whether and how to embark on the production of a new edition. An immediate reality was that a new volume had to be comprehensive enough to retain the durable parts of the increasingly obsolete earlier edition while capturing the myriad new advances. That significantly greater breadth and depth would require an expanded editorial team. We were fortunate that the three of us together were sufficiently familiar with current experts across our exciting and rapidly evolving field to recruit a stellar group of authorities in their respective specialties. Most auspiciously, although we had not worked so closely together before, we all brought our experience with the previous edition and a commitment to the high standards that Al Evans imparted to everyone involved in the four earlier editions of the text.

The time elapsed since the earlier edition also meant that many chapters and the roster of authors had to be entirely replaced or substantially modified by a largely new group of contributors since relatively few of those involved in the earlier chapters remained available. In the end, dozens of new authors were engaged.

Perhaps the most difficult decision had to be made primarily by Springer. Despite the fact that the publishing world was undergoing a revolutionary transformation to digital media, a determination had to be made on whether a printed book could still be both relevant to the discipline and financially viable. In that regard, during the several years since the first conversations about the new edition with William Tucker, Khristine Queja, and others at Springer, they have steadfastly supported the project even in such an uncertain environment surrounding print publications. To vindicate their judgment as well as our own leadership on the venture, we aspired to a product that would greatly surpass a typical new edition; we hope readers conclude that it meets that test by any reasonable measure.

The text now contains four sections. The first covers principles and methodology, including new chapters on methods of detection and modeling and a largely new perspective on surveillance and biomarker epidemiology. Astonishing technologic progress is reflected in the chapters discussing the proliferation of virologic and immunologic assay platforms, routine applications of RT-PCR, and more recent incorporation of nucleic acid sequencing into research and even clinical diagnostic identification. Some chapters also cite early dividends from the expanding disciplines of bioinformatics and computational biology. The chapter on disease surveillance systems and techniques highlights sophisticated approaches to data gathering, with ever faster reporting aided not only by conventional electronic transmission capability but also increasingly by the hardware and software on portable devices that power social media. Although surveillance still depends heavily on seroepidemiology, biomarker studies of viral infections in large populations now increasingly involve collection and storage of samples other than serum, opening further opportunities to study host-agent interactions at the cellular and molecular level. A new chapter on modeling focuses on the more theoretical aspects of transmission, particularly person-to-person transmission; on the other hand, reference to decision models on projected future numbers of cases, clinical utility of a diagnostic assay, or cost-effectiveness of interventions to combat particular infections appear in the chapters addressing those agents.

The remaining sections categorize viruses and the infections they cause into three groups: those involved primarily in acute disease, those involved primarily in chronic disease including malignancy, and those involved in both. Of the 47 chapters—13 more than in the previous edition—each has been substantially revised or written entirely anew. Where an earlier single chapter may have covered multiple viruses related to each other either clinically (e.g., hepatitis, gastroenteritis) or epidemiologically (e.g., vector-borne diseases), they are now treated more expansively. Four separate chapters cover hepatic diseases (hepatitis A, hepatitis B and D, hepatitis C, and hepatocellular carcinoma); three cover gastroenteritis due to a number of enteric viruses (noroviruses, sapoviruses, astroviruses, rotaviruses, enteroviruses, and hepatitis E virus); and six separate chapters cover countless viruses transmitted by arthropods or small mammal vectors. Although prion-associated spongiform encephalopathies are not viral diseases, the chapter on these conditions reflects recognition that many of their clinical and epidemiologic features resemble those of chronic viral infections closely enough to be instructive in this context.

Viral Infections in Humans has now been in print for more than 40 years. Many dozens of basic, clinical, and population scientists have contributed to one or more editions. And each successive edition has built on the solid foundations laid by colleagues who have preceded us. Of the 90-odd authors connected with this fifth edition, we three editors are among only 9 who also contributed to the fourth. Many who participated earlier are no longer alive, and we thought it was fitting at least to honor those listed below who have passed away during the years since the previous edition, including Caroline Breese Hall, who shared in preparing the chapter on HHV-6 included in this volume.

Abram S. Benenson	2003
Francis L. Black	2007
Floyd W. Denny	2001
Alfred S. Evans	1996
Clarence J. Gibbs Jr.	2001
Eli Gold	2011
Caroline B. Hall	2012
Joseph L. Melnick	2001
Robert E. Shope	2004
Thomas H. Weller	2008

We remember all of them here in gratitude and admiration. Each made noteworthy—some even monumental—contributions to our field, and each unquestionably enhanced the value of this latest edition.

Finally, we owe special thanks to our wives—Leanne, Elizabeth, and Maryellen—who have patiently endured the many annoying diversions of our attention.

Birmingham, AL, USA — Richard A. Kaslow
New York, NY, USA — Lawrence R. Stanberry
Galveston, TX, USA — James W. Le Duc

Contents

Part I Concepts and Methods

1 Epidemiology and Control: Principles, Practice and Programs 3
Richard A. Kaslow

2 Diagnosis, Discovery and Dissection of Viral Diseases 39
W. Ian Lipkin and Thomas Briese

3 Immunological Detection and Characterization 47
Robert L. Atmar

4 Surveillance and Seroepidemiology 63
Ruth Jiles, Monina Klevens, and Elizabeth Hughes

5 Viral Dynamics and Mathematical Models 81
Nimalan Arinaminpathy, Charlotte Jessica E. Metcalf, and Bryan T. Grenfell

Part II Viruses Causing Acute Syndromes

6 Adenoviruses 99
Xiaoyan Lu, Amita Joshi, and Phyllis Flomenberg

7 Alphaviruses: Equine Encephalitis and Others 123
Scott C. Weaver and Ann M. Powers

8 Arenaviruses: Lassa Fever, Lujo Hemorrhagic Fever, Lymphocytic Choriomeningitis, and the South American Hemorrhagic Fevers 147
Daniel G. Bausch and James N. Mills

9 Bunyaviruses: Hantavirus and Others 173
Alexander N. Freiberg, Dennis A. Bente, and James W. Le Duc

10 Coronaviruses 199
Arnold S. Monto, Benjamin J. Cowling, and J.S. Malik Peiris

11 Enteroviruses and Parechoviruses: Echoviruses, Coxsackieviruses, and Others 225
M. Steven Oberste and Susan I. Gerber

12 Enteroviruses: Enterovirus 71 253
Mong How Ooi and Tom Solomon

13 Enteroviruses: Polio 277
Olen M. Kew

14 Filoviruses: Marburg and Ebola 337
Thomas G. Ksiazek

15 Flaviviruses: Dengue 351
Stephen J. Thomas, Timothy P. Endy, and Alan L. Rothman

16 Flaviviruses: Yellow Fever, Japanese B, West Nile, and Others 383
Stephen J. Thomas, Luis J. Martinez, and Timothy P. Endy

17 Hepatitis A Virus 417
Daniel Shouval

18 Hepatitis E Virus 439
Xiang-Jin Meng

19 Influenza Viruses 455
John J. Treanor

20 Noroviruses, Sapoviruses, and Astroviruses 479
Ben A. Lopman, Jan Vinjé, and Roger I. Glass

21 Orthopoxviruses: Variola, Vaccinia, Cowpox, and Monkeypox 501
Brett W. Petersen, Kevin L. Karem, and Inger K. Damon

22 Paramyxoviruses: Henipaviruses 519
Stephen P. Luby and Christopher C. Broder

23 Paramyxoviruses: Measles 537
William J. Moss and Diane E. Griffin

24 Paramyxoviruses: Mumps 553
Steven A. Rubin

25 Paramyxoviruses: Parainfluenza Viruses 579
Janet A. Englund and Anne Moscona

26 Paramyxoviruses: Respiratory Syncytial Virus and Human Metapneumovirus 601
James E. Crowe Jr. and John V. Williams

27 Parvoviruses 629
Kevin E. Brown

28 Rhabdovirus: Rabies 651
Kira A. Christian and Charles E. Rupprecht

29 Rhinoviruses 675
Ian M. Mackay and Katherine E. Arden

30 Rotaviruses 713
Monica Malone McNeal and David I. Bernstein

31 Rubella Virus 733
Walter Orenstein and Susan E. Reef

Part III Viruses Causing Acute and Chronic Syndromes and/or Malignancy

32 Hepatitis Viruses: Hepatitis B and Hepatitis D 747
Alison A. Evans, Chari Cohen, and Timothy M. Block

33 Hepatitis Viruses: Hepatitis C 765
Ponni V. Perumalswami and Robert S. Klein

34 Hepatitis Viruses: Hepatocellular Carcinoma 785
Ju Dong Yang, Roongruedee Chaiteerakij, and Lewis R. Roberts

35 Human Herpesviruses: Cytomegalovirus 805
Robert F. Pass

36 Human Herpesviruses: Herpes Simplex Virus Types 1 and 2 829
Christine Johnston, Rhoda Ashley Morrow, and Lawrence R. Stanberry

37 Human Herpesviruses: Human Herpesvirus 6 855
Mary T. Caserta and Caroline Breese Hall

38 Epstein-Barr Virus (EBV): Infectious Mononucleosis and Other Nonmalignant EBV-Associated Diseases 867
Karen F. Macsween and Ingólfur Johannessen

39 Kaposi's Sarcoma-Associated Herpesvirus: Epidemiology, Biological Characteristics and Pathogenesis 897
Ronit Sarid and Maria Luisa Calabrò

40 Human Herpesviruses: Malignant Lymphoma 933
Jennifer A. Kanakry and Richard F. Ambinder

41 Epstein-Barr Virus: Nasopharyngeal Carcinoma and Other Epithelial Tumors 953
Lawrence S. Young, Christopher W. Dawson, and Ciaran B.J. Woodman

42 Human Herpesviruses: Varicella and Herpes Zoster 971
John W. Gnann Jr.

43 Human Immunodeficiency Viruses Types 1 and 2 1001
Richard A. Kaslow, Emily J. Erbelding, and Paul A. Goepfert

44 Human Papillomaviruses: Cervical Cancer and Warts 1063
Georgios Deftereos and Nancy B. Kiviat

45 Human T-Cell Leukemia Viruses Types 1 and 2 1105
Edward L. Murphy and Roberta L. Bruhn

46 Polyomaviruses: Progressive Multifocal Leukoencephalopathy and Other Diseases 1135
Raphael P. Viscidi, Loubna Tazi, and Keerti V. Shah

Part IV Other Transmissible Agents

47 Prion Diseases 1165
Ermias D. Belay and Jason C. Bartz

Index 1187

Part I

Concepts and Methods

Epidemiology and Control: Principles, Practice and Programs

1

Richard A. Kaslow

1 Introduction: Infection and Disease

The epidemiology of infectious diseases is concerned with the circumstances under which both infection and disease occur in a population and the factors that influence their frequency, spread, and distribution. It is critical to distinguish between infection and disease because the factors that govern their occurrence may be different and because infection without disease is common with many viruses. Infection indicates the introduction and multiplication of a biological agent within a host, leading to an interaction often manifest as an immune response. It is determined largely by environmental factors that govern exposure to the agent and by both intrinsic susceptibility and personal behavior of the host. Disease represents the host response to infection when it is severe enough to evoke a recognizable pattern of clinical manifestations. The factors that influence the occurrence and severity of this response vary with the characteristics of virus involved, its portal of entry, and the dose or inoculum size; but the most important determinants for many common infections lie within the host. Of these, the age and general health at the time of infection, genetic background, and immune status of the host are the most crucial.

This chapter deals with the principles, observational methods, and control techniques applicable to viral infection and disease in general; these concepts and approaches are explored in greater detail in individual chapters concerned with specific viruses or groups of viruses. For broader and fuller presentations of the epidemiologic principles, see texts in Suggested Reading, and for widely accepted definitions, see Ref. [1].

2 The Agent

This section addresses general properties of viruses that are important to an understanding of their epidemiology but not their basic genetic, chemical, or structural composition or details of their physiologic or multiplicative properties. Chapters of this book on specific viral infections provide some information on these topics. Other sources to be consulted include textbooks on basic virology, such as Fields Virology [2] and others, and books on the more general topic of microbiology and infectious diseases [3, 4].

Several intrinsic properties of all pathogens, including viruses, are of importance in the production of infection and disease; these properties can be quantified and permit comparisons among viruses. One property, *infectivity*, is ability to infect the preferred target cell in a standard assay, usually measured as the minimum number of infectious units or particles required. It may involve the capacity for attachment to, entry into, and multiplication within a variety of host cells. A second property, *pathogenicity*, is defined as the ability of an infectious agent to produce clinically significant disease. A third property, *virulence*, has been used synonymously with the previous two terms but more formally refers to the proportion of infections that produce serious disease, classically measured as a ratio of fatal cases to the total number of infections. A fourth property is what might be described as adaptability, a reflection of genetic responsiveness to external perturbations often determined by the type and organization of its nucleic acid. Over their long evolutionary history, most viruses have either gradually accumulated key mutations or even integrated entire host genes that alter their capacity to cause disease or permit them to evade or circumvent specific host mechanisms of resistance. The proper series of mutations may have enabled a virus to utilize an alternative biochemical pathway or conferred variable degrees of resistance to antiviral agents. Rapidly replicating RNA viruses like influenza, human immunodeficiency virus, and hepatitis C virus are more error (mutation) prone than many DNA viruses. More sophisticated mechanisms of evasive

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_1,

adaptation have been adopted by larger DNA viruses like the herpesviruses. One such mechanism utilized by human herpesvirus 8 is exemplified by the incorporation of several viral homologues of human genes (e.g., *IL6*, *IRF3*), which may mimic their human counterparts and/or usurp their function [5, 6]. All of these properties are factors that may influence not only the capacity to initiate infection and produce disease but also the transmissibility of the agent.

3 The Host

Characteristics of the host that influence the occurrence of both infection and disease are numerous and highly variable. Some host factors that alter resistance and susceptibility to infection are identical to those that modulate the development and natural history of disease, but many others affect only one or the other. Age, sex, and race are the most longstanding and obvious factors for both.

Most of the effect of age on resistance to infection either is attributable to the development of immunity over time or reflects the mode of transmission. Infants and young children are susceptible to a whole range of infections that confer lifelong immunity once acquired. Many viral infections that are now largely prevented wherever vaccines are available (e.g., measles, mumps, rubella, varicella, and rotavirus) and others like respiratory syncytial virus have historically caused major childhood morbidity and mortality. Acquisition of certain herpesviruses (herpes simplex virus, cytomegalovirus, and Epstein–Barr virus) begins in the perinatal period via congenital transmission followed by slow and steady increases until adolescence, most likely through relatively casual direct contact. Then occurrence accelerates somewhat for the next several decades during the period of more intimate oral or sexual contact before leveling off after middle age.

The severity of an acute infection and the course of chronic one infection may also differ by the age at acquisition. For reasons not well understood, hepatitis A in older children and adults can be much more clinically apparent than in younger children who are often asymptomatic. Similarly, poliovirus is much more likely to produce paralytic disease in older persons than in young children. The age at which an individual becomes infected with HIV-1 is a strong determinant of the natural history of that infection (see Ref. [7] and Chap. 43).

For most viral infections, especially those occurring principally in childhood, the two sexes appear approximately equally susceptible. In adolescents and adults, differential rates of acquisition by sex may be due to obvious differences in anatomy or in the mode of transmission, as in the case of human papilloma virus and HIV-1, respectively.

Differences in infection rate by race or ethnicity can be divided into those known or likely to have genetic or other biologic origins versus those most likely due to other factors that correlate closely with race. Genetic factors are discussed below. For the nongenetic explanations, race is usually a surrogate marker for some other often readily apparent factor. Geographic distribution is the most obvious reason for large racial differences. Viruses that have reservoirs or life cycles that involve nonhumans would be expected to occur only in regions of the world where the animal populations may coincide with humans of one particular racial group. Exposure may differ by race because of behavioral differences. New HIV-1 infections in young gay men in the United States have surged more in blacks because of their relatively exclusive exposure network (see Chap. 43). HIV-2 is heavily concentrated in individuals of West African and Portuguese ancestry because the virus probably originated and mainly spread in the former Portuguese colonies on the west coast of sub-Saharan Africa.

Other host biological and behavioral factors are known or likely to influence acquisition of viral infection: general nutritional status and specific micronutrient or vitamin deficiency, cigarette smoking, medication, use of alcohol and other non-medicinal substances, occupation, marital status, and sexual practices.

Many of the above-mentioned factors may not only predispose to or protect from infection but also modulate the nature, severity, or course of disease. Table 1.1 contains a list of the host factors implicated with varying degrees of certainty as modulators of occurrence, severity, pace, or duration of some viral diseases.

It is biologically based immunity that is the fundamental host characteristic governing not only acquisition but also, probably more profoundly than the other factors, the pathogenesis and evolution of infection. Indeed, the influences of age, sex, race, and some of those others reflect in part the accompanying biologic functions that vary with those characteristics. There are many examples in which these host factors are almost certainly operating as surrogates for immune

Table 1.1 Host factors that influence the occurrence, course, or severity of disease

11. Psychological status (e.g., motivation, emotional crises, attitudes toward illness) [8]

status. Age is prime example. Childhood respiratory and enteric viruses produce life-threatening disease in infants but little or no illness in adults who have developed natural immunity. Conversely, infections with hepatitis A and polio viruses are often asymptomatic in young children but may produce significant clinical hepatitis and paralytic poliomyelitis in older individuals. Aging adults develop increasingly severe infections as their immunity in general and specifically to previously encountered viruses wanes. Sex differences in disease expression are generally less obvious. Disease due to influenza virus is more or less equally common and severe in men and women in general, but pregnant women experience more serious illness [9].

Apparent racial disparities exist in rates of infection, disease frequency, or expression. Various sources of surveillance data suggest that persons of African ancestry in the United States have higher rates of influenza, HCV, HPV, and other viral infections, while those of Asian ancestry have higher rates of HBV infection. However, in each case these differences are readily attributable to geographic, socioeconomic, or behavioral influences on acquisition, as noted earlier, and race is simply a marker of some combination of those factors rather than signifying an underlying immunologic or other biologic basis for the difference. On the other hand, some racial or ethnic differences in the disease manifestations (severity or natural history) will undoubtedly prove to be due to underlying immunogenetic heterogeneity.

Immunity exists in a continuum ranging from lowest (i.e., complete susceptibility) to highest (i.e., complete resistance). Resistance is either intrinsic or induced, and it can be induced either naturally or artificially. The basis for natural resistance or immunity to viral infection is briefly discussed just below; the strategy and resources employed for inducing resistance by immunization are addressed later in this chapter.

Mediators of natural resistance include components of primary defense systems such as cilia, mucus, the integument, and other physical and chemical inhibitors. However, resistance is even more dependent on the principal organs involved in generating the immune response—spleen, bone marrow, lymph nodes, and other lymphoid tissue—the structures on which the highly complex cellular and humoral immune systems are founded. Multiple cellular arms of the immune system dedicated to defending against viral infection. They operate through dozens of known and as-yet-unknown interlocking pathways in which monocytes; macrophages; dendritic cells; a wide array of T-helper, suppressor, and regulatory cells along with B lymphocytes and plasma cells are all orchestrated to stimulate or respond to each other in a coherent and effective manner. They may do so by a variety of mechanisms. Communication and function may occur through direct cell–cell contact or binding between receptor–ligand pairs on cell surfaces. Alternatively or additionally, these and other specialized cells may secrete cytokines, chemokines, complement, peptides, or other immunoactive substances, for which their target cells carry surface or intracellular receptors. Thus, countless different cell types in elaborate interlocking pathways execute any of a variety of assigned functions—signaling, activating, inhibiting, attracting, killing, etc.

Humoral immunity is generated by a cascade of interactions among dendritic cells, T and B lymphocytes, and plasma cells culminating in the production of immunoglobulins that serve as antibodies to the virus that initiated the response. Once activated by a virus, the humoral immune system engages in sequential production of immunoglobulins of the IgM, IgG, and IgA classes in different proportions that bind to surface or intracellular antigenic components of the virus. This binding improves with avidity (tightness) and affinity (antigen specificity) that increase during the days or weeks following onset of infection. The antibodies, often in conjunction with complement or other proteins, may neutralize or kill the virus directly or recruit cells with cytotoxic capabilities into the vicinity to accomplish that task.

Both cellular and humoral systems demonstrate what are known as innate and adaptive responses. Certain effector cells and molecules preexist in the host before any pathogen is encountered. These relatively unvarying elements have been recognized as the "first responders" because they mediate intrinsic or innate functions that are automatically and uniformly invoked in the first hours and days after a viral infection or other foreign intrusion. Soon after the innate response is underway, the adaptive parts of the systems are activated. Dendritic and other cells use molecules on their surface to present antigenic fragments to effector T lymphocytes individually in a process exquisitely specific to the offending virus. This specificity is generated by the huge variation in the human leukocyte antigen (HLA) genes that encode those surface proteins used for microbial antigen presentation. These molecules not only activate helper and cytotoxic T lymphocytes but also interact with another set of cognate receptors on the surface of natural killer (NK) cells; these NK cell receptors are also encoded by highly complex multigenic systems such as the leukocyte receptor complex (LCR), the natural cytotoxicity receptor (NCR) family, and the killer lectin-like receptor (KLR) family. The antibody-mediated humoral response is likewise largely adaptive. As with cell-mediated antigen presentation and the cytotoxic systems, the organization of the genes encoding immunoglobulins are likewise programmed for genetically governed rearrangements to provide for maximum adaptability and specificity. Moreover, not only do most antibodies bind with specificity for a particular class of viruses or a single member of the class, they also undergo structural maturation over time to conform even more closely to the specific target antigen.

All of these processes depend primarily on differential expression of hundreds to thousands of genetic loci relatively directly involved in the immune response. Many of the simplest, often monogenic immunodeficiencies with Mendelian patterns of inheritance and the infectious diseases that complicate them have been well catalogued, although new examples continue to surface [10]. On the other hand, very little of the overall genetic contribution to more complex multigenic infectious traits have yet been elucidated, but research in this field is charging ahead. An example of very direct genetic mediation of resistance to viral infection is the remarkable protection against HIV-1 infection afforded by the deletion of a portion of the gene for the viral co-receptor (*CCR5*) in individuals of European ancestry, described further in Chap. 43. Other clear instances of genetic mediation are the increased susceptibility to norovirus infection among carriers of the O blood group antigen compared with carriers of A or B antigen [11] and the predisposition of children with polymorphisms in the Toll-like receptor 3 gene (*TLR3*) to herpes simplex viral encephalitis [12]. In the past two decades, the explosion of knowledge in immunology and genetics has paralleled the rapid advances in molecular and computational technology. A more detailed summary of the rapidly expanding knowledge of immune system function is beyond the scope of this overview. The reader is referred to textbooks and the most current reviews of specific subjects for more complete coverage [13–15].

4 The Environment

The external environment can exert its influences on the virus itself or its mode of spread or on the biological or behavioral aspects of the host response. Although viruses survive or die within defined ranges of such physical factors as temperature, humidity, and air currents, variability between viral groups is high. Chemicals may be used as antiseptics or microbicides to kill viruses prophylactically, and the list of pharmaceuticals now available for antiviral therapy has been growing rapidly (see Sect. 10). These environmental factors may enhance or diminish survival of viruses, but they probably have a greater impact on routes of transmission and on patterns of host behavior.

In addition to physical and chemical factors, biological variables play a role as well. For insect-borne agents like the equine encephalitis viruses, whose survival may depend on migration patterns of an avian host or on overwintering in a mammalian reservoir, the environment exerts an obvious role in restricting transmission of infection and occurrence of disease to those areas that have the proper temperature, humidity, vegetation, and other features necessary for the insects. For viruses potentially transmitted by water, such as hepatitis A virus and noroviruses, a warm environment with poor sanitation and fecal contamination clearly increases exposure and transmission efficiency.

Climate also alters the social behavior of the host. In settings where high temperatures promote not only contact of hosts with water through swimming or drinking but also viral replication, transmission of waterborne gastrointestinal diseases is increased in polluted areas. Warm weather also brings closer contact with insect vectors of arboviruses and with dogs and other animal sources of rabies. Conversely, in the cooler seasons, people collect indoors, where crowding promotes transmission of airborne and droplet-borne infections. Spread in indoor environments is amplified by relative concentration of military personnel in barracks, residents of assisted living facilities, and assembly and dispersal of students coinciding with the periodic openings and closings of educational institutions. Furthermore, the relatively hot and dry environment in many homes and commercial buildings may impair the protective mechanisms on mucous surfaces and promote entry and attachment of certain respiratory viruses.

In tropical settings, heavy monsoon rains bring groups indoors and closer together much as they do during winter in colder climates. The incidence of common upper respiratory diseases in college students was as high in the warm climate where the University of the Philippines is situated as in the intemperate winters at the University of Wisconsin [16]. Community studies in India [17], Trinidad [18], and Panama [19] have documented high morbidity from influenza and other respiratory diseases in tropical settings where people aggregate inside, as with heavy rainfall or school attendance.

Cultural as well as physical environment can contribute to the spread of infection, as exemplified by the patterns of spread of HIV infection among gay bathhouse patrons, injectable substance abusers in “shooting” galleries, women offering sexual favors in exchange for crack cocaine [20], and long-distance truck drivers patronizing commercial sex workers [21].

5 Agent, Host, and Environment Interaction

It is obviously the interplay of those three cardinal elements that dictates where, when, and in whom viral infection occurs. Their interaction further determines whether the infection produces disease, how soon it begins, how it manifests itself, how severe it becomes, and how long it lasts.

To initiate infection a virus must be in the appropriate structural and functional state, reflected in the intrinsic properties described above. It must also be present in a quantity sufficient to penetrate the target host. That quantity, the *inoculum*, is the amount of virus available to be transmitted; and the minimum size of a viral inoculum needed to initiate infection varies with infectivity,

a property discussed earlier, as well as with other features of those three cardinal elements. Upon introduction of the minimum inoculum and successful attachment to and penetration of its target cells, the infection is established. Then, again depending on various features of the agent, host, and environment, the virus elicits a response that may or may not manifest clinically.

The degree of response an agent can evoke in the host immune system is known as its immunogenic potential or *immunogenicity*. It commonly refers to the ability of the natural infection to confer protection against reinfection or significant disease upon reexposure. This protective ability has typically been measured as the quantity of antibody that neutralizes or incapacitates the virus, but viruses may generate antibodies that do not neutralize or protect. Many of the classic acute childhood infections (e.g., measles, mumps, rubella, chicken pox, and other exanthematous conditions) are not merely strongly immunogenic but also usually confer lifelong immunity. In contrast, other viruses can either readily alter their antigenic makeup like influenza and some flaviviruses or produce persistent chronic infection like herpesviruses; by a variety of mechanisms, they have ingeniously avoided generating highly neutralizing antibody. HIV-1 is the master of evasive and adaptive mechanisms that allow it both to evolve rapidly and to persist for years without stimulating antibodies that neutralize.

In the context of immunization, immunogenicity represents the extent to which a vaccine can provide the same or similar degree of protection achieved in the course of natural infection. Many of the regimens for vaccination against those highly immunogenic infections have succeeded in mimicking very high levels of neutralizing antibody if not lifelong protection. The more basic biologic characteristics of the agent and the host that determine immunogenicity are addressed in texts on virology and immunology (see Sect. 1).

6 Incubation and Latency Periods

The interval of time between the sufficient exposure and the appearance of the first symptoms in the human host is the intrinsic *incubation period*. Viruses transmitted by arthropods or other animals have their own (extrinsic) incubation periods that vary with both the response within the animal and the external environmental factors that affect the animal populations. However, here the reference is only to the intrinsic incubation period. The variation in this interval in different diseases is considerable (Fig. 1.1). Viruses that do not require distant spread but are able to produce disease through multiplication at the site of implantation, such as the respiratory tract, tend to have short incubation periods on the order of 2–5 days. Arthropod-borne viral infections like dengue and yellow fever may have onsets as early as 2–3 days after a mosquito bite [22], whereas inoculation by small mammals may lead to longer incubation periods [23]. Viruses that require hematogenous spread and involve distant target organs such as the skin or CNS have incubation periods of 2–3 weeks. Rabies virus, dependent on spread along nerves, has a long and variable incubation period ranging from 8 days to a year or more. Of course, transmission of the prion-associated kuru is exceptional with onset documented as long 34–56 years after exposure [24]. In some diseases (e.g., poliomyelitis, dengue, hepatitis, and infectious mononucleosis), early symptoms or even a rash may accompany the period of initial invasion or viremia. With these infections an early phase may not be clinically recognized or occurs before the patient seeks medical care.

Knowledge of incubation periods has many practical uses. Epidemiologically, the former helps define the period of infectiousness: a patient is not usually infectious until close to the time of the appearance of clinical symptoms. In epidemics, knowledge of the mean, minimum, and

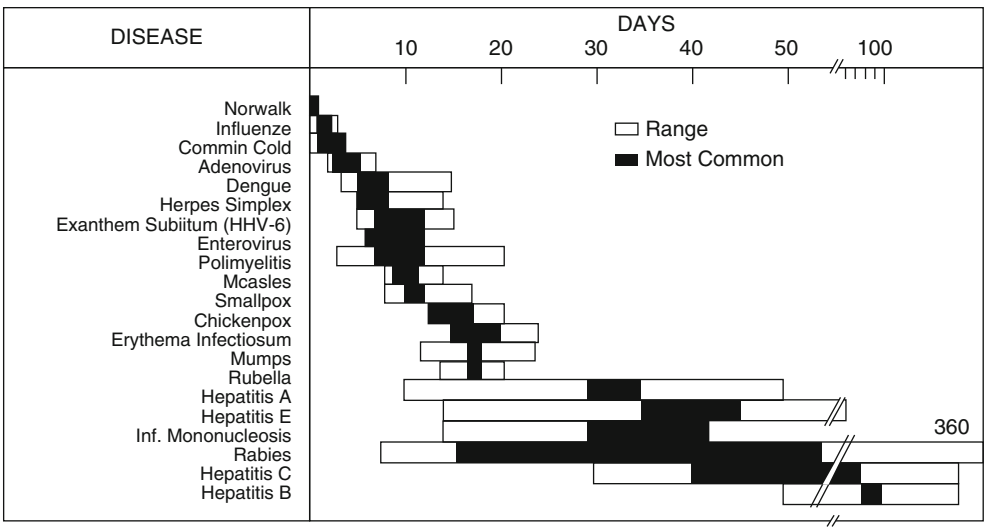

Fig. 1.1 Incubation periods in viral diseases (Based on data from Heymann [25]; Evans and Kaslow [210])

maximum intrinsic incubation periods can be used to identify the probable time of exposure to the index case or other source of infection. The duration of infectivity depends on the persistence of the virus and its exit into the environment. Clinically, the duration of the incubation period helps to identify the likelihood of viral exanthem after a known exposure or to differentiate hepatitis A from hepatitis B infections. For prophylaxis, it determines the feasibility of prevention of the clinical illness by immunoglobulin, as in hepatitis A and varicella zoster infections, rubella, and rabies, as well as the potential success of postexposure rabies vaccination.

In addition to the viruses that produce acute infections, there are delayed effects of certain common viruses in which the "incubation period" represents a true or apparent interval of "latency" lasting several to many years, during which there is little if any viral replication. Examples include the relationship of measles virus to subacute sclerosing panencephalitis, in which infection in infancy may be associated with involvement of the CNS some 5–10 years later [26]. Certain papovaviruses cause widespread inapparent infections in childhood. Rarely, reactivation occurs later in life in the form of progressive multifocal leukoencephalopathy. This phenomenon is seen in patients with Hodgkin's disease in association with depression of cell-mediated immunity and more recently in AIDS patients [27].

With HIV infection, a primary clinical response may occur within the first 2 months or so after infection in a substantial proportion of newly infected persons (see Sect. 7.1 and Chap. 43). During the subsequent clinically quiescent period, CD4 lymphocytes are destroyed at highly variable rates. Accordingly, clinical latency continues until immunosuppression is significant enough to permit new opportunistic pathogens to superinfect or long-latent agents to reactivate and produce clinical disease. The average time from initial HIV infection to that clinical event may be shorter or longer depending not only on the degree of viral control and immunosuppression under host genetic influence but also on the other cofactors required for any specific clinical AIDS outcome. For example, Kaposi's sarcoma tends to occur at a somewhat earlier stage of immunosuppression than cerebral atrophy with dementia or lymphoma for reasons presumably related to the unknown determinants of these conditions. Besides differences in the properties of the virus itself, such as the capacity to penetrate cells or induce syncytium formation in vitro, the route of transmission and host factors determine the rate of progression of HIV infection. The average AIDS-free interval is shorter for infants and children and for recipients of large volumes of blood products. The interval is longest among the youngest adults and then gradually shorter with increasing age [7]. There is also conclusive evidence for differential predisposition due to immunogenetic factors.

As with HIV infection, the latency period for different outcomes of HTLV-I varies. The interval between presumed infection via breast milk and onset of adult T-cell leukemia/lymphoma differs from the interval between presumed sexual transmission and onset of tropical spastic paraparesis or myelopathy. The concept of a latency period is also applicable to long-delayed virus-induced cancer as seen with an EBV-induced nasopharyngeal carcinoma KSHV-induced Kaposi sarcoma, HBV- and HCV-induced hepatocellular carcinoma, and HPV-induced cervical carcinoma (see Chaps. 34, 39, 40, 41, 44, and 45). In kuru, the latency period from exposure by ingestion of infected brain or other tissues or by absorption via abraded skin at a cannibalistic feast to the onset of disease can actually be as long as several decades (see Chap. 47) [24].

7 Patterns of Response

The response to viral infection varies along a biological gradient in terms of both the nature and the severity of the clinical syndrome produced. That variation is the product of the interaction of agent, host, and environment. The emphasis here is on the biological gradient as manifested in the human as a whole; qualitative and quantitative differences in responses that occur at the cellular and molecular levels are more properly the subject of basic virology and immunology texts.

7.1 The Biological Gradient

Response to a virus by an individual may range from completely asymptomatic to severe or fatal. The ratio of inapparent (or subclinical) to apparent (or clinical) responses varies from one virus to another; representative examples are shown in Table 1.2. The clinical response may be abrupt or more gradual, sometimes appearing long after the initial infection. It may be self-limited or arise from viral persistence or reactivation or both.

GBV-C infection increases with age but produces no known clinical illness [28]. Initial infection with BK and JC strains of polyomavirus, which show high prevalence and rates of acquisition of antibody in school children and adults [29, 30], is not known to affect them clinically. However, in immunocompromised patients (e.g., with AIDS, Hodgkin's disease, or renal transplantation), previously asymptomatic JC virus infection may evolve into progressive multifocal leukoencephalopathy[31]. Other primary or often reactivated infections are common in immunodeficient states; regardless of their clinical expression in normal hosts, most of the herpesviruses are more likely to cause mild to life-threatening complications.

Table 1.2 The gradient of subclinical/clinical ratio in selected viral infections (inapparent/apparent)

Virus	Clinical feature	Age at infection	Estimated subclinical/clinical ratio	Percentage of infection with clinical features
GBV-C	None known	Child to adult	∞	0
Poliomyelitis	Paralysis	Child	±1,000:1	0.1–1
Epstein–Barr	Heterophile-positive infectious mononucleosis	1–5	>100:1	1
		6–15	10–100:1	1–10
		16–25	2–3:1	35–50
Hepatitis A	Jaundice	<5	20:1	5
		5–9	11:1	10
		10–15	7:1	14
		Adult	2–3:1	35–50
Rubella	Rash	5–20	2:1	50
Influenza	Fever, cough	Young adult	1.5:1	60
Norovirus	Gastroenteritis	<2	1:5	60–90
HIV-1	Multiple	Any age	1:99	99
Measles	Rash, fever	5–20	1:99	99+
Rabies	CNS symptoms	Any age	0:100	100

A second group of viruses cause predominantly mild or asymptomatic infection when acquired in early childhood but symptomatic and sometimes severe clinical disease when infection is delayed. Examples of this are hepatitis A, poliovirus, and EBV.

At the other end of the spectrum are acute infections caused by agents like measles and rabies viruses or chronic infection with a virus like HIV-1 or the agents of spongiform encephalopathies, in which clinically recognized illness usually accompanies the infection but the course of infection may vary from days to decades. Rabies infection of man is the epitome of an infection from which death is virtually inevitable after characteristic symptoms develop.

The subclinical/clinical ratio for HIV-1 infection defies the more straightforward categorization possible for many other viral infections. A syndrome resembling mononucleosis with fever, fatigue, headache, lymph node swelling, joint and muscle aching, rash, sore throat, and other features occurs frequently in newly infected individuals. However, the proportion reported to have experienced this syndrome is higher or lower depending on the method of ascertainment (e.g., presentation at a sexually transmitted disease clinic, follow-up of cohort of initially uninfected homosexual men) and the clinical definition [32–34]. Likewise, the vast majority of HIV-1 infections follow a highly variable course—for a median of about 9 years in most studies of untreated individuals—free of the serious (AIDS-defining) illness; and on the average, HIV-2 infection progresses even more slowly. However, laboratory evidence usually indicates that immunologic deterioration is continuing at some rate even when the infection is clinically silent. The natural history of HIV infection and the factors that modulate it are addressed in detail in Chap. 43.

The biological gradient of many viral infections can be viewed as analogous to an iceberg in which clinically apparent illness represents only a small proportion of the response pattern and the usually larger amount represents unrecognized and inapparent infection. A similar analogy may exist at the cellular level. Figure 1.2 portrays these concepts, but Table 1.2 demonstrates that the precise shape of the iceberg for any given infection can vary considerably at the clinical level.

7.2 Clinical Syndromes: Manifestations, Etiologic Agents, and Frequencies

The tissue and organs targeted by human viruses can respond to infection in a limited number of ways; any of several viruses (or other causative agents) may trigger the same general response pattern. The clinician must often rely on epidemiologic and clinical features and simple laboratory tests in making a tentative etiologic diagnosis. This diagnostic reasoning may be based heavily on the known frequency of potential causative agents in the age group of the patient, the specific geographic or physical setting, the season, and their epidemic behavior. This section summarizes the major clinical syndromes produced by some of the more common human viruses. It includes (1) a very brief description of the clinical manifestations; (2) identification of major etiologic agents; (3) general frequency distributions by factors such as age and geography, not necessarily applicable at special times such as an epidemic or off-season or in settings like hospitals, nursing homes, and day-care facilities; and (4) selected other features relevant to the understanding of their occurrence in populations. For more detail, consult the chapter corresponding to the agent of interest or more specialized texts.

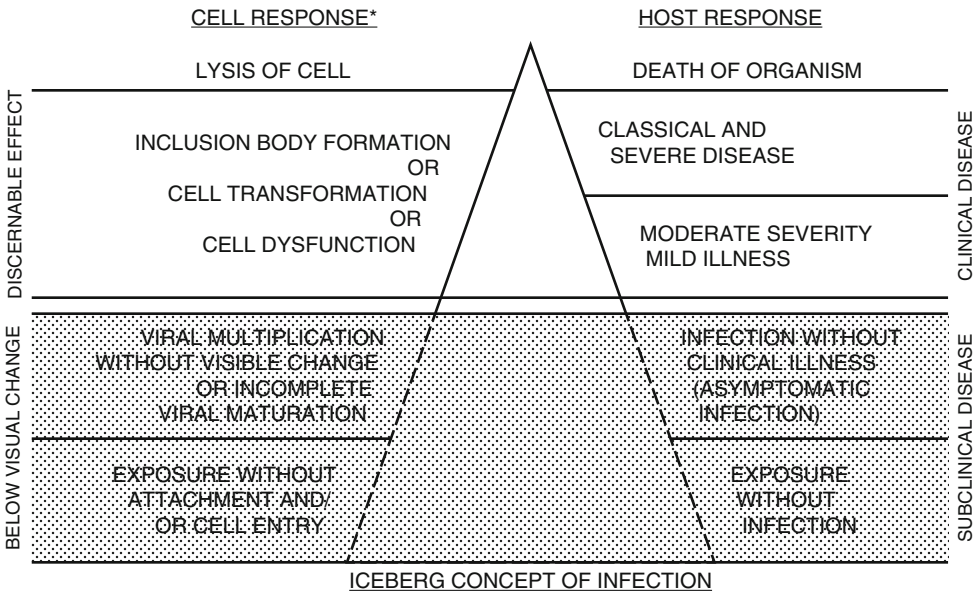

Fig. 1.2 "Iceberg" concept of infectious diseases at level of the cell and at level of the host. Within any cell population, varying patterns of cell response also occur. *Generic response [208] (Reproduced in Evans and Kaslow [210])

It is important to note that in recent years newer sample collection approaches, rapid immunologic assays, and highly sensitive molecular techniques have gradually supplemented and, in certain cases, supplanted the more traditional virologic and serologic tests, but they have come into use unevenly in different places (Chap. 2). Therefore, generalizations made in this discussion must be tempered by consideration of the methodology for sampling, detection, and identification that may have been used to generate the findings at different times in different settings.

7.2.1 Common Respiratory Tract Syndromes

Many viruses and viral groups can evoke symptoms and signs in the upper respiratory tract (e.g., eye, ear, nose, and throat symptoms; Viral infections of the lower respiratory tract trigger cough with little or no sputum production, shortness of breath, and changes in breath sounds on examination). Fever is less prominent than with bacterial or fungal infection.

Viral upper respiratory infection (URI) is extremely common in most temperate climates; it is the most frequent cause of absence from work or school in the United States [35]. A combination of rhinitis and pharyngitis (common cold) occurs most frequently in children under 5 years old, who may have multiple episodes in a single year. URIs are still frequent in older children, but incidence declines steadily through adulthood to greater than 60 years of age. Other manifestations of viral infection include sinusitis, which may be clinically or radiographically apparent in a very large proportion of those with viral URI [36].

Approximately nine of ten children under 2 years old have experienced an episode of otitis [37]. The usual viral etiologies are respiratory syncytial virus, parainfluenza (types 1–3), influenza (A and B), enterovirus, and rhinovirus [38]; however, the distribution of pathogens differs by age and location. Exposure to day care or a family member with a URI may be a predisposing factor.

Influenza virus is the leading cause of both upper and lower respiratory infections in middle-aged and older adults. Up to one-fifth of the entire US population may develop influenza in any particular season. Seasonal influenza typically lasts from November until March. However, in an atypical year, influenza activity may be present in summer and early autumn, as was true of H1N1 in 2009, when it overlapped with seasonal influenza, and of swine-associated H3N2v infection that occurred in 2012 in the setting of late summer county fairs [39].

Several viruses causing respiratory tract infection are relatively recent discoveries if not new to humans, and they are responsible for an appreciable proportion of viral respiratory tract infection (see Chaps. 10, 26, and 27). Human metapneumovirus can cause upper and lower respiratory tract infections (i.e., a cold, cough, bronchitis, pneumonia, and exacerbation of asthma) in people of all ages but more severe forms at the extremes of age and complicating immunosuppression. Coronaviruses, although known for years in animals and as the cause of more benign URI, came to attention dramatically during the large epidemic of severe acute respiratory syndrome (SARS) in 2003, and resurfaced again in the variant form producing Middle East Respiratory

Syndrome (MERS). Since then a succession of new human coronavirus strains has been associated with outbreaks of both upper and lower infections in different parts of the world. An even newer member of the parvovirus family, a bocavirus, has been at least presumptively linked with respiratory symptoms and otitis media [40].

Over the years, numerous investigators have tried to estimate the relative frequency of the different viral etiologies of clinical syndromes of acute respiratory diseases [40–48]. However, not surprisingly, the advent of newer more sensitive diagnostic techniques has made it increasingly clear that the distributions of viral pathogens vary greatly not only by age and season but also by geography and proximity to animal populations, previous human population experience, and other factors.

7.2.2 Gastroenteritis

This syndrome consists of nausea, vomiting, and/or diarrhea of varying severity, with relatively little fever or other features (e.g., significant abdominal pain or gross fecal blood) more typical of bacterial gastroenteritis. Worldwide, gastroenteritis causes serious morbidity and mortality, with the greatest toll in children under 5 years old, due to severe dehydration. In a study from the mid-1980s in the United States, diarrhea occurred in children under age 3 years in childcare at a rate of approximately three episodes per year [49]. Members of four families, rotaviruses, noroviruses, enteric adenoviruses, and astroviruses account for most of the disease caused by viruses, and each has epidemiologic characteristics that depend heavily on age and geography. Infections with these viruses tend to occur continually in children but only sporadically in adults. In the developed world, mortality is quite low although illness and hospitalization are more common.

Prior to the introduction of an effective vaccine, rotavirus infections were the leading cause of diarrheal illness in children under 2 years of age in the United States and many well-developed countries. The toll is still great in children under 5 years old in a number of places throughout the world, where it may account for as much as 30 % of mortality due to diarrheal disease [50]. As coverage with the vaccine expands, that picture is expected to change dramatically [51]. Caliciviruses and particularly the most notorious member of that family, norovirus, are now the leading cause of gastroenteritis among adults in the United States; these infections often occur in epidemic form as "winter vomiting disease" and are responsible for more than 90 % of outbreaks [52]. Facile interpersonal spread accounts for high secondary attack rates in family members and health-care personnel attending ill patients.

Viral gastroenteritis caused by adenoviruses and astroviruses has been studied more selectively, mostly in the United States. Specific serotypes of adenoviruses tend to cause disease in a year-round, endemic form, primarily in very young children. Up to 15 % of gastroenteritis in some settings may be due to astrovirus infection. Older children and adults are less affected. The infection is probably transmitted person to person, and it has caused infection in hospitalized and immunodeficient patients [11]. As many as another 10 % of cases in children may be caused by astroviruses, often in institutions like day-care centers and hospitals, where an even higher proportion of the transmitted enteric infections may be due to this agent [53, 54]. Elderly and immunocompromised patients appear to be at elevated risk [55, 56].

7.2.3 Common Central Nervous System Syndromes

Multiple viral agents are involved as causes of the syndromes of inflammation of the spinal cord (aseptic meningitis) and the brain (encephalitis) or a combination (meningoencephalitis). Comprehensive reviews of these infections can be found in Refs. [57–59]. The clinical features of these syndromes are quite variable, from mild headache and/or stiff neck with or without fever and subtle changes in cortical function (i.e., orientation, wakefulness, concentration, etc.) to more profound manifestations of spinal cord or brain dysfunction (including cranial nerve abnormalities; compromise of critical brain stem function; confusion, irritability, and poor feeding in very young children; and seizures). In younger children, long-term complications may include hydrocephalus, vision and hearing loss, weakness or paralysis, cranial nerve deficits, and learning and behavior problems.

The annual incidence of aseptic meningitis in the United States from all causes is approximately 11 in 100,000 persons, leading to 25,000–50,000 hospitalizations, mostly in children. However, many more mild and unconfirmed cases must go unreported. Again, the distribution of etiologic agents varies strongly with age, geography, and availability of vaccines.

The incidence of viral meningitis in infants may be as much as ten times that in older children. Worldwide, overall incidence is less easily estimated. Enteroviruses (echoviruses, coxsackieviruses, and others) are among the major causes in infants, and they may account for at least 80 % of cases in countries where vaccines against mumps, polio, and measles have significantly lowered the incidence of meningitis accompanying those conditions. On the other hand, in Asia, Japanese B encephalitis virus accounts for many thousands of meningitis cases each year and probably hundreds of thousands more that remain clinically inapparent.

Additional, less common causes include other flaviviruses (West Nile virus; see below), herpesviruses (VZV and others), lymphocytic choriomeningitis virus, other arboviruses (Eastern and Western equine encephalitis), and HIV-1. Because both enteroviral and arboviral infections show strong peaks in occurrence during the spring, summer, and early fall, the overall incidence in aseptic meningitis exhibits clear seasonality.

Encephalitis is less common than meningitis due to viral infection in the United States, with an annual incidence of about 20,000 cases or 3–8 in 100,000 persons. However, because many cases are not seen as part of an outbreak, an etiologic diagnosis requires a brain biopsy; therefore, only more severe and hospitalized cases are likely to receive such a specific diagnosis. HSV-1, the most frequent cause, is responsible for about 10 % of those cases. Arboviruses account for another 150 to several thousand cases, with variability according to the intensity of seasonal occurrence and striking peaks during sporadic epidemics. These have included Venezuelan equine encephalitis (1969–1971, several hundred cases), St. Louis encephalitis virus infection (1975, 3,000 cases), West Nile virus (encephalitis or meningitis, 2,800 cases in 2003 and 2,700 cases in 2012), and smaller numbers of La Crosse encephalitis and Western equine encephalitis cases [59]. In centers where concerted diagnostic effort is made, additional agents of sporadic cases of encephalitis and rarer central nervous system syndromes include other herpesviruses (EBV and VZV) and influenza A virus.

As with meningitis, accurate international estimates of the incidence of encephalitis are unreliable, but epidemic disease patterns similar to those in the United States occur throughout the world. For example, in a 1995 outbreak of Venezuelan equine encephalitis in Colombia and Venezuela, of the 75,000 humans estimated to have developed infection, neuroinvasive disease occurred in about 3,000, and 300 people died. Recently, henipaviruses in the paramyxovirus family have accounted for clusters of encephalitis and related neurologic disease in Australia along with Malaysia and Singapore (see Chap. 22).

7.2.4 Ocular Syndromes

Redness, watering, photophobia, feeling of irritation, and swelling of the membrane covering the eye (conjunctivitis) and the cornea (keratitis) are often severe symptoms epidemic keratoconjunctivitis (EKC) [60]. Outbreaks are commonly caused by very contagious human adenovirus infections. They are often nosocomial and have frequently occurred in such settings as the neonatal intensive care unit and ophthalmologic clinics, where contaminated contact lenses, eye drops, or instruments used for tonometry or slit-lamp examinations have been the modes of transmission (see Chap. 6).

Table 1.3 Viral causes of common exanthems

Type of rash	Examples[a]
Macular/papular	CMV, HHV-6, HBV, HIV
	Measles, atypical measles (vaccine)
	Rubella
	Echovirus
	Enterovirus 71
	Coxsackievirus
	Adenovirus
	Parvovirus B19 (erythema infectiosum)
Vesicular/pustular	Varicella zoster virus
	Smallpox
	Eczema herpeticum
	Eczema vaccinatum
	Coxsackievirus (esp. A16)
	Enterovirus 71
	Adenovirus [63]
	EBV [63]
	CMV [63]
Petechial or purpuric	Coxsackievirus (esp. A9)
	Echovirus, esp. 9
	EBV
	Atypical measles (vaccine)
	Parvovirus B19 [64]
Erythema multiforme	HSV-1 [65]
	Coxsackievirus A

7.2.5 Common Cutaneous Syndromes

Many viruses can produce one or more forms of eruption of the skin (exanthem). The most common acute viral infections involving the skin are listed in Table 1.3; many are classic exanthems of childhood including measles, rubella, varicella, erythema infectiosum or fifth disease caused by parvovirus B19, and roseola infantum (exanthem subitum) caused primarily by human herpesvirus type 6 (HHV-6) [61]. Rashes also occur in children or adults with coxsackieviruses and echoviruses [62], with certain adenoviruses (such as type 7), occasionally with EBV mononucleosis (often brought on by a reaction to ampicillin), and with other herpesviruses. HIV also causes a rash in a small proportion of newly infected patients. The distribution of these agents as causes of cutaneous conditions clearly varies by age, geography, vaccination status, and other host factors. The circumstances in which these many combinations of types of rash and agents are observed are not easily generalizable; the chapters on the individual agents should be consulted.

7.2.6 Hepatitis

Five principal agents are currently recognized as widespread causes of viral hepatitis: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis delta virus (HDV), and hepatitis E virus (HEV). However, viruses in a number of other families can produce hepatitis. In the parts of the world where yellow fever virus is prevalent, the syndrome is common. Less common agents are several herpesviruses (HSV-1, CMV, and EBV). All are associated with inflammation of the liver but with different severity, ranging from asymptomatic to acute mild liver tenderness and jaundice, often accompanied by malaise and anorexia, to fulminant hepatic failure in a fortunately small fraction of cases.

Two of the agents (HAV and HEV) produce more acute, usually mild to moderate self-limited illness, with milder illness in younger individuals. As enteric pathogens, they occur in geographic distributions that reflect socioeconomic conditions in those regions. Hepatitis A tends to occur sporadically in older individuals where immunity is high, often because poor sanitation permitted the virus to saturate the population at younger age. Conversely, epidemic HAV disease is more often seen in populations left susceptible as a result of better hygiene. In the United States and other countries where the vaccine against HAV is widely used, the decline in cases of hepatitis A has been striking. About 1.5 million cases occur annually worldwide. Hepatitis E is found worldwide, with different viral genotypes determining the disease distribution. Globally, genotypes 1 and 2 account for 70,000 deaths and 3.4 million cases often in outbreaks particularly in South and East Asia but in other developing countries as well, whereas genotype 3 occurs more sporadically in countries with better sanitation [67].

The three others (HBV, HCV, and HDV) have strikingly different clinical patterns. Both HBV and HCV may produce a range of symptoms including an acute syndrome much like that of HAV and HEV. However, a small proportion of HBV and the majority of HCV infections become chronic and often lifelong. In their chronic forms both infections may remain essentially quiescent for a lifetime or progress at quite variable rates to chronic inflammation and cirrhosis, with or without symptoms along the way, and both are responsible in some proportion for virus-induced hepatocellular carcinoma (see Chaps. 32, 33, and 34). Of the approximately two billion persons with HBV infection worldwide, 240 million have some degree of persistent infection of the liver, and 600,000 succumb to the sequelae [68]. The patterns of occurrence of these diseases are driven primarily by geographic and behavioral factors. Highly effective transmission by the parenteral, sexual, and perinatal routes accounts for the ubiquitous distribution of hepatitis B with particularly high prevalence in Asia. Until the introduction of vaccine, high prevalence in childbearing adults who transmitted the infection perinatally translated to high rates of chronic childhood infection and perpetuated the cycle. Throughout the world and in proportion to their representation in each population, hepatitis B has affected injection drug users (IDUs), recipients of contaminated blood products, those exposed to contaminated medical equipment, and men who have sex with men.

Because HCV is transmitted more by the parenteral and less by the sexual route, in the developed world, hepatitis C has been more confined to IDUs and others who have been exposed to contaminated blood and needles. Central Asia and East Asia along with North Africa and the Middle East have the highest prevalences of the HCV infection (>3.5 %) [69] as well as its incident sequelae hepatitis, cirrhosis, and cancer. Because of the highly variable absolute and relative prevalences of HBV and HCV infection and the other risk factors for those complications, it is difficult to estimate the incidence of HCV-induced cirrhosis or cancer or the risk attributable to HCV.

The delta virus (HDV) is an unusual partially defective RNA virus, closely dependent on the presence of HBV for its pathogenic expression if not for its multiplication. When HDV coinfects simultaneously with HBV, it may trigger an acute hepatitis syndrome but generally does not appreciably alter the course of disease. However, when HDV superinfects in a preexisting case of HBV infection, progression to cirrhosis is considerably more likely and often more rapid. The defective virus was first described in Europe, but it has been found at high prevalence in countries of sub-Saharan Africa, South America, and Asia where HBV is highly endemic, more often in parenterally infected blood product recipients or injection drug users and occasionally in men who have sex with men.

7.2.7 Perinatal Conditions

Infections of the fetus, neonate, and infant may be acquired from the mother in utero via placental transfer or during passage through the birth canal or from other individuals postpartum via nosocomial and other similar close contact. The major syndromes and their etiologic agents are tabulated below (Table 1.4). The specific clinical manifestations vary by agent and timing of infection relative to gestation. Vertically transmitted rubella, HSV-1/HSV-2, and cytomegalovirus infections have long been implicated as causes of especially severe congenital multiorgan anomalies [70]. Estimates of occurrence of perinatal infection vary according to location, personal hygienic and sexual activities, obstetric practices, utilization of vaccines, and other factors. Table 1.4 catalogues the major clinical consequences of the large number of agents responsible for perinatal infections.

The adverse outcomes of rubella during pregnancy, once numerically and clinically very important, have thankfully been virtually eliminated in the United States and other countries with effective vaccination programs. The fetal complications of the other vaccine-preventable diseases

have also been drastically reduced. That has left CMV as the most common serious congenital disease due to viral infection in the United States [71]. It may infect more than 2 % of all pregnant women. About one-third of women with primary infection will transmit the virus to their newborn infants, but acquisition by mother and infant varies greatly with age, location, and socioeconomic conditions [72]. Both infection and serious sequelae are more common with primary than with recurrent infection. Congenital infection may be symptomatic in as many as 15 % of infected neonates [73]. Although these infections are usually benign, the virus can produce anomalies such as microencephalopathy, chorioretinitis, deafness, and mental retardation in a small proportion of those infected. Irreversible anomalies due to CMV infection occur in more than 5,000 children (0.1–0.2 %) each year.

Herpes simplex virus infections occur quite variably among pregnant women in different geographic, ethnic, and socioeconomic subpopulations. Infection in infants is almost always complicated by mucocutaneous (skin, eye, and mouth) lesions (75 %), encephalitis (57 %), pneumonia (18 %), or disseminated infection with combinations of the three (30 %). Prompt recognition is important because antiviral therapy is often effective in reducing morbidity. Estimates of incidence come from multiple sources. An early study from a single location found a frequency of 1 per 1,500 live births [74]. A more weighted population-based extrapolation from 2006 US hospitalization data yielded an incidence of 9.6 per 100,000 births [75].

The risk of perinatal HBV infection is primarily that of transmission of the virus from mothers who are chronically infected (i.e., HBsAg carriers). Although infection is not teratogenic and the reported impact on gestational age or birth weight must be quite infrequent [76], there are adverse consequences for the infected neonate who receives no immunoprophylaxis. About 5–8 % become hepatitis B surface antigen carriers during the first 6 months of life. Moreover, young adults infected in infancy are far more likely than those not infected until later to manifest not only persistent antigenemia but cirrhosis and, after an even longer latency period, hepatocellular carcinoma. Rates of infection in pregnant women show great geographic variation. Congenital and intrapartum HBV infection transmitted by maternal carriers has long been considerably more common in Asia and Africa than in Europe and the Western Hemisphere and has remained so. The pattern is changing in some places and will continue to do so wherever infant vaccination has been used routinely for more than two decades, and the earliest universally vaccinated birth cohorts are well into their childbearing years.

Untreated HIV-1 infection is transmitted from about 25–30 % infected mothers to their child/children. Adverse outcomes of pregnancy similar to those of perinatal herpesvirus and certain other infections have been reported with fetal and neonatal HIV-1 infection in some settings, but more recent systematic studies have not revealed clear causal associations [77, 78]. An accelerated course of infection and certain distinctive features (e.g., lymphocytic interstitial

pneumonitis) have been observed, potentially attributable to the unique attack on the immune system. Several regimens of antiretroviral agents alone or in combination have proved increasingly effective in interrupting perinatal transmission.

Parvovirus B19 has been repeatedly linked to anemia, neurological anomalies, hydrops fetalis, and fetal death (see Chap. 27). In an earlier prospective study of 156 mothers infected with this virus, 12 % delivered babies with some abnormality [79]. The investigators estimated the overall fetal risk to be 9 %, although higher in the second trimester, and the transplacental transmission rate to be 33 %. Adverse outcomes, particularly fetal loss and hydrops (a syndrome associated with destruction of red blood cells in utero), follow a proportion of the infections with this virus [79]. With a predilection for myocytes, it has also been implicated in myocarditis [80, 81].

7.2.8 Genital Tract Syndromes

Two families of viruses, HSV-1 and HSV-2, and several subtypes of HPV are common causes of conditions of the genital tract. Both HSV types can produce a spectrum of features ranging from no or minimal symptoms to an episode of fever; headache; myalgia; regional adenopathy; painful, tender blisters and ulceration on the epithelial surfaces of the genital organs and adjacent areas, including the anus and rectum; and dysuria. Small proportions of infected persons develop complications such as aseptic meningitis and proctitis (in men). Symptoms are more frequent and prominent with primary than with recurrent infection. Genital HSV infections are acquired through sexual contact, beginning with sexual debut and increasing through the earlier years of highest sexual activity in most areas of the world, where they are often the leading cause of genital ulcer disease. In recent years type 1 has matched or surpassed type 2 as a frequent cause of primary genital infection, particularly in younger persons. Infection with one of the two HSV types is extremely common; tens of millions of people in the United States have genital HSV infection [82]. Estimates from CDC indicated that in 2008, approximately 776,000 new HSV-2 infections occurred, with half being in persons under 25 years of age [83].

The two major manifestations of HPV infection are genital warts and squamous cell neoplasia. HPV types 6 and 11 and less frequently other types are responsible for genital warts (condyloma acuminata) on epithelial surfaces in the genital and anal area. The annual incidence of new cases of genital warts in the United States is about 360,000 persons [84]. Within the past decade, the cumulative incidence of genital warts in Scandinavian women up to age 45 years was about 10 % [85]. Among the unvaccinated group of women followed in a multinational trial of quadrivalent vaccine, approximately 1 % of the women developed warts each year [86]. HPV types 16 and 18 and less frequently other types cause a spectrum of cervical and vaginal cytological abnormalities that are largely benign but in diminishing proportions may progress to higher-grade neoplasia and culminate in invasive cervical carcinoma in a minority of women carrying those specific types. Annually worldwide, HPV causes about 500,000 cases of cervical cancer and ten million additional cases of premalignant neoplasia [87]. About 80 % of the cases and deaths occur in the developing world. The invasive cancer has a 50 % case fatality ratio. Analogous pathologic processes lead to anal and penile carcinoma, largely in men who have sex with men. The incidence rates of these cancers appear to be considerably lower than rates of cervical cancer in the same population [88].

7.2.9 Urinary Tract Syndromes

Acute hemorrhagic cystitis is the most prominent abnormality of the urinary tract caused by viruses. When the bladder inflammation is caused by the principal etiologic agents in children (adenoviruses, particularly serotypes 11 and 21 of subgroup B), hematuria may be recognized along with pain or burning, but the condition is often less symptomatic. Another possible viral etiology of a urinary tract syndrome (manifested as renal tubular damage) is BK virus, which, like other polyomavirus-related infections, tends to be pathogenic primarily in immunosuppressed patients.

7.2.10 Febrile Illness with Hemorrhage

Viral hemorrhagic fever may begin with a nonspecific prodrome of fever and chills, malaise, myalgia, headache, rash, flushing, and in some cases vomiting and diarrhea. These may rapidly progress to a multiorgan syndrome with petechial and more extensive bleeding but which is often less life threatening than vascular collapse with varying degrees of pulmonary edema, hypotension, shock, and renal failure. Variations of this syndrome are caused by a numerous and growing list of mostly vector-borne viruses in four families: arenaviruses, filoviruses, bunyaviruses, and flaviviruses (Table 1.5). Collectively, the viruses that produce this syndrome are found throughout the world although each individual agent is confined to the region where the principal arthropod vector or other animal reservoir lives. Certain of the diseases occur sporadically, for example, when a single individual has incidental contact with an infected animal. The occurrence of a cluster of cases is more ominous; because of the often fulminant illness and the unpredictable human-to-human propagation of cases, including nosocomial transmission, publicity about the event can have disproportional community impact. These phenomena have typified the ominously large outbreak of Ebola virus infection in West Africa. From time to time, one of these illnesses may present an immediate, major public health problem with hundreds of cases; there is, for example, concern about the potential for hemorrhagic dengue on a large scale in Southeast Asia.

Table 1.5 Families of viruses that may cause hemorrhagic fever

Arenaviridae	Bunyaviridae	Filoviridae	Flaviviridae
Argentine hemorrhagic fever	Crimean–Congo hemorrhagic fever (CCHF)	Ebola hemorrhagic fever	Dengue[a]
Bolivian hemorrhagic fever	Hantavirus pulmonary syndrome (HPS)	Marburg hemorrhagic fever	Kyasanur forest disease
Sabia-associated hemorrhagic fever	Hemorrhagic fever with renal syndrome (HFRS)		Omsk hemorrhagic fever
Venezuelan hemorrhagic fever	Rift Valley fever		Tick-borne encephalitis
Lassa fever			
Lymphocytic choriomeningitis (LCM)			

Adapted from [89]
[a]Dengue may occur in hemorrhagic form in certain circumstances (see Chap. 15)

Overall, the patterns of occurrence of these diseases are too variable to allow generalizations about their geographic distribution or the magnitude of the problem; they are addressed more individually in Chaps. 8, 9, 14, and 15.

8 Occurrence and Spread in Populations

In the broadest terms, viral propagation within an individual depends on properties such as the efficiency of spread from cell to cell, either by direct involvement of contiguous cells or by transport via body fluids to other susceptible cells; the number of cells infected; and the consequences of viral multiplication on the cell itself and on the organism as a whole. Further biochemical and physiologic details of these cellular processes are the subjects of more basic science texts. The next several sections are concerned with the occurrence and propagation of infection in populations, along with factors that influence those events.

Survival of human viruses depends on their long-term viability in human populations. Sustained viability, in turn, depends on the patterns of occurrence and propagation—within a host and between hosts. A virus must be capable of (1) infecting a host chronically without killing its cells; (2) infecting a host acutely and severely but escaping from the dying host cells as an intact, replicable entity in a manner that ensures its transport to a new susceptible host; or (3) infecting chronically or acutely but rapidly adapting to biological adversity such as exhaustion of susceptible hosts. Herpesviruses and other persistent viruses have evolved to establish durable relationships with their immunologically competent hosts. Arboviruses can destroy their hosts as long as the former can survive and replenish themselves in their nonhuman reservoirs and vectors. It is the viruses like influenza A and HIV, endowed with the greatest adaptability in the form of antigenic variation, that pose the greatest threat because they are not self-limited in their pathogenicity or in their dependence on favorable environmental conditions. Without its capacity for antigenic variation, influenza virus would, like measles or rubella virus, probably depend for survival on the temporal accumulation of new susceptibles. However, as noted earlier HIV has the powerful dual advantage of a retrovirus—capacity not only to vary its antigenic structure but also to establish latency for years.

8.1 Routes of Transmission

The major routes of transmission of selected viral infections are listed in Table 1.6. Viruses that have several alternate routes have an increased chance of infection. The sequence of events in transmission involves release of the virus from the cell, exit from the body, transport through the environment in a viable form, and appropriate entry into a susceptible host.

Some viruses are released from cells at the end of the cycle of multiplication. Others do not complete this cycle (incomplete viruses), and some are less effective at escaping (e.g., vaccinia). Many viruses are released from cells by budding, acquiring a lipoprotein coat or envelope as they go through the cell membrane; these include herpesviruses, togaviruses, myxoviruses, paramyxoviruses, and coronaviruses. Nonenveloped viruses not released by budding are the adenoviruses, parvoviruses, poxviruses, picornaviruses, and reoviruses. Some of these latter are released by cell lysis. Once released, viruses find their way to new hosts via one or more portals such as the respiratory tract (influenza, adenoviruses, RSV), skin (VZV and smallpox virus), blood (HIV, HTLV-I and HTLV-II, HBV, HCV, and arboviruses), gastrointestinal tract (enteroviruses, noroviruses, caliciviruses), genital tract (HIV, HTLV-I, HSV-2, and HPV), and placenta (rubella, HIV, CMV, HSV-1, and HSV-2). A more detailed presentation of these major routes of spread follows.

8.1.1 Respiratory

The respiratory route is probably the most important method of spread for most common viral diseases of man and is the least subject to effective environmental control.

Viruses transmitted principally by the airborne route include the agents of many classic childhood infections (e.g., rhinoviruses, measles, rubella, mumps, varicella, influenza, parainfluenza, respiratory syncytial virus). Of course, these

Table 1.6 Transmission of viral infections

Routes of exit	Mode of transmission	Example[a]	Factors	Routes of entry[b]
Respiratory tract	Bite	Rabies	Animal	Skin

[b]Transmission does not always follow standard routes (Modified table from Evans and Kaslow [210] (Table 3), Springer has copyright)

[c]Likelihood of transmission by this route is controversial

are also transmitted among adults by this route as well. Others are transmitted by more direct contact with the nose or mouth or their mucosal secretions (e.g., EBV, HSV, and rabies virus).

Various other factors that affect airborne transmission of respiratory viruses include the intensity and method of propulsion of discharges from the mouth and nose, the size of the aerosol droplets created, and the resistance to desiccation. Much of the early work on the transmission of respiratory viruses was done by Knight and his group [90]. Direct transmission of infection occurs via personal contact such as kissing, touching of contaminated objects (hands, handkerchiefs, soft drink bottles), and direct impingement of large droplets produced by coughing or sneezing. These last two behaviors are regarded as personal contact because of the short range of the heavy droplets formed.

They also create aerosols varying in size up to >20 μm that permit transmission of infection at a distance. Dispersion of an aerosol depends on air currents and on particle size. In still air, a spherical particle with a unit density of 100-μm diameter requires 10 s to fall the height of the average room (3 m), and 40-μm particles require 1 min, 20-μm particles 4 min, and 10-μm particles 17 min. This means that particles under 10 μm have a relatively long circulation time in the ordinary room. Particles 6–10 μm or larger in diameter are more readily trapped upon direct impact in the nose and nasopharynx. Further into the airway, flow diminishes to the point where smaller particles 0.5–5 μm in diameter settle on the tracheal and bronchial walls by sedimentation, and particles of 0.5 μm in diameter or smaller can enter and deposit in the alveoli. As infectious secretions are discharged in large numbers by coughing or sneezing, the initially hygroscopic particles of 1.5-μm diameter lose moisture and shrink in ambient air and then regain their original dimensions from the saturated air as they are again deposited in the respiratory tract. Of course, virus particles in an aerosol may not necessarily settle at a level in the respiratory tree with the optimally susceptible cells for that agent.

High concentrations of particles of rhinovirus (and other viruses, including influenza) on fingers, hands, and hard surfaces indicate that infection via hands may be at least as important a route of spread as aerosols containing lower concentrations. This is supported by the continual inadvertent

contact of hands with the nose or eyes [91]. Therefore, frequent hand washing, using antiseptic-containing fluids, sprays, or gels, is recommended for controlling the spread of rhinoviruses, respiratory syncytial virus, and influenza and other viruses [92–95].

Aerosolization of certain viral agents may occur from suction devices and from catheters in intensive care units and from blood products in dialysis units. These include not only respiratory and intestinal agents but also agents such as HBV that circulate cell-free in the blood and cell-associated viruses such as CMV, EBV, HIV, and HTLV-1. Viruses aerosolized from urine or fecal material can be inhaled; hantavirus and arenaviruses are examples of agents that may be spread by aerosols created from soil containing the rodent urine or feces in which those viruses are excreted.

8.1.2 Enteric (Oral–Fecal)

Transmission by the oral–fecal route via the gastrointestinal tract as the portal of entry is probably the second most frequent means of spread of common viral infections.

The major enteric viruses are enteroviruses, rotaviruses, and calici-, polio-, echo-, and coxsackieviruses, along with HAV and HEV. Adenoviruses and reoviruses also multiply in and shed from the intestinal tract, but this route of transmission is not usually of epidemiologic importance. Despite their name, although enteroviruses multiply in cells lining the gastrointestinal tract, they rarely produce local disease there; they rather target the central nervous system and skin and produce their major symptoms and pathology in those organs. Likewise, hepatitis A and E viruses attack the liver, not enteric mucosal cells.

Viruses can directly infect susceptible cells of the oropharynx, but to induce intestinal infection, virus-containing material must be swallowed, successfully resist the hydrochloric acid in the stomach and the bile acids in the duodenum, and access susceptible cells in the intestine. Viruses with envelopes do not normally survive exposure to these acids, salts, and enzymes in the gut.

Agents excreted via the gastrointestinal tract must successfully infect other susceptible persons via fecally contaminated hands, food, water, milk, thermometers, insects, or other vehicles. Both HAV and HEV are stable viruses in water and, when present in sufficient dosage, may not be inactivated by ordinary levels of chlorine. Outbreaks of viral hepatitis have occurred from sewage-contaminated water, as in the huge outbreaks in New Delhi, India, in 1955 [96], and subsequently often due to HEV and in less dramatic attacks elsewhere. Furthermore, HAV, at least, can persist over long periods in oysters and clams obtained from fecally contaminated waters. Milk and water have also served as vehicles of transmission of other viral agents: caliciviruses and poliomyelitis viruses. This is especially hazardous because these foods are so often eaten without having been cooked. Hepatitis viruses and the enteroviruses also flourish in certain institutional settings (mental hospitals, institutions for retarded children, some prisons) and in countries where personal hygiene is lacking or difficult to practice or where poor environmental control is present.

For viruses spread by enteric routes, environmental control is much more effective than for those transmitted by the respiratory route. Thus, good personal hygiene, especially washing of hands after defecation, proper cleanliness and cooking of food, pasteurization of milk, good waste disposal, and purification of drinking water supplies have all proved to be effective preventive measures. On the other hand, some enteroviruses may also multiply in the respiratory tract and be transmitted by the respiratory route; therefore, this alternate pathway is of epidemiologic importance even in the face of good personal and environmental hygiene.

8.1.3 Direct Cutaneous Contact

Direct penetration of intact skin is a less common route of viral entry, and when it occurs, the viruses are usually carried in fluid or some other vehicle. Human papillomaviruses, the agents causing warts, enter through abraded skin and anogenital epithelium; prions, the agents of kuru, may also gain access that way. With rabies, viral penetration of the skin invariably involves an animal bite or some other source of contaminated biological fluid.

The skin serves as a portal of exit for those few viruses that produce skin vesicles or pox lesions that release infectious particles on rupture. These include herpes simplex, smallpox, varicella zoster, and vaccinia viruses. The viruses of certain maculopapular exanthems may also be present in the skin, as in rubella, but this does not seem to be an important avenue of escape, since vesicles are not formed and skin involvement occurs late in the disease, when the virus may be bound by antibody; indeed, the antigen–antibody complex may be responsible for the rash itself.

8.1.4 Sexual

The genital tract serves as a portal of both entry and exit for viruses that infect the genital tissues themselves and more remote target organs. It is also the source of intrapartum infection as the fetus passes through the birth canal. Herpes simplex types 1 and 2 cause ulcerative lesions of the anal and genital mucosa and the surrounding skin. Sexual transmission of these viruses can produce oropharyngeal lesions as well. These and other viruses (most frequently, CMV, HIV, HBV, and HPV) can also be transmitted to their target cells in the anogenital epithelial layer (HPV), in nearby subepithelial lymphoid system (HIV and CMV), or in remote hepatic tissues (HBV). Receptive anal intercourse is a particularly important method of spread of these infections. Three of these four viruses (CMV, HIV, and HBV) along with rubella virus are present in cervicovaginal secretions and can infect

infants perinatally (see Sect. 8.1.5). Finally certain types of HPV, principally 16 and 18, cause a substantial proportion of cervical infection leading to a spectrum of mucosal abnormalities including cervical cancer.

CMV, HBV, and HIV are present in the semen and/or female genital secretions and can be transmitted during either heterosexual or homosexual intercourse [97–101]. Long-term asymptomatic cervical or semen carrier states exist and make recognition and control difficult.

The presence of other genital infections has been shown in repeated studies to predispose to transmission of HIV-1 by the HIV-1-infected partner and acquisition of HIV-1 by the susceptible partner. Most epidemiologic data indicate that the ulcerative lesions of syphilis, chancroid, and HSV-2 infection mechanically facilitate penetration of the epithelial barriers of the genital tract by HIV [102, 103]. However, suggestions of predisposition by non-ulcerative infections like gonorrhea, chlamydiasis, trichomoniasis, and bacterial vaginosis are consistent with an alternative to enhanced epithelial penetration, namely, recruitment and activation of macrophages and other inflammatory cells responsive to the mucosal breach (see Chap. 43).

8.1.5 Intrauterine and Intrapartum

Viruses may infect the fetus either by direct contact via the birth canal or by hematogenous spread via the placenta to the fetus within the uterus. Herpes simplex virus and CMV infections can initiate intrauterine infection by more direct local contact, whereas CMV, hepatitis B, rubella, varicella, and HIV all infect the placenta by the hematogenous route. CMV is the most common congenital infection, whereas congenital rubella has sharply declined wherever vaccination has become routine. Acquisition of EBV or HBV in the early postnatal period is associated with persistence of infection and substantially increased risk of subsequent cancer (see Chaps. 32, 34, 40 and 41).

8.1.6 Blood-Borne

Direct inoculation of viruses into the blood requires some object sharp enough to penetrate the skin and the wall of a blood vessel. That can happen naturally through the bite of an arthropod vector (see Sect. 8.1.7) or iatrogenically through an injection, either with an inadvertently contaminated needle (e.g., by an injection drug user or in medical practice) or for administration of medicinal blood products (e.g., a transfusion). The agents best known for transmission by this route include hepatitis viruses (HBV, HCV, and HDV), retroviruses (HIV and HTLV), and herpesviruses (EBV, CMV). The mechanism of transmission for each of these viruses is similarly straightforward, with the likelihood of infection dependent on a combination of the intrinsic viral properties described above (Sect. 2), the delivery mechanics, and the dose or the size of the inoculum delivered.

8.1.7 Vector-Borne: Insects and Mammals

Humans may be primary or incidental hosts for numerous vector-borne viral infections. They may be transmitted through direct injection by mosquitos, ticks, flies, and other arthropods; they may also be spread directly through saliva during the bite of larger mammal; or they may be spread more indirectly through aerosolization of urine from a rodent. For some viruses, their life cycle involves multiplication in their vector. In many arboviral infections, virus acquired from the human or animal host during viremia requires a period of multiplication in the vector before it is infectious. Examples of this include the transmission of yellow fever virus by *Aedes aegypti* mosquitos and of the seasonally epidemic St. Louis, California, and equine encephalitis viruses. The vector life cycles can be complex, including overwinter survival with transovarian or sexual transmission within mosquito populations.

A range of mammals (dogs, bats, raccoons, skunks, foxes, and others) carry rabies virus in their tissues and bodily fluids including saliva. They can transmit to a human during a bite, with the likelihood of transmission varying according to several factors: the mammalian species, the level of viremia, the duration of its infection, the nature and location of the bite, and others. Bats may also transmit henipaviruses and coronaviruses. Rodent species can also carry and transmit viruses in their urine or feces. Examples of rodent transmission include hantaviruses and Lassa fever virus. The viruses transmitted by vectors can vary greatly in their host range from a fairly high degree of species specificity (as with dengue in *Aedes aegypti* or Lassa fever virus in one or possibly more closely related rat species) to a much broader range (as with rabies in a number of different mammalian families).

Another kind of transmission by a vector is simply mechanical, involving adherence of material containing virus to an insect and transportation from one host to another. This type requires neither incubation time in the insect vector nor any specificity for either the arthropod host or the virus. Enteric viruses like polio and possibly hepatitis viruses may be carried in this way.

8.1.8 Urinary

Interestingly, although viruses such as CMV and measles are excreted in the urine, this portal of exit has not been established as being of epidemiologic or clinical importance. Considering the wide variety of viruses that can multiply in human kidney tissue cultures in vitro and the likely role they play in immune complex nephritis, it seems surprising that renal infections with these viruses are not observed more frequently in humans.

8.1.9 Nosocomial

The unique populations and physical circumstances found in hospitals and other health-care facilities lead to the

transmission of many viral infections by several of the foregoing routes. The more than two-dozen viruses that have been documented as being nosocomially transmitted include many viruses that affect the respiratory tract as well as those transmitted through the respiratory tract to other organs and cells (e.g., CMV, HSV-1, HSV-6, and VZV) [104], hepatitis viruses (including HAV, HBV, and HCV) [105], enteric viruses (mainly rotavirus [106] and caliciviruses [107]), the viruses of several exanthems (rubella and measles) [108], and picornaviruses [106, 109–111].

Respiratory Route

Respiratory tract infections spread by droplets or droplet nuclei like influenza may disseminate naturally through both the relatively vulnerable patients and the personnel in close proximity to each other. Nosocomial respiratory syncytial virus (RSV) infection in patients and staff has been a major concern in the pediatric nursery, intensive care wards, or other population groups [92] at high risk due to crowding and often an immature immune system. Outbreaks among adults and elderly patients in health-care facilities have also been reported, with influenza being a major concern [112–115]. In these settings, infections, diseases, and outbreaks of CMV, HSV, VZV, enteroviruses, myxoviruses, metapneumoviruses, and parainfluenza viruses have also occurred [116–118].

Although viruses may also theoretically be transferred from one patient to another by contaminated ventilating equipment, with the exception of occasional reports about herpesviruses (CMV and HSV-1) [119, 120], this type of nosocomial transmission has not been recognized as an important one. Lack of concerted effort to detect viruses rather than their actual absence may explain the dearth of information about this phenomenon.

Enteric Route

As noted above, enteric viral infections are very common in acute and long-term health-care settings, and outbreaks (mainly due to rotavirus [106] and caliciviruses [121]) can involve large numbers of patients. The circumstances in which they are transmitted within health-care facilities do not differ greatly from those operating outside them (Sect. 8.1.2), although they appear to have a tendency to attack immunocompromised patients.

Direct Contact with Biologic Tissue and Fluids

Transmission of cutaneous and mucosal viral infections in health-care settings by direct contact is not especially common (VZV, HPV, HSV). Although viruses naturally transmitted through the skin following bites (rabies, in particular) rarely propagate that way in hospital settings, contact by personnel with tissue, saliva, and other secretions from transplant patients infected with rabies virus has led to serious consequences [122]. Corneal transplant has also been associated with transmission of the slow (Creutzfeldt–Jakob) virus [123]. These incidents have prompted the transplantation community to adopt exacting protocols for excluding organs and tissue that may be infected with potentially harmful viruses. Lassa fever, Ebola, and Marburg viruses have often been transmitted as nosocomial infections [124]. Lassa fever, in particular, has infected patients and staff, especially in the obstetrical wards via infected placentas.

Blood-Borne Route

Blood transfusion has long been a potential source of viral infection, and with each significant pathogen discovered to be transmissible by transfusion (HBV, HIV-1/HIV-2, HCV, HTLV-I/HTLV-II, and West Nile virus), the US Food and Drug Administration has orchestrated the development and implementation of universal donor screening [125]. Other viruses that are capable of transmission by blood products (e.g., CMV, EBV, parvovirus B19) appear to be relatively harmless and/or ubiquitous enough that screening is not deemed necessary.

Of major concern for patients is accidental exposure during procedures where there is direct contact with a potentially contaminated tissue (e.g., transplantation) or instrument (e.g., needle, dental or dialysis equipment, or endoscope). In regions of the world with adequate resources and training, universal blood precautions and the use of safety measures for disposing or auto-inactivating contaminated needles have largely but not entirely [126] eliminated percutaneous transmission of HBV, HCV, HIV, and other viruses by needlestick injuries. During the first 20 years of the HIV-1 epidemic in the United States, 57 cases of infection were due to occupational injury in health-care personnel [127]. From 1999 to 2012, no further cases had been documented. The Centers for Disease Control (CDC) continues to collect data and inform personnel about those risks [128, 129].

8.2 Measures of Occurrence

Incidence is the number of new events (e.g., instances of infection or cases of disease) occurring in some time interval. Generally, the *incidence rate* is the number of new events divided by the number of people at risk. The incidence rate may be expressed more specifically as the number of events per unit of population per unit of time or as the number of events in a fixed total population during a fixed total time period. The latter is considered a cumulative incidence but is often called an "attack rate" in an epidemic setting, where the total time period under consideration is established by the circumstances.

In the public health context, incidence may refer to new infections or new cases of disease. In the past, *incident*

infection was usually documented by isolation or pathologic visualization of newly acquired virus or by an assay for seroconversion—the appearance of new specific antibody or a defined increase in the titer or concentration of preexisting antibody; occasionally, new infection would be recognized by a change in the concentration of a specific biomarker like an enzyme. In the current molecular era, a variety of techniques for detecting viral nucleic acid are being used to establish newly acquired infection (see Chap. 2). In calculating an infection incidence rate, the denominator would ideally consist of all individuals in a population considered to be both exposed to the agent and susceptible (i.e., lack antibody or other evidence of prior infection).

Incident disease has always meant the presence of clinical manifestations—some combination of self-reported symptoms, objective physical signs, and positive results of specific diagnostic tests; and the disease incidence rate, is based on all individuals in a population whether or not they are infected.

Mortality can be thought of as the incidence of death. In calculating mortality, because the number with infection is seldom known, the total population is customarily used as the denominator, even though that rate generally underestimates the actual rate of death due to a specific viral infection. The case fatality ratio, another measure of the deadliness of an infection, is the proportion of all persons with cases who have died.

In public health practice, the populations at risk or infected can only be estimated with variable degrees of accuracy depending on the circumstances. Evidence of prior infection is often not available. Commonly, the best estimate possible is simply the total population present during a particular time interval within the geographic area or physical space (e.g., hospital) encompassed by the detection or reporting system. Public health agencies generally tabulate statistics for infection or disease in the form of annual rates.

Prevalence is the number of persons with infection or cases of disease existing at a designated time or in a time interval. The *prevalence rate* is the number of such cases divided by the population at risk. The time period involved may be a given instant of time (point prevalence) or a fixed period such as a year (period prevalence). The term *period prevalence* thereby incorporates both the number of new (incident) cases and the duration of illness (number of old cases persisting from the previous reporting period). It is used most commonly for chronic diseases.

Prevalence of infection is usually measured by a test for the presence of a substance (e.g., antibody, antigen, fragment of nucleic acid, or other component) in biological fluid or tissue samples from a given population at the time of their collection. In calculating a prevalence, the denominator consists of persons whose samples were tested. For viral infections, the prevalence of antibody (i.e., seroprevalence) represents the cumulative rate of infection with the agent over recent and some years past depending on the persistence of the antibody. For neutralizing or other long-lasting antibody, it reflects the cumulative or lifetime experience with that agent. If the antibody measured is present only transiently, as is often true of immunoglobulin M (IgM) antibody, then its prevalence indicates infection acquired within a recent period and may even approximate incidence. As with antibody, the detection of nucleic acid could signify either recent or more persistent infection, depending on the natural history of the infection. In calculating a viral disease prevalence, the denominator is usually all individuals in the total population.

It should be clear that the number of new (incident) cases and the number of existing (prevalent) cases are related to each other. More specifically, the prevalence of infection or disease is determined by the duration of incident cases: the longer the duration of an incident condition, the higher the number of prevalent cases of that condition. That proportionality can be represented as prevalence = incidence × duration. More strictly speaking, the term in the equation should be average duration, which may vary considerably for more chronic infections. Two corollaries of this relationship are that the prevalence of acute self-limiting illnesses of short duration would closely mirror the incidence, and the more variable the duration of the condition, the less reliable the relationship in a particular population may be.

8.3 Patterns of Occurrence

Infections at the population level do not happen randomly; they occur in patterns, with different characteristics and in different magnitudes.

8.3.1 Secular, Periodic, and Seasonal Trends

Secular trends in occurrence with no obvious periodicity have been observed over longer intervals than a single year. Numbers may rise or fall depending on natural factors. Short- or long-lived climate changes can alter the balance of vector and host populations, leading to significant increases or decreases in incident arboviral infections. Local populations experience gradually declining rates of a particular strain of respiratory virus as population-level immunity develops following repeated exposures.

Other factors, natural or human in origin, may produce periodic fluctuations that are not strictly seasonal because they do not recur each year at the same time. In the absence of high levels of vaccination, herd immunity to a disease like measles may produce periodic but not strictly seasonal waves of new cases every 2–4 years depending on how fast new susceptibles are introduced into a population (see Sect. 8.3.2). Human migration may account for periodicity

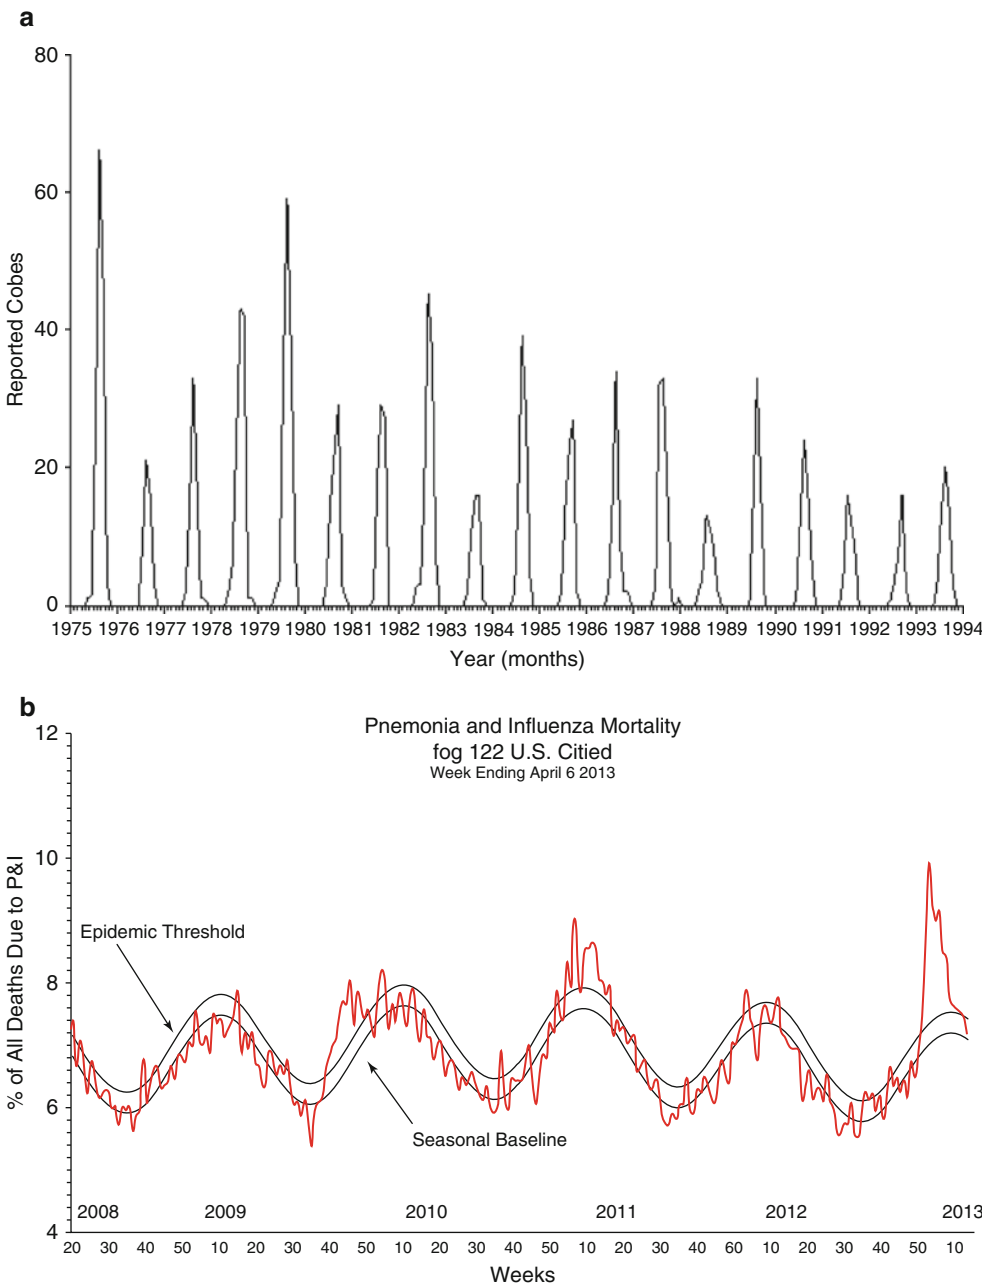

Fig. 1.3 Seasonal occurrence of selected viral diseases. Panel (**a**) Arboviral infections (of the central nervous system)—cases due to California serogroup viruses, by month, United States, 1975–1993 (Reproduced from Koo et al. [130]). Panel (**b**) Pneumonia and influenza mortality for 122 US cities, week ending April 6, 2013 (Reproduced from CDC [131])

that is predictable but might not occur every year in the same season.

Seasonality is one pattern that has been characteristic of many viral infections in the absence of widespread vaccine-induced immunity. Many of the childhood viral diseases (e.g., measles, rubella, mumps, chicken pox, polio, influenza gastroenteritis, etc.) and certain viral diseases of adults (e.g., vector-borne meningoencephalitis and influenza) show striking natural seasonal fluctuation.

For some of these illnesses, the explanation is obvious—rising incidence in summer parallels the resurgence of the vector population (e.g., for mosquito-borne encephalitis viruses, Fig. 1.3, Panel a) or the return of favorable conditions for replication (e.g., for enteric viruses) during warmer weather. For others (many respiratory infections), the conventional explanation is that increases in the winter reflect a combination of environmental factors (temperature and humidity) that both directly enhance the viral replication and transmissibility and indirectly lead to more conducive host behavior (more time spent indoors under artificial conditions of heat and ventilation). For a number of the diseases where vaccines have been effective at radically decreasing the incidence, the seasonality is barely or no longer discernible.

8.3.2 Endemic and Epidemic Occurrence

Infection and infectious diseases occur in populations in different patterns. Incidence rates may be constant or may show seasonal or secular trends. When the pattern of a given condition is stable or constant over a period of years, it is usually considered *endemic*. A number of chronic viral infections have affected certain populations in more or less the same pattern for decades; although their patterns may be distinctive in different subgroups, infections with herpesviruses, like cytomegalovirus, Epstein–Barr virus, and HHV-6, have largely remained endemic. Some could even be considered *holoendemic*—affecting entire populations, nearly universally and more severely in childhood and less so in older individuals. In contrast, an *epidemic* or outbreak of disease is recognized as the occurrence of cases in excess of the number expected for a population based on its past experience. The definition of "excess" is an arbitrary one and depends on the relative concentration of recent and previous cases in the place, time period, and population group of interest. In a country or region where a naturally occurring disease has not been seen for years, a few instances (e.g., encephalitis cases in summer) or even a single case (e.g., of poliomyelitis anywhere in the Western Hemisphere or Japanese B encephalitis in a country where none has been documented for years) could be deemed an epidemic. On the other hand, a large and rising number of cases of winter respiratory illness (e.g., due to the introduction of a new influenza strain) may signify normal seasonal fluctuation. For that pattern to be declared an epidemic usually requires application of more sophisticated criteria (i.e., deaths from influenza and pneumonia in 122 cities exceeding established threshold based on a 5-year average), for example, with the 2012–2013 season (Fig. 1.3 Panel b). When several continents are involved, as is the case with the global distribution of HIV/AIDS, the disease is said to be *pandemic*.

Three essential requirements for an outbreak of viral disease are the presence of an infected host or contaminated reservoir, an adequate number of susceptibles, and an effective method of contact and transmission between them. If the agent is not endemic within the community, then the introduction of an infected person, animal reservoir, or vector of transmission is needed to initiate a naturally occurring outbreak. While the infection may have long been endemic in some remote place, an accident of nature (e.g., importation of an animal carrying the agent) or change in human behavior (e.g., a lapse in hygienic practice in a hospital) triggers its emergence in a new location. This is particularly important in an island or isolated population group, where a virus disappears after no more persons remain susceptible, if persistent viral excretion does not occur to permit infection of newborns. Rubella, for example, disappeared from Barbados for 10 years despite an accumulation in the number of susceptibles to a level representing about 60 % of the population and despite the existence of a large tourist trade [132]. The introduction of more susceptibles or of more infected persons may tip this balance. On the other hand, antibodies to viruses characterized by persistent or recurrent viral excretion, such as herpesviruses and adenoviruses, have been present in every population thus far tested, no matter how remote or isolated [133].

Of recent, an increasing concern is a possible deliberate introduction of an agent capable of spreading mass illness and death. The leading viral candidates for use in an attack of bioterrorism (i.e., those causing smallpox, hemorrhagic fevers, arboviral encephalitis, or a severe pulmonary syndrome) are those for which the target population has little or no immunity. To be effective as an agent of bioterrorism, the proportion of susceptibles to infection with the candidate would need to be high, and the pattern and magnitude of the ensuing epidemic would therefore be particularly difficult to predict.

A critical characteristic of populations that strongly influences its experience with infectious diseases in general and the occurrence of an epidemic in particular is *herd immunity*. The herd immunity level is the cumulative proportion of persons immune to a given disease within a community. This proportion is, in turn, highly dependent on such variables as the probability of contact between a source of infection and the susceptible person, the portal of entry accessible, the contagiousness of the agent, and the degree of individual host immunity (all of which are often quantitatively summarized as the *basic reproduction number* (*or ratio*)). The term refers to the average number of new cases of infection transmitted by an index case during its interval of infectivity (see Chap. 5) [134, 135]. High prevalence of protective antibody to a virus among persons in a given community makes an outbreak with that virus most unlikely. Herd immunity to highly communicable infections such as measles, mumps, rubella, and influenza appear to require levels of antibody at least 75 % and even as high as 94 % to be effective (Table 1.7).

Table 1.7 Basic reproduction numbers and herd immunity thresholds for selected vaccine-preventable viral diseases

Disease	R_0	Herd immunity threshold (%)
HIV/AIDS	2–5	–
Influenza (1918 A/H1N1)	2–3	–
Measles	12–18	83–94
Mumps	4–7	75–86
Polio	5–7	80–86
Rubella	6–7	83–85
Severe acute respiratory syndrome (SARS)	2–5	–
Smallpox	5–7	80–85

Adapted from [136–140]

In an open college community, a preexisting level of immunity to rubella of 75 % failed to prevent an outbreak of this disease [141]. In a rubella outbreak among military recruits with a 95 % level of immunity, 100 % of the susceptibles were infected [142]. Close and prolonged contact is apparently extraordinarily efficient at spreading infection. Other principles are also worth emphasizing: (1) the concept of herd immunity is even less valid where several strains of virus exist and cross protection is not complete; (2) even the identical strain of virus that does not naturally confer complete immunity (e.g., certain herpesviruses) may reinfect; (3) reactivation of latent infection may produce disease, especially in immunocompromised hosts; and (4) the presence of antibody in the forms usually measured for such persistent viruses as HIV or hepatitis C indicates that humoral immunity is incomplete at best.

9 Investigative Approaches

9.1 Descriptive Epidemiology

The first steps in understanding infection and disease in populations constitute so-called descriptive epidemiology. It generally involves integrating the data that best characterize the phenomenon under investigation in the terms discussed in the preceding sections: the agent, environment, and host; the distinctive pathogenetic features; the patterns of occurrence in time and place; and the mode(s) of transmission. The technologies for detecting and defining the agent, quantifying environmental conditions, and profiling the immune status of the host have all been advancing at an exceedingly rapid pace. So have the noninvasive and imaging procedures for characterizing the clinical and pathophysiologic features of the disease. They have facilitated the pinpointing in time and location of cases of infection or illness, often revealing early key information about the origins and the mode of transmission of infection.

The next steps after cases are recognized involve systematically defining, counting, and reporting their occurrences; tabulating their frequencies; comparing their rates; graphing their trends; and evaluating and communicating the results of these efforts. The usual approaches for capturing and interpreting these events in the context of public health and disease control come under the broad heading of surveillance, which is covered in detail in Chap. 4.

9.2 Analytic Epidemiology

Beyond the collection of data for descriptive and surveillance purposes, insight into infectious disease at the population level also emerges from more sophisticated computational and pictorial representation of the salient events and relationships. Hypothesis testing and other formal evaluation of causal relationships, exploration of co-determinants of infection and illness, and recognition of patterns of occurrence all involve rigorous comparisons of data from exposed, infected, and/or diseased individuals with similar data from unexposed or unaffected individuals. That form of inquiry has come to be called analytic epidemiology, the basic methods of which are summarized below. Finally, in conjunction with these numerical and graphical methods, advances in the theory and methods of mathematical statistics have refined empirical and predictive models of virus–host adaptation, transmission and vector dynamics, incidence, epidemic trajectories, and other phenomena of infectious disease. Chapter 5 is a concise view of current approaches to modeling of viral transmission dynamics.

The analysis of the results assembled and integrated during the data gathering and descriptive phase primarily involves evaluating relationships or associations with standard measures. These measures and the investigative approaches to estimating them are summarized very briefly here; more elaborate treatment of the epidemiologic and statistical principles underlying them can be found in any of several textbooks on epidemiology as noted in Sect. 1.

9.2.1 Cohort Studies

The search for associations in epidemiologic data often consists of comparing rates of infection in cohorts of individuals exposed and unexposed to a specific risk factor or rates of disease in cohorts of infected and uninfected individuals. Cohort studies may be cross-sectional or longitudinal in design. In the former, the exposure and the outcome are measured in the population at a single time point. There are many relationships for which the timing of the exposure relative to the disease cannot be established through cross-sectional observation; however, there are many others for which the pathogenesis is understood or the exposure is unambiguously antecedent to the outcome (e.g., genetically mediated rapid progression of HIV infection or shingles in an individual with serologic evidence of VZV infection). In contrast, longitudinal cohort studies are often more powerful because the temporal relationship between the exposure and the outcome can be explicitly established. Although ulcerative inflammation due to HSV-2 is a risk factor for acquisition of HIV infection, it could also be a more prominent consequence of HIV-induced immunosuppression. Only longitudinal observation of precise temporal relationships between the onset of these two infections and the timing of their clinical manifestations would allow definitive inferences about causality.

The most informative measure of association in a cohort study is usually the *relative risk*, used synonymously with risk ratio or rate ratio. Relative risk is estimated as the ratio of the rate of the event (infected or ill) among exposed or infected persons, respectively, to the rate of such an event in the unexposed or uninfected persons. In cohort studies in which all or representative samples of individuals exposed and unexposed to a virus are observed for a period of time until some proportion of each sample develops disease, a

Table 1.8 Standard analytic table for estimating relative risk and relative odds

	Infected/ill	Uninfected/well	
Exposed/infected	a	b	$(a+b)$
Unexposed/uninfected	c	d	$(c+d)$
	Affected $(a+c)$	Unaffected $(b+d)$	Total $(a+b+c+d)$

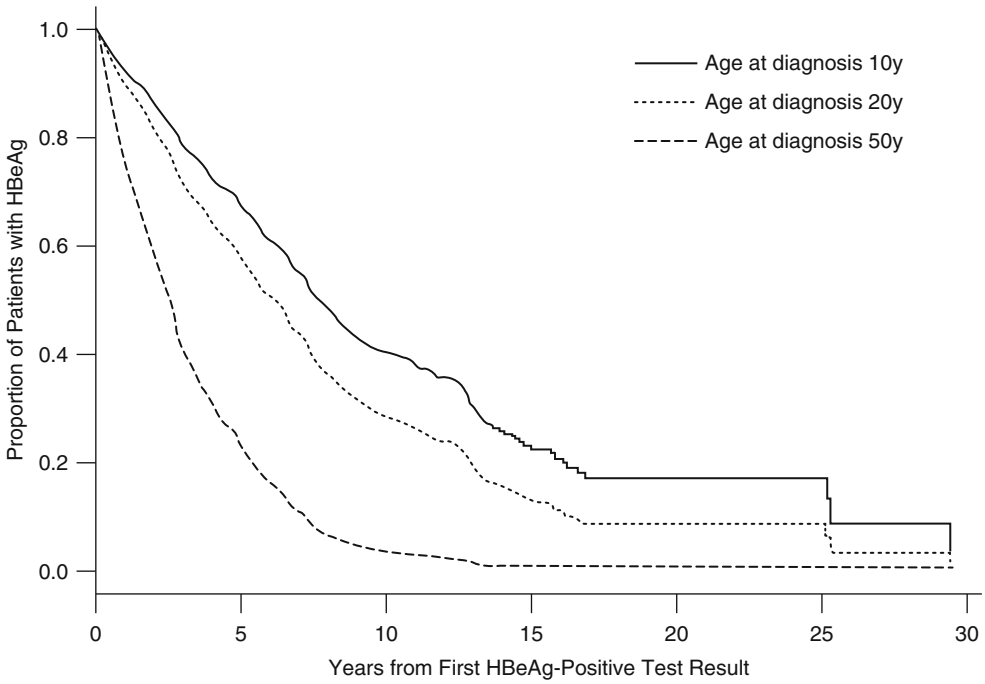

Fig. 1.4 Predicted survival curves (time from first HBeAg-positive result to clearance) at ages 10, 20, and 50 years. Significant covariates included in the model are age at diagnosis of HBsAg (including a nonlinear effect), an interaction of initial recorded status of HBeAg (positive or negative) and age, and the number of HBeAg measurements recorded. The overall probability of clearing HBeAg within 10 years was 72.5 %. In those who cleared HBeAg, the median time to clearance was 5.6 years (range, <1 to 29.4 years). Older carriers were significantly more likely than younger ones to clear HBeAg ($P<0.001$) (Adapted from McMahon et al. [143])

"true" relative risk is calculated as the ratio of the eventual cumulative incidences in the groups with and without exposure or $[a/(a+b)]/[c/(c+d)]$ (Table 1.8).

For conditions that develop over variable lengths of time, if the actual time between exposure/infection and disease is known, it is often preferable to incorporate that time element into the estimate relative risk. That can be done either graphically in survival (Kaplan–Meier) plots (Fig. 1.4) or numerically by application of statistical techniques of which a very useful and popular one is known as a (Cox) proportional hazards regression, yielding a *relative hazard*. Several useful pieces of information about the timing of events can be extracted from the survival curves. As in other regression models, a proportional hazards model can include multiple factors to be assessed for their independent contribution to the outcome (disease).

9.2.2 Case–Control Studies

When an investigation can only be done feasibly on infection or disease that has already occurred following presumed exposure to some etiologic agent in the past, properly designed comparison of those exposed and affected (cases of infection or disease) with those exposed and unaffected (controls) can provide a valid measure of association. When the available cases and, for efficiency, only a small subset of all the non-cases are compared, the putative causal relationship is measured as the *relative odds*, a term synonymous and interchangeable with the *odds ratio*. Based on mathematical principles, for diseases that are uncommon in the population, the relative odds, calculated as $[a\times d/b\times c]$, represent a close approximation to the relative risk (Table 1.8). The case–control study design is especially productive in epidemic situations where the investigation needs to be structured around cases that are reported or sought in the absence of a clear causal exposure. The analysis of case–control studies is usually performed with the technique of logistic regression, which can accommodate independent variables other than the putative causal factor. The major limitation is the many forms of bias that can distort the estimate of the strength of the key relationship, due to difficulties in selecting and assessing study subjects with the tight comparability necessary for proper analysis.

9.3 Investigation of an Epidemic

This brief introduction to the strategy and tactics of epidemic investigations is best supplemented by more extensive guidance found elsewhere [144–146]. From the earlier discussion of the origin and nature of epidemics, it should be clear that no two are exactly alike, but just

Table 1.9 Investigation of an epidemic

1. Determine whether an outbreak is occurring
2. Verify the diagnosis
3. Establish a case definition
4. Enumerate cases
5. Conduct descriptive analyses of the preliminary data
6. Develop hypotheses about the cause of illness and the source of infection
7. Evaluate the hypotheses with analytic methods
8. Conduct additional epidemiologic, environmental, or laboratory studies
9. Develop and implement prevention and control measures
10. Communicate the findings

Adapted from Dicker et al. [145] (CDC publication, no copyright)

as there are patterns to endemic occurrence of disease, there are patterns to epidemics. A systematic approach to their investigation should take account of those patterns by incorporating the sequence of steps outlined in Table 1.9, although this list is neither exhaustive nor in strict priority order of execution.

Outbreaks may come to attention in a variety of ways. An insightful clinician may suddenly see one or more unexpected cases of a syndrome or atypical presentations of infection, just as happened at the onset of the HIV/AIDS epidemic [147]; or a laboratory may identify an unusual viral strain in the course of routine testing (e.g., a novel influenza variant) [148]; or a health department officer may recognize a cluster of cases of, say, norovirus gastroenteritis as multiple entries in computerized syndromic surveillance system [149]. With any such initial event, it may not be possible to establish a diagnosis only at the level of a clinical syndrome and not with etiologic specificity. At this initial stage, a somewhat specific but simple working definition should include key epidemiologic and clinical features for the purposes of case finding. This definition can be altered in its sensitivity or specificity later, when the spectrum of clinical features has been clarified and laboratory studies have been completed. The definition is primarily for the purposes of beginning to enumerate cases. This enumeration is accompanied simultaneously with the organization and analyses of the clinical data and construction of a plot (epidemic curve) of cases according to onset or recognition and/or a plot of the location of cases. Categorization by occurrences by infection, case, or death may provide information about the seriousness of this outbreak relative to previous ones.

Even at this early point, if the pattern of cases or other information reveals a likely mode of transmission, control measures should be instituted. Not surprisingly many epidemics of viral infection result from person-to-person spread, particularly by the respiratory route, in open communities or in relatively closed populations like health or extended care facilities. Vector-borne spread also accounts for a significant portion of epidemic viral infection throughout the world (see Chaps. 7, 8, 9, 14, 15, and 16,). Common source outbreaks of viral infections from water, food, milk, or other environmental sources have not historically been as common as those due to bacterial infections. However, such outbreaks have been recognized increasingly in recent years. Some examples include spread of adenoviruses by tonometers in eye clinics or in swimming pools, hepatitis A by public water supplies or by seafood, or enteroviruses by fecally contaminated water, food, or milk (see Chap. 17).

As the nature, magnitude, mode of transmission, and likely etiologic agent of the outbreak become clearer, the analyses can be refined and focused on more conclusive tests of hypotheses about individuals or other sources and the modulating factors such as age, sex, occupation, recreation, and other geographic or social characteristics of cases. The results of these analyses may assist in excluding or adding cases and focus control measures on individuals most directly affected as well as those at continued risk. The epidemiologic discovery of the cause and other features of the outbreak along with the implementation of control measures will further oblige and enable the investigative team to communicate effectively with the numerous stakeholders in a typically quite visible public health event.

10 Control and Prevention

The basic strategy for controlling a disease is to break one or more links in the chain of causation or pathogenetic continuum. Any such a strategy must rest on the fundamental knowledge of the agent, host, and environment for the particular infection; the control may be physical, chemical, or biological in nature. In the simplest terms, control at the level of the agent usually means incapacitating or destroying it with a physical force as with ultraviolet or light or freezing. A variety of chemicals can also be used externally, particularly on inanimate surfaces (i.e., virucidal disinfectants such as detergents, methylene blue, and chlorine or other compounds that depend on the activity of hypochlorite). At the level of the environment, the strategy might involve an engineering solution such as improving water supplies or sewage disposal or installing negative-pressure ventilation systems, or it might involve avoiding, suppressing, or eradicating the vector population using a widely sprayed insecticide or some other intervention that alters the vector habitat. Effective prevention can also be achieved at the personal level with behavioral intervention to prevent contact (e.g., isolating or cohorting infected individuals in separate rooms, wearing protective clothing such as masks or gowns, applying a topical insect repellant, or washing hands with any of a variety of antiseptic agents). Because of space limitation, for more information on the principles and practices of isolation and barrier, sanitation, disinfection and antisepsis, environmental engineering,

and vector control, the reader is referred to more general texts and references on selected topics here; many others on these numerous topics are available [95, 150–153].

The remainder of this section will concentrate on strategies that depend on biological activity of pharmaceutical agents that can be injected, ingested, or topically applied in humans. These are antiviral products that target specific strains or broad classes of viruses and vaccines and immunobiologics that capitalize on specific host responses to particular viruses.

10.1 Therapy and Chemoprophylaxis

Strategies for designing antiviral agents focus on the numerous vulnerable points in the replicative cycle of a virus that are, ideally, distinct from any point along the synthetic pathways of the human host. There is a growing list of candidate drugs with established clinical antiviral efficacy, and new compounds can now be designed in silico with computer programs that can produce exquisitely precise models of protein–protein interactions that help predict their likely biologic effects. Of course, as promising as these advances are, the ideal is rarely achieved. Limitations still include the poor correlation of effects predicted by in silico, in vitro, or animal studies with those observed in humans, strain differences in response, easy emergence of resistance, and unforeseen acute toxicity. Delayed adverse consequences like oncogenicity and teratogenicity are also a concern.

Each chapter on individual viral infections provides more information about the antiviral pharmaceuticals in use or in trial for those viruses. For another review of antivirals used in specific infections, refer to Ref. [154]. Here simply for rapid reference and comparison is a summary tabulation of the diseases and viruses (other than HIV/AIDS, which is covered in greater depth in Chap. 43), the corresponding antiviral drugs available at the time of publication, their mechanism of action and/or stage of replication affected, and their use for treatment and/or prophylaxis (Table 1.10).

In addition to the antiviral agents covered here, several new candidates in familiar classes as well as new classes of drugs are under experimental and in some cases human investigation. They include numerous new drugs of several classes for HCV; cyclopropavir for CMV infection; a methanocarbathymidine compound active against several herpesviruses; a drug similar to cidofovir with activity against polyoma-, adeno-, pox-, and herpesviruses; favipiravir, which inhibits replication of influenza and probably arena-, bunya-, and hantaviruses; pleconaril and other drugs that inhibit picornaviruses; drugs targeting kinase pathways; and other agents with a broader antiviral spectrum, such as those that bind to the uniquely viral intermediary double-stranded RNA while initiating apoptosis [155–157].

10.2 Immunization

Each chapter on a viral infection for which an effective or promising immunizing agent is available includes details of that virus-specific immunization. This section presents

Table 1.10 Antiviral drugs licensed/generally available for human use

Condition	Virus	Agent	Mechanism of action	Treatment (Rx), prophylaxis (Px)
Cold sores, fever blisters, labial herpes	HSV-1	Acyclovir, ganciclovir, famciclovir, zanamivir, valacyclovir, vidarabine[a] foscarnet, and others	Nucleos(t)ide analogue, inhibits deoxypyrimidine kinase as a competitive substrate	Rx, Px
Genital herpes	HSV-2			
Chicken pox, zoster	VZV			Rx
Cytomegalovirus	CMV	Cidofovir, fomivirsen, foscarnet		
Influenza A	Influenza A virus	Amantadine, rimantadine	Interferes with ion channel protein (M_2) and uncoating	Rx, Px
Influenza A	Influenza A virus			
Respiratory syncytial virus	RSV	Rimantadine		Rx
Influenza A and B	Influenza	Oseltamivir, zanamivir	Blocks release by inhibiting neuraminidase	Rx, Px
Chronic hepatitis B	HBV	Adefovir, emtricitabine, lamivudine, tenofovir	Nucleos(t)ide analogue	Rx
Chronic hepatitis C	HCV	1. Interferon-α	1. Cytokine initiating intracellular immune response cascade	Rx
		2. Ribavirin	2. Nucleoside analogue	
		3. Boceprevir, telaprevir, simprevir	3. Inhibits replication by binding to the nonstructural protein, serine protease	
		4. Sofosbuvir	4. RNA polymerase	
Respiratory syncytial virus infection	RSV	Ribavirin	Nucleoside analogue	Rx

general perspectives and more concrete information, including the objectives of vaccination, types of immunization for viral infections, schedules for immunizing target populations with agents licensed in the United States, prospects for eradication of viral diseases, and national and international programs concerned with immunization. For deeper treatment of the principles and practice of vaccinology, consult Ref. [158].

10.2.1 Active Immunization

Active vaccines are administered with the goal of stimulating antibody production by the host to provide a high degree and long duration of protection but with no or minimal accompanying illness. The full set of objectives for creating a good vaccine for active immunization is listed in Table 1.11. Both live and killed vaccines are used, and Table 1.12 compares the two types. Active viral vaccines containing live attenuated virus (measles, mumps, rubella, and smallpox viruses, poliovirus, adenovirus, and VZV) have generally been more immediately, broadly, and durably protective than killed vaccines or other constructs, especially when they are administered by the natural portal of entry to produce local immunity. However, there are a growing number of exceptions to that rule—live virus preparations that are less fully successful (e.g., VZV vaccine against herpes zoster, nasally administered influenza vaccine) while certain non-replicating types formulated as recombinants that appear to provide unexpectedly high protection (e.g., HBV and HPV vaccines). In the case of hepatitis A, both inactivated and live attenuated formulations are highly effective, although immunity generated by the latter may be somewhat longer lasting [159].

Limitations to the wide applicability of live vaccines include the difficulty of successfully attenuating the candidate strain without reversion to virulence, the avoidance of viral persistence and the risk of reactivation, and the elimination of possible oncogenicity. These have been major hurdles for vaccines against herpesviruses, and it is difficult to measure some of these attributes in the laboratory. Efforts to produce live vaccines with temperature-sensitive mutants that replicate in the upper respiratory but not in

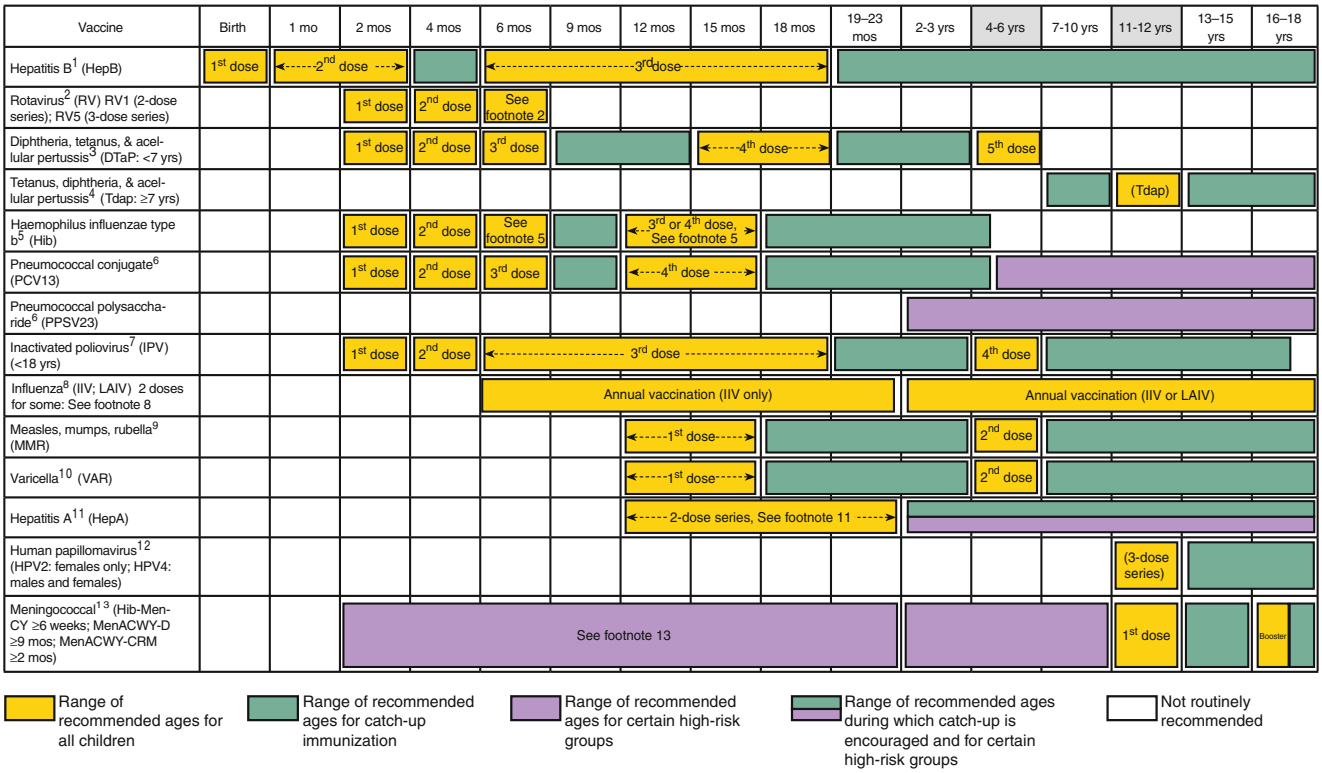
Table 1.11 Objectives for a vaccine

1. Elicit a good humoral, cellular, and/or mucosal immune response that correlates with protection against clinical disease and reinfection
2. Provide protection lasting at least several years and preferably a lifetime, similar to that induced by natural infection that leads to lifetime immunity
3. Result in minimal immediate side effects or adverse reactions or mild disease and result in no delayed effects (e.g., late reactivation, CNS involvement, or cancer)
4. Require a simple regimen for administration in a form and a schedule acceptable to the target population and the general public
5. Pass a favorable cost/benefit analysis, where the health and economic benefit of administration clearly outweighs the cost and risk of natural disease and the adverse consequences of administration

Table 1.12 Comparison of live and killed vaccines

	Live	Killed
Immune response		
Humoral antibody (IgG)	+++	+++
Local antibody (IgA)	+++	+
Cell-mediated immunity	+++	+
Duration of response	Longer	Shorter
Epidemiologic response		
Prevents reinfection by natural route	+++	++
Stops spread of "wild" virus to others	++	+
Some vaccine viruses (polio) spread to others	+++	0
Creates herd immunity if enough persons are vaccinated	+++	0
Characteristics of the vaccine		
Usually heat stable, may need to keep below freezing point until just prior to administration	++	0
Vaccine virus may mutate or increase in virulence	+	+
Antigenic site limited or lost during preparation (e.g., formalin treatment)	0	+
Contraindicated in immunosuppressed persons	+++	0
Side reactions:		
Systemic (viremia)	+	0
Local	0	++
Number of doses for successful take	1	2–3

The table is a simplification and may not apply to all vaccines. Some live vaccines, e.g., polio, are relatively heat stable. Knowledge of the presence of and degree of protection by cell-mediated immunity is inadequate for many vaccines



This schedule includes recommendations in effect as of January 1, 2014. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combinationvaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at http://www.cdc.gov/vaccines/hcp/acip-recs/index.html. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (http://www.vaers.hhs.gov) or by telephone (800-822-7967).Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, i ncluding precautions and contraindications for vaccination, is available from CDC online (http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm) or by telephone (800-CDC-INFO [800-232-4636]).

This schedule is approved by the Advisory Committee on Immunization Practices (http/www.cdc.gov/vaccines/acip), the American Academy of Pediatrics (http://www.aap.org), the American Academy of Family Physicians (http://www.aafp.org), and the American College of Obstetricians and Gynecologists (http://www.acog.org).

Fig. 1.5 Recommended immunization schedule for persons aged 0 through 18 years—United States 2013. These recommendations must be read with the footnotes that follow [161]

the lung have culminated in the licensure of a cold-adapted nasal influenza vaccine recommended for use in healthy 2–49-year-olds.

A comprehensive overview of general immunization principles and recommendations can be found in Ref. [160]. The schedule for immunization of immunocompetent infants, children, and adolescents is shown in Fig. 1.5 [161], and for immunocompetent adults in Fig. 1.6 [211]. They reflect recommendations that took effect in 2013 and will obviously be modified as new agents and regimens are found to be effective.

The above pages of the CDC website are the definitive sources of information about the requirements for immunization and details of administration, precautions, contraindications, and other aspects in the United States. References to CDC recommendations are also available for immunization in other specific situations: health-care personnel [162], special health conditions [163], pregnancy [164], and international travel [165].

10.2.2 Passive Immunization

Passive immunization with an Ig preparation is an expedient useful in short-term prevention primarily when it can be administered soon (preferably within hours) after exposure and when it contains a sufficiently high titer of antibody that will be effective against the agent.

Some preparations are derived from persons known to be convalescent from the disease and from persons hyperimmunized against it or by selecting only donors shown to have high antibody titers. Passive immunization is generally limited to well-defined exposures to rabies virus or in immunocompromised patients who are susceptible to HAV, HBV, VZV, CMV, and vaccinia (unlikely in the absence of smallpox immunization but potentially useful if vaccinia virus gains acceptance as a carrier for other antigens).

10.3 Disease Eradication and Elimination

Smallpox was the first and only disease to have been officially declared eradicated from the earth. From the moment of that historic accomplishment in 1977, this consummate success of the WHO eradication program has inspired initiatives to replicate it with other diseases. The definition of *eradication*, telegraphed in Table 1.13, can be more fully understood in

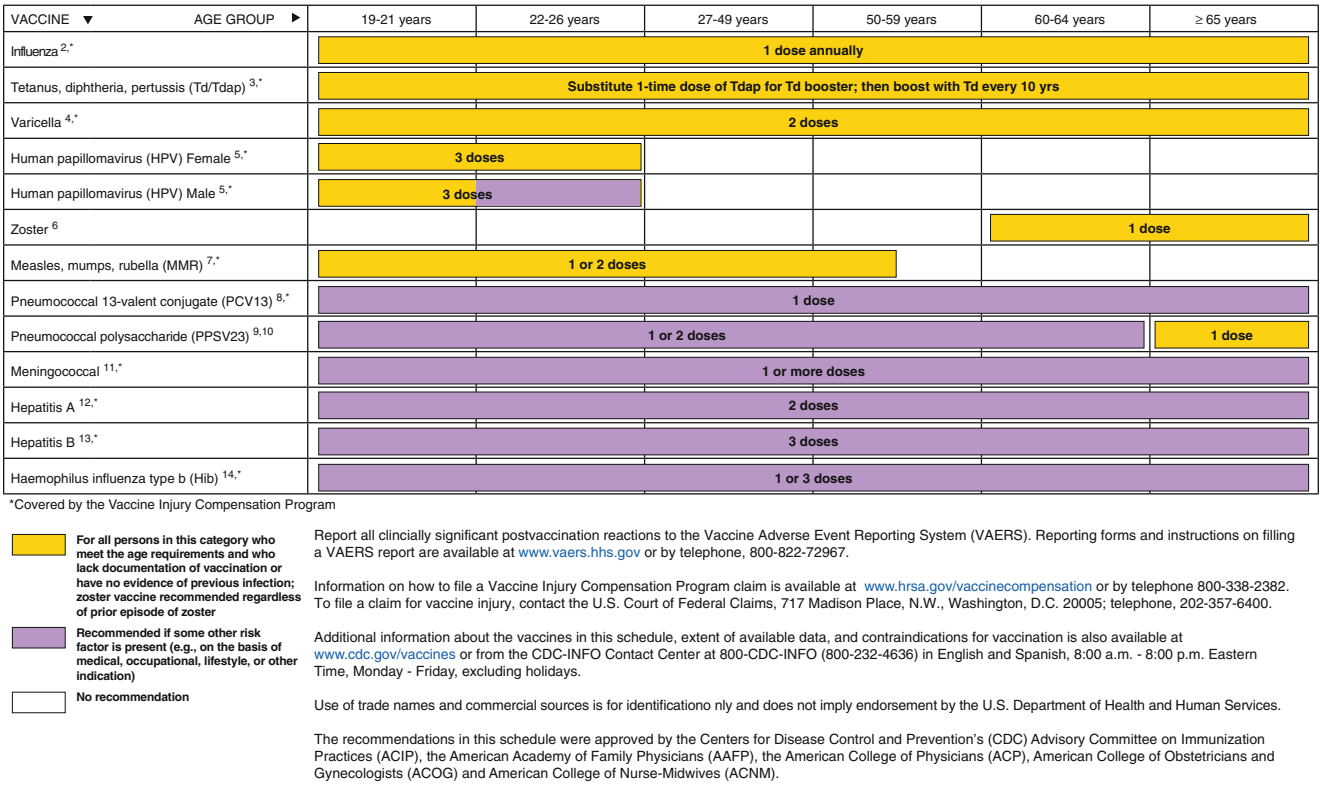


Fig. 1.6 Recommended adult immunization schedule by vaccine and age group [211]

the context of viral infection as "…disappear[ance] from all countries of the world because transmission of the causative organism has ceased in an irreversible manner" [166]. A less ambitious goal, *elimination*, denotes disappearance of the causal agent within a large geographic area; this goal has often been viewed as an intermediate step toward eradication. The critical distinction made in Table 1.13 is that once a disease is eradicated, it is no longer necessary to maintain the elaborate public health apparatus required for ongoing surveillance and control. The implications for achieving either result in practice are that (1) every real or potential occurrence in every location within the target area must be taken seriously, (2) the infection and the interventions to control it must be carefully monitored, (3) program structure and function must be nimble and thorough in response to any suggestion of difficulty or failure, and (4) the rising cost of preventing each successive case cannot be allowed to justify diverting resources away from the goal [167].

Only a few other viral diseases have come close enough to meeting the criteria for potential eradication or elimination to receive serious consideration. In 1993 the International Task Force for Disease Eradication promulgated its list of recommended target diseases for eradication or elimination, and the Task Force recommendations and assessment were updated

Table 1.13 Disease eradication

Definitions
Eradication
Zero disease globally as a result of deliberate efforts
Control measures no longer needed
Elimination
Zero disease in a defined geographic area as a result of deliberate efforts
Control measures needed to prevent reestablishment of transmission
Criteria for assessing the eradicability of a disease
Scientific feasibility
Epidemiologic susceptibility (e.g., no nonhuman reservoir, ease of spread, naturally induced immunity, ease of diagnosis)
Effective, practical intervention available (e.g., vaccine, curative treatment)
Demonstrated feasibility of elimination (e.g., documented elimination from island or other geographic unit)
Political will and popular support
Perceived burden of the disease (e.g., extent, deaths, other effects; relevance to rich and poor countries)
Expected cost of eradication
Synergy of eradication efforts with other interventions (e.g., potential for added benefits or savings)
Need for eradication rather than control

Reproduced from Ref. [167]

Table 1.14 Diseases considered as candidates for global eradication by the International Task Force for Disease Eradication

Disease	Current annual toll	Chief obstacles for eradication	Conclusion
Measles	780,000 deaths, mostly among children	Lack of suitably effective vaccine for young infants	Potentially eradicable
Mumps	Unknown	Lack of data on impact in developing countries; difficult diagnosis	Potentially eradicable
Poliomyelitis	2,000 cases of paralytic disease; 200 deaths	Insecurity; low vaccine coverage; increased national commitment needed	Eradicable WHA 41.28 (1988)
Rubella	Unknown	Lack of data on impact in developing countries; difficult diagnosis	Potentially eradicable
Diseases/conditions of which some aspects could be eliminated			
Hepatitis B	250,000 deaths	Carrier state, infections in utero not preventable; need routine infant vaccination	Not now eradicable, but could eliminate transmission over several decades
Rabies	52,000 deaths	No effective way to deliver vaccine to wild animals that carry the disease	Could eliminate urban rabies

Reproduced from Ref. [169]

in 2008 (Table 1.14) [168, 169]. Global efforts against both poliomyelitis and measles have been the most concerted. The successes and setbacks are covered in the respective chapters on the two conditions (Chaps. 13 and 23).

Although the original Task Force and those who have updated their work acknowledged certain key obstacles, in reality, even when the commitment is strong, funding is seldom entirely sufficient for the tasks at hand, motivation of all key stakeholders is difficult to sustain, and political and social insecurities remain an unpredictable threat. The intensive effort to eradicate polio has been a test case. In 1988 WHO formally initiated its campaign to eradicate poliomyelitis. Under the overall leadership of WHO, it and numerous public and private organizations (e.g., CDC, Rotary International, UNICEF, and the Bill and Melinda Gates Foundation) have persevered in this mission for more than 20 years [170]. It is noteworthy that even before the inception of this more coordinated effort, in 1979 Rotary International began its remarkable commitment to polio eradication, and for three decades, through its worldwide chapters, it performed tireless vaccine campaign work that has recently captured the attention of major news organizations [171, 172, 176]. By 2006 polio remained endemic in only four countries, whereupon gains continued but began to be punctuated by periodic setbacks. Then new blows began to be struck in late 2012 as a result of lethal attacks on healthcare workers conducting polio immunization campaigns in Pakistan and Nigeria and even on their police escorts [173], as well as introductions into countries where war had degraded the public health infrastructure. Continual political and social unrest has fueled the spread of lies about motives of the health workers and the consequences of immunization [174]. All of this turmoil has seriously threatened the eradication program.

Unfortunately, even in the United States, where widespread if not universal elimination of other childhood viral diseases is at least imaginable, there have been very recent resurgences of measles [175], mumps [176], and chicken pox [177], most likely for a combination of reasons: waning immunity despite what had been deemed adequate vaccination recommendations and coverage, gaps in coverage among minority and other populations, and more general resistance to vaccination stimulated by negative publicity in social media along with pockets of objection on religious grounds.

10.4 Programmatic Approaches to Immunization

10.4.1 United States

Creating, testing, producing, licensing, recommending, and monitoring vaccines share many aspects with analogous steps involved in pharmaceutical development and marketing. Descriptions of those elaborate processes are beyond the scope of this chapter. On the other hand, because vaccines are administered almost entirely to basically healthy individuals, often on a global population scale, various distinctive programmatic features of their use are worth considering here briefly. The following summary of the major domestic and international programs involved in vaccine development and delivery may help the reader to appreciate the enormous commitment to immunization for prevention and control of viral infections in general and to understand how a vaccine for any specific infection covered in this text fits into this larger context.

In the United States, besides certain private sector pharmaceutical manufacturers, the National Institute of Allergy and Infectious Diseases [a component of the National Institutes of Health within the Department of Health and

Human Services (DHHS)], the Department of Defense, and other agencies conduct and/or support a broad variety of basic microbiological and immunological research fostering the creation of new and better vaccines. The Food and Drug Administration oversees the development and licensure of all vaccines for human use; through many years of legislation, regulation, and policy-making, this agency has built an elaborate system for ensuring that the products of vaccine manufacturers are safe and effective. Such pre-market design, development, and production activities are beyond the scope of this chapter. Although these Federal agencies remain closely involved with monitoring and reviewing the safety and effectiveness of vaccines once they are licensed and distributed, the National Vaccine Program and CDC are the DHHS components in the US Federal government that have primary authority for implementing and monitoring their use in populations. The DHHS and particularly the CDC are engaged in other activities related to vaccine use, but the following paragraphs highlight its principal responsibilities.

National Vaccine Program Office

This group oversees and coordinates all of the DHHS agencies and offices involved with vaccine development and utilization. In 2010, in part with a view toward achieving the immunization-related objectives established by the Federal government in *Healthy People 2020*, the NVP/DHHS published *the 2010 National Vaccine Plan*, a carefully articulated set of goals and objectives and recommendations on how to reach them [178]. The five overarching goals of the plan are to (1) develop new and improved vaccines; (2) enhance the vaccine safety system; (3) support communications to enhance informed vaccine decision-making; (4) ensure a stable supply of, access to, and better use of recommended vaccines in the United States; and (5) increase global prevention of death and disease through safe and effective vaccination. There also a separate implementation plan, which details the tactics to be pursued in meeting the goals [179].

Surveillance of Vaccine-Preventable Diseases

Through its long-standing relationships with state and local health departments, CDC has implemented increasingly elaborate systems and methods for reporting of selected infectious diseases, a number of which are viral and a subset of which are vaccine preventable. These systems are reviewed in detail in Chap. 4.

Vaccines for Children Program (VFC)

In 1994 the Federal government initiated and began to fund this program to provide free vaccines to children for whom they would otherwise be unaffordable [180]. As administered by CDC, the program currently provides vaccines against the following viral infections: hepatitis A, hepatitis B, human papillomavirus, influenza, measles, mumps, poliomyelitis, rotavirus, rubella, and varicella zoster. There is general agreement that VFC had been a vital force in ensuring relatively high levels of immunization in vulnerable populations, thereby contributing to the major successes in reducing vaccine-preventable diseases in the past two decades.

Advisory Committee on Immunization Practices (ACIP)

This committee is chartered by Federal law [181] to advise CDC and, in effect, all government agencies and the public at large about the appropriate use of vaccines to control those diseases for which immunizing agents are available. The committee meets regularly to review statistics on vaccine-preventable diseases; new experimental and other research findings relevant to vaccine safety and efficacy; information about current vaccines, including labeling and package inserts; newly licensed products; policies and guidelines of other organizations; cost considerations; and other aspects of immunization policies and programs. Recommendations may be forthcoming on any of those topics; in addition, recommendations may also cover for modification of schedules, for administration of vaccines in the Vaccines for Children Program, or for introduction of new vaccines into the program. This advice carries heavy weight throughout the public health, health-care provider, public and private health insurance, and legal communities. The primary legal authority for matters of public health and disease control is vested in the states, and most of them follow ACIP guidelines closely.

Vaccine Adverse Event Reporting System (VAERS)

In 1986, congressional legislation required CDC and FDA to develop this system for receiving, monitoring, and responding to reports of potential side effects and complications of immunization [182, 183]. Every effort is made to document any such untoward event following administration of a licensed vaccine, regardless of the degree of certainty about the causal relationship to the vaccination. Each year, the system receives some 30,000 reports of events, the vast majority of which are mild.

10.4.2 International

WHO

In 1974 the World Health Assembly, encouraged by the success of the smallpox eradication campaign, created the Expanded Program on Immunization (EPI) [184] to ensure that children everywhere would receive routine immunizations. The early goals of the program were to assist in developing the appropriate immunization policies and systems. In its evolving role, it has promoted the key objectives of service delivery, vaccine storage with temperature control (cold chain maintenance), timely vaccine distribution, surveillance of disease and vaccination rates, health-care personnel training, and efficient program management.

More recently (2006), WHO and UNICEF produced the Global Immunization Vision and Strategy (GIVS) [185] aimed at reducing morbidity and mortality from vaccine-preventable diseases during the decade ahead, not just in children but in all segments of the population. The strategy includes immunizing more broadly, introducing a range of new vaccines and technologies, integrating vaccination and other preventive health care, and coordinating programs on a global level. The overall strategy contains numerous goals from which countries can select to tailor their own specific programs. Within only a few years after its adoption, GIVS has been successful in stimulating the establishment of a number of national immunization plans.

GAVI

As a culmination of the World Economic Forum in Davos, Switzerland, at the beginning of the new millennium, major stakeholders in the global immunization (UN agencies, donor governments, vaccine industry leaders, aid organizations, and others) formed a consortium called the Global Alliance for Vaccines and Immunization (GAVI). The mission of this entity is to bring new vaccines to all children of the developing world. The specific goals include intense focus on the more than 20 million children worldwide in poor areas who would otherwise remain unvaccinated against vaccine-preventable diseases, acceleration of delivery of new vaccines to the poorer countries as soon as possible after they are available in the wealthier ones, and channeling support for academic and industrial research on new vaccines targeted to the developing world.

Early GAVI efforts in the realm of viral diseases concentrated on vaccines against hepatitis B and yellow fever. Lately, attention has turned to delivery of rotavirus, the second dose of measles, human papillomavirus, Japanese encephalitis, and rubella vaccines. Two examples of current initiatives include the intention to immunize 700 million children against measles and rubella by 2020 and plans for administering HPV vaccine to 180,000 preadolescent girls in the first phase of a campaign to protect girls in many developing countries against cervical cancer. The alliance has depended heavily on grants and donor government pledges along with private philanthropic contributions, but it has substantially capitalized on more innovative financing for purchases of existing vaccines and for mutual assurances about the future availability of vaccines and the funds needed to purchase and deliver them. More details about the goals and accomplishments of GAVI to date can be found at Ref. [186].

Bill and Melinda Gates Foundation

As a powerful force in the quest to control vaccine-preventable diseases, for years this foundation has supported both traditional and innovative approaches to the development and delivery of vaccines for the places in greatest need [187]. The strategy incorporates five themes: making routine vaccines available, introducing new vaccines as they become available, using innovative and market-based approaches to financing and implementing immunization programs, promoting decisions about the deployment of vaccines based on scientifically sound evidence, and advocating for the support for vaccine programs by other stakeholders. The Supporting Independent Immunization and Vaccine Advisory Committees Initiative is one of those funded by the Gates Foundation to promote National Immunization Technical Advisory Groups (NITAGs) [188]. These groups provide recommendations on immunization policies and programs (e.g., schedules for administration of existing vaccines, improved coverage, and introduction of new vaccines) [189].

10.5 An Emerging Challenge to Immunization

Government and nongovernment organizations alike are engaged in an enormous multipronged worldwide immunization enterprise. There are many natural and legitimate concerns about the prospects for continuing success with each vaccine-preventable disease. The obstacles in every domain—scientific, political, economic, cultural, and others— are formidable. It was especially distressing to learn that one of those obstacles, opposition on religious/ethnic grounds, had motivated the murder of innocent Pakistani and Nigerian health workers in 2012–2013 [190, 191]. In retrospect, such extreme but, hopefully, isolated acts should not be all that surprising as part of the spectrum of social or religious opposition to vaccination campaigns in countries with poorly educated populations. However, on a more ominous note, beginning in the 1990s, the United States and other developed countries have witnessed a gradual increase in the numbers of parents who are refusing to permit their children to receive required routine immunizations. Because the refusals have tended to concentrate among certain subsets of the population who may be clustered geographically [192, 193], the relatively higher proportions of children whose parents have denied them vaccination have led to outbreaks of vaccine-preventable disease [194]. The resulting increased risk of such diseases as measles engenders particular concern because children unvaccinated against them not only are vulnerable in their own right but also pose significant risk to their contacts who may remain unprotected—because of exemption from vaccine requirements, a medical precaution or contraindication for live vaccine, vaccination exclusion for young age, or inadequate response to vaccine [195].

Religious beliefs have often been cited reasons for requesting exemption, but other anti-vaccine forces are at work too [196]. Although incidents with contaminated products had raised largely transient concern in the more distant past [197],

it was the reported but now thoroughly discredited research on the role of vaccination as a cause of autism that probably accounted for the first more serious and lasting rupture in public confidence in the benefits of immunization in general [198, 199]. The news media, in their predilection for controversy, have not always presented a properly *iunbalanced* view of the facts and claims [200]. Mass migration to the Internet as a primary source of health information has led to a proliferation of online websites highlighting anecdotal attributions by parents of various other adverse events to vaccines. While unsupported allegations are unfortunate, their appeal to parents of ill children as easy explanations or as sources of comfort or even justifications for tangible compensation is also understandable. However, more disturbing are print- and web-based testimonies by supposed experts in field of vaccines including radical, unfounded assertions about research that links vaccination to various deleterious biological and clinical consequences. Some of these arguments appear to have arisen from distrust of government [201]. Other claims are likely motivated by anecdotal experiences, favorable publicity, and/or financial benefits that may accrue from sales of books and other materials [202–205]. Regardless of the origins or current forces driving this anti-vaccine sentiment, the recent experience with deliberate discontinuation or refusal of routine immunization has provided ample forewarning of how this growing multifaceted anti-vaccine movement could reverse decades of progress.

As one reaction to this movement, some clinicians have discontinued or have considered discontinuing their provider relationship with patients who refuse vaccines. However, the American Academy of Pediatrics Committee on Bioethics has advised against this and recommends that clinicians address vaccine refusal by respectfully listening to parental concerns and discussing the risks of non-vaccination to the health of their patients and to the health of their community [195, 206, 207]. While neither confrontation nor rejection is an acceptable response, health professionals must devise effective countermeasures against this emerging challenge to the most fundamental strategy for control of viral infections.

Diagnosis, Discovery and Dissection of Viral Diseases

2

W. Ian Lipkin and Thomas Briese

Only a few years ago, viral diagnosis was largely an exercise for academic researchers and public health practitioners with focus on epidemiologic analyses and outbreak prevention, detection, and control. Opportunities for therapeutic intervention were limited to only a few applications such as herpesvirus infections, influenza, and HIV/AIDS; hence, once a bacterial or fungal infection was excluded, clinicians were limited to providing supportive care for what was presumed to be a viral syndrome. Public health organizations tracked the incidence of viral infections and the development of resistance to the few antiviral drugs in use and provided input to governments and the pharmaceutical industry regarding selection of vaccine targets. More recently, interest in viral diagnostics has burgeoned with the advent of new tools for detection and discovery, global recognition of pandemic risk, high-throughput drug screening, rational drug design, and immunotherapeutics. An additional impetus has been the implication of viruses in chronic illnesses not previously attributed to infection. The objective of this chapter is to review the factors responsible for the rise in awareness of viral infections, methods for diagnosis and monitoring viral infections, and future prospects for improvements in discovery, detection, and response to the challenges of clinical virology.

1 Emerging Infectious Diseases and Biodefense

In an era when travel and trade are increasingly global, patients with what were once considered exotic infectious diseases restricted to the developing world, like dengue fever, Ebola, or chikungunya, now present in clinics and emergency rooms in North America and Europe. Nonstop flights of less than 24 h connect the world's major airports; hence, physicians must be prepared to expect the unexpected. In New York City, for example, more than 12 million passengers annually pass through John F. Kennedy (JFK) airport from more than 100 international destinations. With this traffic volume in one metropolitan airport alone, it is not surprising that human and stowaway passengers like mosquitoes have been implicated in the transmission of West Nile virus, HIV, influenza virus, *Mycobacterium tuberculosis*, SARS coronavirus, and chikungunya virus. Exotic agents can also transit internationally in legal and illegal (bushmeat) food products and companion animals. The annual traffic in bushmeat through Charles de Gaulle airport in Paris is estimated at 273 tonnes [1]. In work with nonhuman primate, rodent, and bat bushmeat seized at JFK by the Wildlife Conservation Society, EcoHealth Alliance, and the Centers for Disease Control and Prevention, we have found evidence of infection with retroviruses, herpesviruses, and pathogenic bacteria [2]. Illegal importation of companion animals such as birds, primates, and rodents has been linked to outbreaks of poxviruses and Salmonella [3, 4].

Approximately 70 % of emerging infectious diseases are zoonoses—infections that are transmitted to humans from wildlife or domestic animals [5, 6]. The majority of zoonotic diseases can be attributed to anthropogenic change. Loss of wildlife habitat to development and consumption of bushmeat necessitated by poverty or due to cultural preference increases opportunities for cross-species jumps. Global warming may also increase the geographic range of phlebotomus insects like mosquitoes and ticks that serve as reservoirs and vectors for infectious agents [7]. Given that there

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_2,

are more than 50,000 vertebrate species, if we assume an average of 20 endemic viruses per vertebrate species, the potential reservoir of vertebrate viruses can be estimated at one million. Although it is unlikely that all of them can be transmitted to humans and cause disease, it is sobering to consider the challenge of detecting and responding even to 1 % of them (10,000 novel viruses).

In the aftermath of the fall of the Twin Towers on September 11, 2001, in New York City, and the anthrax attacks that followed, many western governments became concerned about bioterrorism. Early investments in surveillance for biological weapons gave way to surveillance for emerging infections when sober reflection led to recognition that the latter were more likely threats to public health. However, advances in synthetic biology over the past decade have been so dramatic that clinicians and public health practitioners must again consider the possibility that high-threat known and novel pathogens may arise through deliberate genomic manipulation either in the form of bioweaponeering, inadvertent release of high-threat human pathogens, or legitimate gain-of-function research, whereby low-risk agents become high risk. The scientific and larger communities are currently grappling with the implications of gain-of-function research in the context of experiments designed to understand virulence and transmission of H5N1 (avian) influenza viruses [8–13].

2 Impact of Mechanisms of Pathogenesis on Viral Diagnostics

Establishing a causative link between a virus and disease can be straightforward or complex. In some instances, the virus responsible for the induction of disease is present at a site of organ pathology, and there is precedent for the same or a related virus causing similar disease. A classic example is herpes encephalitis where the detection of herpesvirus sequences by polymerase chain reaction (PCR) in the cerebrospinal fluid (CSF) of a patient with encephalitis provides a clear diagnosis and suggests a specific therapeutic intervention [14]. PCR alone can be inadequate. In West Nile encephalitis, PCR of CSF is less reliable than assays of CSF for IgM antibodies to the virus [15, 16]. In some instances, the footprints of an agent cannot be found in or adjacent to the affected organ but can be detected in other compartments. PCR detection of enterovirus, for example, in the feces of a patient with aseptic meningitis, provides strong evidence of enteroviral meningitis [17]. Despite these examples of success, an etiological agent is not identified by any test in up to 70 % of what is presumed to be viral encephalitis. Similar figures pertain in viral pneumonias.

There are several explanations for surveillance and diagnostic failure. In some instances, the problem is simply lack of access to the appropriate sample. Infectious agents that do not shed into saliva, nasopharyngeal secretions, blood, urine, CSF, or feces may be detected in tissue biopsies. Alternatively, pathogenetic mechanisms may be indirect, or consequences of infection may be delayed obscuring the relationship between the causative agent and the disease.

The most straightforward mechanisms for viral pathogenesis are cellular damage due to replication and lysis, apoptosis, autophagy, or immune responses to proteins expressed on infected cells. However, viruses can also induce systemic damage through cytokine storm resulting in shock, acute respiratory distress, and/or organ failure, cause immunosuppression resulting in opportunistic infection, or break tolerance for self, resulting in autoimmune disease. Infection can be cryptic, impairing differentiated cell functions like hormone secretion, inducing neoplasia, or impairing developmental programs that may not become apparent for months or years. In summary, the challenge in viral diagnostics is to develop strategies for not only detecting footprints of the agent itself in target tissues but also enduring shadows of infection in accessible compartments.

3 Culture

Once the mainstay of viral diagnostics, culture now receives less emphasis in clinical microbiology, chiefly because assays require days rather than hours; thus, information obtained is unlikely to directly impact patient management. Culture nonetheless continues to play an important role in public health as well as basic and clinical research because it enables insights into pathogenesis and the efficacy of drugs, antibodies, and vaccines. The presence of virus can be detected by changes in cell morphology at the level of light microscopy including lysis, rounding, and syncytia formation—fusion of cells as revealed by an increase in size and the presence of more than one nucleus—visualization of pathognomonic structures by electron microscopy; or viral proteins that bind antibodies as revealed through immunohistochemistry or immunofluorescent microscopy. A wide range of cell lines has been established for culturing viruses. Some are immortalized; others are primary cultures that can only be propagated for a few generations. Although some viruses can grow in many cell types, others have fastidious requirements. Some viruses have never been cultured despite implication in disease. In some instances, propagation failure may be overcome by adaptation with serial passaging in the presence of a second, permissive type of cell (cocultivation), the use of antibodies or RNAi to suppress innate immune responses, or cells obtained from genetically modified animals. However, serial passaging can lead to adaptation, including changes in virulence (the capacity of the virus to cause disease) or tropism (the cells and organs the virus

can infect). Indeed, serial passage may be utilized to develop less virulent strains that can be used as vaccines. A potential confound in characterizing samples that may contain more than one virus is that the culture environment can select for the agent that is more fit to replicate—that may or may not be the agent of interest. In an attempt to address this potential confound as well as to propagate viruses that fail to grow in simple cultures, investigators have developed cultures that include more than one cell type. In some instances these complex cultures are designed to replicate the architecture of an organ like the respiratory tract. An alternative to culture in cells is animal inoculation. An advantage of animal inoculation is that the presence of a wide range of cell types is associated with expression of a wide range of receptors that may allow virus entry. Most investigators use suckling mice because their innate immune responses are immature. Others use mice genetically modified to abrogate immune responses.

4 Molecular Assays

Nucleic acid tests (NATs) have largely replaced culture in viral diagnostics due to advantages in cost, speed, and ease of use. Common NAT platforms include polymerase chain reaction (PCR), in situ hybridization, microarray, and high-throughput sequencing.

4.1 Singleplex Assays

These assays, designed to detect individual viruses, are the most common NATs employed in clinical microbiology. They take several forms, but quantitative real-time PCR, wherein nucleic acid replication results in either cleavage or release of a fluorescence-labeled probe oligonucleotide that binds to a sequence region between the regular forward and reverse primers, is the most popular. The continuous ("real time") reading of the reporter fluorescence signal affords these systems with unprecedented dynamic range and low false-negative rate. The required equipment, thermal cycler with fluorescence detector and (laptop) computer for data analysis, is cost competitive, and rugged battery-powered instruments are available for field use. Loop-mediated isothermal amplification (LAMP) tests do not require programmable thermal cyclers [18–20]. In the laboratory, LAMP products are detected in conventional dye-stained agarose gels, but in field applications the estimation of product accumulation through turbidity or dye reading by the naked eye is also possible [21]. The sensitivity of all such assays is highest when primers and/or probe sequences perfectly match the selected single genetic target. Fluorescence-based TaqMan or molecular beacon assays, for example, typically have detection limits of <10 molecules per assay. Although ideal for detecting and quantitating a specific known agent [22, 23], these assays may nonetheless fail with templates of variable sequence composition, especially if this affects the region of reporter molecule binding. This can be particularly challenging in the diagnosis of RNA virus infections as RNA viruses are characterized by high mutation rates and include species with high genetic strain variability. In comparison, consensus PCR assays are less likely to be confounded by sequence divergence but are also less sensitive than the specific PCR assays. Nested PCR tests that can employ consensus or specific primers in two sequential amplification reactions with either one (hemi-nested) or two (fully nested) primers located 3′ with respect to the first primer set may both accommodate sequence variation and be more sensitive than fluorescent or beacon-based singleplex assays. However, whereas in quantitative fluorescence- or beacon-based real-time assays reporter readings are taken indirectly without opening the reaction vessels ("closed system"), nested PCR systems bear a high risk of contamination because of the transfer of (amplified) material from the first to the second, nested reaction [24, 25], even if scrupulous experimental hygiene is observed. Recently, automated (closed) systems have been developed that allow contamination-free transfer between separate reaction compartments of single-use cartridges that may present new opportunities for nested assay design.

4.2 Multiplex Assays

As signs and symptoms of disease are rarely pathognomonic of a single agent, particularly early in the course of an illness, many microbial candidates must be entertained simultaneously. Multiplex NATs provide such an opportunity. The number of candidates considered may range from 10 to 50 with multiplex PCR systems to thousands with microarray platforms to the entire tree of life with unbiased high-throughput sequencing approaches. However, genetic targets compete for assay components in multiplex assays, and thus they may be less sensitive than a singleplex assay. In compensation, multiplex assays provide the advantage of consistently interrogating each sample for a wide range of agents without the selection bias introduced by singleplex testing. This comprehensive coverage is particularly important for surveillance and applications.

4.2.1 Multiplex PCR

Multiplex PCR assays are more difficult to establish than singleplex assays because primer sets may differ in optimal reaction conditions (e.g., annealing temperature or magnesium concentration). Furthermore, complex primer mixtures are more likely to result in primer-primer interactions that reduce assay sensitivity and/or specificity. To advance multiplex

primer design, we developed Greene SCPrimer, a software program that automates consensus primer design over a multiple sequence alignment with customizable primer length, melting temperature, and degree of degeneracy [26].

Gel-based multiplex PCR assays are limited by size differentiation of the amplification products in agarose gels and the concomitant requirement for short product sizes (approx. 90–250 base pairs) to ensure high sensitivity and fidelity [24, 25]. Multiplexing can be achieved in fluorescence- or beacon-based real-time assays to the degree by which different fluorescent reporter emission peaks can be unequivocally separated. At present up to five fluorescent reporter dyes are detected simultaneously, although multiplexing may be increased to some extent by double-labeling strategies and/or melting curve analyses. "Sloppy Molecular Beacons" address this limitation in part by binding to related targets at different melting temperatures [27]; however, they are not suited to detect targets that differ by more than a few nucleotides.

The Bio-Plex (or Luminex) platform employs flow cytometry to detect multiple PCR amplification products bound to matching oligonucleotides that are attached to differently colored fluorescent beads [28, 29]. By combining multiplex PCR amplification systems with various protocols for direct or indirect (tag-mediated) bead hybridization of the products, assay panels have been developed that permit detection of up to approx. 20 genetic targets simultaneously [30–32]; the most commonly used respiratory panels range from 9 to 20 plex [33–37]. Like real-time PCR, these assays rely for assay specificity on a three-oligonucleotide interaction with the target sequence. They are thereby limited in their tolerance for mutated or variant templates when compared to mass spectroscopy (MS)-coupled platforms that require only two oligonucleotide-binding sites, such as MassTag PCR or the Ibis T5000 system.

Two platforms are established that combine PCR with MS for sensitive, simultaneous detection of large numbers of targets. The Ibis T5000 system uses matrix-assisted laser desorption/ionization (MALDI) MS to directly determine the molecular weights of the generated PCR products and to compare them for identification with a database of known or predicted product weights [38–40]. MassTag PCR uses atmospheric pressure chemical ionization (APCI) MS to detect molecular weight reporter tags attached via a photo-cleavable linkage to PCR primers [41]. Whereas the Ibis system or the subsequent electrospray ionization (ESI)-based Plex-ID system requires analytical MS to determine the exact weight of the PCR products and thus depends on advanced mass spectroscopic data analysis, MassTag PCR can be performed using smaller instruments and does not require sophisticated analyses because it only records the known masses of the 40–80 reporter tags used in a given multiplex test. The Ibis system may be able to alert of variants of known organisms via a divergent PCR product weight, but like MassTag PCR, it too requires subsequent sequencing of the product for detailed characterization. A wide variety of syndrome-specific MassTag PCR panels have been developed and applied to the detection of viruses, bacteria, fungi, and parasites associated with acute respiratory diseases, diarrheas, tick-borne diseases, encephalitides/meningitides, and hemorrhagic fevers [41–50].

Although multiplex PCR methods are designed to detect known agents, they can nonetheless facilitate pathogen discovery. MassTag PCR requires only two differently tagged primers per target that may include degenerate positions to address genetic variation of larger taxonomic groups such as a whole species or genus, and its use to investigate influenza-like illness in New York State revealed the presence of a novel rhinovirus clade by the employed conserved enterovirus/rhinovirus primer set [42]. This discovery enabled follow-up studies across the globe wherein this third species of rhinovirus, rhinovirus C, was implicated not only in influenza-like illnesses but also in asthma, pediatric pneumonia, and otitis media [44, 51–63].

4.2.2 Microarray Assays

Whereas multiplex PCR systems support rapid high-throughput diagnosis with highest sensitivity for a limited number of agents, microarray-based systems provide detection of all known pathogens for which sequence information is available, but at the expense of some degree of sensitivity. Modern printing technologies can generate high-quality arrays with several million features, a printing density that enables not only detection of a wide range of infectious agents but also discrimination of medically important types or subtypes. Examples of the latter application include respiratory virus resequencing arrays that identify the different influenza virus HA and NA subtypes [64–68].

The discovery array platforms currently in use are the GreeneChip and the Virochip [69, 70]. The panmicrobial version of the GreeneChip, addressing viruses and in addition pathogenic bacteria, fungi, and parasites, led to the recognition of *Plasmodium falciparum* infection in a case of unexplained fatal hemorrhagic fever during the 2004–2005 Marburg virus outbreak in Angola [70]. A variant of the GreeneChip facilitated recently the implication of Reston Ebola virus in a respiratory disease outbreak on pig farms in the Philippines [71]. In 2003, the Virochip supported the characterization of the SARS coronavirus and was also used subsequently to diagnose parainfluenza virus 4 and infection with a human metapneumovirus variant in cases of acute respiratory disease [69, 72, 73].

Both platforms rely on random PCR strategies to amplify and label nucleic acids for detection. In comparison to multiplex consensus PCR methods employed with some targeted array applications or resequencing arrays, this limits

sensitivity especially with complex sample types. In tissue specimens, for example, the sensitivity may not exceed 10^6–10^7 copies per assay because host and pathogen nucleic acids compete for PCR reagents. Thus, these platforms have been more successful with samples containing comparatively low levels of competing nucleic acid, such as virus culture supernatant, serum, respiratory specimens, spinal fluid, or urine. Improvements in sensitivity to a range of 10^3–10^4 copies per assay have been achieved with methods for host DNA digestion and/or the depletion of host ribosomal RNA (rRNA) prior to amplification through subtraction or use of random primers selected for lack of complementarity to rRNA [74].

In current array platforms, virus detection is achieved via fluorescent reporter systems—either through direct incorporation of fluorescent nucleotides into the PCR product that is bound to the array or with a "sandwich approach" whereby fluorescent-branched chains of DNA are added to the product after it is bound to the array [75, 76]. However, new arrays are in development that will detect viral sequences through changes in electrical conductance. Such platforms would enhance portability by eliminating the need for fluorescent scanners. They may also increase sensitivity and reduce costs by eliminating the need for PCR amplification.

5 High-Throughput Sequencing

High-throughput sequencing has transformed microbiology by enabling discovery as well as diagnostics. Unlike PCR or array methods where investigators must choose the pathogens to be considered or are limited by known sequence information, high-throughput sequencing has the potential to simultaneously detect not only all viruses but also bacteria, fungi, and parasites. Although the technology is presently limited to specialized laboratories, sequencing is becoming increasingly accessible as instruments become smaller, methods become more user friendly, and costs decrease. Over the past 10 years, the cost has decreased 10,000-fold from $5,000 per 1,000 nucleotides in 2001 to $0.5 per 1,000 nucleotides in 2012 [77]. Even more impressive perhaps is the time required to generate sequence data. Projects that required weeks only a decade ago are now completed in hours [78].

Current sequencing platforms analyze libraries of amplified nucleic acids. However, some platforms in development will have the capacity to directly sequence nucleic acid. Irrespective of the platform, raw sequence reads are filtered for quality and redundance before assembly into contiguous sequence streams. These streams, known as contigs, as well as reads that cannot be assembled, are aligned to databases using bioinformatic algorithms that examine homology at the nucleotide and deduced amino acid levels in all six potential reading frames [79]. The alignments allow identification of known and novel agents, as well as detection of genetic features that may be associated with drug or vaccine resistance, or provide insight into provenance and evolution.

6 Proof of Causation

Finding the nucleic acid footprint of a virus is frequently only the first stage in implicating it in disease. There is no functional equivalent in viruses to the pathogenicity islands found in bacteria, wherein specific sequences acquired through horizontal gene transfer confer specific pathogenic properties. The best established criteria for proof of causation in infectious disease were developed in the late 1800s by Koch and Loeffler [80]. Known as Koch's postulates they stipulate that an agent be present in every case of the disease, be specific for the disease, and be sufficient to reproduce the disease after culture and inoculation into a naive host. In the 1930s, Rivers suggested that the development of specific immunity to an agent following the appearance of disease could be used in demonstrating causation [81]. Adapting the original postulates to the molecular era, Fredricks and Relman later established that microbial sequences may be used as surrogates for culturing the actual organism [82]. Lipkin and colleagues recently established levels of confidence in the strength of association between an agent and a disease that considers viral burden and distribution, specific immunity, and prevention or amelioration of disease with use of specific drugs or vaccines [12]. Given the sensitivity of molecular methods, it is imperative that physicians and researchers consider the biological plausibility of an assay result and, where feasible, pursue confirmation with an independent assay, particularly when engaged in pathogen discovery.

7 Future Perspectives

NATs are rapidly replacing classical culture methods in clinical microbiology laboratories. Although some NATs, such as microarrays and high-throughput sequencing, still require substantial investment in equipment and personnel, diagnostic platforms are becoming more accessible and less expensive through miniaturization and improvements in methods for bioinformatic analysis. Systems using handheld microarrays, for example, are in development that will ultimately enable diagnosis at the bedside or in the field. Benchtop sequencers are also in production. It is inevitable that as sequencing costs continue to decrease, clinicians will seek information concerning not only the presence of a single candidate organism but also the predisposition of the host to disease based on genetic factors and coinfections with other microflora. These improvements will bring dramatic benefits to medicine and public health.

Immunological Detection and Characterization

3

Robert L. Atmar

1 Introduction

Immunological methods are valuable strategies for the diagnosis and characterization of viral infections. These methods rely on antigen–antibody interactions, and they can be adapted to allow direct detection of the virus (antigen detection) or to identify the host's immune response to the virus infection (antibody detection). The methods are also used to identify and characterize virus isolates following in vitro or in vivo propagation. Although molecular detection is often more sensitive than antigen detection, immunological methods still have an important role in the study of the epidemiology, pathology, and assessment of clinical disease associated with viral infection.

The development of simple, rapid, and often relatively inexpensive antigen detection test kits has revolutionized both clinical care and laboratory practice. An understanding of various detection methods is increasingly important in the design and interpretation of epidemiologic studies. The vast array of laboratory tests now permits enhanced detection of viral antigens, although the clarification of the classic issue of "causation" of disease remains blurred.

The significance of detection or lack of detection of a virus or viral antigen remains difficult to interpret. Isolation of a virus from a normally sterile site, such as tissue, cerebrospinal fluid (CSF), or blood, is generally highly significant and usually establishes the etiology of the infection. The identification of certain viruses, such as influenza or respiratory syncytial virus (RSV) in respiratory specimens, also is diagnostic because an asymptomatic carrier state has not been shown to exist. However, prolonged and generally asymptomatic excretion or shedding of other viruses can make the determination of the effect of a particular virus on the disease process very difficult. Viruses such as cytomegalovirus (CMV), adenoviruses, and enteroviruses are shed in disease states but also may be shed asymptomatically for prolonged periods of apparent good health. An additional complicating factor is the differentiation of primary infection from reactivation of disease, a problem common to the study of infections with viruses such as herpes simplex (HSV) or CMV, especially in immunocompromised hosts such as transplant recipients or patients infected with HIV. Interpretation of laboratory results in such situations requires a thorough understanding of the pathogenesis and epidemiology of the virus.

Failure to detect a virus or viral antigen does not necessarily mean that the virus was not present previously or did not cause disease. Although failure to detect a virus may be a result of inappropriate or inadequate specimen collection and handling, it may also be a function of the time course of the disease, the age or antibody status of the patient, and the technical resources available to detect or cultivate the virus. The investigator today has many options to diagnose the presence or past presence of a viral infection, but careful epidemiologic and laboratory studies are still required to ultimately link the viral agent to a specific disease process.

2 Historical Background

The recognition of immune-mediated virus neutralization dates back to the late 1800s when Sternberg extended observations of other scientists of the time and described the neutralization of vaccinia infectivity using serum from a recently vaccinated calf [1]. It was another several decades before diagnostic viral serological methods were developed, including complement fixation in the 1930s and hemagglutination inhibition in the 1940s [2]. Immunofluorescent methods for detecting virus antigen were developed in the 1950s by labeling virus-specific antibodies with a fluorescent reporter such as fluorescein isothiocyanate [3]. A little more than one decade after the initial description in 1959 of the

radioimmunoassay [4] for detecting human plasma insulin, the method was adapted for virus antigen detection [5]. The radioisotope used as a reporter was replaced later during the 1970s with enzymes such as alkaline phosphatase and horseradish peroxidase that allowed colorimetric detection [6]. The method was also readily modified (see below) to allow detection of antibody. A further modification of immunoassay detection methods followed with the use of substrates that allowed detection of the antigen–antibody interaction via measurement of a chemiluminescent reaction.

The diagnostic procedures used for evaluation of specific viral infections are presented in individual chapters of this book. However, certain common aspects of immunological methods used for virus diagnosis are important for the design and implementation of epidemiologic studies. These general issues are addressed below.

3 Principles of Antigen–Antibody Interactions

An antigen is defined as a substance capable of stimulating an immune response when introduced into the body (e.g., of an immunized animal). When the immune response is the production of antibody, the generated antigen-specific antibody can bind directly to the antigen. The portion of the antigen recognized by and specifically interacting with the antibody molecule is called an epitope. An antigen may have more than one epitope. When this occurs the epitopes either may be distinct molecular structures (and thus distinct epitopes) or they may be the same molecular structure (the same epitope) repeated many times. The portion of the antibody interacting with the antigen is called a paratope. The ability of the epitope and paratope to bind to each other is the basis of the specificity of an antigen–antibody interaction.

The binding of antibody to antigen is thought to be the result of electrostatic and van der Waals bonding over short distances, with the kinetics of the reaction following the law of mass action. The law can be represented mathematically as follows:

$$K_d = [Ag \cdot Ag] / [Ag]$$

where K_d is the dissociation constant, [Ag · Ag] is the concentration of the antigen–antibody complex, [Ag] is the antigen concentration, and [Ab] is the antibody concentration.

From this law, the formation of antigen–antibody complexes reaches equilibrium, and the amount of complex formed is proportional to the concentration of the antibody and antigen present. The binding constant is a measure of the strength of interaction between one epitope and one paratope and is also referred to as the affinity of the antibody. The higher the affinity of a paratope for a corresponding epitope, the greater the strength of binding and the lower the K_d value.

A related concept is antibody avidity, which is a measure of the overall binding strength of an antibody to the corresponding antigen. Antibody avidity is correlated to its affinity, but it is also affected by the number (or valency) of interactions between the antibody and antigen. For IgG antibody, the valency is up to two. Since the antigen–antibody interaction is in equilibrium, the presence of multiple binding interactions can maintain the antigen–antibody complex once formed during periods of dissociation between an epitope and paratope.

There are many factors that affect the interaction between an antigen and antibody and the ability to one or the other in a diagnostic assay. These include the temperature of the reaction conditions and the ionic strength of the solutions used in the assay. As noted above, antibody affinity and concentration are particularly important when developing an antigen detection assay. The relative concentration of antigen-specific antibody is lowest in postinfection sera. It can be increased through hyperimmunization with the antigen to generate polyclonal antisera, and the relative concentration can be increased further by affinity purification of the antibody. The highest relative concentrations are reached through the generation of monoclonal antibodies, and selection of high-affinity monoclonal antibodies for use in diagnostic assays is now widely used in the development of antigen detection assays [7].

Another factor that can influence the assay development is nonspecific interactions between the antibody and other substances in the reaction mix (e.g., attachment to the reaction vessel, other microbial antigens). Although these are generally low-affinity interactions, the concentrations of the competing substances can be high enough to affect the readout of the assay. Many of the low-affinity interactions can be removed by washing steps, use of blocking reagents and use of lower concentrations of antibody, but each antibody used in a diagnostic assay should be evaluated for the presence of these nonspecific reactions. In addition, the use of appropriate controls can identify problems with assay performance [8].

4 Specimen Collection

The appropriate collection of specimens is of the utmost importance for the successful identification of viruses in clinical samples. The source of the specimen, the timing of collection in relation to onset of symptoms, the rapidity and method of delivery to the laboratory, and the clinical and epidemiologic data provided to the laboratory all are important variables that relate to the likelihood of successful identification of a viral pathogen. Knowledge of the restrictions of the diagnostic assay to be used is also important; many antigen detection assays are only approved for use when applied to a limited number of clinical sample types. For example, some influenza antigen assays should only be used with nasal swabs while other assays are approved for detection

of influenza in a broad array of respiratory samples types, including nasal aspirate, nasopharyngeal swab, throat swab, and bronchoalveolar lavage [9].

4.1 Source

The clinical syndrome caused by a virus and its pathogenesis of infection determine the specimen(s) that is most appropriate for virus identification. Viruses that primarily cause disease at a mucosal surface or cause vesicular skin lesions generally can be identified in specimens taken from those sites. However, viruses causing generalized or congenital disease or causing symptoms in an internal organ (e.g., central nervous system) often can be identified in specimens taken from multiple different sites. Viruses that cause respiratory tract disease such as influenza viruses, RSV, and rhinoviruses are most frequently identified in samples of respiratory secretions; viruses that cause gastroenteritis, such as rotaviruses, caliciviruses, and astroviruses, are identified in fecal specimens; and viruses that cause generalized or congenital diseases, such as measles, CMV, and mumps, are identified from respiratory secretions, urine, and blood. However, antigen detection methods may not be available for some of these different sample types. Furthermore, some samples may be more likely to yield a positive sample than others (e.g., fecal specimen vs. rectal swab for rotavirus and bronchoalveolar lavage for respiratory viruses in immunocompromised patients) [10, 11]. The reader is referred to specific chapters for information on the ideal specimen type for specific viruses.

4.2 Timing of Collection

Specimens to be used for virus identification should be obtained early in the course of the illness. For many viral infections, viral shedding begins before the onset of symptoms, peaks during the illness, and disappears around the time that symptoms resolve. There are notable exceptions; enteroviruses and adenoviruses may be shed in the feces for weeks to months, and congenitally acquired CMV is shed in the urine for prolonged periods. Some factors that influence the likelihood of successful virus identification include the type of virus, the site from which the sample was obtained, the test being used, the age of the patient being sampled (e.g., younger children shed influenza viruses longer than adults), and the immune competence of the patient (e.g., immunocompromised hosts shed HSV from genital lesions longer than do immunocompetent adults) [12].

A serum sample should be collected early in the course of illness for potential use in identification of a viral infection. For some viral infections, the identification of IgM antibody or the presence of high titers of antibody is sufficient to confirm a virus infection. A second, or convalescent, serum sample should be obtained 2–4 weeks later to look for a rise in virus-specific antibody titer.

4.3 Clinical Data

Clinical information may be useful in helping one choose the types of diagnostic assays that should be performed on a clinical specimen. The time of year and age of the patient are examples of epidemiologic information that will influence the likelihood of identifying certain viral infections. For example, rotavirus infections occur seasonally and are more common in young children, while norovirus infections often occur in outbreaks and are more common in older individuals. Enteroviruses are the most common cause of viral meningitis and tend to occur seasonally in epidemics, whereas HSV type 1 is the most common cause of sporadic viral meningoencephalitis. Knowledge of the pertinent epidemiologic information will permit the use of appropriate enzyme immunoassays (EIAs), immunofluorescence assays, and other diagnostic methods to identify a potential viral pathogen in the clinical specimen.

5 Detection of Viral Antigens

The detection of viruses or viral components is the foundation of diagnostic virology. Although the detection of antibodies to specific viral proteins remains an important element of viral epidemiology, the ability to isolate and/or characterize viral pathogens initially is critically important. The performance of any diagnostic test in a reproducible, sensitive, and specific manner is crucial in the study of viral diseases. Combinations of various techniques, including centrifugation-enhanced tissue culture, antibody–antigen detection, and detection of viral nucleic acid, can be used to supplement classic tissue culture methods.

Methods for the detection of virus-specific antigens have allowed rapid identification of a wide variety of viruses (Table 3.1). Specific monoclonal antibodies conjugated to biochemical markers may provide high levels of sensitivity and specificity [13]. The key to the success of the assays outlined below is the use of reliable virus-specific antibody. Molecular biological techniques that permit the production of relatively large quantities of avid monoclonal antibodies have facilitated viral antigen detection.

5.1 Latex Agglutination Techniques

Viral-specific antibodies linked to latex beads can be used to detect viral antigens in a clinical sample. The presence of viral antigen in the sample results in cross-linking of the beads that can be identified by visual inspection. This

strategy has most commonly been applied to detection of viral enteric pathogens like rotavirus and adenovirus, and it has the advantage of low complexity and providing rapid results (in less than 15 min). However, a major disadvantage is its relatively lower sensitivity (<70 %) compared to other antigen detection methods (>80–90 %) or culture [14, 15].

5.2 Immunofluorescence Techniques

Viral-specific antibodies conjugated to a fluorescein-labeled moiety have been used to identify viral pathogens since the late 1950s [16]. Immunofluorescence (IF) assays are widely used for the rapid detection of viruses in clinical samples and for definitive identification of a virus in tissue culture that may allow viral antigens to be sought before or after cytopathic effect (CPE) is evident. In the direct IF test (Fig. 3.1), the virus-specific antibody labeled with a fluorescent dye such as fluorescein isothiocyanate or, less commonly, rhodamine isothiocyanate is allowed to react for a short time with cells obtained from a clinical specimen or from an inoculated cell culture. After allowing time for an antigen–antibody reaction to occur, the slides are washed and examined microscopically for direct visualization of the fluorescence of the infected cells in the specimen. In the indirect IF test, two different antisera are used: an unlabeled virus-specific antibody capable of binding to a specific viral antigen is used first and is followed by a fluorescein-labeled, species-specific antibody directed against the species in which the first antibody was raised. If a reaction occurs between the first antiserum and the clinical specimen, the second antibody will bind to the antigen–antibody complex and fluorescence of the virus-infected cells can be detected.

The two IF methods each have advantages and disadvantages. Both tests allow an assessment of the quality of the sample in that samples that do not contain cells are poor quality and cannot be interpreted. The indirect IF is usually more sensitive because several fluorescein-conjugated molecules potentially are able to bind to each virus-specific antibody molecule attached to the viral antigen, resulting in amplification of the fluorescence. The direct IF test may offer enhanced specificity due to lower background fluorescence. The indirect IF method requires more reagents and more time to perform. Whether monoclonal or polyclonal antisera are optimal for use in either test method is still debated. The use of monoclonal antibodies generally

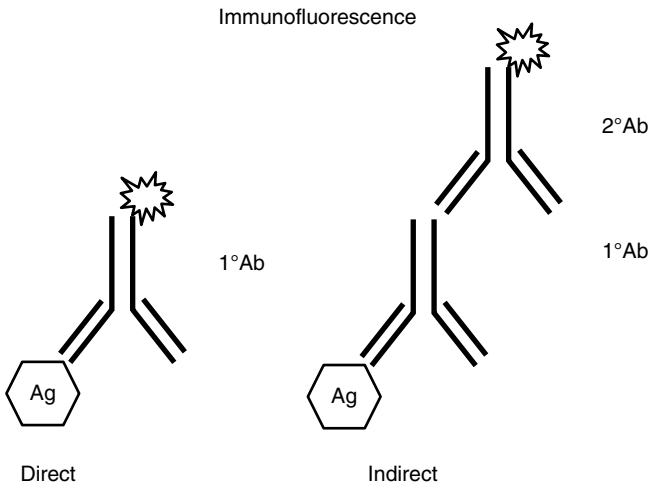

Fig. 3.1 Schematic of immunofluorescence. *Ag* antigen, *Ab* antibody

provides the lowest background but may be limited by the high specificity of these reactions. This problem can usually be overcome by using a pool of monoclonal antibodies.

The use of IF for the direct detection of viral antigens in clinical samples and the confirmation of viral growth in cell cultures has increased with the widespread commercial availability of relatively inexpensive antibodies specific for many of the herpesviruses and respiratory viruses. The IF method has the advantage of allowing rapid viral diagnosis in properly obtained specimens [17–20]. When working with large numbers of clinical specimens, the time required for sample collection, processing, and interpretation of the stained slide becomes substantial. The enthusiasm for this technique in clinical specimens has varied due to the time and degree of technical competence required to read such samples, the availability of other, the less labor-intensive antigen detection methods, and the frequency of false-negative results obtained because of the dependence of the assay on having a high degree of viral antigen expression in the clinical sample. Nevertheless, the appropriate use of this test can result in reliable and sensitive rapid diagnosis from clinical samples. The use of IF for the detection of RSV in pediatric patients by an experienced laboratory can detect up to 90–95 % of the samples positive by culture [21, 22], although many laboratories report rates of 60–80 % [23–25].

The combination of IF techniques with cell culture has increased the sensitivity of cell culture while providing a positive result in a shorter time period. With the use of centrifugation or other methods of enhancement of viral replication and pools of varying antibodies, cell cultures can be incubated between 1 and 3 days and then stained for a variety of virus antigens using indirect or direct IF methods. For some viruses, such as CMV or VZV, specific antibodies directed toward early or nonstructural antigens permit the rapid diagnosis within 48 h, well before CPE would be visualized under routine cell culture conditions [26, 27]. Disadvantages of IF techniques include the need for fluorescent microscopes, difficulty in the interpretation of clinical specimens that have a high level of nonspecific fluorescence, and the fact that prepared slides are not generally stable over periods longer than 1 month [20].

5.3 Immunocytochemical Staining

Immunocytochemical staining is a sensitive and specific method for detecting viral antigens with labeled antibodies. This technique, pioneered by Coons [28] in 1942, has been used to study the structure and function of a variety of viral proteins and continues to be utilized in both the research and clinical laboratories. It has been used both for detection of viral infection of a monolayer prior to the appearance of cytopathic effect and in rapid screening assays for drug resistance [29, 30]. This method utilizes reagents similar to those used in the IF assay except that the fluorescent marker is replaced by an enzyme. When enzyme-specific substrates are provided, a colored precipitate forms at the site of reaction. Typical enzymes used to detect viral antigens include alkaline phosphatase and horseradish peroxidase. A major drawback of alkaline phosphatase-based reagents is their lack of stability; a major drawback of peroxidase as a marker is the fact that this enzyme is endogenous to some mammalian tissue, thus requiring either elimination of the endogenous enzyme or use of a nonmammalian enzyme, glucose oxidase [31].

Advantages of immunoenzymatic staining compared to IF staining include the virtual permanence of stained preparations and the ability to view slides using an ordinary light microscope. Both direct and indirect staining with immunoperoxidase and other enzymes have been utilized to detect many viruses. Refinements have been developed that allow even greater sensitivity than that seen with indirect staining without the need to conjugate enzyme to an antibody. For example, a modification of these techniques has been a four-layer sandwich technique involving (1) virus-specific antibody raised in species X, (2) an excess amount of a second antibody raised against the species X antibody, (3) a complex of peroxidase and antiperoxidase antibody (raised in species X), and (4) reducing substrate for peroxidase [32]. The second antibody acts as a bridge, binding to both the virus and the antiperoxidase antibody. Similar unlabeled assay methods have been described for alkaline phosphatase–antialkaline phosphatase and glucose oxidase–antiglucose oxidase [33, 34]. The sensitivity of antigen detection has been further improved by more recently developed signal amplification methods, including avidin–biotin complexes (binding of 4 biotins per streptavidin), chain polymer-conjugated technology where multiple enzyme and antibody molecules are

attached to an inert molecule such as dextran, and the use of tyramine conjugates as substrates for horseradish peroxidase that allow signal amplication as much as 100-fold [35].

5.4 Radioimmunoassay

Radioimmunoassay (RIA) techniques have been valuable for the detection of many compounds in laboratories and clinical medicine. Initially, the technique was developed for the determination of endogenous human plasma insulin levels [4]. The first important use of RIA in diagnostic virology was for the detection of hepatitis B surface antigen [5]. The original RIA described by Yalow and Berson [36] was a competitive binding assay in which the competition between an unlabeled antigen and a radiolabeled antigen reacting with a limited amount of antibody over a short period of time was monitored. Variations in RIA methods have been developed, with the most common being the direct and indirect solid-phase RIA. In the direct solid-phase RIA, antigen or antibody are captured on a solid support and detected by radiolabeled (usually ^{125}I) antibody or antigen, respectively. The amount of signal increases proportionally to the amount of antigen or antibody present in the sample. In indirect assays, the capture of antigen or antibody to the solid phase prevents the binding of labeled antibody or antigen, respectively, so that the amount of signal detected is inversely proportional to the amount of antigen or antibody present. RIA methods currently are utilized mainly for the detection of antigens and antibodies of viral hepatitis [37]. The use of RIA for the detection of various hepatitis markers has demonstrated the assay's high degree of sensitivity. For the most part, RIA methods have been replaced by EIA for routine diagnostic purposes due to the complexity of the assay, the use of radioisotopes, lack of standardized commercially available reagents, and high equipment costs.

5.5 EIA

Enzyme immunoassays, or EIAs, have gained widespread acceptance in virology laboratories for the detection of a variety of viral antigens and antibodies. The assays used in this method rely on antibodies directed against a specific virus or viral antigen that are adsorbed or directly linked to polystyrene wells in microtiter plates, plastic beads, or membrane-bound material. When viral antigen is present in a specimen, it binds to the immobilized "capture" antibody and a second "detecting" antibody conjugated to an enzyme such as horseradish peroxidase or alkaline phosphatase then attaches to the antigen, forming a three-layer "sandwich" consisting of the immobilized antibody, the antigen, and the detecting antibody with enzyme attached (Fig. 3.2). A substrate

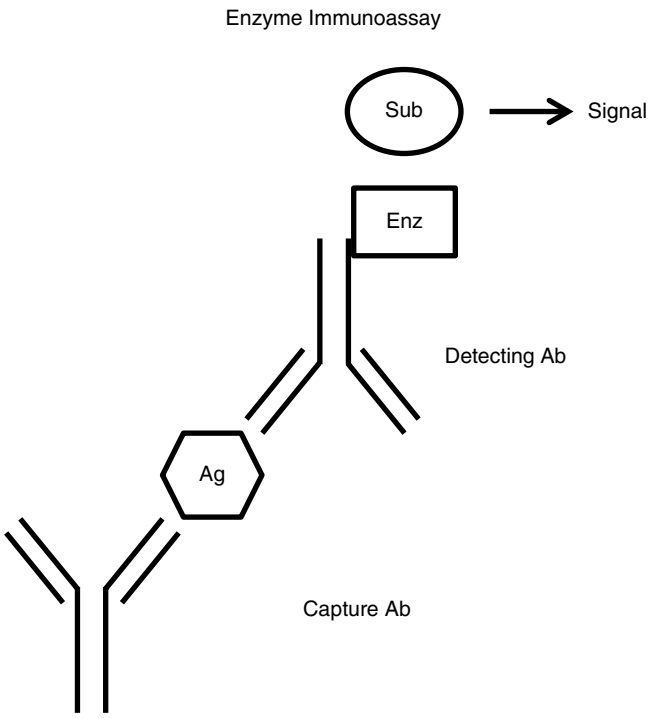

Fig. 3.2 Schematic of sandwich enzyme immunoassay. *Ag* antigen, *Ab* antibody, *Enz* enzyme, *Sub* substrate

specific for the enzyme is added and a color reaction occurs that can be monitored by spectrophotometry or by direct visualization. The test is quite simple to run, requiring only standardization of reagents and techniques such as dilution, incubation, and washing. The principles involved in EIA are similar to those involved in immunofluorescence and RIA, but the EIA test has the distinct advantages of being simple to perform, utilizing reagents that have long shelf lives, are inexpensive, and do not require sophisticated technical evaluation to determine results. Advantages of the EIA technique also include sensitivity (less than 1 ng/ml), specificity, rapidity, safety, automation potential, and low cost, particularly when many specimens require evaluation.

Variations in the methodology for EIA testing include the materials used, the procedures for incubation and detection, and the interpretation of results. Many different test kits are commercially available and in widespread clinical use for the detection of common viral pathogens such as RSV, influenza, adenovirus, HIV, norovirus, and rotavirus; EIA tests have been devised and reported for nearly all virus groups and continue to be used widely for clinical and research purposes.

5.6 Optical Immunoassay (OIA)

The OIA utilizes a virus-specific antibody coated onto a thin molecular film on a silicon wafer surface. The clinical sample

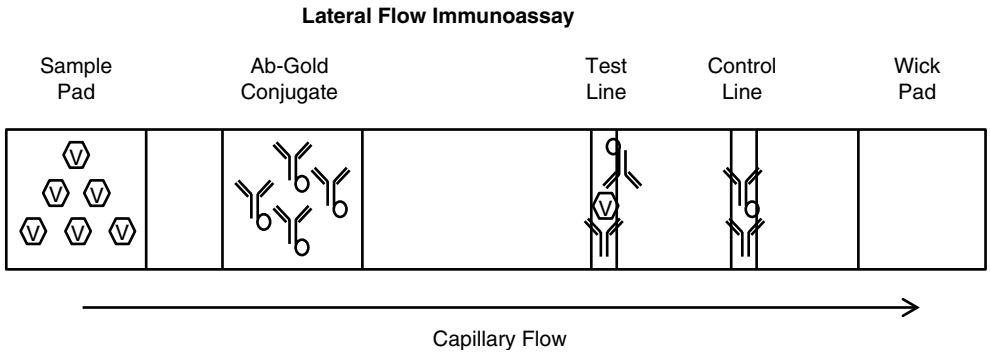

Fig. 3.3 Schematic of lateral flow immunoassay. *V* viral antigen, *Ab* antibody

is treated to extract and expose any viral antigens present and is then placed on the surface of the chip. Viral antigen is captured and the resulting antigen–antibody complex changes the optical thickness of the film on the chip. The change in the surface thickness is magnified through addition of a second virus-specific antibody conjugated to horseradish peroxidase followed by addition of a substrate such as tetramethylbenzidine (TMB). The presence of virus antigen is then detected by a change in the color of reflected light from gold to purple. Kits have been developed for influenza and respiratory syncytial virus detection [38, 39].

5.7 Lateral Flow Immunoassay

The lateral flow immunoassay, also called the immunochromatographic assay, is an immunoassay that is performed on chromatographic paper along a single axis (Fig. 3.3). The clinical sample is applied to an absorbent pad and then is drawn by capillary action through a conjugate pad. If viral antigen is present in the clinical sample, it will interact with a virus-specific antibody conjugated to a colored particle (often colloidal gold). The fluid in the sample carries the antigen–antibody complex to a reaction membrane to which another virus-specific antibody has been immobilized in a line perpendicular to the capillary flow direction. The antigen–antibody–conjugate complex is captured and can be observed as a colored line on the membrane. The sample is carried further across the reaction membrane to a control line. Antibody specific for the antibody–conjugate is immobilized along the control line, and visualization of the control line indicates that the sample migrated across the membrane and picked up the antibody–conjugate as designed. An absorbent pad is beyond the reaction pad and acts as a waste reservoir, drawing the clinical sample across the other pads by capillary action.

The simplicity of the lateral flow immunoassay design allows the use of these assays as point-of-care tests. Results can usually be obtained within 15 min of sample collection. Tests have been developed for detection of respiratory and enteric virus as well as dengue viruses [40–43].

5.8 Time-Resolved Fluoroimmunoassay (TR-FIA)

The TR-FIA is an immunoassay that replaces the reporter molecule with a lanthanide metal. When exposed to the appropriate wavelength of light, the lanthanide will fluoresce [44]. Compared to fluorescein and background autofluorescence, which have fluorescence decay times of less than five nanoseconds, the lanthanides have much longer decay times of 1,000 to 1 million nanoseconds [8]. The format of the antigen detection TR-FIA is similar to that of a sandwich EIA, where a microtiter plate is coated with a virus-specific capture antibody and is then blocked. The clinical sample and antibody conjugated to the lanthanide is added next, and after a suitable incubation period, the unbound components are removed by washing. An enhancement solution is added and the well is exposed to the appropriate wavelength of light. A fluorometer is used to measure fluorescence for 1 s, and the pattern of fluorescence allows the separation of antigen-specific signal from background fluorescence. Several different lanthanides are available for use, but europium is frequently used because of its long fluorescence decay time and the difference between its excitation wavelength (~340–360 nm) and emission wavelength (~615 nm) [8]. TR-FIA has been developed for detection of a variety of viral pathogens [45].

6 Laboratory Methods for Virus Characterization

Further characterization of a virus obtained from a clinical specimen is frequently desirable once an agent has been isolated. This can be done in a variety of ways, depending on what is known about the virus and what additional information is being sought. For example, if a previously unrecognized virus is recovered, characterization of its physicochemical as well as biological, antigenic, and genomic properties would be useful. Various immunological methods can be used for this purpose because of the general availability of immune reagents for most human viruses. Immunofluorescence,

radioimmunoassay, and enzyme immunoassay formats may be used in a fashion similar to that described for the virus detection in clinical specimens (Sect. 5). Other methods for virus identification and characterization include virus neutralization assays, hemagglutination-inhibition assays, and epitope-blocking enzyme immunoassays using monoclonal antibodies.

6.1 Neutralization Assays

Virus neutralization assays detect the loss of virus infectivity that results from the interaction of virus with specific antibody. Unknown viruses may be identified using virus-specific antisera, and antibody to a specific virus present in a serum sample can be detected or quantitated (see Sect. 7.1). The loss of infectivity can be measured in a number of ways, depending on the biological systems capable of supporting virus growth, the types of viruses being sought, and the capabilities of the laboratory performing the studies. The principal biological systems used for neutralization assays are tissue culture, embryonated chicken eggs, and adult and suckling mice [46]. Cell culture systems are used most commonly because they support the growth of a large number of viruses, are widely available, are easier to work with than the other two systems, and lack an immune system (that may influence test results). Embryonated hen's eggs and mice are used as for primary isolation. Neutralization cannot be measured for some viruses (e.g., norovirus) because their infectivity cannot be measured in currently available culture systems.

Pools of virus-specific antisera have been used to decrease the number of neutralization assays needed to serotype enteroviruses [47]. Each serum pool contains antisera to a discrete number of enteroviruses, and antiserum to a given enterovirus is present in one to three pools. Thus, the pattern of neutralization obtained from the use of only eight intersecting serum pools allows the identification of 42 different enteroviruses [48]. Methods for the production of intersecting serum pools have been published [49].

6.2 Hemagglutination and Hemagglutination-Inhibition Assays

The ability to agglutinate erythrocytes, a property shared by many viruses, can be used for the identification of some of these viruses. The differential hemagglutination of rat, human group O, and monkey erythrocytes by different adenovirus serotypes allows their separation into groups so that fewer type-specific sera need to be used in neutralization or hemagglutination-inhibition assays [50]. Type-specific antisera can be used to prevent hemagglutination (hemagglutination inhibition) and permit the identification of influenza A and B viruses, parainfluenza viruses, and adenoviruses [51].

6.3 Agar Gel Immunodiffusion

Agar gel immunodiffusion, or agar gel precipitation, has been used for the characterization of a variety of viral antigens using standard, or reference, antisera. A thin layer of agarose is made in a plate or on a slide, and small wells are cut into the agarose. The unknown antigen and known antiserum are placed in separate wells, and the proteins in the wells diffuse through the agarose. If the antiserum reacts with the virus antigen, a precipitation band appears. Though less sensitive than other methods and largely replaced by molecular assays, this method offers high specificity and is simple to perform. It has been used for the identification of orthopoxviruses, typing of influenza viruses, and subtyping of hepatitis B viruses [51–53]. It also has been used to characterize unknown sera with known virus antigens [54].

6.4 Antigenic Characterization

The antigenic differences or similarities between vaccine and wild-type strains or among virus strains that have been isolated from different geographic locations or at different times may be examined in a number of ways. The availability of monoclonal antibodies permits the examination of these relationships and may detect differences or similarities that cannot be detected by polyclonal antisera [55, 56]. These assays examine the ability of a given monoclonal antibody to interact with a particular virus strain and are performed using the same formats used for polyclonal antisera: RIA or EIA, neutralization (if antibody is neutralizing), immunoprecipitation, hemagglutination inhibition (if the virus has hemagglutination activity), and so forth.

Monoclonal antibodies also have been used to map antigenic sites on virus proteins. When a virus is grown in the presence of a monoclonal antibody that normally neutralizes it, the only progeny virus will be escape mutants, or viruses that are no longer neutralized by the antibody. Frequently, escape mutants arise after substitution of a single nucleotide, resulting in a single amino acid change, and the location of the change can be determined by sequencing the virus gene(s) encoding the viral protein(s) important in neutralization (e.g., rotavirus) [57, 58]. A less precise map of antigenic sites can be obtained through the use of a panel of monoclonal antibodies by determining whether an individual monoclonal antibody competes with other monoclones for an antigenic site and whether the antibody has activity against the escape mutants raised by a different monoclonal antibody [59].

7 Serological Diagnosis

The detection of newly developed, virus-specific antibody or the detection of an increase in titer of preexisting antibody is important in viral diagnosis and is one of the most commonly used methods in epidemiologic studies of viruses. Most primary infections or reinfections result in the production of specific antibodies. In addition, viruses such as EBV, HIV, rubella, hepatitis A and B viruses, and arboviruses are difficult to detect directly and the serological diagnosis may be the only practical means of identifying the particular agent.

The detection of specific IgM antibody may be used to suggest a recent infection in a single serum specimen. Detection of specific IgM antibody in the neonate is useful to diagnose congenital infections, because maternal IgM antibody does not cross the placenta. IgM antibody also is useful to detect acute disease in a variety of other clinical situations, including infection with CMV, rubella, hepatitis A and B, and EBV. Limitations to the use of IgM detection include the following: (1) IgM-specific antibody is not restricted to primary infection and may be seen with reactivated disease, particularly with herpesviruses such as HSV or varicella–zoster; (2) false-positive responses may occur in the presence of rheumatoid factor or false-negative results from competition by IgG antibody for binding sites on the antigen; (3) IgM antibody may persist for months to a year or more after an infection occurred; and (4) heterotypic reactivation of IgM may be found with some infections (such as CMV or EBV). For example, removal of Coombs antibody from sera is necessary for the EBV–VCA–IgM test; otherwise, false-positive results may arise. Methods useful for the detection of viral-specific IgM will be described below, but, in general, diagnosis using a single IgM sample needs to be carefully controlled to exclude the detection of IgG or other interfering substances.

Many different serological techniques have been used in the diagnosis of viral infections (Table 3.2). Factors involved in the selection of a specific antibody assay include specificity, sensitivity, speed, technical complexity, cost, and availability of reagents (Table 3.3). All antibody assays rely on the proper collection and storage of sera and, ideally, the comparison of acute and convalescent specimens collected at an interval of at least 2 weeks. The development of newer techniques, such as EIA, for antibody determination is replacing some of the older methods, such as complement fixation, but an understanding of the available methods is important prior to choosing a laboratory test to evaluate a specific question.

Table 3.2 Serological diagnosis of detected viruses

	Serological method[a]			
Virus	Neutralization	Complement fixation	Hemagglutination inhibition	Immunoassay (EIA, IF)
Adenoviruses	+	+		+
Arboviruses	+	+	+	++

Table 3.3 Comparison of serological methods used to detect viral antibodies

Method	Sensitivity[a]	Specificity	Cost	Time to Dx	Availability
Neutralization	+++	++	Expensive	>1 week	Research
Complement fixation	+	+/++	Inexpensive	<1 day	Widely available
Hemagglutination inhibition	++	++	Inexpensive	<1 day	Research/reference labs
Enzyme immunoassay	+++	++	Inexpensive	<1 day	Widely available
Immunofluorescence	++/+++	++	Moderate	<1 day	Research/reference labs
Radioimmunoassay	+++	++	Expensive	1–3 days	Research
Immunoblot (Western blot)	++/+++	+++	Expensive	<1–3 days	Research/reference labs

[a]+ relatively low, ++ moderate, +++ high

Problems specific to serodiagnosis of a viral infection include the broad cross-reactivity among some virus groups, such as the coxsackie A viruses that cross-react with antibodies to coxsackie B and echoviruses. Another serious limitation of this approach to diagnosis is the failure of some individuals, particularly young children or immunocompromised patients, to mount a detectable antibody response to a specific infection. However, serological methods remain extremely important in epidemiologic studies because results are not dependent on obtaining a specimen at the peak of illness, tests can be performed retrospectively for a variety of agents simultaneously, and large-scale studies can be conducted in a timely and cost-effective manner.

7.1 Neutralization

Serum specimens may be assayed for neutralizing antibody against a given virus by testing serial dilutions of the serum against a standard dose of the virus. The antibody titer is expressed as the highest serum dilution that neutralizes the test dose of virus. As a bioassay, neutralization assays are highly specific and quite sensitive. For many viral agents, the neutralizing antibody level is directly correlated with immunity, an important clinical and epidemiologic endpoint. Disadvantages of the assay include the time required to obtain a result and the relatively high cost, due to the labor intensity and requirement for cell culture and titered viral stocks. Neutralization assays may be carried out in a variety of systems and the endpoint measured by a number of different procedures. Different neutralization systems include plaque reduction neutralization, sometimes using complement enhancement, where the number of virus plaques in control wells are compared with the number seen in cultures inoculated with the virus–serum mixture; microneutralization, an assay performed in microtiter plates requiring small amounts of sera; and colorimetric assays. Colorimetric assays rely on markers indicating metabolic inhibition of the virus in cell cultures or on antigen–antibody reactions with antibody tagged or reacted with enzyme-linked antibodies. Colorimetric assays are generally analyzed by measurement of optical density and have the advantage of being less time-consuming and costly to set up and analyze than other assays. Colorimetric assays often are more sensitive than assays relying on inhibition of CPE [60].

The type of assay used to assess antibody is very important, particularly in the evaluation of susceptibility to vaccine-preventable or epidemic viruses such as measles or rubella, where low levels of antibody may be predictive of protection. Direct comparison of various laboratory methods used for the detection of virus-specific antibody may be important in designing studies or evaluating study results. For example, analysis of CMV antibody using neutralization by plaque reduction has shown poor correlation with CMV antibody using EIA [61]. Different neutralization methods also may give differing results, as has been shown in the analysis of antibody to RSV, where microneutralization assays appear to be more indicative of biological protection than either direct or competitive ELISA methods or complement-enhanced plaque reduction [62].

In general, measurement of neutralizing antibody is the most specific method that reflects immunity, although other tests for some viruses may be surrogate markers for this. However, neutralization tests are rather expensive since a demonstration of inhibition of viral replication in cell culture, embryonated egg, or laboratory animal (such as the suckling mouse) is required.

7.2 Complement Fixation

The complement fixation (CF) test is a relatively simple technique that may be used successfully with a large variety of viral antigens. First developed in 1909 by Wasserman and coworkers [63, 64] for the detection of syphilis antibodies, CF has been adapted to test for antibodies to many bacterial and fungal pathogens of animals and man. The CF test relies on competition between two antigen–antibody systems for a fixed amount of complement, with the result ultimately demonstrated by the lysis of erythrocytes. The serum is heated at 50 °C for 30 min to inactivate any complement that may be present. Antigen and a known amount of complement are added to dilutions of serum. The complexes formed between the initial antigen and antibody bind the available free complement, thus preventing further reaction of the complement in the second step of the assay. In the second step, a

hemolytic indicator system using red blood cells (RBCs), which have been reacted with hemolysin to sensitize them to complement, is used to detect the free complement. The RBCs are reacted with hemolysin, or antibody to the RBC, and added to the assay. Lysis of the RBCs occurs if free complement is present. Thus, the presence of hemolysis at the conclusion of the assay is indicative of the absence of specific antibody, whereas the formation of clumped RBC (often referred to as a "RBC button") indicates a positive test reaction. Antibody titers can be calculated using standard endpoint determinations. Antibodies detected by CF are primarily of the IgG class and develop during the convalescent stages of illness. The greatest application of the CF test lies in the demonstration of a rise in antibody in convalescent compared with acute sera. The CF test has been widely used for the serodiagnosis of many human viral pathogens because of its broad reactivity and effectiveness in detecting changes in antibody titers and it is often the standard against which new methods are compared. The CF test has largely been replaced in many laboratories by enzyme immunoassays, but it continues to maintain its usefulness in some circumstances because reagents are relatively inexpensive and readily available and the test is rapid, reliable, and relatively easy to perform [65]. Another advantage of this assay is that many antigens can be easily tested in the same sera samples simply by changing the antigen but keeping all other reagents and conditions the same. The CF test is also adaptable to microtiter and automated methods.

Despite the widespread use of the CF assay over time and in many epidemiologic studies, the assay has some unique problems: (1) the test relies on a cascade of interactions involving multiple biological reagents that must be carefully monitored; (2) it is relatively insensitive because high concentrations of antigen are required to produce CF complexes and the assay is unable to detect small changes in antibody concentrations or low levels of antibody that may be predictive of protection in other assay systems (such as VZV or measles) [66, 67]; and (3) sera containing antibodies to host cell components or anti-complementary sera will not give a valid result. Newer laboratory methods, such as EIA methods, are now available commercially and have largely replaced CF tests for many viral pathogens because of their ability to discriminate between IgG and IgM antibody, increased sensitivity, and enhanced specificity at a similar cost.

7.3 Hemagglutination Inhibition

The hemagglutination-inhibition test (HAI) is based on the ability of some viruses to attach to receptors on certain species of erythrocytes and cause hemagglutination (Sect. 6.2). While HAI may be used to identify an unknown virus with virus-specific antisera, it also is useful for the detection of virus-specific antibodies in the serum. HAI may be used to evaluate antibody titers of influenza viruses, parainfluenza viruses, adenoviruses, rubella, arboviruses, and some strains of picornaviruses and noroviruses [68, 69]. In this assay, serial dilutions of sera are allowed to react with a defined amount (4 HA units) of viral hemagglutinin. Subsequently, agglutinable RBCs are added and the ability of the virus to agglutinate the RBCs is measured. Properly treated sera containing antibody specific to the virus will prevent agglutination of the RBCs, resulting in formation of RBC buttons in the test wells; sera lacking specific antibody will result in RBC agglutination. Nonspecific viral inhibitors can give rise to false-positive results in some systems, requiring that the sera be properly prepared prior to use. The specificity of the assay varies somewhat with the particular virus, with influenza and parainfluenza virus systems being more specific than the arbovirus system [69]. For example, the HAI test can identify specific strains of influenza viruses, whereas it identifies only the group-specific antigens of the arboviruses (with neutralization tests required for strain identification). Advantages of the HAI assay are its simplicity, the low cost for reagents and equipment, and speed of the assay. Disadvantages of this assay include the fact that the system only works with those viruses that cause hemagglutination and that nonviral-specific serum components may also inhibit hemagglutination, thereby invalidating the test results.

The immune adherence hemagglutination method is another method that has been used in the clinical laboratory. After an initial reaction between viral antigens and specific antibodies is allowed to occur, complement is added and binds to the antigen–antibody complex, if present. Human erythrocytes then are added and reaction to the antigen–antibody–complement complex with the C3b receptor causes hemagglutination. This method, commonly used as a microtiter procedure, has a well-defined endpoint and is rapid, inexpensive, and more sensitive than CF [70]. Disadvantages of this method include the inability to differentiate between different immunoglobulin subclasses and its difficulties with viruses that themselves agglutinate RBCs.

The direct agglutination of sheep or horse RBCs by serum is a diagnostic test for the heterophile antibody of infectious mononucleosis. Removal of an inhibitory (Forssman) antibody by adsorption of the sera with guinea pig kidney extracts is required before testing. The hemolysis of beef cells by sera from patients with acute infectious mononucleosis due to EBV is another diagnostic test that does not require adsorption but is less sensitive (see Chap. 37).

Red blood cells or latex particles can be coated with viral antigens and used to determine the presence or absence of viral antibodies in reactions called passive hemagglutination and passive latex agglutination, respectively. If viral antibodies are present, the antigen-coated red blood cells or latex particles are agglutinated. This assay is subject to a prozone effect, in which an excess of antibody reduces or eliminates agglutination leading to a false-negative result. To circumvent

this problem, negative samples can be diluted and the assay repeated. Commercial kits are available for the qualitative identification of antibodies to VZV and rubella virus [71].

7.4 Immunoassay Techniques

7.4.1 Enzyme Immunoassay

Enzyme-based immunoassays (EIAs), sometimes called enzyme-linked immunosorbent assays or ELISA, are widely used for many purposes, including the detection of antigen-specific antibody. This methodology has replaced other methods in many laboratories in part due to the commercial availability of test materials and complete test kits. The most commonly used immunoassays employ a four-layer approach: antigen is bound directly to a surface, the unknown serum sample is then added, an enzyme-conjugated antihuman IgG or IgM is added next, and an indicator system is used to determine the amount of reaction between the enzyme-linked antibody and the antigen–serum reaction. As discussed in Sect. 5.5, this method has gained widespread use due to its sensitivity, specificity, safety, simplicity, low cost, and ability to be automated. The system lends itself to automation because of readily available microtiter diagnostic systems and because multiple tests for different antigens may be run by varying only the initial antigen in the system. Clinical specimens from various sources besides serum or plasma, such as respiratory secretions, cerebrospinal fluid, and breast milk, also may be tested in this system. The EIA test may also be read visually and so is useful in developing countries unable to afford the photometric reader used in developed countries to accurately quantitate the antibody content.

Difficulties inherent in immunoassay techniques include those associated with obtaining and standardizing purified, sensitive, and specific IgG and IgM reagents. Although many of these reagents are commercially available, there can be variability in the specificity of the reagents so that during assay development the reagent specificity should be assessed. In general, results from different laboratories using different reagents are not directly comparable. Specific analysis for subclasses, particularly IgM, requires careful standardization and quality control to assure reliability and specificity of the assay. Attention to such detail is critically important in assays with life-threatening implications, such as the EIA assays currently used in blood banks to detect the presence of antibody to HIV or hepatitis B and C. Evaluation and standardization of tests, including commercially available kits, and comparison among different products prior to use in research and clinical settings remain an important part of EIA.

The lateral flow immunoassay described in Sect. 5.7 can be modified to detect viral antibody. Antihuman immunoglobulin or protein A labeled with conjugate is used in the reagent pad in place of viral antibody conjugates, and the labeled conjugate can interact with virus-specific antibodies in the clinical sample. Recombinant viral antigen is used to capture the virus-specific antibody–antibody–conjugate complex in a "test" line, and a "control" line containing antihuman immunoglobulin is present to indicate that the assay performed as intended. The test format provides a rapid qualitative answer with sensitivity and specificity similar to that obtained by more complex laboratory-based enzyme immunoassays [71, 72]. These assays can be applied to serum as well as to saliva, and they have been developed for several different viruses including HSV, HIV, hepatitis C virus, and chikungunya virus [72–75].

Epitope-blocking assays using monoclonal antibodies have been used to examine serological responses to a number of viruses [76–81]. These assays measure the ability of a test serum to block the binding of a monoclonal antibody to a virus antigen. They have been particularly useful in determining serotype-specific immune responses to multivalent vaccines and in determining which of a number of cross-reactive virus strains is responsible for a natural infection in a given host.

7.4.2 Other Immunoassays

Other variations of the immunoassay include isoelectric focusing and affinity immunoblotting. These techniques are useful because of enhanced sensitivity, particularly for diagnosis in the congenitally infected infant or for the differentiation of passively acquired antibody from endogenous antibody. Isoelectric focusing relies on the separation of serum antibody in thin-layer gels, with subsequent antibody detection by a reaction with antigen-coated membranes [82]. Clonal-specific antibodies can be detected by this method, which may discriminate, for example, between unique maternal and fetal antibodies.

The TR-FIA assay can be modified for detection of virus-specific antibodies by coating the well of the microtiter plate with viral antigen and labeling antihuman immunoglobulin with the lanthanide reporter. The availability of lanthanides with distinct emission spectra allows multiplexing of the assay such that different antibody isotypes (e.g., IgG and IgA) can be measured in the same well [83, 84].

Radioimmunoassay techniques for the sensitive detection of antibody to viral antigens, pioneered in the 1970s for the serodiagnosis of hepatitis B, are used by research laboratories but otherwise are not widely utilized [5]. Immunoassays that do not require radioisotopes and require less technical expertise, such as the EIA and IF tests, are more commonly available.

7.4.3 Immunohistochemical

The most commonly used immunohistochemical technique to detect antibody is the immunofluorescence technique (IF). Whereas direct techniques are used commonly to detect

antigen in infected tissue or cells, indirect immunohistochemical techniques are used to detect antibody in sera or other bodily fluids. Variations on the indirect IF test, such as amplification immunoassay systems utilizing various sandwich techniques (double indirect IF or anticomplement IF) or chemical amplification systems utilizing biotin–avidin complexes, are used in research settings [65]. Indirect IF methods are available in many laboratories for a variety of assays, although more automated techniques such as EIA are replacing IF techniques in many clinical settings.

In the indirect IF test, tissue or cells containing viral antigen are fixed on a glass slide, a serum dilution is added, and a fluorochrome-conjugated antibody indicator system is used to detect the resulting reaction. The conjugated detector antibody can be varied to specifically measure the presence of antibody classes, such as IgG, IgM, and IgA. IF techniques provide sensitive methods to detect antibody that can be related to immunity to viruses, such as VZV, to detect congenital infections in newborns based on IgM-specific antibody, and to detect epitope-specific antibody [65, 85]. In particular, the anticomplement-amplified indirect IF technique, utilizing a four-layer reaction including antigen, patient serum, complement, and fluorochrome-conjugated anti-C3 antibody, has been useful for the detection of the nuclear antigen of EBV, or EBNA [65]. The inclusion of standard positive and negative sera is needed in each test and independent reading by two observers is recommended to minimize errors in interpretations.

Advantages of indirect immunohistochemical methods include (1) the ability to use the system to detect antibody to many diverse viruses by varying only the initial step in the reaction, (2) the higher sensitivity and specificity compared with CF, (3) the simplicity and relative speed of an individual test, and (4) the reproducibility of the test by experienced personnel. Disadvantages of the test include the technical complexity, the lack of automation, the requirement for specialized cells and reagents, and the need for special equipment, such as a fluorescence microscope and darkroom.

7.4.4 Immunoblot

An immunoblot, also referred as a Western blot, is another widely used method for the detection of antibody to specific viral antigens. This technique relies on the incubation of patient serum with partially purified whole virus or recombinant viral proteins that have been separated by electrophoresis in a polyacrylamide gel and transferred onto nitrocellulose paper [86]. The assay is based on the same principal as EIA but has the advantage of identifying antibodies specific for several antigens of the same virus simultaneously. Quantitation of the specific reactions can be determined by a densitometer. Difficulties with immunoblots include the expense and time required for the test, the technical requirements for performing and interpreting the test, and the problems encountered with preparing reagents such as purified virus and labeled antihuman IgG. The time interval from virus acquisition and seroconversion by immunoblot may vary for different patients, as well as different viruses, indicating that diagnosis of infection by immunoblot analysis, while extremely sensitive, is not always definitive [87]. Furthermore, analysis by immunoblot will not differentiate maternal from fetal HIV infection in many cases. Despite these problems, the immunoblot assay is widely used today in laboratories around the world as the "definitive" confirmatory test for HIV, and it is also used as a confirmatory test in some circumstances for the serological diagnosis of hepatitis C virus infection [88]. It also has been used to differentiate type-specific serological responses to herpes simplex virus type 1 (HSV-1) and HSV-2 [89].

8 Interpretation of Laboratory Tests

Virus infection is usually identified by either detection of the virus or identification of a serological response to the virus. For some viral infections, both are required. However, the interpretation of the viral diagnostic assays must be made in the context of the assay sensitivity and specificity along with seasonal, clinical, and other epidemiologic factors.

Difficulties arise in interpretation of serological tests when only a single convalescent serum sample is obtained and a high antibody titer is found or if high titers are present in both acute and convalescent sera without a fourfold rise. These results can reflect either current infection or persistently high antibody levels from a previous infection. Significance may be attached to these findings if the disease is a rare one in which the presence of antibody is unique, if the test reflects a short-lasting antibody, or if specific immunoglobulin M (IgM) antibody can be demonstrated. A rapid drop in antibody titer in a subsequent specimen is also suggestive of a recent infection. Sequential testing of other family members also may be useful, since they may be in different stages of apparent or inapparent infection with the same virus. In an epidemic setting, comparison of the geometric mean antibody titer of sera collected early in illness from one group of patients with that from another group of patients convalescing from the same illness may permit rapid identification of the outbreak.

At times, a virus may be identified or an antibody rise demonstrated that is not, in fact, causally related to the illness. Sometimes dual infections with two viruses, or with a virus and a bacterium, occur, and the interpretation of the role of an individual viral pathogen in the disease process may be very difficult. On other occasions, no virus is isolated or the serological rise is not sufficient to demonstrate whether a specific virus is the real cause of the illness. A list of common causes for false-positive and false-negative results is given in Table 3.4.

Table 3.4 Viral diagnosis: some causes of false-positive and false-negative tests

False positive
Antigen detection
1. Persistent or reactivated virus from prior and unrelated infection
2. Two microbial agents are present, and the one isolated is not the cause of the disease
3. Mislabeled specimens
4. Cross-contamination within the laboratory
Serological rise
1. Cross-reacting antigens
2. Nonspecific inhibitors
3. Double infection with only one agent producing the illness
4. Rise to vaccination rather than natural infection
False negative
Antigen detection
1. Viral specimen taken too late or too early in illness
2. Wrong site of multiplication sampled, e.g., throat rather than rectal swab
3. Improper transport or storage of specimen
4. Low assay sensitivity
Serological rise
1. Specimens not taken at proper time, i.e., too late in illness or too close together to show antibody rise
2. Poor antibody response–low antigenicity of the virus or removal of antibody by immune-complex formation
3. Wrong virus or wrong virus strain used in the test
4. Nonspecific inhibitor obscures true antibody rise
5. Wrong test used for the timing of the serum specimens

9 Unresolved Problems

Many problems still must be resolved in the area of viral diagnosis. The development of newer molecular assays with improved sensitivity have supplanted many antigen detection methods with lower sensitivity, but the ease of performance of the antigen detection methods still makes these assays attractive to many laboratories. While molecular methodologies offer the potential for great sensitivity and specificity, they often require specialized equipment for their performance. Ultimately, the ideal diagnostic test will be rapid, easy to perform, inexpensive, sensitive, and specific and will not require the use of specialized equipment. However, even if such a test is developed, the significance of the identified virus to the observed disease process will remain in the hands of the epidemiologist, virologist, and clinician.

Surveillance and Seroepidemiology

4

Ruth Jiles, Monina Klevens, and Elizabeth Hughes

1 Introduction

The term *surveillance* was employed for years in the restrictive sense to imply follow-up of exposed persons to determine whether disease developed within the limits of the incubation period. The dictionary definition of surveillance is "close observation, especially over a spy or criminal" [67]. Surveillance, in the context of health, has been defined as the systematic collection of data pertaining to the occurrence of specific diseases, the analysis and interpretation of these data, and the dissemination of consolidated and processed information to contributors, programs, and other interested persons. The Centers for Disease Control and Prevention (CDC) has described surveillance as the collection of "health related data essential to the planning, implementation, and evaluation of public health practice, closely integrated with the timely dissemination of these data to those responsible for preventing and controlling disease and injury" [89].

Surveillance systems are developed and implemented for the ultimate purpose of preventing or controlling diseases. Historically, the principles of surveillance were well described and documented by Langmuir [57] and other officials of the US Public Health Service, CDC [6, 66], and by Raška [76, 77] for the World Health Organization (WHO) [108].

The techniques of surveillance and uses of surveillance data were applied first to infectious diseases and subsequently to occupational, environmental, and chronic diseases, as well as to injuries and emergency preparedness [6, 14]. *Healthy People*, the principal document of the US Department of Health and Human Services that outlines the health objectives for the United States, relies heavily on surveillance data to establish goals, baseline measures, and monitor progress towards achieving those goals [94]. The importance of surveillance and the need for improving surveillance techniques, both in developed and developing countries, have been well documented [68]. To improve data quality and timeliness of reporting, electronic transmission of surveillance data, mainly laboratory results, was initially implemented in the United States and France [39, 95]. Early challenges included standardization of case definitions and reporting methods among official sources. These issues were addressed in the US National Notifiable Disease Surveillance System through consensus and development of standard case definitions and reporting protocols.

This chapter discusses the background and elements of traditional surveillance, the concept and uses of serological and molecular epidemiology, and their application to the control of viral infections.

2 Surveillance

Traditionally, surveillance was based on the occurrence and reporting of a case of clinical disease or death. Currently, other life and infection-related events, such as births, hospitalization, risk behaviors and exposures, treatment, and healthcare system encounters, are also under surveillance.

2.1 Historical Background

A more detailed history of public health surveillance was published by Declich and Carter in 1994 [24] and summarized

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_4,

in an earlier version of this chapter [33]. Based on these accounts, various governmental actions to prevent spread of infections and diseases occurred during the seventeenth century. However, it is widely accepted that public health surveillance dates back to 1662, when John Graunt published the *Natural and Political Observations Made Upon the Bills of Mortality*. Graunt analyzed London's mortality data collected for the Bills of Mortality and was the first to count the number of deaths from specific causes (numerator), estimate the population (denominator), and use the information to determine death rates [41].

During the eighteenth century, some colonies in Rhode Island implemented various specific components of public health surveillance, requiring tavern keepers to report cases of "contagious" diseases such as smallpox, yellow fever, and cholera among their customers.

During the nineteenth century, several significant contributions were made in public health surveillance. Sir Edwin Chadwick, Secretary of the Poor Law Commission in England, used surveillance data to demonstrate that poverty and disease were associated and suggested improvement in the living conditions of the poor. In the United States, Lemuel Shattuck related living conditions to infant and maternal morbidity, mortality, and rates of death. He recommended collection of health data by such factors as age, gender, and occupation. William Farr, founder of a modern concept of surveillance, as the first Compiler of Abstracts for England and Wales, set up a system that not only tracked births and deaths, but also routinely recorded cause of death by occupation. Farr developed a nosology that is the basis for the International Classification of Diseases (ICD) (See http://www.cdc.gov/nchs/data/misc/classification_diseases2011.pdf).

Surveillance concepts and methodologies were developed in response to national needs for disease surveillance or in response to epidemics. Surveillance data were needed to define the magnitude of the problem and to inform policy/decision makers and others who were responsible for development, implementation, and/or evaluation of prevention and intervention programs and policies. Use of the term "surveillance" in the United States began in 1949 with the development of a modified program at the CDC called "Surveillance and Appraisal of Malaria." In 1951, the concept was applied to the residual smallpox cases in the United States.

On April 28, 1955, the Surgeon General of the United States directed the establishment of a "National Poliomyelitis Surveillance Program" in response to paralytic polio cases following the use of Salk vaccine (the "Cutter Incident"). Based on this program, established at the CDC, surveillance methods became an effective tool in following trends in the disease, in measuring the effectiveness of polio immunization programs, and in detecting suspected vaccine-associated cases. Likewise, other surveillance systems and units were developed in response to occurrence of other epidemics. WHO established regional, national, and international control programs with surveillance as an essential component of each type of control program. While European unification was anticipated, individual countries employed different approaches to surveillance; thus, there were concerns about comparability of data and coordination of activities [27]. The AIDS epidemic which began in the late 1970s and early 1980s forced many countries to establish new surveillance systems and improve existing ones.

While a set of legal and ethical principles of surveillance had been evolving gradually prior to the early 1980s, the pressing need for accurate information about HIV infection led to a broad array of new surveillance practices that have continued to test the balance between individual and community interests and responsibilities.

2.2 Types of Surveillance

Surveillance systems may be classified in a variety of ways: based on the method of reporting (passive or active), purpose of the system (Behavioral Risk Factor Surveillance System or BRFSS) [11], location (clinic based), or target population (Youth Risk Behavior Survey YRBS) [21].

The most common type of surveillance is passive. In passive surveillance the reporter, usually a physician or laboratory, regularly transmits a summary of all the cases of the specified disease or diseases observed to health authorities during the reporting period.

The US National Notifiable Disease Surveillance System (NNDSS) is an example of passive reporting [17]. States send case reports of nationally notifiable diseases to the CDC on a weekly basis. States determine which diseases are reportable within their jurisdiction and who (laboratory, physician, clinic, or some combination) initiates the report. State epidemiologists and CDC subject matter experts collaborate, through the Council of State and Territorial Epidemiologists (CSTE), to develop case definitions and define reportable data elements for reportable diseases. Generally, laboratories and/or physicians report cases to the local health departments, local health departments report cases to state health departments, and state health departments notify CDC of confirmed cases. Most laboratory reports and some physician reports are submitted electronically. However, reporting can be accomplished in print, by telephone, even using toll-free numbers or automatic recording devices available at all hours. Time and lack of resources greatly limit such a system to a small percentage of most reportable diseases, but as long as the system and requirements remain unchanged, the changes in incidence may reflect meaningful patterns of disease.

Active surveillance requires contacting the reporters at regular intervals and request for specific data on cases of

specified diseases. It permits more extensive data collection on epidemiologic features of certain diseases. CDC's Behavioral Risk Factor Surveillance System (BRFSS) is an active surveillance system [11]. States contact residents by telephone and administer a standardized questionnaire to eligible consenting adults aged 18 years or older to obtain information about a variety of chronic diseases and related risk behaviors. Relevant to viral infections, the BRFSS includes questions about receipt of influenza, shingles, and human papilloma virus vaccination. The BRFSS has also been used by CDC to provide state-specific estimates of HIV-related behaviors such as ever tested for HIV, where tested, and why tested. Some states conduct active surveillance for HIV/AIDS using other data sources.

For a few diseases, some special clinical feature of the disease may be used to estimate prevalence data. For example sudden severe acute lower respiratory illness may indicate hantavirus infection or jaundice may be evidence of hepatitis. In some instances, surveillance is based on laboratory data, as with the isolation of the agent or results of a serological test. In the case of viral hepatitis, the CDC/CSTE case definition includes both clinical features and laboratory test results. Most surveillance systems cover political jurisdictions (e.g., national, state, and county). However, some surveillance systems cover high-risk or specific population groups, requiring special reporting methods. Examples are military populations, hospitals, day-care centers, and homes for the elderly. Most surveillance systems incorporate a list of reportable diseases, but the focus of the reporting may be on specific disease entities, such as congenital defects as a reflection of the impact of rubella and cytomegalovirus infections [28].

An example of surveillance in a special population and location is CDC's school-based Youth Risk Behavior Survey (YRBS) [21]. In this survey, questions related to viral diseases, for example, HIV, are self-reported by participating high school students.

2.3 Sources of Surveillance Data

A wide variety of data sources are used for surveillance purposes. Some data sources were designed for the purpose of surveillance and are ipso facto "surveillance systems." Other data sources are used secondarily for surveillance. Sources of surveillance data vary from country to country, state to state, and across local jurisdictions. Availability of surveillance data is dependent on resources available to support the system, such as appropriate laboratory facilities and trained personnel. Table 4.1 lists some data sources that are commonly used for surveillance purposes. These sources are consistent with elements of surveillance summarized by WHO [108].

Table 4.1 Selected sources of data for surveillance

1. Viral statistics
2. Reportable disease systems
3. Surveys
4. Sentinel surveillance
5. Syndromic surveillance
6. Registries
7. Laboratory records
8. Pharmacy records
9. Administrative data

2.3.1 Vital Statistics

The oldest form of surveillance is mortality registration. In most countries, death registration is legally required. As a result, almost all deaths are included in the registries. Causes of death listed on the death certificate is dependent on the presence/absence of a physician or family member who is knowledgeable about the health of the deceased; severity of disease, complexity of the disease, associated illnesses, and whether or not an autopsy or diagnostic laboratory testing was performed. For many viral diseases, such as hantavirus, rotavirus, and influenza, only a small percentage of cases are fatal. However, the case fatality rate is high for other viral diseases, such as AIDS, rabies, Lassa fever, and certain hemorrhagic fevers. Thus, occurrence of viral infections is likely underestimated from the death certificate data. However, vital records are important to document severe complications of viral infections. In addition, surveillance from vital records can be useful for comparing viruses. For example, by 2007 in the United States, the number of deaths associated with HIV was lower than the number associated with hepatitis C [59].

Birth certificates are often used to monitor conditions such as congenital defects (due to rubella and cytomegalovirus infection), diseases transmitted from mother to child (e.g., hepatitis B virus infections), and other conditions of newborns that may impact immediate or long-term health status.

2.3.2 Reportable Disease Systems

The reporting of cases of specified infectious diseases also is legally required in most countries. The US National Notifiable Diseases Surveillance System includes over 70 diseases, of which approximately 30 are viral diseases including 6 arboviruses, 6 hepatitides, and 6 types of hemorrhagic fevers. Reportable disease systems form the backbone of surveillance for most state and local health departments and for many CDC programs. The advantages are that (1) reports are usually made by physicians and/or laboratories, (2) laboratory confirmation is generally available, and (3) there is typically an organized system of regional or national tabulation and reporting. The disadvantages are as follows: (1) the absence of some viral diseases from the required list; (2) the notorious underreporting of diseases despite legal

requirements, primarily because of lack of resources to support both reporting and education of physicians about the need to report; and (3) the variability of reporting efficiency from one jurisdiction to another. Lack of rapid, reliable, inexpensive diagnostic techniques also represents a discouraging obstacle to accurate identification and reporting of many viral diseases [17].

2.3.3 Surveys

Many types of surveys of infectious disease have been used in public health. Formal surveys support the collection of standardized information using standardized methods. Although survey data can be collected quickly over a wide geographic area, the cost of data collection may be prohibitive. The National Health and Nutrition Examination Survey (NHANES), conducted by the National Center for Health Statistics, a component of CDC, uses a complex sampling design to collect nationally representative data on the health and nutritional status of the US noninstitutionalized civilian population [16]. NHANES is a source of data for a number of infectious disease programs, mainly because the laboratory and physical examination components allow both confirmation of case status and collection of health information. For example, the Division of Viral Hepatitis at CDC uses NHANES data to estimate the prevalence of chronic hepatitis B and C for the US noninstitutionalized adult populations (see Sect. 3.3.2).

2.3.4 Sentinel Surveillance

Sentinel surveillance is used as a less costly alternative to population-based surveillance. Sentinel surveillance systems collect data from a sample of reporting sites. Generally a select group of reporting sources—hospitals, healthcare providers, agencies—are recruited to report all cases of one or more notifiable conditions. In the United States, sentinel sites report all cases of influenza-like illness to their state health department on a weekly basis. A network of sentinel providers in British Columbia, Canada, demonstrated the usefulness of sentinel surveillance in documenting the effectiveness of influenza vaccine [49].

2.3.5 Syndromic Surveillance

Syndromic surveillance uses clinical information about signs and symptoms of disease, before a diagnosis is made, as an early warning signal of a potential outbreak. Many syndromic surveillance systems use electronic data from hospital emergency room visits. The value of such systems relies on accurate assessment and coding of symptoms, as well as accurate data entry.

2.3.6 Registries

Registries are often established, usually at the state level, to collect information about persons diagnosed with a disease or condition. For example, cancer registries collect information about type of cancer, anatomic location, stage of disease at diagnosis, treatment, and outcomes. Childhood immunization registries maintain a record of vaccinations received by children within the jurisdiction of the registry [19].

2.3.7 Laboratory Records/Investigations

Laboratory identification of the causative agent of many viral infections has become a routine part of clinical care. Laboratory records are especially useful for public health surveillance. Appropriate laboratory facilities and experienced personnel are needed for the isolation and/or serological identification of the majority of viral infections. These may exist in national or regional public health laboratories, in specialized virus diagnostic institutes, or in university settings.

2.3.8 Pharmacy Records/Investigations

Pharmacy data may be used to identify those who are treated for specific diseases, monitor uptake of new medications, and evaluate effectiveness of specific treatments. For example, when treatment for HIV/AIDS first became available, prescriptions for zidovudine were used to identify potentially unreported cases [54].

2.3.9 Administrative Data

These data consist of electronic records prepared usually for billing or other administrative accounting and are sometimes available in a de-identified format and at no cost for public health use. Data from health plans such as Kaiser Permanente, Medicare, and Medicaid have proven to be useful to supplement routine surveillance data. Hospital discharge data, like insurance/health plan data, provide useful information on diagnosis, surgical procedures, other billed treatments, complications, length of stay, laboratory data, and associated costs. In addition to the wealth of data available in these sources, another attraction is that these data are already collected in electronic form, requiring fewer resources to analyze and summarize.

2.4 Surveillance Networks and Health Information Exchanges

2.4.1 Surveillance Networks

Surveillance networks grew out of the need for a more global approach to surveillance of infectious diseases. Surveillance of infectious diseases was often inadequate in the developing world due to a lack of resources and public health infrastructure. The need for early warning of outbreaks of emerging and reemerging diseases led the Federation of American Scientists to support the establishment of the first infectious disease network, the Program for

Monitoring Emerging Diseases (ProMED-mail) in 1993 [74]. ProMED-mail is an Internet-based system for reporting and disseminating information on infectious diseases outbreaks and acute exposures to toxins that impact human health. This open-source network receives reports from clinicians, public health officials and epidemiologists, laboratory scientists, medical missionaries, journalists, and laypersons. The editors also search the Web and press reports for information. A panel of experts screens, reviews, and investigates reports before they are posted to the website. ProMED-mail allows comparison of reports by geographic location. Thus, users of the system can identify similar outbreaks in both space and time.

Other surveillance networks include Canada's Global Public Health Intelligence Network (GPHIN) [75] and the World Health Organization's Global Outbreak Alert and Response Network (GOARN) [103, 104].

GPHIN, started in 1999, monitors internet websites, news wires, and other internet media to gather and provide information on disease outbreaks and other public health events. This network collects information about infectious diseases, outbreaks, contaminated food and water, natural disasters, bioterrorism events, and safety of products, drugs, and medical devices. GPHIN is part of GOARN [75].

GOARN, started in 2000 by WHO, links existing networks of government and academic centers of excellence, networks of laboratories, medical centers, scientific institutions, and other international organizations. The goal of GOARN is to provide countries with resources and expertise necessary to respond to infectious disease outbreaks. GOARN provides and coordinates technical support, investigates the event, assesses risk, streamlines processes to rapidly deploy field teams, and supports national preparedness [103, 104].

CDC surveillance systems may be viewed as networks connecting the Federal agency with local, state, and territorial health departments and international partners. A number of these surveillance networks focus on viral diseases. An example is the Influenza Surveillance Program [18]. The program which started in 1972 collaborates with local, state, and territorial health departments, clinical laboratories, healthcare providers, and emergency departments to collects and analyzes information on influenza in the United States. Information is collected from five categories of influenza surveillance: viral surveillance, including surveillance for novel influenza A viruses; outpatient illness surveillance; mortality surveillance; hospitalization surveillance; and geographic distribution. Information from these five categories of surveillance is used to track influenza-related illnesses and deaths and to provide a comprehensive overview of activities. CDC also collaborates closely with WHO in global surveillance, including surveillance for novel influenza viruses and in influenza vaccine strain selection.

WHO's Global Influenza Program provides technical support and guidance to Member States and maintains global surveillance for influenza. Virologic and epidemiologic data are collected from countries, areas, and territories through the influenza surveillance and monitoring system. Two platforms are provided for data collection and sharing: FluNet for virologic data and FluID for epidemiologic. These systems allow tracking of global trends, spread, and impact of influenza [106].

2.4.2 Health Information Exchanges

During the late 1900s and early 2000s, there were concerns about the ability of the United States to respond to possible acts of bioterrorism. Beginning with the anthrax attacks shortly after the September 11, 2001 destruction of the World Trade Center, epidemics of such emerging viral infections as West Nile virus, avian influenza, and SARS became a major issue in protecting the health of all Americans [58]. In response, the President of the United States signed Executive Order 12225 on April 27, 2004, which created the Office of the National Coordinator of Health Information Technology (ONCHIT) [58]. The primary objective of this order was to formalize the administration of the office and to advance the development and growth of health information technology as vital to improving the quality of healthcare while reducing its cost. The first step in the process to achieve this critical objective was to use medical records maintained by healthcare providers to build a national network of electronic health records on the majority of Americans, by the year 2014 [13].

Health information exchange (HIE) can be described as the "electronic movement of health-related information among organizations according to nationally recognized standards" developed by the Health Resources and Services Administration (HRSA) [92]. HIE encompasses two major concepts: the electronic sharing of health-related information among organizations and an organization that provides services to enable the electronic sharing of health-related information [15, 46]. The primary goal of HIE is to facilitate access to and retrieval of patient clinical data to provide more efficient, timely, effective, equitable, and safe healthcare. HIE secondary goals are to improve bidirectional communication, to enhance case reporting, and to focus on technology, interoperability, utilization standards, and harmonious collaboration between all patient-centered healthcare providers [13, 97]. The potential of HIEs to integrate the electronic transfer of vital health information among providers and public health agencies is critical in the effort to improve healthcare quality and increase safety for patients [46].

In 2007, CDC funded Health Information Exchanges to support situational awareness project [12]. The objectives of this project were to connect public health providers and organizations

with HIEs in order to improve public health with real-time awareness of the health and status of healthcare facilities within communities, bidirectional communication between healthcare entities, and enhanced case reporting [93]. An example of a successful merge of a HIE with a state partner is the Indiana Health Information Exchange (IHIE) [40, 48]. The IHIE displayed the interoperability of health information exchange by incorporating clinical messaging service ($DOCS_4DOCS$®) to improve communication between healthcare providers and public health agencies. With this system, clinical result messages can be forwarded to all physicians or targeted to clinical practices or specific geographical areas [90]. In 2009 and 2010, the $DOCS_4DOCS$® public health messaging system was utilized to alert nearly all physician practices and public health agencies about H1N1 influenza, a syphilis outbreak, an update on rabies treatment, and new vaccination requirements for school children [48].

Another example of a successful HIE is the Northwest Public Health Information Exchange (NW-PHIE) in Washington and Idaho states [90]. This HIE evaluated new influenza surveillance efforts and compared these with existing influenza surveillance data feeds through the Influenza-Like-Illness Network (ILINET). Results indicated that the NW-PHIE data were timelier, more stable, more extensive, and more broadly representative of the community. The NW-PHIE data accurately reflected trends in ILINET activity at the state and community levels [13].

HIEs benefit public health by improving the safety of patients and ensuring quality of healthcare. HIEs augment patient safety by serving as the connecting point for a standardized, organized process of data exchange across regional, state, and local jurisdictions; reducing duplication of services which may result in lower healthcare costs; reducing operating costs by automating many day-to-day organizational tasks; providing management of the data exchange process; and, most importantly, improving communication between providers and patients [46, 93].

3 Seroepidemiology

3.1 Introduction

Seroepidemiology is the systematic collection and testing of blood samples from a target population, or a sample of a population, to identify current and past experiences with infectious diseases by means of biological markers (i.e., antibody, antigen, or other tests). Findings from the tests are the outcomes that, when analyzed, are used to describe patterns and potentially identify factors associated with the outcomes. Seroepidemiologic studies are used worldwide to measure and characterize infectious diseases in the population. Sources of seroepidemiologic data are widely available and may be collected for other purposes (e.g., blood donor screening), but can be useful for public health purposes. In the context of viral infections, seroepidemiology serves at least three objectives:

1. To supplement surveillance data and inform immunization and public health planning programs
2. To generate hypotheses about the potential association between risk and occurrence of viral infectious diseases
3. To assess old and newly recognized viruses in different population groups

Just as epidemiology is concerned with the occurrence and distribution of clinical cases in different populations, serological epidemiology is concerned with the occurrence and distribution of various components of the blood that indicate past or current infection, that are biochemical markers for certain chronic infections, or that reveal the genetic attributes of strains in various population groups. The epidemiologic characteristics are detected in the laboratory rather than at the bedside; thus, laboratory support is fundamentally necessary to conduct seroepidemiologic surveys. Fortunately, laboratory testing is a part of routine clinical care and is readily available in most countries.

Largely based on the availability of resources to monitor any given viral infection, we might consider that seroepidemiologic data can be classified as:

1. The primary objective of the survey (i.e., a planned and designed survey or study)
2. A secondary use of specimens or data collected for other purposes (i.e., screening programs including blood donors, clinics for high-risk individuals, and other remnant sera)

As a primary objective, serological surveys are frequently integrated with other public health efforts. This section considers the history, methods, and uses of seroepidemiology as either a primary or secondary objective of data collection. As in the surveillance section, we draw heavily on the experience in the United States, but recognize excellent seroepidemiologic studies conducted in other countries.

3.2 Historical Background

The introduction of serological tests for the diagnosis of disease provided the basis for later serological surveys. As early as 1916, the Wassermann test was applied routinely to patients attending a prenatal clinic at Johns Hopkins Hospital by Williams [102] but this was more of a case-finding procedure than an attempt to delineate disease patterns. In 1930, the development of a neutralization test for poliomyelitis led Aycock and Kramer [4] to use the procedure to define the immunity pattern of a given population; this is a landmark in the history of serum surveys. In 1932, Soper et al. [85] mapped out the occurrence of yellow fever in Brazil by

antibody surveys under the auspices of the Rockefeller Foundation, and this technique has been widely used subsequently in studying arbovirus infections. Antibody surveys for influenza also date back to the mid-1930s. The discovery of swine influenza virus by Shope [83] in 1931 and of human influenza virus by Smith et al. [84] in 1933 was rapidly followed by population studies to measure antibody to these viruses among persons of different age groups [2, 9, 37].

The Yale Poliomyelitis Study Unit under Dr. John R. Paul employed serological survey techniques as early as 1935, and his analysis with Riordan of the poliomyelitis pattern in Alaskan Eskimos is a classic study [71]. He became one of the foremost users and promoters of the concept of serological epidemiology, and through his work and writing [69, 72], the utilization of this technique in public health practice and research studies has become a reality. The World Health Organization also took note of this development in 1960 and established three WHO Serum Reference Banks to practice and promote seroepidemiology in New Haven, Connecticut; Prague, Czechoslovakia; and Johannesburg, South Africa. An additional bank was established in 1971 in Tokyo, Japan. The activities and principles of these banks have been reviewed in two *WHO Technical Reports* [105, 107], in a book [72], and in several other publications [70, 73, 81]. Although WHO no longer formally supports these banks, the rationale for proper collection, cataloging, and storage of specimens for use by both primary and collaborating investigators has gained wide application in public health and academic research institutions. For example, WHO collected sera from household surveys in rural areas for the evaluation of the effectiveness of penicillin in mass eradication programs for yaws [42].

Seroepidemiologic techniques were critical to the discovery by Blumberg et al. [7] in 1965 of a particular antigen in the serum of an Australian aborigine; it was uncovered in the course of genetic studies of β-lipoprotein. Since the agent from which the antigen was derived could not be isolated or cultivated in the laboratory, serological surveys using immunodiffusion tests were carried out to detect its presence in the sera of different population groups and different disease entities. The results provided the sole initial evidence that this "Australia antigen" was associated causally with hepatitis B or "long-incubation hepatitis" [8]. Herpes viruses, HHV-6 and HHV-7, were not immediately recognized in association with previously defined disease entities, although the former has been unequivocally shown to be the major, if not the only, causal agent of exanthema subitum.

Many countries recognize the value of such biological resources and have created sizable repositories of serum and, increasingly, tissue or other cellular material containing nucleic acid suitable for molecular and genetic analysis. Seroprevalence studies of many different infections and from many countries have been published.

3.3 Methodology

3.3.1 Ethical Issues

Seroepidemiologic studies were used early in the HIV epidemic because there was a need to determine the unbiased frequency of infection in different populations. A series of serosurveys were conducted to cover different populations including persons attending STD clinics [100], childbearing women [43], and youth training programs [23]. To protect the identity of infected persons, these surveys were conducted anonymously and data were unlinked, such that notifying the person whose blood was tested was not feasible. The ethical issues discussed over time are described by Fairchild and Bayer [36]. The issues included participant consent, the participant's right to know and to control their information, and the responsibility of the health officials to inform the individuals of their test results. When treatment became available, serosurveys continued as long as voluntary counseling and testing was available to survey participants. As clinical data became a more complete source of similar surveillance information, the use of serosurveys became ethically indefensible [36].

Currently, in the United States, Federal Regulations (45 CFR 46.111) require that studies involving human research subjects satisfy the following rules: (a) risks to participants are minimized; (b) risks to participants are reasonable relative to anticipated benefits, if any, to participants, and the importance of the knowledge that may reasonably be expected to result; (c) selection of participants is equitable (i.e., could any special problems arise when research involves vulnerable populations, such as children, pregnant women, fetuses, prisoners, mentally disabled persons, economically or educationally disadvantaged persons); (d) informed consent will be sought from each prospective participant or the participant's legally authorized representative; (e) informed consent will be appropriately documented; (f) the research plan makes adequate provisions for ensuring the safety of participants; and (g) there are adequate provisions to protect the privacy of participants and to maintain the confidentiality of data. Institutions conducting epidemiologic studies maintain "Institutional Review Boards" to ensure that investigators address the above ethical requirements.

3.3.2 Statistical Considerations

When serosurveys are designed as primary data collection, representativeness of the population is usually desirable. In the United States, NHANES combines interviews, physical examinations, and laboratory specimens from a nationally representative sample of about 5,000 persons each year. These persons are located in different geographic areas called primary sampling units, of which 15 are visited each year. Health interviews are conducted in respondents' homes, whereas health measurements are collected in specially designed and equipped mobile centers.

NHANES uses a complex sample survey design [16]. Primary sampling units are generally single counties, where the sampling frame is all counties in the United States. The additional stages of selection in the probability design consist of clusters of households, where each person in a selected household is screened for demographic characteristics, and one or more persons per household are selected for the sample. As with any complex probability sample, the sample design information must be used when undertaking statistical analysis of the NHANES data. In particular, sample weights and the first stage of the cluster design need to be considered. Participants are compensated for participation and receive a report with their health results.

For rapid surveys or for surveys in developing countries, WHO has developed methods for cluster sampling that are more easily implemented and analyzed than multistage probability sample surveys [5]. Using this method, and assuming the survey is conducted to meet several health information needs, the first step is to plan carefully to ensure best use of resources. Sampling is conducted in several stages, starting with regions of a country, then districts within regions, then communities (e.g., villages, blocks, etc.) within the districts and households within the communities. Ideally, the community sampling framework should be a list of all the communities in the region, and there should be a measure of the population size of the community in order to sample with probability proportionate to size. This assessment is helpful because weighting at the time of analysis then becomes unnecessary. The total population divided by the number of communities to be selected determines the sampling interval, which will be used to select the communities after a random start. Also ideally, there is enumeration of the households within the selected communities such that a simple random sample can be selected. If that framework is not available, methods from the 30×7 Expanded Program on Immunization can be used since the selection of households is conducted in the field using a central start; interviews are conducted until information on seven children aged 12–23 months are completed [22, 45]. A slight modification to the above rapid method is "compact segment sampling," proposed by Milligan et al. [62]. In this method, the communities to be sampled are divided into segments of equal population size; then, one segment is randomly selected and all households in the segment are included in the sample.

An important analysis issue for sample surveys of any methodology is whether data have been collected consistently over time. When the same items have been collected using consistent methods, comparisons can be made over time, adjusting for the distribution of the age of the population.

3.3.3 Sources of Biological Material

When serostudies are designed for primary data collection, the collection of blood specimens can be targeted to a carefully and statistically selected sample of the population of interest. To achieve efficiencies from this type of study, serological surveys should be multipurpose in nature and can include measurement of antibodies, genetic material, and other clinical laboratory markers of health or illness. In the United States, the NHANES has produced a nationwide population-based health profile for more than two decades. As one of its many components, it has provided valuable seroprevalence data on a variety of viral infections, for example, measles, poliomyelitis, herpes simplex virus (HSV), hepatitis A virus (HAV) [53], and HBV [98].

Table 4.2 Sources of human biological materials for surveillance where planned serum surveys from targeted populations are the primary objective

Objective	Sources of biologic materials
Primary	Planned serum surveys from target populations
Secondary	Entrance and periodic examinations of different groups (military, industry, health clinics)
	Blood donors in Red Cross and similar programs (e.g., transplantation donors)
	Public health laboratories:
	Serological tests for HIV (e.g., premarital)
	Other immunologic and diagnostic tests
	Healthcare facilities:
	Entry tests for blood chemistries or syphilis
	Diagnostic tests for infectious diseases
	Blood banks and transplantation programs
	Prenatal; clinics (e.g., hemodialysis)
	Employee health services
	Counseling and testing sites, clinics for sexually transmitted diseases
	Drug treatment clinics

A list of several sources of material for survey analysis is shown in Table 4.2. Examples of sources of specimens for secondary use include blood collected for routine tests during physical examinations for the armed forces or industry or during an outpatient visit or admission to a hospital and from neonates screened for specific heritable disorders. Sera sent to a public health laboratory for serological tests for syphilis, viral diagnosis, or other diagnostic tests have also been employed. These collections of sera may not be representative of the age, sex, and geographic distribution of the entire population; the nature of the biases introduced must be recognized and evaluated. However, they are economical to obtain and sometimes may reveal important information about the presence or absence of a certain virus in the community or about the occurrence of a recent outbreak. An example of this type of serostudy was the description of the frequency of HIV and hepatitis B and C infection among injection drug users in several US cities [63].

Specimen Management. The collection and management of specimens depends on the type of specimen (e.g., viruses might be identified in stool samples, oral swabs). For blood, the specimen must be collected and separated under sterile

conditions. Aliquots of 0.5 ml each have been used by the WHO and CDC and are very useful for microtiter tests; several replicates of the entire collection may be prepared at the time of aliquoting so they can be shipped to other laboratories for testing. Sera are usually stored at −20 °C, often in a commercial warehouse. Temperatures of −70 °C are best but are more expensive to maintain. Lymphocytes can also be separated from anticoagulated blood, frozen at low temperatures in fetal calf serum and dimethyl sulfoxide (DMSO), and later thawed for examination of stable cell surface markers and other cell-associated products. Cellular material, even in extremely low concentration and a nonviable state, may be quite suitable for amplification and identification of fragments of nucleic acid. These techniques offer powerful tools for detecting genes characteristic of specific infectious agents and other biological material of interest.

3.3.4 Laboratory Tests

The general principles and techniques of laboratory testing for viral infections are presented comprehensively in Chaps. 2 and 3 of this text. The antibody tests most suitable to serological surveys of specific viruses are detailed in each corresponding chapter of this book. The criteria for a satisfactory test include simplicity, sensitivity, specificity, reliability, ability to detect long-lasting antibody, minimal interference from nonspecific inhibitors, the availability of satisfactory reagents, and the safety of the test for the laboratory technician [29, 107]. The microtiter procedure developed by Takatsy in 1950 in Hungary and popularized in this country by Sever [82] in 1962 has become the standard method in serological survey laboratories. It is adaptable to a wide variety of antibody determinations, it requires a minimal amount of serum (usually 0.1 ml) and other ingredients, and large numbers of sera can be efficiently tested. Several automated methods of dilution and of adding various reagents have been introduced to speed the testing even more [107].

The development of simple tests such as the enzyme-linked immunosorbent assays (ELISA) for antibody measurement in microtiter plates has provided a sensitive method for identification of antibody in serum samples from survey populations and can indicate both past and current infections [109]. The use of monoclonal antibodies in this and other antibody tests permits highly specific identification of individual strains of the virus, a special advantage in determining whether a new strain has been introduced in a community or if reinfection or reactivation has occurred in the individual. Commercial kits for many antibodies are now available, and new formulations are continually being devised for a variety of clinical, public health, and research applications. Detection of virus and genetic characterization of viruses can be accomplished using polymerase chain reaction (PCR) methods. Handling of specimens for PCR depends on two components: the source and virus, for example, varicella zoster virus can be identified in dried blood specimens, which can be stored at ambient temperature indefinitely. In general, PCR requires specialized kits that differ for qualitative or quantitative detection. Sequencing of select regions of amplified genetic material can be used to describe strains of virus circulating in a region or country; however, because of cost, these methods are frequently restricted to determine transmission during investigations of acute clusters of disease [1].

A full list of laboratory tests conducted using specimens collected as part of the NHANES 2009–2010 can be found here: http://www.cdc.gov/nchs/nhanes/nhanes2009-2010/lab_methods_09_10.htm.

3.4 Advantages and Limitations

The use of serological surveys is an important means of supplementing morbidity information, such as that obtained from routine case surveillance. Advantages are listed in Table 4.3. Because many viral infections may be clinically mild or inapparent, laboratory confirmation is necessary for accurate diagnosis of even overt cases. Data from serological surveys can reveal *total* burden of infection (apparent and inapparent), both currently and in the past. Selection of tests that reflect antibody of long duration permits measurement of the cumulative experience of the population tested with the disease in question; selection of a test based on short-lived antibody such as immunoglobulin M (IgM) allows identification of a recent infection or epidemic. Testing of two sera spaced in time permits measurement of the incidence of infection during the interval period.

An important advantage of carefully planned prospective serosurveys is that participants can become a cohort for other studies. For example, to determine the frequency with which hepatitis C-infected persons in the United States were aware of their infection, the National Center for Health Statistics conducted a follow-up survey of positive cases. A full interview with these participants yielded not only awareness, but also whether they sought medical care for their infection and their knowledge, attitudes, and practices related to hepatitis C [25].

Table 4.3 Advantages and limitations of seroepidemiologic studies by data collection objective

	Primary	Secondary
Advantages	Sample is representative of the target population	Less expensive
	Many possibilities of lab markers and behaviors	Saves time
		No participation bias from volunteers
Limitations	Expensive and labor-intensive	Convenience sample might not be representative of the population of interest
	Time consuming to design and implement	

An advantage of serostudies in providing information to guide vaccination programs is that serostudies measure immunity and are likely more reliable than self-reported vaccination coverage [26]. Another advantage is that aliquots of sera from a collection can be shipped, frozen, over long distances to a number of specialized reference laboratories for testing; therefore, the work can be divided among participating laboratories.

The disadvantages of seroepidemiology are the cost, time, and effort involved in the selection of the target population, the collection and analysis of data and blood, and the need for and cost of laboratory facilities equipped to carry out the tests. There must also be a satisfactory means of measuring antibody for the particular virus to be studied, and the method of carrying it out must be simple enough to allow performance on a large-scale basis. Finally, because serostudies designed for primary data collection are labor-intensive and prospective, there are significant delays in the availability of data. For example, the NHANES data require about 2 years between the end of data collection and the availability of datasets for public use.

3.5 Uses of Serological and Molecular Techniques

3.5.1 Prevalence

Prevalence from serosurveys, or seroprevalence, is defined as the number of persons whose sera contain a particular biomarker among the total number of persons examined at that point in time (frequently, 1 year). Unlike "case prevalence," which indicates the existence of disease at the time of the survey, the presence of antibody reflects the cumulative experience, past and present, with an infectious agent. The prevalence is a function both of prior and current infection and of the duration of the antibody tested. In contrast, antigen indicates presence of the virus at that time; in cases of latent or asymptomatic infection, it indicates prevalence of chronic infection.

Many antibodies such as the neutralization antibody for poliomyelitis or yellow fever virus; antibodies to the HIV core, polymerase, and envelope; and the hemagglutination-inhibition antibody for influenza, parainfluenza, rubella, measles, or arboviruses last for years, perhaps a lifetime. Thus, the cumulative experience of a population can be measured and infection acquired in childhood can be detected in persons of middle or perhaps even old age. Some waning of antibody titers (sometimes below the lowest detectable levels) may occur in older age groups after a childhood infection or vaccination. Similarly, the viral capsid antigen (VCA)-IgG antibody to Epstein–Barr virus measured by the indirect immunofluorescence test has been found to be of long duration; even complement-fixing antibodies to cytomegalovirus, herpes viruses, or dengue virus have been found to persist for years following infection.

Measurement of IgG and IgM antibody by tests such as the ELISA or immunofluorescent antibody tests provides a simple way in a single serum sample of reflecting current and past infection, respectively. Although IgM antibody usually denotes a primary infection, certain viruses such as herpes viruses may induce IgM on reactivation. It should also be reemphasized that unlike prevalence data for clinical infectious disease, serological prevalence data reflect total infection rates, representing both clinical and subclinical (or asymptomatic) infections.

Multipurpose antibody surveys have been carried out in a number of countries. In the United States, the successive NHANES surveys have provided large numbers of serum specimens for estimating cumulative exposure to various infections in representative samples of the population. For example, NHANES was critical in an understanding of hepatitis A immunity in the United States because a vaccination program was initiated in 1996 targeting select higher incidence areas. Stratifying seroprevalence by country of birth and race/ethnicity (Fig. 4.1) showed the higher levels of immunity among foreign-born and US-born Mexican Americans of any age. The impact of the initial vaccination strategy was evident in an analysis of seroprevalence stratified by geographic region and age group (Fig. 4.2) [53].

In a Barbados seroprevalence study [32], a 10 % household sample was randomly selected from a middle- and lower-socioeconomic-level community of 10,000 persons in Bridgetown. The results illustrate the type of information that can be derived from this type of study. Of 100 sera from children under age 10 tested, 30 % lacked protective levels of antitoxin against both diphtheria and tetanus, indicating the need for intensifying the immunization program against these diseases. The prevalence of protective levels against tetanus is a good indicator of the level of public health practice, since this antitoxin is acquired almost exclusively by immunization procedures and not through natural infection. The age distribution of antibodies to various viruses may provide useful information on the behavior of these infections in the community and of the need for immunization programs. On this basis, an active rubella immunization program was initiated in girls aged 12 years or younger. In subsequent years through 1978, a few sporadic cases were reported yearly, but no epidemic occurred [34]. Even sporadic serosurveys have demonstrated utility, for example, the researchers from the Barbados effort conducted a similar survey in St. Lucia [31]. They found important and unexpected differences compared to Barbados, including a higher prevalence of antibodies to dengue and rubella among young persons.

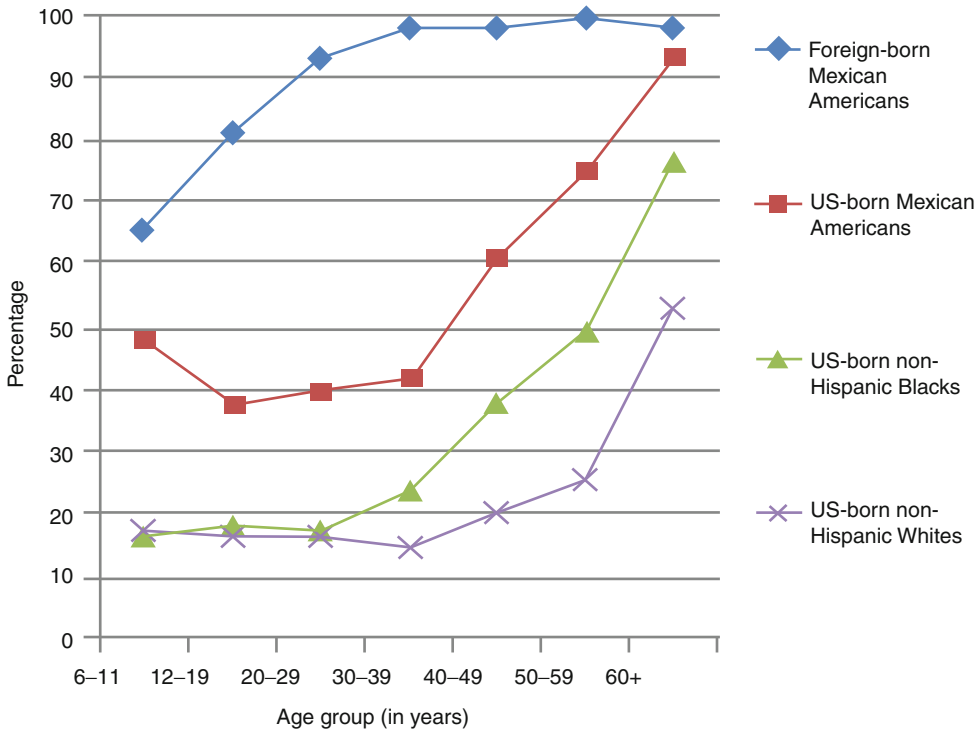

Fig. 4.1 Age-specific seroprevalence of antibodies to hepatitis A virus by country of birth and race/ethnicity, NHANES, 1999–2006

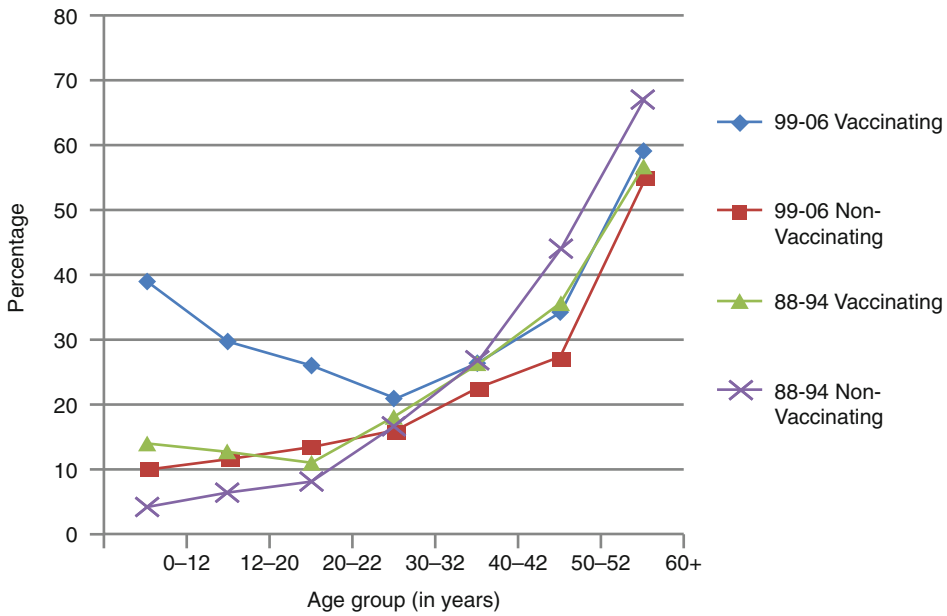

Fig. 4.2 Age-specific seroprevalence of antibodies to hepatitis A virus among US-born people by residence in vaccinating or non-vaccinating states based on 1999 recommendations, NHANES, 1988–1994 and 1999–2006

Initial tests for poliomyelitis antibody employing conventional microtiter neutralization procedures indicated that 27, 42, and 54 % of those tested at 1:5 or 1:8 serum dilution lacked antibody to poliomyelitis types 1, 2, and 3, respectively [32]. Subsequent tests on 304 sera using a 1:2 serum dilution and longer serum–virus incubation periods indicated that only 13.1 % lacked type 1 antibody, 6.5 % type 2 antibody, and 14.3 % type 3 antibody [34]. This emphasizes the need for sensitive methods for detecting low levels of antibody. Two mass poliomyelitis programs were carried out after the 1972 survey, one in 1974–1975 and another in 1977–1978. There have been no reported cases of poliomyelitis since 1972.

The 1972 Barbados serum collection was tested for human retroviruses after the agents were discovered. The HTLV-1 antibody was found in 4.25 % overall, rising in age from a 2.7 % prevalence for persons aged ≤10 years to 9.0 % among those aged 61–70 years [78]. Females had a higher prevalence rate (5.8 %) than males (2.3 %). The adult pattern raised the possibility of sexual transmission, and this was

strengthened by the finding of a prevalence rate of 14.1 % among persons with a positive VDRL test for syphilis as compared with 3.5 % of those who were VDRL negative. There was evidence of household clustering and of vertical transmission.

Advances in laboratory detection of viruses in oral fluids allow surveillance in high-risk groups with less-invasive techniques. For example, unlinked anonymous surveillance among injection drug users seeking services in England and Wales has been ongoing since 1990 [88]. The authors found that the prevalence of hepatitis C infection decreased from 70 % in 1992 to 47 % in 1998 before rising again to 53 % in 2006. Prevalence among women injecting drug users was higher than among men, and that prevalence was highest in certain geographic areas that could be targeted for prevention.

3.5.2 Incidence

Incidence is best calculated from cohort studies such that the appearance of the viral infection can be captured with a known denominator of a well-defined population of persons at risk. However, cohort studies are costly and subject to attrition over time.

Many prospective serological and clinical studies were used to investigate HIV infections and the development of AIDS and related clinical syndromes among high-risk populations such as gay men, injection drug users, persons with hemophilia, and their contacts. Some of the earliest studies were based on cohort methods using sera originally collected for evaluation of HBV vaccine, and others started afresh with a new cohort [50]. The findings in the New York [86] and San Francisco cohorts [10] were as follows: (1) the prevalence level of HIV antibody was 6.6 % in New York at entry into the study in 1978, and rose to 10.6 % by 1984; (2) in San Francisco the entering prevalence was 4.5 % in 1978, but rose dramatically to 73.1 % by 1985; and (3) the rate of viral infection (seroconversion) among those lacking antibody on entry was 5.5–10.6 % per year in New York and 11.2 % in San Francisco. Among gay and bisexual men entering the Multicenter AIDS Cohort Study (MACS) in Baltimore, Chicago, Los Angeles, and Pittsburgh in late 1984 and early 1985 [50], seroprevalence ranged from 23 to 49 %. In a pattern similar to those in other cohorts, the incidence rate of new infection in the MACS, documented at 3–5 % per year in early 1985, declined rapidly during the next 3 years to about 1 % [52]. In Africa and Thailand, measurements of seroprevalence and incidence among prostitutes and other high-risk groups have repeatedly demonstrated the alarming increases that have taken place over a very few years. Transfusion-associated HIV infection systematically documented through serosurveillance of hemophiliacs and other recipients [3, 54, 55], soon after known parenteral exposure, provided an important resource for comparative research on the natural history of HIV infections and the development of AIDS. Further details of serological studies of HIV infection can be found in Chap. 43.

The calculation of incidence is possible from such cohort studies because clinical, laboratory, and self-reported data are collected on participants at regular intervals. Therefore, negative results are available, such that a time period can be calculated between the first positive and the most recent previous negative result. Taken together, these and other cohort studies have yielded critical data for the empirically based projections about burden of infection and disease in select populations.

3.5.3 Outbreak Detection

The advances in genetic characterization and communication online have combined to expand the scope and breadth of serosurveillance into early detection of clusters of infectious diseases. In the United States, norovirus is the most common cause of foodborne disease outbreaks. Surveillance to detect early clusters of disease is conducted through routine notifiable diseases methods and by a laboratory network called CaliciNet [96]. It is a national surveillance network that includes a database for public health laboratories to submit gene sequences from human caliciviruses (noroviruses and sapoviruses) identified from outbreaks. The information is used to link norovirus outbreaks that may be caused by common sources (such as food), monitor trends, and identify emerging norovirus strains.

Measles in the United States provides an excellent example of the use of technology in outbreak detection. In 2000, the United States achieved measles elimination (defined as interruption of year-round endemic measles transmission) (http://www.cdc.gov/measles/global-elimination.html). However, importations of measles into the United States continue to occur, posing risks for measles outbreaks and sustained measles transmission. During 2011, a total of 222 measles cases (incidence rate: 0.7 per one million population) and 17 measles outbreaks (defined as three or more cases linked in time or place) were reported to CDC, compared with a median of 60 (range: 37–140) cases and four (range: 2–10) outbreaks reported annually during 2001–2010.

Measles has also reappeared in other developed countries, and a web-based, quality-controlled database with epidemiologic and nucleotide data for measles infection in the WHO/Europe region was developed: the Measles Nucleotide Surveillance (MeaNS) [60, 79]. The major objectives of the MeaNS initiative are to function as an epidemiologic surveillance tool and to monitor progress in measles control. Dynamic reports and graphical charts can be created on any user-selected fields in the MeaNS database (e.g., genotype or sequence variation in a geographical location or time period). Information about MeaNS is available at http://www.hpa-bioinformatics.org.uk/Measles/Public/Web_Front/main.php.

3.5.4 Diagnostic Serology

Sera sent to large hospitals or public health laboratories for various tests can be frozen and stored for later antibody testing against other antigens. The specimens must be adequate in amount and free of bacterial contamination. Specimens sent for viral antibody tests usually fulfill these criteria and are accompanied by minimal demographic and clinical data concerning the patient. There are many uses for this type of collection. All sera or exanthems coming from patients with central nervous system, gastrointestinal, or respiratory infections can be tested at the time of receipt or, later, against a battery of viral antigens in order to reveal the profile of agents likely to have caused the syndromes. An example of this was the evaluation of the importance of a new virus, called "the California encephalitis virus" in the causation of infections of the central nervous system by testing of all sera received in a state public health laboratory for this syndrome [44]. In Wisconsin, 5.7 % of 351 sera received in the state laboratory over the period 1961–1964 revealed evidence of the new California viral infection [91]; in Minnesota, 4.1 % of 1,617 retrospectively tested sera contained this antibody. A second and related application is the determination of the clinical spectrum associated with a newly discovered virus; this is accomplished by testing stored sera from patients with a variety of clinical syndromes and looking for evidence of infection with the new agent.

A third application for sera stored over time is the measurement of *secular trends* or antigenic shifts in viruses over time. This is especially useful in relation to influenza viruses. A fourth use, employing freshly received sera from high-risk populations, is the search for influenza antibody patterns that may reveal the beginning of an outbreak or a change in the antigen composition of currently circulating strains; this was used by Widelock et al. [101] at New York City public health laboratories. Comparison of the geometric mean antibody titer to influenza sera from persons in the acute phase of an unidentified respiratory illness with the titer in others convalescing from a similar illness may permit early identification of an outbreak without waiting for serial samples from the same persons.

Finally, investigators in South Australia made efficient use of samples taken in conjunction with blood donation. They searched for evidence of Ross River virus activity in different locations during the arbovirus season by measuring IgA-, IgG-, and IgM-specific antibody in samples from Red Cross blood donors. Differences in antibody prevalence by region indicated prior activity and helped identify endemic areas but revealed that acute infection had not occurred in that year at frequencies high enough to be detected [99].

3.5.5 Evaluation of Immunization Programs

The effectiveness of an immunization program is traditionally judged on the basis of clinical cases or epidemic behavior. A program is regarded as effective when cases decrease or epidemics do not occur. This information may be biased by the possibility that the decrease in clinical cases is related to poor reporting or that insufficient time has elapsed for another epidemic to have occurred. Currently, our knowledge of the utilization of vaccines depends on such sources as sales records of manufactures, public clinic and physicians' data, direct interviews, and school entry surveys [20]. Because of the inadequacy of these traditional surveillance techniques in determining the need for and the effectiveness of a given vaccine, serological surveys could play an even larger role in evaluation of immunization programs. Although the necessity for a venipuncture reduces the ease and acceptability of this method, public health professionals and physicians can help surmount such barriers by conveying the importance of seroepidemiology for such purposes. Newer techniques that obviate the requirement for blood sampling may further encourage the application of biological tools to the evaluation of vaccination effectiveness.

The uses of serological epidemiology in immunization programs are summarized in Table 4.4. Much of this information could be obtained in no other way. Serological surveillance has been of particular importance for the new epidemiologic settings created by substituting vaccine immunity for natural immunity as for poliomyelitis, measles, rubella, and to a lesser extent mumps and influenza [30]. With vaccines against HBV universally recommended for infants in the United States and a vaccine against varicella zoster virus, the patterns of susceptibility to and the distributions of these infections have changed substantially.

Table 4.4 Uses of seroepidemiology in immunization programs

1. Cross-sectional surveys to determine the need for immunization programs in:
(a) Different age groups
6–20 months—measure duration of maternal antibody
School/college entry—identify omissions, failures, loss of protective antibody
(b) Different geographic areas
(c) Different socioeconomic groups
(d) High-risk occupational groups
2. Follow-up measurements in immunized persons to determine:
(a) Proportion developing local, humoral, cell-mediated immune responses
(b) Quality and extent of response
(c) Nature and degree of interaction between vaccine components
(d) Duration of response
(e) Level of protection against disease and asymptomatic infection
(f) Degree of spread of live vaccine strains to exposed and susceptible contacts
3. Periodic serological surveillance to identify groups who are not receiving vaccines or who have inadequate responses

Patterns of susceptibility and immunity to all of these viruses may now vary from place to place, from age group to age group, and in various socioeconomic settings, depending on the immunization program instituted by health departments and the activities of physicians and clinics rather than on the inherent epidemiologic characteristics of the natural infection and disease. The methods of immunization practice, the frequency of repeated immunization programs, and the quality and duration of vaccine immunity will increasingly constitute the major determinants of the patterns of these diseases.

Over the years, serological surveys in American cities, such as Syracuse [56], Cleveland [38], and Houston [61], have uncovered serious deficiencies in the antibody patterns for viral diseases for which vaccines are available. The US military has used this approach to similar advantage. A national serosurvey of 1,547 Army recruits entering in 1989 at ages 15–24 years documented 15–21 % seronegativity for measles, mumps, and rubella; 7 % for varicella zoster virus; and 2.3, 0.6, and 14.6 % for poliovirus types 1, 2, and 3, respectively [51]. Likewise, a pre-vaccination survey of 1,568 US Navy and Marine entrants identified important differences in susceptibility to measles; susceptibility was greatest among males, younger recruits and whites [87]. Serosurveillance has also been used effectively in the developing world for such purposes as a general assessment of success in the WHO Expanded Program on Immunization [35] and a specific comparison of HIV-infected and uninfected Zairian infants for responses to polio vaccine [80]. The importance of surveillance programs and serological surveys to evaluate immunization programs has long been recognized [30, 47]. Thanks to testing of antibodies to hepatitis B that allow distinguishing immunization (where antibodies to hepatitis B surface antigen are positive and antibodies to hepatitis B core are negative), from past or from chronic infection, seroprevalence in NHANES has guided the US vaccination program for hepatitis B. Wasley et al. compared findings from the 1999–2006 NHANES with previous surveys and found that a history of infection with HBV had decreased from 1.9 to 0.6 % among children. Prevalence of antibodies consistent with immunization increased from 20.5 % in 1999–2002 to 25.2 % in 2003–2006 [98].

Hepatitis B also was examined in a study of data from 10 European countries. Residual sera were combined with sera from samples available at national serum banks [65]. Testing assays and algorithms were standardized to allow cross-country comparisons. The authors also collected information on country-specific vaccination policies. Six of the ten countries reported low levels (<3 %) of antibodies to hepatitis B core antigen. Of the eight countries testing for HBV surface antigen (HBsAg), Romania had the highest prevalence (5.6 %); the remaining seven countries had prevalence <1 %. Countries can apply findings from such comparisons to modify and adjust their own vaccination policies.

3.5.6 Biomarkers

Revolutionary advances in immunology and molecular biology have opened the possibilities for intensive analysis of humoral and cellular material—what some are calling broadly "molecular epidemiology"—analysis that will clarify the role of viral infection in the pathogenesis of autoimmune, degenerative, neoplastic, and even "genetic" diseases and will facilitate targeted drug and vaccine development. An example of one such possibility for molecular study is a European network for hepatitis B virus. The HepSEQ (http://www.hepseqresearch.org) is a pioneering online resource for the management, characterization, and tracking of hepatitis B infection in the area. An important use will be to detect mutations of the hepatitis B virus such as those consistent with antiviral resistance [64]. This information will be helpful in identifying transmission patterns that will guide prevention efforts.

4 Summary

Systematic collection of cases of infection or disease and of biomarkers of infection or immunity is an essential tool in the prevention and control of viral diseases. Surveillance and seroepidemiology have provided critical epidemiologic information to support public health policy at the local, national, and international levels. Continued advances in laboratory methods and communication systems will expand the applications of surveillance and refine their precision and efficiency.

Viral Dynamics and Mathematical Models

5

Nimalan Arinaminpathy, Charlotte Jessica E. Metcalf, and Bryan T. Grenfell

1 Introduction

The application of mathematics to explore the dynamics and control of viral infections has a long history, which predates its application in many other fields of biology, as well as the germ theory itself [1]. A particularly fruitful area for development has been the dynamics of acute immunizing infections, with their relatively simple natural history and rich notification time series [2–4]. The last three decades have seen a considerable upsurge in the use of mathematical and computational models to explore the dynamics and control of a wide range of viral infections. This phase arose initially from developments in ecological population dynamics [4]; it was then greatly accelerated, both by the explosion in computational power and by the emergence of human immunodeficiency virus (HIV) infection, severe acute respiratory syndrome (SARS), and other potential pandemic threats [5].

In this chapter, we review basic concepts in infection dynamics and control, via a synthesis of epidemic models and data. We begin with acute immunizing infections, focusing on measles as a case study of the impact of herd immunity and other determinants of epidemic dynamics. We then extend the discussion to dynamical modeling applications to a range of other acute and chronic viruses, with a variety of more complex life histories. After a brief discussion of models for the within-host dynamics of viruses, we conclude with suggestions for gaps in knowledge and future research needs.

2 Dynamics of Acute Immunizing Infections

2.1 Observed Epidemic Patterns

Acute immunizing infections typically generate recurrent epidemics in large communities. We illustrate these patterns with the best documented case – the dynamics of measles in large cities in England and Wales [2, 3]. Figure 5.1a shows the time series of raw weekly notifications for measles in London from 1944 (shortly after measles cases became notifiable) to 1994.

These data indicate three fairly distinctive dynamical eras:

- 1944–1950: Principally annual epidemics.
- 1950s–1960s: Regular, mainly biennial epidemic cycles, with intervening small annual peaks – incidence rates are markedly *seasonal* (Sect. 2.4).
- 1970s onwards: The vaccine era brought declining incidence, with increasing irregular, lower-amplitude epidemic cycles. By the end of the series shown in this figure, cases became very sporadic, with increasing levels of mis-notification of clinically identified cases [7].

As well as these fluctuations in individual large cities, there are also rich dynamical patterns in the *spatial spread* of epidemics among large and small communities (Sect. 4). Regional and temporal demographic variations, especially in *birth rate*, can also markedly influence dynamics (Sect. 2.4).

2.2 Epidemic Dynamics: The SEIR Model

The striking epidemic patterns of acute immunizing infections are particularly well documented for widely notifiable infections such as measles. The process of explaining these

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,

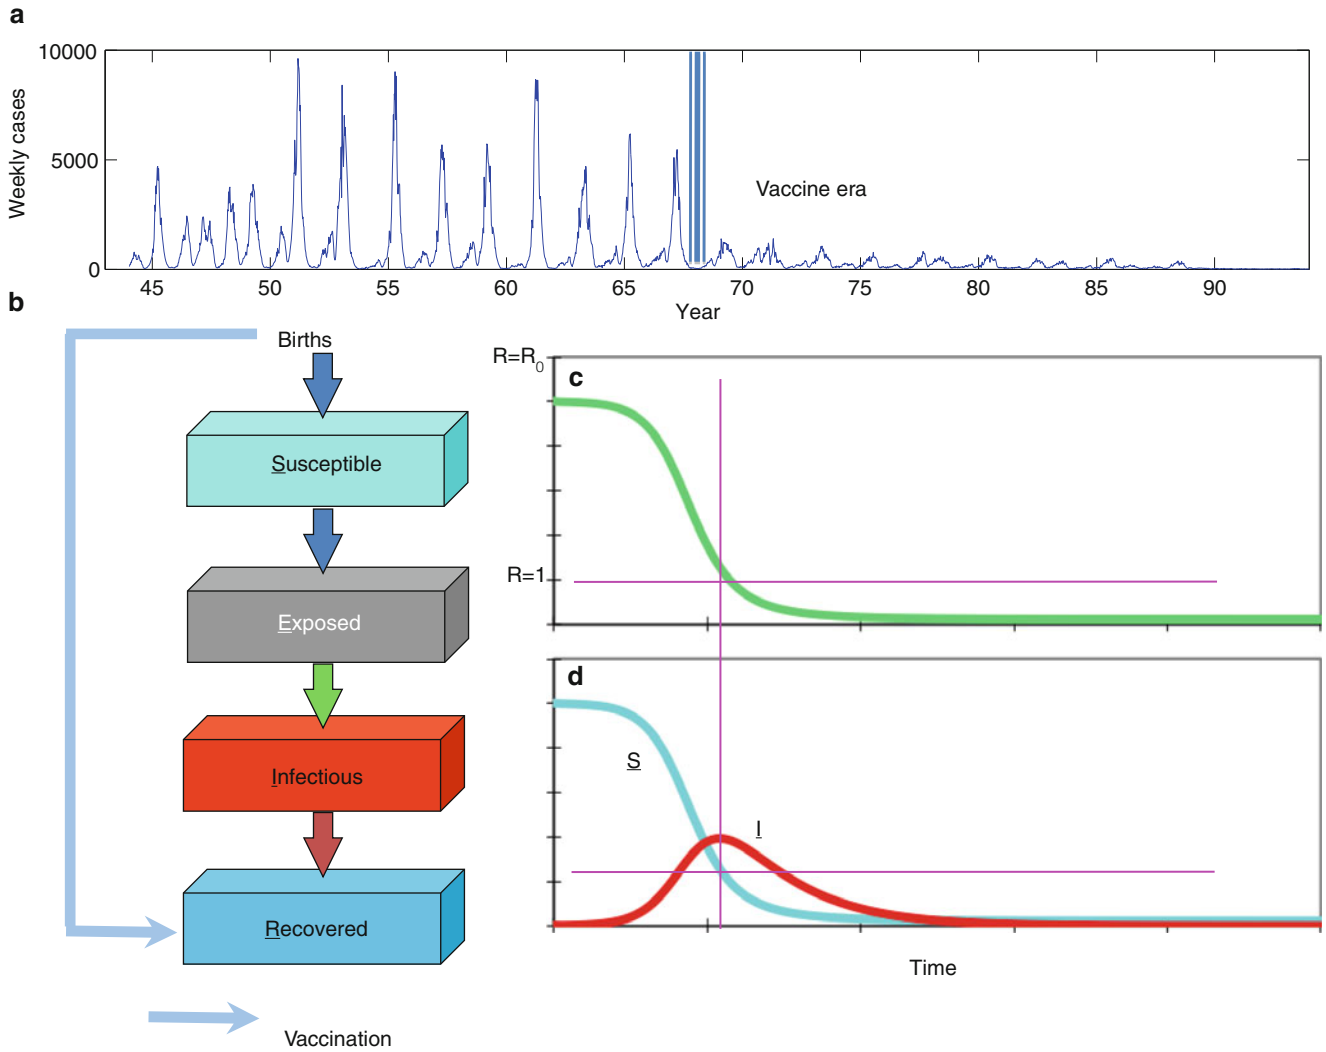

Fig. 5.1 (**a**) Observed spatiotemporal dynamics of measles in England and Wales, showing weekly aggregate time series of notifications for London. (**b**) Basic flows of individuals captured by the SEIR model. (**c**) Schematic time series of numbers of susceptible individuals, arising from flows in panel **b**, and in particular following the introduction of one infectious individual into a wholly susceptible population; the effect of birth rate on susceptibility is ignored. (**d**) Corresponding dynamics for the proportion of the population susceptible (line marked "*S*") and the proportion infected (line marked "*I*") (**b**, **d**: Taken from Fig. 2, Grenfell [6]. Figure found on p. 38)

cycles, as well as that of addressing associated public health issues, has spawned an extensive analytical literature, spanning public health epidemiology, theoretical biology, and population dynamics [4, 5, 8–10]. The key conceptual tool has been a family of compartmental dynamical models, based on the SIR (susceptible-infected-recovered) paradigm [2–5, 11, 12]. As described below, the SIR family successfully captures many key features of the epidemiological dynamics and control of viral infections.

The basic SIR formulation embodies the dynamics of immunizing infections. Because viruses reproduce rapidly in the host, we ignore within-host kinetics in the simplest SIR models (but see Sect. 8); depending on model details, this leads to a compartmentalization of the host population between (as yet uninfected) susceptible individuals, infected, recovered, and other classes. An initial taxonomic split here is between the SIR model (which crudely assumes that all infected individuals can pass on infection) and the SEIR (susceptible, exposed, infected, recovered) model, which adds an "exposed" (infected but not yet infectious) class [4]. SIR and SEIR models have qualitatively very similar dynamics [13]; however, we describe the latter with its more realistic depiction of viral incubation. The basic SEIR model, illustrated in Fig. 5.1b, reflects the following set of biological assumptions; we use measles as the classic acute exemplar here [14]. After a few months of maternally derived passive immunity, infants enter the virus-naïve "susceptible" (S) class; susceptibles can then become infected by close contact with infectious individuals (generally via

respiratory aerosol for measles). Infection moves individuals into the "exposed" (E) class, where they incubate but do not transmit the infection for around a week; this leads to the infectious (I) class, where virus is shed, again for approximately a week, after which individuals enter the recovered state (R). In the basic SEIR model, recovered individuals are assumed to be immune for life, both to clinical disease and to retransmitting the infection. However, subclinical infection (and hence boosting of immunity [15, 16]) is in principle possible. The lifelong sterilizing immunity induced by such an infection also makes this an excellent potential vaccine candidate [4]. For the SEIR model, vaccination is at its simplest assumed to be delivered to a proportion p of infants at the end of the maternal immunity period (i.e., near the effective "birth" of susceptibles). For individuals who seroconvert, immunity is then often assumed to be lifelong, moving susceptibles into the recovered class (Fig. 5.1c). There is also a considerable literature exploring more operationally realistic age distributions and immunogenic characteristics of vaccines in specific cases [5, 17].

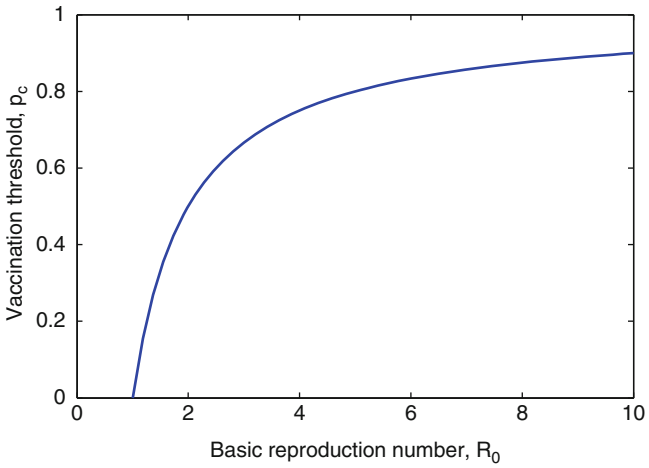

Fig. 5.2 The critical vaccination threshold (p_c) and its dependence on the basic reproduction number, R_0. In the region above the *blue line*, vaccination succeeds in local elimination of infection. Even in the region below the line, however, vaccination can substantially reduce overall transmission

2.3 Herd Immunity and the Impact of Vaccination

We can lay bare much of the dynamical behavior of immunizing epidemics by considering the case of the "simple" epidemic (Fig. 5.1c, d), in which the outbreak occurs sufficiently rapidly to ignore processes of host birth and death. The talismanic quantity here is the basic reproduction number (or ratio) of infection, R_0 [4, 5]. At its simplest, R_0 is defined as the total number of secondary cases caused by an infectious individual when introduced into a well-mixed fully susceptible population. To illustrate the ensuing dynamics, consider an epidemic of infection with $R_0>0$. Since each case initially causes R_0 secondary infections, the epidemic increases more or less exponentially over the first few infectious generations (Fig. 5.1c). However, these dynamics rapidly deplete the susceptible pool. This brings us to the other key parameter of epidemic spread: the *effective* reproduction number, defined as $R=[S/N]R_0$. Here, S/N is the proportion of susceptibles in the population and R is the realized value of R_0 as the epidemic develops [4]. Since S declines over the course of the epidemic (Fig. 5.1c), so does R (Fig. 5.1d).

This progressive decline in secondary infection rates through the epidemic is a manifestation of the key epidemiological process of *herd immunity* [18] – increasing natural immunity of the population that indirectly protects the remaining susceptibles from infection. Eventually, the effective reproduction ratio declines through unity (Fig. 5.1c) as population immunity increases; this corresponds to the herd immunity threshold, above which the epidemic will always decline, even if reintroduced to a closed population. This threshold is thus also a key aim of vaccination campaigns [4, 5]. Remembering that $R=[S/N]R_0$, the associated susceptible proportion at the herd immunity threshold ($R=1$) becomes $s_c=1/R_0$ (Fig. 5.1c); thus, immunizing at a level above $p_c=1-s_c=1-1/R_0$ will eliminate local transmission. As described below, these calculations have been refined considerably to allow for heterogeneities in transmission with age, space, and other characteristics (Sects. 3, 4, and 5). Nonetheless, our simple expression for p_c is an extremely useful metaphor for epidemic control: (1) because of indirect protection, not everyone needs to be vaccinated to eliminate transmission (corresponding to $p_c<1$) and (2) the effort required to increase this level of immunization increases with transmission rates. The latter point is made clear by a simple plot of p_c against R_0 (Fig. 5.2); more transmissible immunizing infections such as measles are harder to control than less transmissible agents such as smallpox. However, this refers to "random" mass vaccination; more targeted strategies such as ring vaccination coupled to active surveillance can promote elimination even below p_c, given (as with smallpox elimination [19]) the right biological characteristics and logistics. Partial immunity and other characteristics of the population can complicate the picture still further (see Sect. 5.2 below). Nonetheless, the metaphor that more transmissibility necessitates a stronger vaccination effort remains.

2.4 Seasonal Transmission and Recurrent Epidemic Dynamics

2.4.1 Observed Epidemic Patterns in Developed Countries

In the simplest analysis of an immunizing infection (Sect. 2.2), sustained cycles of infection will disappear, and the infected proportion in the population will settle to a constant level

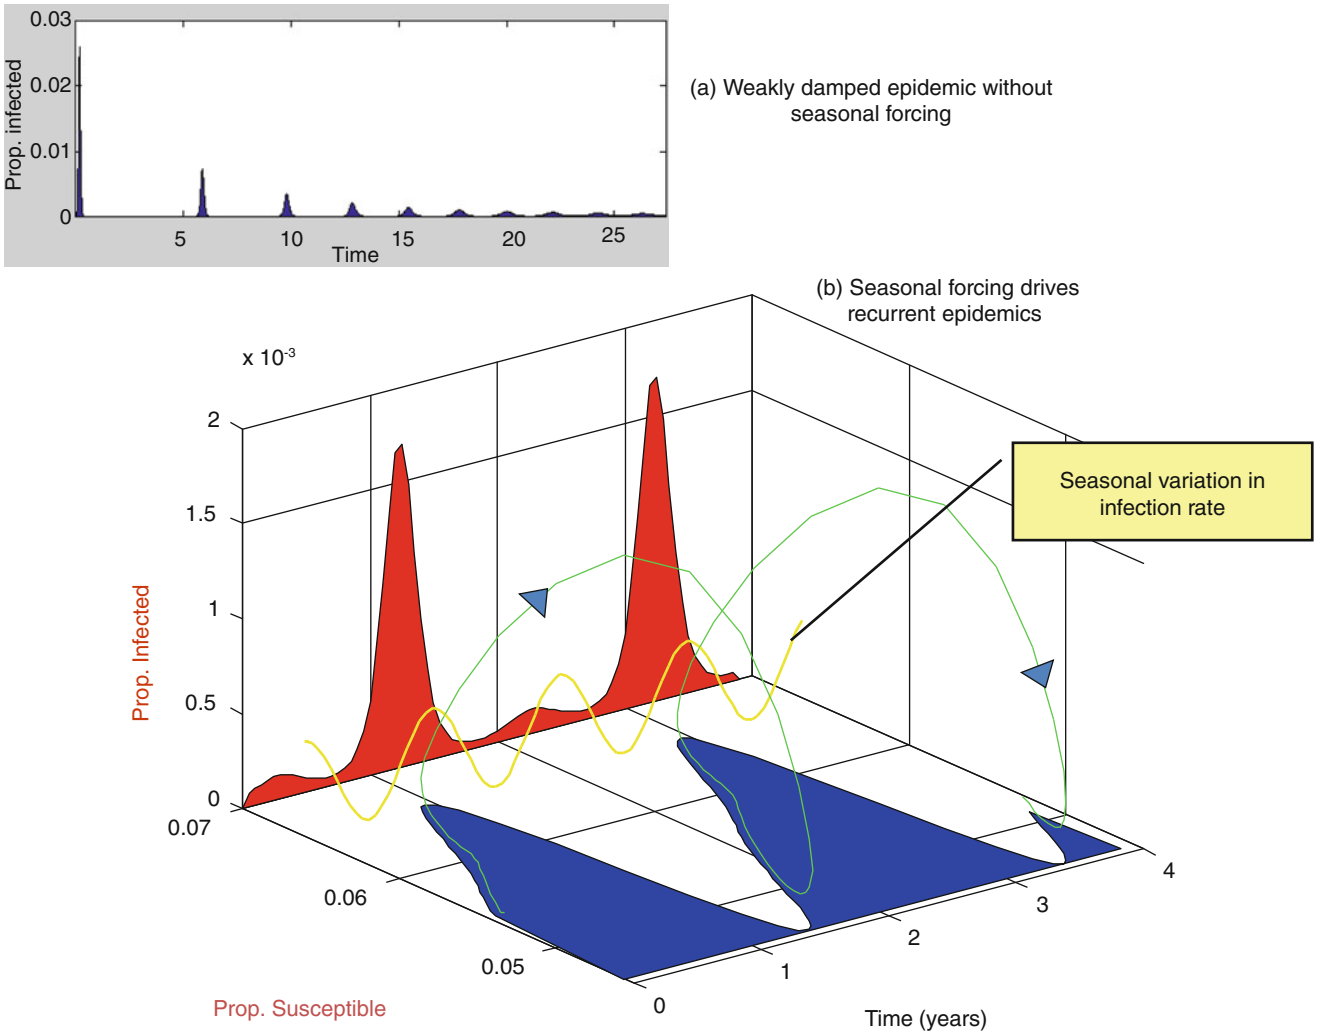

Fig. 5.3 (**a**) Simulated SEIR dynamics for measles with a birth rate, but in the absence of seasonal forcing of transmission rate; for full model specification and parameters, see Grenfell and Bolker [20]. (**b**) Same model, with sinusoidal forcing of the infection as shown (forcing amplitude set to 0.2; Grenfell and Bolker [20]). The green trajectory shows the joint dynamics of susceptible and infectious densities through time; area plots show the dynamics of infectious and susceptible individuals (Taken from Fig. 3 in above book chapter, found on p.39)

(Fig. 5.3a). The question of what maintains the recurrent epidemics [9] generally observed for immunizing childhood infections (e.g., Fig. 5.1) drove researchers to seek the key aspect of biological realism missing from the simplest SEIR model. For measles in England and Wales, seasonal variation in transmission driven by increased contact rates of children when schools were in session rapidly emerged as a possible candidate [12, 21] and has since received considerable empirical support [2, 3]. Stochastic fluctuations in incidence could in principle also contribute to the maintenance of cycles [22, 23]; however, for measles, the predominant driver is seasonality in transmission [2, 3]. Birth rate may modulate the periodicity of recurrent cycles driven by seasonality through its role in determining the rate of susceptible replenishment [24]. For example, for most of the postwar pre-vaccination era in London, seasonality generated sustained cycles by resonating with the biennial epidemic tendency of measles dynamics. However, during the postwar baby boom, births achieved sufficient levels to shift measles dynamics into annual cycles (Fig. 5.4).

2.4.2 Epidemic Dynamics in Developing Countries

It was realized early that seasonality could also result in more complex dynamics, including chaotic fluctuations, that is, very irregular dynamics with little long-term predictability. Contexts with both high and low birth rates (and both high and low transmission since birth rates and transmission act dynamically in very similar ways for immunizing infections [24]) can promote complex dynamics via coexisting attractors. Until recently, it was thought that chaotic measles dynamics were not likely to

be observed [3, 25], since observed seasonality in transmission was not strong enough to drive the associated violent epidemics. However, recent analyses of measles in Niger revealed very strong seasonality (driven by movement in and out of cities linked to rainfall); this, combined with high transmission rates and the highest birth rate in the world, results in irregular outbreaks consistent with expectations of chaos (Fig. 5.5). Erratic boom and bust outbreaks are expected to continue even as routine vaccination improves; and this suggests that high investment in reactive vaccination and surveillance is important, and pulsed vaccination approaches such as supplementary immunization activities could also play a helpful role in synchronizing dynamics [26].

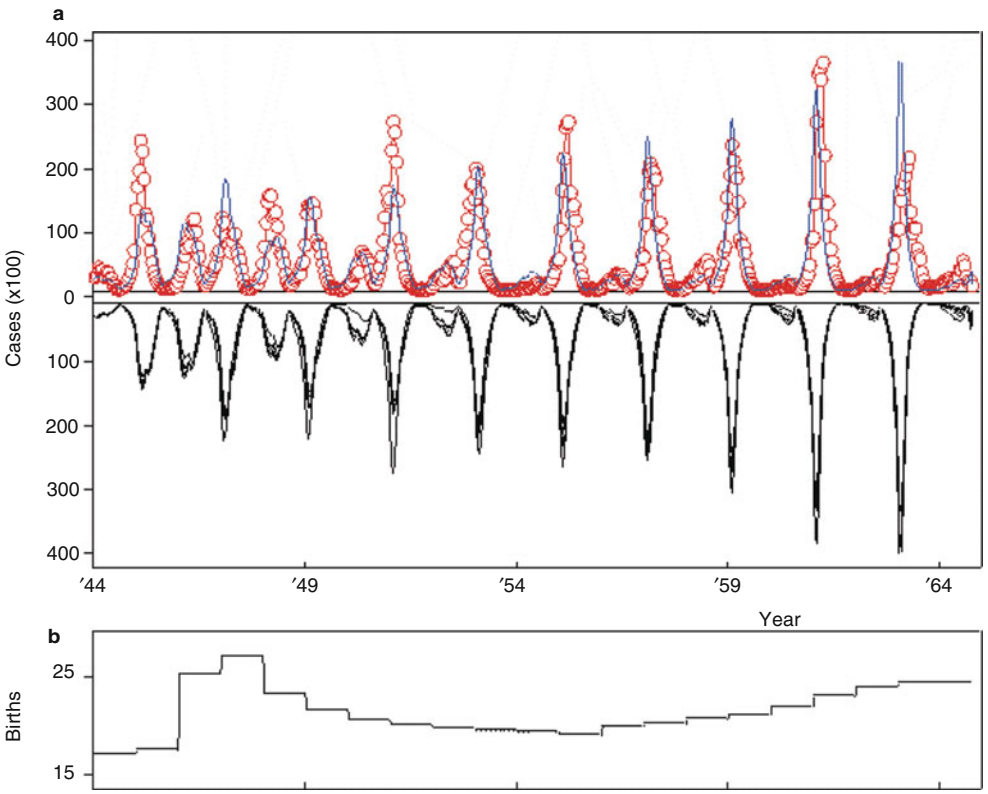

Fig. 5.4 (**a**) Observed pre-vaccinations measles dynamics for London (*red circles*), corrected for under-reporting, along with predictions of an autoregressive time series version of the SEIR model, starting at the observed initial density of cases and susceptibles (for more details, see [126]) (**b**) Birth rates accompanying the dynamics in panel (**a**) (Taken from Fig. 4 in above book chapter, found on p. 41)

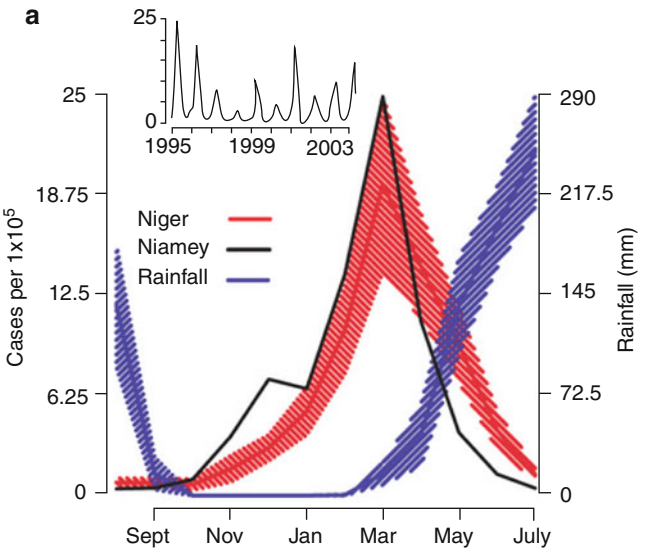

Fig. 5.5 Time series dynamics of measles outbreaks from Niger. (**a**) Mean number of reported measles cases per 10,000 nationwide in Niger from 1995 to 2004, and the mean monthly rainfall over the same time period (*blue*). Shaded regions give ±2 standard deviations. *Black curve*, mean monthly cases of measles in Niamey from 1986 to 2005. *Inset* monthly measles time series from 1995 to 2004. [26]; http://www.nature.com/nature/journal/v451/n7179/images/nature06509-f1.2.jpg)

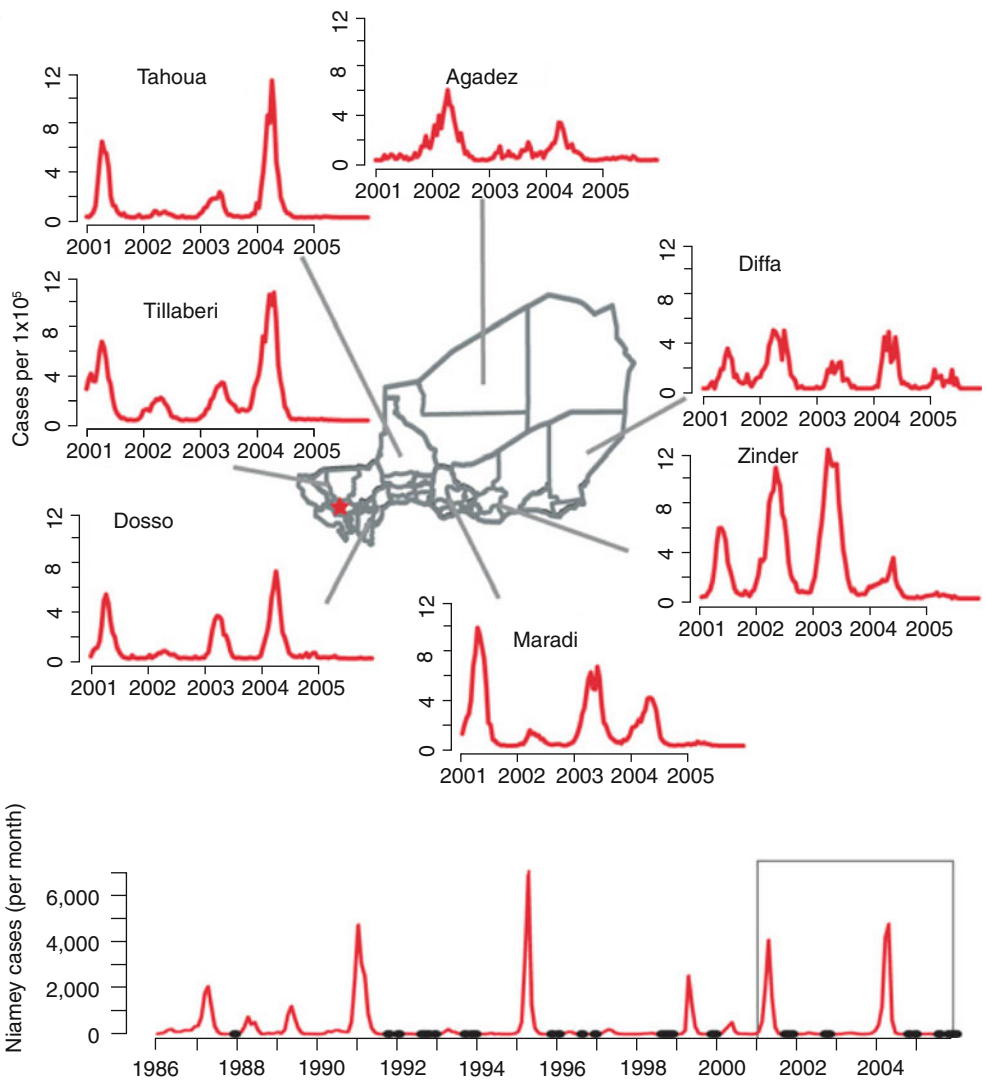

Fig. 5.5 (continued)

3 Age Structure, Demography, and Serological Profiles

The mean age at which individuals become infected by immunizing viral infection is generally lower for infections with higher rates of transmission or R_0 (defined above). Intuitively, this occurs because the faster an immunizing virus is spreading through a population, the younger the age at which individuals are likely to be exposed to it. Host demography modulates this relationship, and higher birth rate countries with an R_0 equivalent to that in lower birth rate countries will tend to have a lower average age of infection [27]. Maternal immunity, or protection of children after birth by transfer of maternal antibodies, will also have an impact, increasing the average age of infection for children whose mothers have been exposed to infection. Since maternal antibodies rarely persist for much more than a year, this effect will be greatest for infections with very low average ages of infection [4]. Beyond these broad descriptors, however, there is the added complication of possible relationships between age and probability of exposure to infection. Such relationships may arise for a variety of reasons. For example, only individuals beyond a certain age may work in areas where the disease is transmitted, or the disease may be only sexually transmitted. As a result, the force of infection, or probability that a susceptible individual will be infected, will show a distinct relationship with age.

For directly transmitted infections, like measles, mumps, rubella, and influenza, the age profile of the force of infection is determined by the rate at which individuals of different ages interact. There are two approaches to estimating this variation. The first is to use age profiles of seropositivity to infer the pattern of the force of infection and, from this, extrapolate to the pattern of contacts over age [28–31]. The link between these age profiles and the force of infection over age can be made since once an individual has been

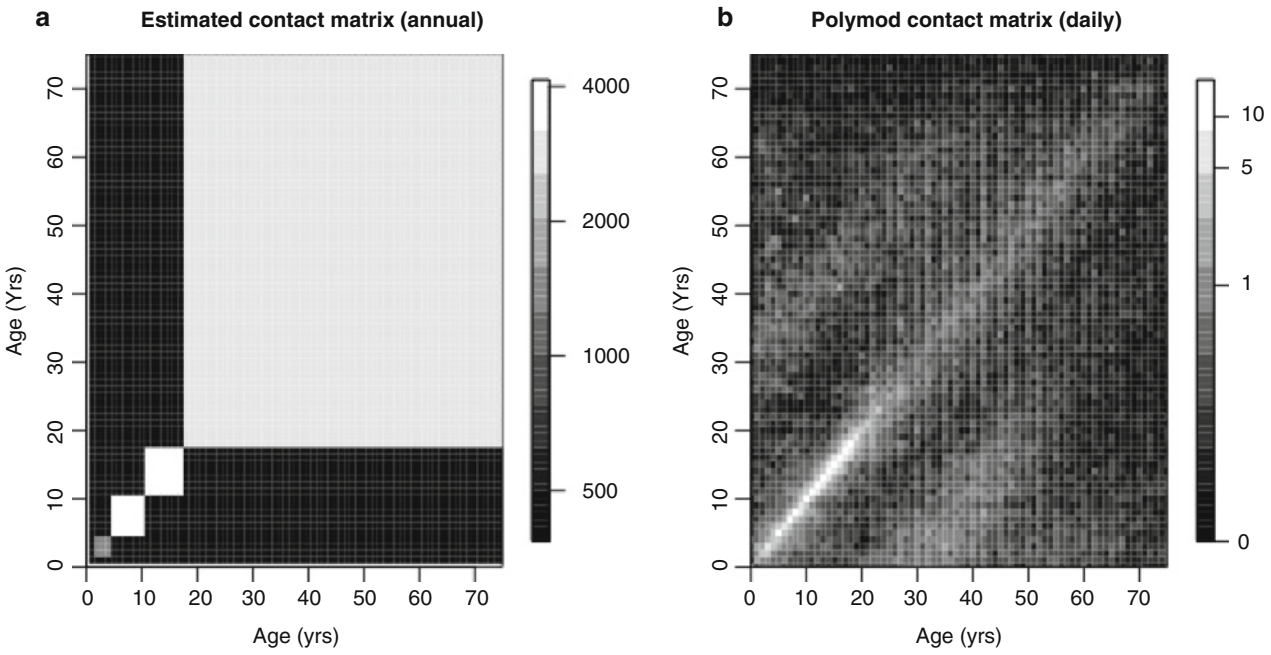

Fig. 5.6 (**a**) Contact matrix (annual) estimated from serology profiles and incidence data using maximum likelihood approaches (Ref. [30]), here showing a semi-assortative mixing matrix; (**b**) POLYMOD contact matrix (daily) obtained from diary studies showing records across all of Europe (Ref. [34])

infected, she/he can never be infected again. Therefore, to be immune at any age, the individual must have contracted the infection prior to that age. On a population level, cross-sectional seropositivity thus provides an indication of the total risk of infection for individuals up to a given age. (Longitudinal age-serological profiles can be even more powerful in quantifying epidemic risk [32]).

The age profile of infection can be framed mathematically [33], and parameters describing contacts between individuals of different ages inferred [31]. The resulting estimated matrix of contacts over age is known as the Who-Acquires-Infection-from-Whom or WAIFW matrix. Alternatively, patterns of contacts between individuals can be directly measured [34], for example, using diary studies (Fig. 5.6); and by combining this with the age profile of infection within the population, the force of infection over age can be inferred [35].

The infection dynamics themselves may also influence the relationship between age and force of infection. If outbreaks are separated by long intervals during which little exposure occurs, individuals may remain susceptible for many years and thus contract the infection at a later age than might be predicted from the age profile of contacts alone [36]. More subtly, detailed network analyses show that even within a single influenza outbreak, the burden of disease can cascade from children (where contacts are highest) to the less connected adults as immunity accumulates within the children, with implications for optimal vaccination distribution [37].

Understanding the processes underlying the average age of infection has a practical importance for any infection where the burden of disease shows an age profile. Rubella is a classic example. Infection during early childhood tends to be mild, but infection during pregnancy may result in birth of a child with congenital rubella syndrome, consisting of a range of birth defects (see Ref. [38]). A realistically complex age structure of mixing, as detailed in empirical studies, may thus be of crucial importance in establishing the burden of disease [39] but also how the burden of disease is likely to change as a result of vaccination.

4 Spatial Dynamics

So far, we have assumed that deterministic, spatially homogeneous dynamics govern infectious disease outbreaks. In fact, epidemics often spread across a heterogeneous landscape of human cities, towns, or rural communities, and this spread depends partly on the links between those locations. This leads us to move from the *deterministic* SIR model described above to *stochastic* models, which account for the random nature of individual infection dynamics and demography – for instance, individuals may or may not become infected with a given average probability, so that by chance, particularly in small populations, no new infections may occur, and the chain of transmission may be broken. During the troughs between epidemic outbreaks in smaller communities, incidence may fall to such low numbers that local extinction is likely.

Based on this observation, Bartlett [9, 40] used analyses of epidemiological data and stochastic models to develop the notion of critical community size (CCS), or population size below which stochastic extinction is expected, which was further developed by Black [41] in studies of measles persistence in insular populations. Bartlett demonstrated the existence of a CCS of around 300,000–500,000 for measles in England and Wales. For measles to persist in locations with a population size smaller than this CCS, immigration of infected immigrants from elsewhere in the metapopulation is necessary. The result is that the spread of measles across England and Wales in the pre-vaccine era resembled traveling waves spreading out from London [6], with a substantial epidemic lag in locations further away. The duration of the lag was also shaped by the size of the local populations. The duration of fade-outs following local extinction contains information on the degree to which a particular location is connected to the metapopulation as a whole [42]. Generally, this points to larger places being more connected. More detailed parametric analyses tend to confirm this (e.g., the gravity model [43]).

Similar processes may operate for immunizing or lethal infections in animal populations, with, for example, the spread of rabies through raccoon populations acting as an invasion wave structured by large landscape features such as rivers [44]. For more complex human infections, features such as imperfect immunity (see Sect. 5.2 below) will tend to shift the age class of hosts who disperse the infection. That shift may impact on the main mechanism of dispersal [45] and move the scenario away from invasion into a locally coupled landscape to a more demographically driven dynamic [46].

5 Comparative Dynamics

So far, we have explored the epidemiological dynamics of acute, immunizing viral infections. Though the resulting dynamics are both important and fascinating from a dynamical perspective, the natural (life) history of most viral infections departs, in one way or another, from this simple case. We review these complexities, and their epidemiological and control implications, in succeeding Sections.

5.1 From Acute to Chronic

A dramatically different life history from the transient infection paradigm represented by measles is observed with infections that are much more persistent (even lifelong). This difference may be expressed in terms of infectious period in individual hosts [4]. To illustrate how increasing infectious period alone modifies the violent epidemics of childhood infections, we retain the assumption of lifelong immunity of the SEIR model and vary the infectious period, from the roughly 1 week of measles to 10 years, corresponding to the approximate average pre-HAART treatment infectious period of HIV [4].

Figure 5.7 explores this comparison, simulating an infection which invades a partly susceptible population (full details are given in Ref. [6]; note that for clarity, the epidemic curves for 1- and 10-year infectious periods are raised above the curves for the more acute infections). Each simulation refers to a virus with a different infectious period. We assume that R_0 is identical for each of these infections. R_0 is roughly given by the product of mean *per capita* infection rate and infectious period; thus, to keep R_0 constant:

- A short infectious period implies a relatively high infection rate.
- A longer infectious period requires a lower infection rate.

This assumption imposes a simple evolutionary constraint on our set of model pathogens in Fig. 5.7, in that fitness (roughly equating to R_0) is kept constant as we increase the infectious period. Figure 5.7 indicates, first, that increasing the infectious period reduces, and eventually eliminates, the tendency for cyclical epidemics [48]; essentially, a longer infectious period "fills in the troughs" following major epidemics. As infectious period increases, we therefore see a transition from seasonally driven biennial epidemics (at the measles extreme of a 1-week infectious period) to low-amplitude annual epidemics (at 1 month). For longer infectious periods (1 year), we see slowly evolving epidemics with little seasonal activity and a modest post-epidemic overshoot. Finally, for a 10-year infectious period, we see a smooth slow epidemic, with an essentially "logistic" rise to a stable endemic plateau of incidence. Though crude, this exercise captures the essential dynamical transmission from the violent epidemics of acute infections to the much smoother and slower epidemic invasion of HIV [4]. Note that the seasonal variation in infection rate is assumed similar for the "measles" and "HIV" cases; however, the latter completely eliminates associated seasonal fluctuations in incidence due to the smoothing effect of prolonged infectious carriage.

Figure 5.7 also illustrates a second major dynamical impact arising from the trade-off of increased infectious period against lowered infection rate. "Fast" infections are much more prey to local stochastic extinction in the deep troughs between epidemics (Sect. 2.4) than the much more endemic incidence promoted by longer infectious period. On the other hand, acute immunizing infections can invade populations much more quickly than chronic infections for the same R_0 (Note that very imperfect immunity (corresponding to 'SIS' dynamics) could generate 'fast' invasion even for relatively chronic infections (Figure 5.7, inset), because of the increased supply of susceptible individuals (Sect. 5.2)). Note that, despite these great variations in dynamics, the assumption of a common R_0 means that the herd immunity

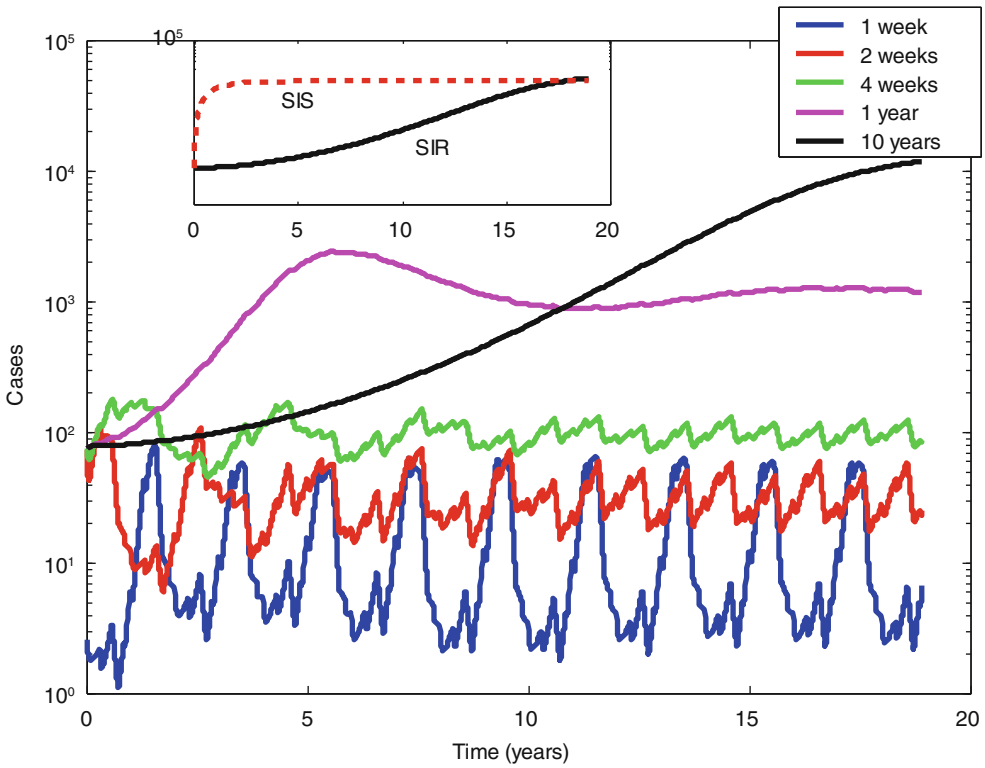

Fig. 5.7 Numerical solutions of seasonally forced SEIR models (see Fig. 5.3b), showing changes in the dynamics of infection caused by increasing the infectious period (see *color key*) while maintaining the basic reproduction number of infection at a constant level. To simulate crudely the initial dynamics of a "novel" infection, the system starts by introducing 6 % infectives into a 20 % susceptible population (a real novel epidemic might be much more violent if everyone is susceptible). *Inset*: Comparing the "slow" dynamics generated by a 10-year infectious period with a (sketched) solution of an SIS model with much faster dynamics (Taken from Figure in Box 2, Grenfell and Harwood [47])

threshold for elimination of infection is the same across this range of behaviors Sect. (2.3).

5.2 Departures from the SEIR Paradigm

We have seen that the SEIR framework (Fig. 5.1b) can be a powerful tool for capturing the dynamics of perfectly immunizing infections such as measles. With its various refinements to incorporate structure in the host population (such as age and spatial distribution), it yields a rich variety of dynamical behavior (Fig. 5.7). Given the range of immunological complexities and different viral life histories, however, it is clear that SEIR dynamics are only part of the story. In such cases, it is often possible to adapt Fig. 5.1b to more faithfully reflect such important biological complexities.

5.2.1 Waning Immunity

Many viruses are capable of reinfecting a host. This may be due to the waning of host immunity over time, as with respiratory syncytial virus (RSV) [49], or due to viral evolution for immune escape (e.g., with norovirus [50] and influenza) [51, 52]: see Sect. 6 for a more in-depth treatment of the latter. In either case, the overall dynamical effect is for recovered, immune individuals to eventually reenter the susceptible pool, as illustrated by Fig. 5.8a.

Where such waning of immunity is appreciable, the implications for vaccination can be profound. As the susceptible pool is replenished not only by births but also by previously immune individuals, the critical vaccination threshold (Sect. 2.3) is raised, making it more difficult to control the spread of infection. For this reason, vaccination against many imperfectly immunizing infections is aimed at direct protection of those receiving vaccine, rather than at raising indirect protection.

5.2.2 Partial Immunity

So far, the models we have considered assume that immune individuals have solid, transmission-blocking immunity, even if this should wane through time. In reality, however, it is common for immunity to be clinically protective (i.e., against symptomatic disease) but only partially protective from infection. This applies, for example, in the case of rotavirus, the leading cause of severe diarrhea in infants worldwide [53, 54]. Figure 5.8b illustrates a model structure developed to capture these dynamics [46].

5.2.3 Host Heterogeneity in Transmission

Recalling the qualitative differences between the dynamics of acute and chronic infections (Fig. 5.7), some viruses show a "mixed" character on the host population level: while some individuals clear infection relatively quickly, others may continue to harbor the virus as "carriers," either in a latent phase or in a chronic infectious state, for a longer period. An example is hepatitis B, in which 5–10 % of adult patients show chronic infection. As illustrated in Fig. 5.8c, this can be represented mathematically by identifying two infectious classes: one acute and the other chronic.

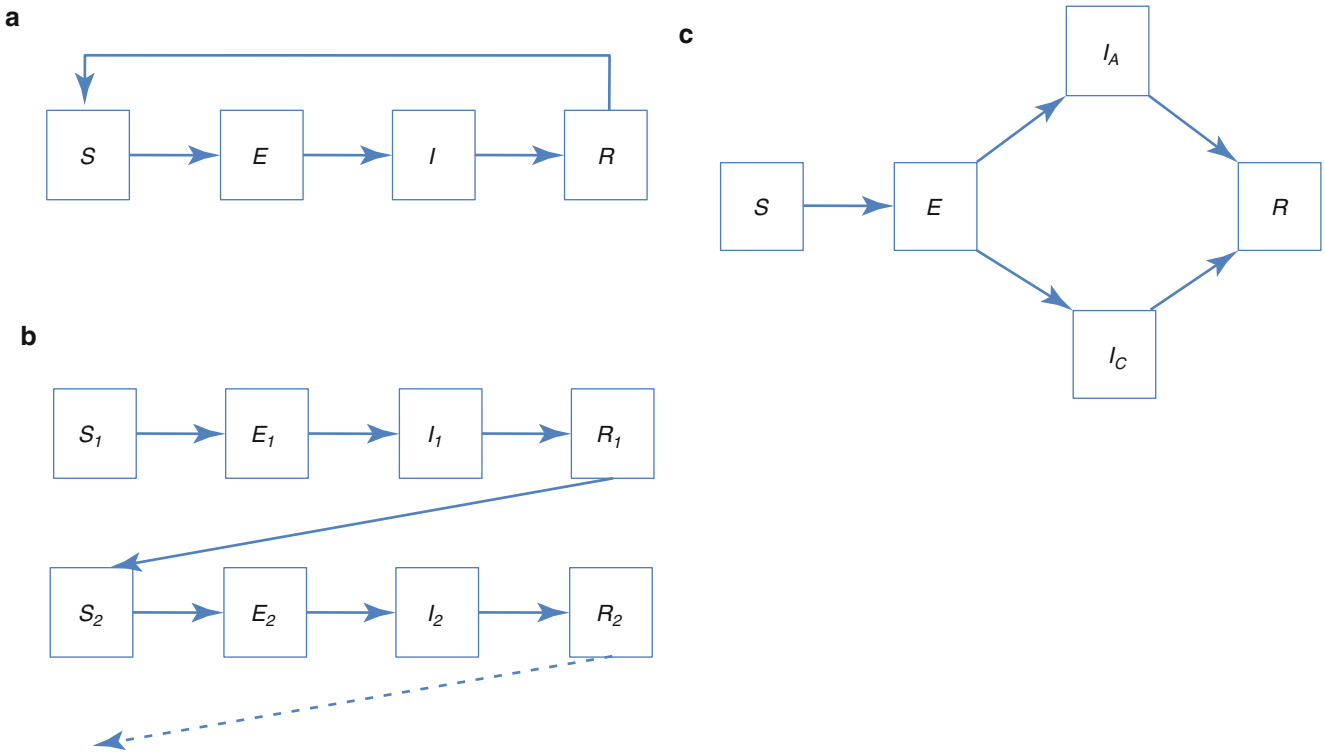

Fig. 5.8 Examples for extensions of the basic SEIR model (Fig. 5.1b). (**a**) Waning immunity can be represented by allowing individuals to return from recovered (R) to susceptible (S) status at a given rate. (**b**) If acquired immunity affords clinical but not sterilizing (transmission-blocking) protection, then additional SEIR stages may be incorporated to capture the corresponding effects on transmission dynamics. (**c**) An example of population heterogeneity, distinguishing "acute" cases (I_A) from "carriers" (I_C), the latter recovering at a slower rate than the former

Such factors can have implications for the dynamics and persistence of infections in a population [55]. In particular, where a disease shows epidemic cycles, facing the possibility of local extinction in the epidemic troughs, the presence of a small number of carrier hosts can facilitate viral persistence in the population, through these troughs. For example, in some cases infection with varicella zoster virus can be followed decades later by infectious shingles, an occurrence which could maintain the virus in small populations [56].

5.2.4 Complex Viral Strain Interactions

Strain structure, vector dynamics, and seasonality in transmission offer yet more complexities, as in the example of dengue [57]. Spread by *Aedes* mosquitoes, dengue has shown a significant emergence worldwide in the last 50 years.

Dengue dynamics are notable for the global circulation of four distinct serotypes (see Fig. 5.9a). Notably, prior immunity to a given serotype can elevate the risk of severe disease from subsequent infection by a different serotype [60–62]. It has been proposed that this arises from antibody-dependent enhancement (ADE) between different serotypes [63, 64], and modeling studies suggest that ADE could play an important role in shaping the epidemiological and strain dynamics of dengue, on the host population level [65–67].

However, there are also indications of a short period of cross-protective immunity (i.e., against all serotypes) for 2–9 months following infection [68], potentially mediating some degree of competition between serotypes. Several studies have addressed the dynamical implications of interactions between ADE and such immunity [69, 70]. Dengue dynamics are therefore complex and multifactorial: an understanding of these effects is important in understanding the potential for unexpected effects from transmission-reducing interventions [71].

6 Dynamics and Evolution of Immune Escape

Had viruses been discovered by the time that Darwin proposed "descent with modification" in the mid-nineteenth century, they may quickly have been recognized as fine examples of evolution in action. Indeed, today there is wide acknowledgment of the inextricable role that evolution plays in viral dynamics [58] and in the control of many different viral infections. RNA viruses in particular, lacking the replication fidelity of a DNA genome, are capable of considerable mutation rates [72]. In the presence of host immunity, natural selection

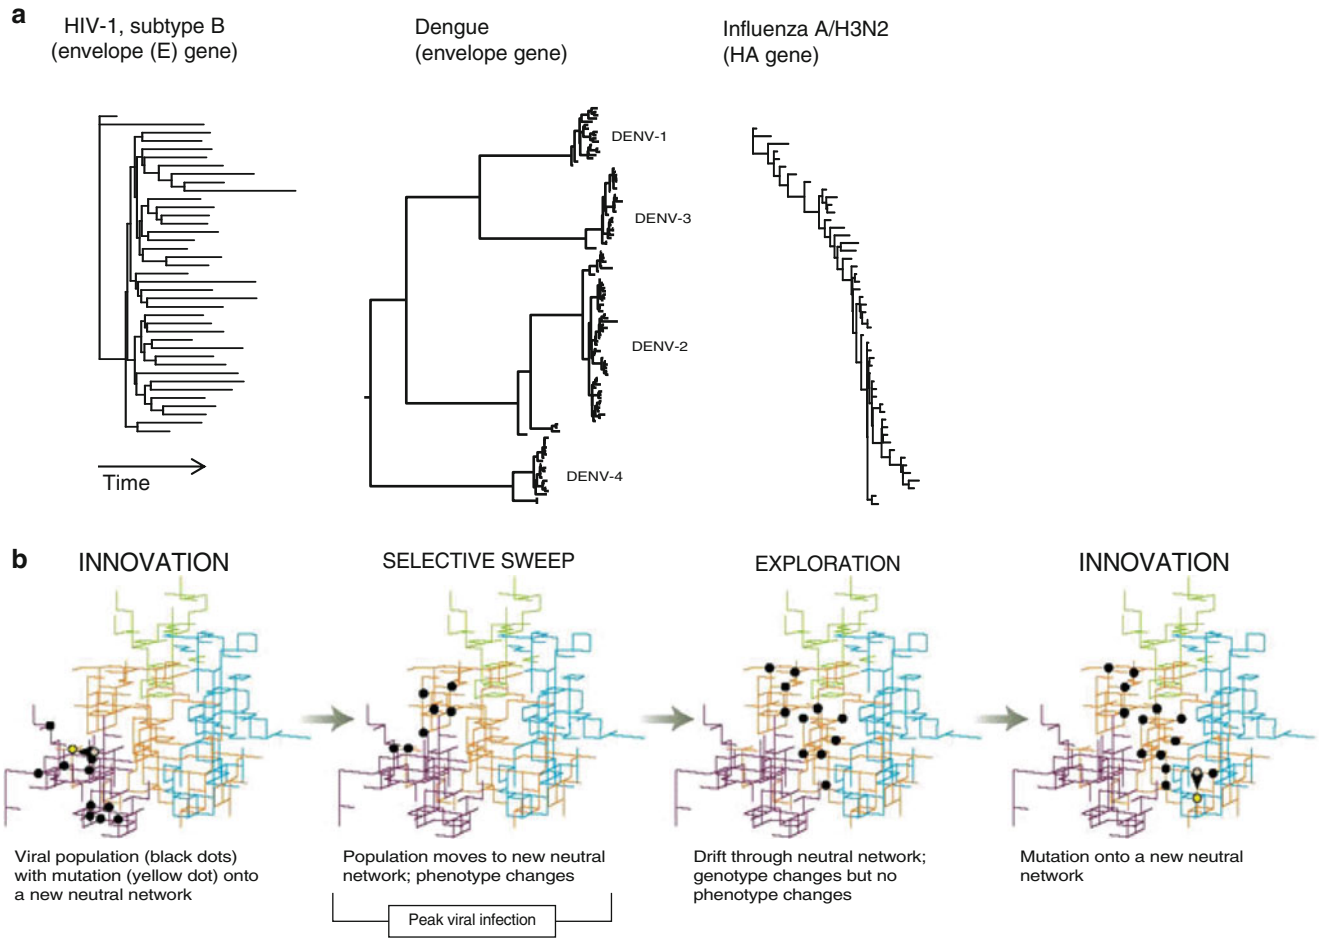

Fig. 5.9 (**a**) A diversity of viral diversity: examples of major human infections showing different patterns of evolution (Taken from (Ref. [58]), and references therein; Adapted from Fig. 1, Grenfell et al. [58]) (**b**) Schematic illustration of the "epochal evolution" model, which seeks to explain notable features in the phylogeny of human influenza A (panel **a**, rightmost phylogeny) (Taken from figure in van Nimwegen [59])

will favor those mutants most capable of evading immunity while still being capable of spreading between hosts.

As a result of these high mutation rates, population-level evolutionary patterns that can arise are quite diverse. Figure 5.9a illustrates how some infections, such as HIV, show significant population-level diversity [73], while others, notably seasonal influenza A, exhibit a markedly different pattern, with a "trunk-like" phylogeny on the population level [74].

The case study of influenza demonstrates not only interesting evolutionary patterns but also the following important features:

(i) The challenges that evolution can pose for infection control
(ii) The complex interplay, across a range of physical scales, between the evolution of a pathogen and its success in spreading in a host population
(iii) The many outstanding questions that remain, in understanding how viruses adapt to continue reinfecting their hosts

In what follows, we explore both within-host and population-level aspects of influenza evolution, with an emphasis on seasonal (interpandemic) influenza. We then set out the prevailing paradigms that seek to explain how these patterns arise, through complex interactions between viral evolution and epidemiology.

6.1 Immune Escape and Herd Immunity

Classic theoretical principles [4] provide a useful framework in which to think about viral evolution, where "evolutionary fitness" is determined ultimately by the capacity for transmission in a given host population. Recall from Sect. 2.3 that in the presence of prior immunity in the population, the effective reproduction number, R, serves as a compact measure of transmission potential. Vaccination aims to lower R through reducing the number susceptible in the population; however, evolving pathogens introduce the complexity of countering this effect, by evading immunity and thus acting

to restore R. Note the combination of immune escape and transmissibility encapsulated in R. In particular, on the scale of the host population and with a given level of existing immunity, the escape mutant with the greatest evolutionary fitness is that which maximizes R [5].

6.2 Molecular Aspects of Viral Evolution

As discussed in Chap. 21, the influenza surface protein hemagglutinin (HA) is a key immune target, with anti-HA antibodies capable of offering sterilizing immunity, that is, the potential to block host infection altogether. Indeed, raising such immunity is a central function of current influenza vaccines. However, HA is also the most variable viral component, continually under selective pressure to escape antibody binding [51]. For these reasons, while influenza evolution is by no means limited to HA, this viral component has attracted the most attention.

An important mechanism of immune escape is through conformational changes of HA epitopes to abrogate antibody binding, without compromising the ability of the virus to attach to host cells [75]. More recently, however, results from mouse experiments suggest that escape mutants can also acquire increased viral avidity for host cells [76]. Another potential immune escape strategy [77] is glycosylation, or the attachment of oligosaccharides to the HA molecule, to occlude epitopes from antibody binding. Such strategies are not without potential functional costs for replication [78], and yet there are indications that human influenza A/H3N2 has been accumulating glycosylation since its introduction into the human population in 1968 [79, 80].

6.3 Population-Level Manifestations of HA Evolution

On a genetic level, the evolutionary pattern for influenza HA (Fig. 5.9a), showing serial replacement of strains through time, is often characterized as "drift." The limited standing diversity, or "trunk-like" phylogeny, is especially paradoxical in light of the relatively high mutation rate of influenza A, where instead several lineages might have been expected to emerge and coexist in the population.

Moreover, how do such *genetic* patterns translate to *antigenic* properties, that is, viral interaction with anti-HA antibodies? In 2004, new techniques allowed a characterization of the antigenic evolution of the influenza subtype H3N2 [74] during the years since its introduction into humans in 1968. The resulting pattern is characterized by "punctuations" in antigenic evolution, occurring roughly every 2–8 years, in contrast with the more gradual pattern of genetic change shown in Fig. 5.9a. These punctuations have great importance for public health, often necessitating major reformulation of current, HA-based vaccines [81].

Two prevailing paradigms explaining these important phenomena, on both the genetic and antigenic levels, are the *epochal evolution* model [82] and that of *strain-transcending immunity* [83]. Both may be considered "phylodynamic" models [58], in the sense of aiming to capture the complex interactions between viral immune escape, viral population genetics, and epidemiology.

The picture of "strain-transcending immunity" [83] invokes a temporary mode of immunity, which immediately follows recovery from infection and protects the individual against infection by all influenza strains. Such broad immunity is postulated to arise, for example, either from T cells or from innate immunity [83]. Over the course of months, this broad immunity gives way to more long-lived, more narrowly acting immunity that is specific to the immunizing strain. On the population level, a key dynamical effect of such immunity structure is to impose population-level constraints on viral diversity, sufficiently strong to maintain a single dominant lineage through time.

The epochal evolution model [82] provides an alternative view. It builds on the proposal by Kimura in 1968 [84] that many amino acid substitutions in nature do not alter evolutionary fitness and are thus *phenotypically neutral*. If influenza HA evolution can be thought of as tracing a series of paths through a space of genotypes, the epochal evolution model proposes that, in phenotypic terms, such a space has a modular structure (Fig. 5.9b) in which each "module" is a group of genotypes sharing the same antigenic phenotype and a transition between modules corresponds to the observed antigenic "jumps." In particular, HA evolution diffuses through the local genotype space, accumulating neutral substitutions and thus genotypic diversity, over several years. Ultimately, a single strain accumulates the substitutions required to transition to a new antigenic phenotype. At this point, the emergent strain – owing to its antigenic novelty – causes a peak in infection and undergoes a selective sweep in the host population, to the exclusion of other strains. Such an event thus acts to periodically control antigenic diversity, maintaining the "trunk-like" shape of the influenza phylogeny.

Alongside these two prevailing paradigms of influenza evolution, yet another model [85] proposes that observed strains are drawn from a limited set of antigenic types, with their selection dependent on niches in host population immunity. While each of these models succeeds in capturing important features of influenza dynamics, they also highlight important gaps in our understanding of viral evolution and how to manage it.

7 Coevolution and the Evolution of Virulence

The degree to which viruses harm hosts varies considerably. Both within and between virus species, some variants may barely affect hosts at all, while others have significant health

impacts, up to and including host mortality [86]. An evolutionary perspective indicates that variation in virulence across clones should be shaped by the costs and benefits of virulence for parasite transmission [87]. The spread and persistence of virulence mutations may be favored if they covary with transmission. However, since host mortality can interrupt transmission, a range of values of virulence may lead to equivalent levels of overall fitness for the parasite [88]. While it is broadly agreed that the theoretical framework and empirical evidence on the existence of virulence-transmission trade-offs need to be further developed and extended [87], there are some systems where the general predictions appear to be borne out (e.g., [89, 90]). Perhaps most famously, the introduction of the myxoma virus into Australia was at first devastating to rabbit populations, causing near 100 % mortality. However, over subsequent years, the virulence of the infection decreased. Various lines of evidence suggest that this occurred in response to selection for increased transmission via decreased virulence – swift rabbit mortality was not an efficient mode of transmission for the virus.

8 Within-Host Dynamics

While we have so far largely discussed virus dynamics on the level of the host population, there are equally important processes to be considered on the within-host level. The "kinetics" of viral infection arise from a complex array of factors including viral replication and variability, the dynamics of the immune response, and pathogenicity to the host [91]. Over the past two decades, mathematical models have played an important role in studying these dynamics, often motivated by the need to understand the actual and potential impact of interventions such as treatment or immunization [91–93].

A major example is HIV infection (see Chap. 43); its clinical course is characterized by an initial acute phase of viral replication, lasting on the order of weeks, followed by an asymptomatic latent phase that can last decades before ultimately progressing to AIDS [94]. Major advances in the 1990s showed that despite the long clinical timescale involved, in vivo HIV replication is in fact a rapid process, with the viral life cycle being on the order of days [95, 96]. Subsequent studies modeling the dynamics of drug resistance underlined the need for early and aggressive drug therapy [97]. Conversely, more recent work capturing the dynamics of the immune response has illustrated how immunity raised by CD8+ T-cell vaccination elicits a response that is too weak and too late to achieve sterilizing immunity [98].

Hepatitis C virus (HCV) represents another major public health challenge and, like HIV, is a rapidly mutating virus capable of continually evading immunity to establish chronic infection [99]. HCV infection is currently treated with broad-spectrum combination antiviral therapy including interferon-alpha, ribavirin, and protease inhibitors, with upwards of 50 % of treated patients being responders; however, there is a need for a more rationally optimized approach. Models capturing viral dynamics in treated and untreated patients have contributed to an understanding of the action of these therapies [100–102], estimates of parameters such as rates of viral growth and of viral RNA clearance [102, 103], and correlates of long-term response to therapy [104].

Modeling approaches have been used to study the kinetics of acute infections too, notably in the context of influenza infection [105]. A key interest, for example, has been the relative importance of target cell depletion, innate immunity, and adaptive immunity in shaping the dynamics of viral infection [106–108].

Overall, while there remain significant gaps in our understanding of these and other major viral infections [103, 109], this work demonstrates the clinically relevant insights that can be derived from a careful study of within-host dynamics [91, 110].

9 Summary and Future Directions

This chapter has broadly outlined the multitude of factors shaping viral dynamics, as well as the role of mathematical approaches in elucidating these factors and their interactions. This growing body of work sets the stage for future directions.

The link between epidemiological modeling and policy is long-standing. Bernoulli's work provides perhaps the earliest case study [1]; recent high-profile examples include the use of models to guide responses to foot and mouth disease in the UK [111], smallpox [112], and influenza [113]. The key criterion of the effective deployment of models for policy is that they are embedded in testable hypotheses, embodying the best possible science. Continuing progress in this area thus calls for better understanding of the basic principles.

Especially in the context of viral evolution, whether in relation to immune escape or virulence, a complete biological framework calls for a linkage of processes across disparate scales, from the macroscopic structure of the host population to the molecular basis of viral replication and transmission. A key task at the heart of this challenge is arguably to quantify transmission potential in terms of immune escape, that is, to measure empirically how changes at the molecular level impact R (see Sect. 6.1). Indeed, recent equine influenza experiments provide some important steps in this direction [114].

New and emerging ways of tracking disease may also help to shed new light on the global spread of viruses and on how they may be better controlled. To name three examples, while disease surveillance continues to operate largely through public health channels, there is increasing interest in the use of alternative sources, including automated

tracking of Internet and social media trends [115, 116]. Second, genetic sequencing and analysis complements existing epidemiological approaches. The advent of high-throughput whole-genome sequencing is expected to shed new light on within-host viral diversity [117], an important aspect in our understanding of viral evolution. Third, any viral infection leaves its mark on the host immune system. Serological studies thus offer another valuable source of information in monitoring diseases [32] and already play an important role in many national surveillance programs (see Chap. 4). While in some cases there remain challenges in the clinical interpretation of quantitative serological data (e.g., Ref. [118]), its future use in estimating, for example, the prevalence of subclinical, but infectious, cases could be of significant value to public health efforts [119–121].

Finally, it is important to consider the role of the hosts themselves. With the host population providing the medium through which viruses spread, important factors in viral dynamics include heterogeneities among individuals (e.g., host genetic variation [122] and "superspreaders" of infection [123]) and patterns of human connectivity and mobility. Various approaches are beginning to unravel some of these patterns, both in the developed [34, 124] and in the developing world [125]. Future developments in such techniques will provide valuable new data for understanding the human role in viral dynamics.

Part II

Viruses Causing Acute Syndromes

Adenoviruses

6

Xiaoyan Lu, Amita Joshi, and Phyllis Flomenberg

1 Introduction

Adenoviruses are among the most widely distributed viruses in nature, infecting vertebrates as diverse as mammals, birds, fish, and reptiles [1]. Those adenoviruses that infect humans (HAdVs) are ubiquitous among the general population and have a worldwide distribution. Most HAdV infections occur in early childhood. They are most frequently associated with febrile upper respiratory tract illnesses with pharyngitis, pharyngoconjunctivitis, or coryza but can occasionally cause pneumonia. Other manifestations of HAdV infections include gastroenteritis, keratoconjunctivitis, and rarely cardiac, genitourinary, and neurologic diseases. Most HAdV diseases are self-limited and do not require therapy. However, severe and sometimes fatal infections can occur in immunocompromised hosts, neonates, and occasionally healthy children and adults. Although there have been no clinical trials performed to document efficacy, severe HAdV infections are most frequently treated with cidofovir, an antiviral agent licensed for the treatment of cytomegalovirus disease.

HAdVs can cause persistent infections, with the virus being shed for months after acute infection. Additionally, HAdVs are heterogeneous and subject to recombination among serotypes. Consequently, new types and variants of established serotypes appear over time.

Certain HAdV serotypes have caused epidemics of acute respiratory disease (ARD) in military training camps. Live enteric HAdV vaccines have been used safely and effectively to prevent outbreaks of ARD in new military recruits since the early 1970s. After the manufacture of the HAdV vaccines was discontinued in 1996, outbreaks of ARD reemerged in both military recruits and some civilians, prompting redevelopment of the vaccines.

Adenoviruses are also under intensive investigation as vectors to deliver foreign genes. Although the immunogenicity of adenovirus vectors and the high prevalence of adenovirus-specific memory immune responses have been obstacles for long-term gene therapy, recombinant adenovirus vectors have potential for use to immunize against other pathogens and as tumor vaccines.

2 Historical Background

In 1953, Rowe et al. [2] described an agent that caused spontaneous degeneration of surgically removed human tonsils and adenoids in tissue culture. In 1954, similar agents were isolated from military personnel with febrile respiratory disease [3], and in 1956 the term "adenovirus" was first adopted [4]. Subsequent studies revealed that these newly discovered agents were a major cause of epidemics of acute respiratory disease (ARD) in military training camps [5].

There is evidence that HAdV infections were present long before the 1950s. Epidemics of ARD were described in military training camps as far back as the Civil War. The adenoviral syndrome epidemic keratoconjunctivitis (EKC) was first described in German workers in the late 1800s [6]. Outbreaks of EKC were commonly observed during World War II in US shipyards, where the disease was referred to as "shipyard eye" [7]. Transmission likely took place in medical facilities where workers sought treatment for foreign bodies or chemical irritation of the eye.

Epidemics of a febrile illness with conjunctivitis related to swimming activities were first described in the 1920s [8]. When diagnostic tools for HAdVs were developed in the 1950s, all swimming-pool-associated outbreaks of pharyngoconjunctival fever were traced to them [9]. HAdVs also became recognized as important causes of febrile respiratory illnesses in infants and young children [10]. Continued outbreaks of ARD in military training camps led to a large number of epidemiologic studies of HAdV infections in the military [11, 12]. These investigations culminated in the development of HAdV vaccines that were introduced in 1971 for use in military recruits to help prevent ARD [13, 14].

3 Virus Characteristics

3.1 Virion Structure and Antigenic Composition

Adenoviruses exhibit a distinct morphology and chemical composition. The virion consists of a 70–90 nm diameter nonenveloped icosahedral capsid that packages a single double-stranded linear DNA genome of approximately 35 kb in length [15]. The capsid is composed of 252 capsomeres, of which 240 are homotrimeric hexons and 12 are pentameric pentons located at the vertices of the icosahedron and from which project a single, variable-length homotrimeric fiber (Fig. 6.1) [16]. The species F enteric HAdVs uniquely possess two different lengths of fibers that occur alternately on the vertexes. Four minor proteins (IIIa, VI, VIII, and IX) that stabilize the structure are also elements in the capsid [17]. Six other proteins are located in the virus core, of which five (V, VIII, Mu, IVa2, and the terminal protein) are associated with the viral genome and the remaining component protease facilitates virion assembly. Type-specific antigenic determinants that give rise to neutralizing antibodies are located primarily on the surface of the hexon capsomere, the fiber, and, to a lesser extent, the penton protein.

Type-specific determinants on the hexon map to loops L1 and L2 of the hexon monomer and are encoded by seven hypervariable regions of the hexon gene, HVR1-6 (L1) and HVR7 (L2) [18]. A genus-specific antigen is located on the interior surface of the hexon. In addition, the fiber is a potent hemagglutinin that also contains type-specific antigenic determinants recognized by hemagglutination inhibition (HI).

3.2 Adenovirus Classification

Adenoviruses are classified within the family *Adenoviridae* and further into five genera: *Mastadenovirus*, *Aviadenovirus*, *Atadenovirus*, *Siadenovirus*, and *Ichtadenovirus*. HAdVs, located within the genus *Mastadenovirus*, are divided into seven species, A–G, based on several of the following characteristics: phylogenetic distance, genome organization, DNA homology (G+C%), number of virus-associated RNA genes, ability to recombine, cross-neutralization, oncogenicity in rodents, and differential ability to agglutinate human and animal erythrocytes [19]. Species B can be further divided into two subspecies, B1 (3, 7, 16, 21, 50) and B2 (11, 14, 34, 35), based on homology of the viral genomes, tissue tropism, and associated disease patterns [20, 21].

There are 51 recognized HAdV serotypes defined classically by serum neutralization (SN) (Table 6.1), and several new "types," including one that belongs to the new species G (HAdV-52), have been recently described by molecular analyses [22]. For further discussion of the use of molecular and immunotyping methods for classifying HAdVs, see Sects. 12 and 12.1, below.

Some HAdVs show considerable intraserotypic genetic variability, best documented by genome restriction fragment analysis [23, 24]. For example, more than 20 DNA variants or genome types of HAdV-7 have been identified among strains isolated worldwide, and regional shifts or replacement of predominant genome types have been documented [25]. Designation of HAdV genome types is based on *Bam*HI as the "type" defining restriction enzyme, with different genome types denoted with a character, e.g., "p" for the prototype strain and then "a" through "k" for *Bam*HI variants. Genome types that are further distinguished by restriction pattern with additional enzymes are given an Arabic numeral (e.g., Ad7p, p1, a, a1-6).

Many HAdV species and serotypes exhibit distinct tissue tropisms and clinical manifestations, reflecting preferential infection of the respiratory, gastrointestinal, and urinary tracts and eyes. Typically, HAdV species B (particularly serotypes 3, 7, 14, and 21), C, and E cause respiratory tract infections, whereas the enteric species F serotypes 40 and 41 and species A (particularly serotype 31) are more commonly associated with infantile gastroenteritis. Species D serotypes 8, 19, and 37 are responsible for most outbreaks of EKC. Naturally occurring intermediate strains, which arise from intermolecular recombination [26] and possess the hemagglutinin (fiber) of one serotype and serum-neutralizing determinants (hexon) of another serotype, are well documented and may exhibit modified tropism and host pathology [20]. For example, species B HAdV-11p, identified in the 1950s in association with acute hemorrhagic cystitis, was later identified in outbreaks of respiratory disease as a novel genome type, HAdV-11a [27, 28]. Subsequent molecular analyses revealed that HAdV-11a (also referred to as HAdV-11/H14 or HAdV-55) is a recombinant virus that acquired the HAdV-14 fiber gene and possibly enhanced tropism for the respiratory tract [28–30].

3.3 Adenovirus Replication

Adenoviruses exhibit a highly restricted host range. Nonhuman primate species are poor hosts for HAdVs, as

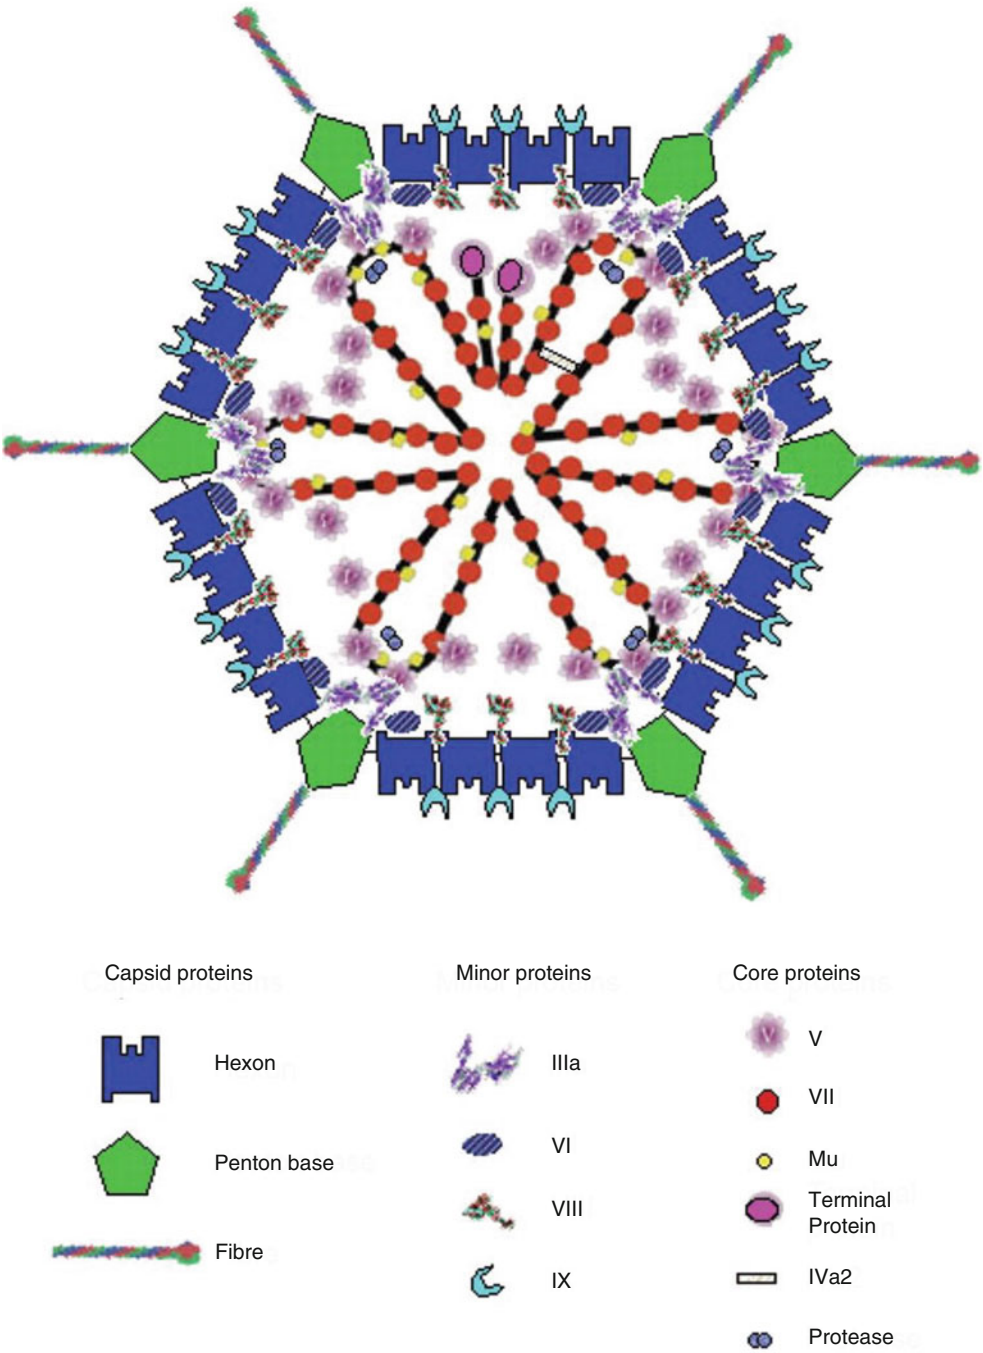

Fig. 6.1 Schematic diagram of the adenovirus virion and associated structural proteins (Reprinted with permission from Russell [16])

shown by the inefficient replication of HAdVs in simian cells unless coinfected with the helper papovavirus, SV-40 [31]. Although most HAdVs do not induce clinically apparent disease in common laboratory animals, hamsters, cotton rats, rabbits, and mice have been used to model respiratory and ocular infections with some HAdVs [32]. All HAdVs can transform cultured rodent cells to a malignant state, and species A, and to a lesser extent species C viruses, can induce tumors in newborn hamsters. However, there is no clear evidence that HAdVs can cause cancer in humans. For further discussion, see Sects. 12 and 12.4, below.

The adenovirus infectious cycle consists of an early and late phase separated by the onset of viral genome replication [15]. The early phase begins with virus entry into the host cell that proceeds by a two-step process: (1) binding of the fiber knob domain to the cell receptor followed by (2) interaction between a specialized motif on the penton base (Arg-Gly-Asp (RGD) peptide sequence) and cellular integrin, as a secondary receptor, triggering virus internalization [33]. Two well-documented HAdV receptors are the membrane cofactor protein (MCP or CD46), shown to bind most species B HAdVs, and the coxsackievirus-adenovirus receptor (CAR),

Table 6.1 Properties of human adenovirus serotypes

Species[a]	Serotypes	Hemagglutination groups[b]	Oncogenicity in newborn hamsters	Fiber length (nm)	DNA			Most common disease syndromes[d]
					% homology[c]	% G+C	Number of *SmaI* fragments	
A	12, 18, 31	IV	High	28–31	48–69/8–20	47–49	4–5	Gastroenteritis
B	3, 7, 11, 14, 16, 21, 34, 35, 50	I	Weak	9–11	89–94/9–20	50–52	8–10	URI, LRI, cystitis
C	1, 2, 5, 6	III	Negative	23–31	99–100/10–16	57–59	10–12	URI, LRI, endemic viruses
D	8–10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, 51	II	Negative	12–13	94–99/4–17	57–60	14–18	EKC, asymptomatic rectal carriage

that binds HAdV serotypes from all other species [34]. Integrins, CD80/CD86, sialic acid, and other cellular glycoproteins have also been implicated as receptors for some HAdVs. Following virus entry and passage to the cell nuclease, selective transcription and translation of the early viral genes occur that facilitate viral genome replication. There are five immediate early transcription units: early region 1A (E1A), E1B, and E2–E4. E1A encodes proteins that activate transcription and induce the host cell to enter the S phase of the cell cycle, and E1B proteins prolong cell survival and block apoptosis. E2 proteins provide machinery for viral genome replication and ensuing transcription of late genes. E3 proteins are nonessential for virus replication but help subvert the host's defense mechanisms to prolong survival of the infected cell in vivo (see Sects. 7 and 8, below). E4 proteins facilitate virus messenger RNA metabolism, genome replication, and shutoff of host protein synthesis. The late phase consists of transcription of the late transcriptional units (L1–L5) that leads to production of the viral structural components, assembly of the virus particles in the nucleus, and eventual release from the host cell. Replication-deficient mutants with deletions of the E1 transactivating region have been developed for use as vectors (see Sect. 11, below).

4 Methodology Involved in Epidemiologic Analysis

4.1 Sources of Data

HAdV disease is not reportable in the United States outside of the military. Nevertheless, numerous studies conducted in military training camps, pediatric institutions, day-care centers, primary schools, groups of families, the broader community, and other settings have allowed a detailed description of the epidemiology of HAdV infections. Global data assembled by the World Health Organization on type-specific HAdV isolates in the early 1980s [35] and more recent data from the United States on the prevalence and risk factors for severe HAdV disease from 2004 to 2006 are also available [36].

4.2 Laboratory Tests

Because the disease syndromes caused by HAdVs are not easily distinguished clinically in the absence of epidemics, laboratory testing is crucial for diagnosis. Laboratory diagnosis can be accomplished by virus isolation, polymerase chain reaction (PCR) assay, antigen detection, or serology. Viral detection is greatly enhanced by proper collection of specimens from affected sites in the early phase of illness. The type of specimen collected is dictated by the clinical presentation of the patient and the type of test to be administered. Throat and nasopharyngeal specimens are suitable for detection of HAdVs in the upper respiratory tract. Fecal specimens or rectal swabs are the specimens of choice for HAdV-associated gastroenteritis and may complement diagnosis of respiratory tract infections as virus shedding from the gastrointestinal tract may persist for prolonged periods after disappearing from the upper respiratory tract. Conjunctival swabs are suitable for HAdVs causing ocular infections. Appropriately timed blood samples collected as soon as possible after the onset of symptoms and 2–4 weeks later are needed to establish diagnosis by serology.

4.2.1 Viral Culture

Isolation of HAdVs in cell culture provides the most conclusive evidence of viral infection. Recovery of the virus is usually not very difficult in the acute phase of illness. With the exception of the enteric HAdVs, most HAdV serotypes can be easily isolated in continuous human cell lines of epithelial origin such as A549, HEp-2, and HeLa. Fibroblast cell lines like MRC-5 and WI38 are generally less sensitive but can grow HAdVs after short adaptation. The enteric HAdVs can be isolated in Graham 293 cells, a human embryonic kidney cell line that was stably transformed with HAdV-5 E1 transactivating region [37]. Centrifugation of specimens directly onto culture cells using the shell vial technique has greatly reduced time for detection [38]. Adenoviruses assemble in the nucleus of infected cells, and the nuclear morphologic changes can be diagnostic on histologic examination. Typical cytopathic effect (CPE) appears as a rounding and clumping of cells in "grape-like" clusters within 1–2 weeks after inoculation. Adenovirus CPE does not immediately result in cell death, however. Rounding and detachment are caused by the penton base-induced cell detachment domain (RGD) located on the penton capsomere that is produced in excessive amounts [39].

4.2.2 PCR Assay

In recent years, the application of molecular methods such as PCR has significantly improved the sensitivity of HAdV detection and shortened the time for reporting test results. Numerous PCR methods have been developed for detection and identification of HAdVs. Conventional PCR assays targeting conserved regions in the hexon, fiber, or VA RNA genes using broadly reactive primer sets are capable of detecting all recognized HAdV types [40–42]. Commercial multiplex PCR assays that can simultaneously detect multiple respiratory pathogens including HAdV are now available that greatly enhance the ability of laboratory diagnosis and epidemiology investigation [43, 44]. Quantitative real-time PCR assays for pan-HAdV detection have become popular [45, 46], particularly in the clinical diagnostic setting. Quantitation of viral load by real-time PCR has aided our understanding of HAdV pathogenesis and has proven to be an essential tool for early diagnosis and monitoring of antiviral therapy in immunocompromised patients, especially in the posttransplant setting [47–49].

4.2.3 Antigen Detection, Histology, and Electron Microscopy

Antigen detection methods using monoclonal antibodies to the hexon group antigen permit rapid detection of HAdVs in clinical specimens. Immunofluorescence (IF) assays are widely used in clinical settings as they permit rapid, specific, and relatively low-cost diagnosis of HAdV infections [50]. Commercial latex and enzyme immunoassays for detection and identification of enteric HAdVs in stool specimens are also available. However, antigen detection techniques tend to be less sensitive than culture and PCR, are not amenable to high throughput, and may be insufficiently informative for epidemiologic studies.

Histologic examination of biopsy or autopsy tissues can help identify HAdV disease. HAdV-infected tissues often reveal cells with enlarged nuclei containing amphophilic or basophilic inclusions with indistinct nuclear membranes known as "smudge" cells [51]. Confirmation of intranuclear adenovirus antigen by immunohistochemical testing can localize infection in affected organs, providing a more definitive diagnosis (Fig. 6.2) [52].

Electron microscopy (EM) has been useful to visualize HAdVs that are not easily grown in cell culture, such as the enteric HAdVs. Because of their unique morphology, HAdVs can be rapidly identified by EM, but the method is insensitive and not widely available.

(**a**) Low-power photomicrograph of lung tissue demonstrating the presence of necrotizing exudates containing fibrin, inflammatory cells, and karyorrhectic nuclear debris (×200). (**b**) Same photomicrograph of lung tissue at higher magnification, demonstrating a degenerating, inclusion-bearing nucleus (smudge cell; ×1,000). (**c**) Immunohistochemical stain showing multiple nuclei containing immunoreactive adenovirus antigen (×400) (Reprinted with permission from Barker et al. [52])

4.2.4 Serology

As noted above, detection of HAdVs in respiratory or gastroenteric specimens can be difficult to interpret, especially when sensitive molecular methods are used. In such cases, serology can be helpful in distinguishing past from present infection. Detection of HAdV-specific antibodies in single serum specimens indicates prior infection with the virus. Seroconversion or a ≥4-fold rise in antibody titer between acute- and convalescent-phase sera is considered evidence of recent infection or possible reactivation of latent virus. Commonly used serological tests include enzyme immunoassay (EIA), serum neutralization SN, and hemagglutination inhibition HI. EIAs are easy to perform, but do not distinguish between serotypes. Although more laborious to perform, SN and HI assays provide type-specific information and have been useful for epidemiologic and vaccine efficacy studies [53].

4.2.5 Virus Typing

In the clinical setting, once a diagnosis of a HAdV infection has been made, further identification of the virus is often unnecessary. However, for research and epidemiologic purposes, species- and type-specific information may be useful to strengthen association with disease and document emergence of new, potentially more virulent strains. For example, detection of species B or E viruses in specimens from persons with acute respiratory illness or species F viruses with gastroenteritis would be more meaningful than detection of species C viruses, due to the latter's tendency to shed persistently from the upper respiratory and gastrointestinal tracts. Detailed molecular analyses documented genetic signatures unique to the recently reemergent species B HAdV-14 [54] and revealed patterns of virus transmission during outbreaks [55].

Identification of a HAdV isolate is classically performed by immunotyping (SN and HI), but these procedures are laborious and time-consuming, and reference antisera are not widely available. In the early 1980s, molecular typing by genome restriction fragment analysis as described above was used as an adjunct to immunotyping [24, 56], but this procedure also depends on culture-grown virus for implementation. Molecular methods have resolved many of these problems and are now used routinely for identification of HAdVs. PCR assays using species- or type-specific primers targeting the hexon, fiber, and VA RNA genes have been used for direct identification of HAdVs in clinical specimens [41, 57–59]. PCR and amplicon sequencing of hexon HVR1-6 [60] and HVR7 [61] have been shown to correlate with SN. The addition of fiber gene sequencing permits identification of some intermediate HAdV strains [62]. The availability of reference hexon and fiber gene sequences in the public domain makes preliminary type identification of HAdV strains possible. Full genome sequencing combined with bioinformatic analysis has allowed for more comprehensive characterization of HAdVs, which has been useful for exploring pathoepidemiology and evolutionary relationships [63].

5 Descriptive Epidemiology

HAdVs most commonly cause disease in infants and young children and are especially prevalent in day-care centers and households with young children. Longitudinal studies performed in families and pediatric facilities documented that species C HAdV infections occur early in life and are often endemic [64, 65]. Transmission among families was extensively investigated by the Virus Watch studies in the 1960s, during which biweekly collection of both fecal and respiratory specimens was performed [65, 66]. These studies identified a large number of asymptomatic infections with species C viruses and demonstrated a high frequency of fecal shedding of virus. HAdVs were found intermittently in fecal specimens for extended time periods, up to 1–2 years. Species F serotypes 40 and 41 cause gastroenteritis in infants and young children. In contrast, a large proportion of species A and D adenoviral infections are asymptomatic [67].

Species B (particularly serotypes 3, 7, 14, and 21) and E (serotype 4) infections tend to occur later and cause symptomatic respiratory disease, including epidemics of acute respiratory disease (ARD) in military recruits [12] and pharyngoconjunctival fever in summer camps [68]. In a study of 1,653 clinical isolates collected from 22 hospital laboratories in the United States between 2004 and 2006, species B HAdV-3 was the most commonly identified (35 %), followed by HAdV-2 (24 %) and HAdV-1 (18 %) [36]. These data are consistent with the fact that HAdV-3 is less prevalent than HAdV-1 and HAdV-2 but is more likely to cause a severe disease that requires hospitalization and/or testing.

5.1 Synopsis of Descriptive Epidemiology

5.1.1 Incidence and Prevalence

The incidence of infection is highest in infants and young children, during which time infections with the endemic species C HAdVs most commonly occur. In one family study, over 90 % of children under age 2 had SN antibodies to HAdV-1 and HAdV-2 [66]. Young children also most commonly shed virus in stool for prolonged periods after the resolution of symptoms. Most transmission occurs among families with young children, and the incidence is higher in lower socioeconomic groups. Rates of HAdV infections are higher in day-care centers and pediatric facilities.

5.1.2 Epidemic Behavior

The species E HAdV-4 and species B serotypes 7, 14, and 21 occur mostly in epidemics; species B HAdV-3 is sometimes endemic and sometimes epidemic.

Table 6.2 Most common adenoviral disease syndromes associated with specific patient populations

Patient population	Clinical syndromes
Infants and young children	Pharyngitis, coryza, tonsillitis, otitis media
	Pneumonia
	Gastroenteritis, mesenteric adenitis
Children	Pharyngitis, coryza, conjunctivitis
	Pharyngoconjunctival fever (PCF)
	Pneumonia
	Gastroenteritis
Adults	Acute respiratory disease (ARD)
	Epidemic keratoconjunctivitis (EKC)
Immunocompromised hosts	Pneumonia
	Gastroenteritis, hepatitis
	Hemorrhagic cystitis, interstitial nephritis
	Meningoencephalitis

5.1.3 Geographic Distribution

The species C HAdVs are endemic in most areas of the world [35]. Certain other types such as the species D HAdV-8 are endemic in underdeveloped countries such as parts of the Middle and Far East and Africa but primarily occur in epidemics in developed countries.

5.1.4 Seasonality

HAdV infections occur throughout the year but are more commonly found in late winter, spring, and early summer in temperate regions [65].

5.1.5 Age

Most children have been exposed to several types of endemic HAdVs by the time they enter school. Infections with the less common species E HAdV-4 and species B serotypes can occur later in life.

5.2 Epidemiologic and Clinical Aspects of Specific Syndromes

The clinical manifestations of HAdV disease vary according to the HAdV serotype and the age and immune status of the host (Table 6.2) [32]. HAdVs are responsible for 5–10 % of febrile illnesses in infants and young children [66].

5.2.1 Respiratory Illness

Infants and young children have the highest attack rates of endemic HAdV infections. These infections commonly present as mild upper respiratory tract illnesses and are most frequently caused by species C serotypes 1, 2, 5, and , to a lesser extent, 6 [69, 70]. Pharyngitis is frequently associated with conjunctivitis, laryngitis, or bronchitis. Fever is common and may be associated with malaise, headache, myalgia, and occasionally abdominal pain [71]. HAdVs are among the most common causes of tonsillitis in young children. Less frequently, HAdVs have been associated with otitis media (in children under age one), a pertussis-like syndrome, bronchiolitis, coryza without fever, or an exanthem.

The species B serotypes 3, 7, 14, and 21 have been associated with a more severe disease compared to the species C viruses [72, 73]. In particular, HAdV-7 has been observed to be one of the most pathogenic serotypes, causing a number of fatal lower respiratory tract infections [74–76]. Pneumonia is more severe in infants than older children and can be associated with extrapulmonary complications such as meningoencephalitis, hepatitis, myocarditis, and nephritis [77–80]. Other rare complications include disseminated intravascular coagulation and a toxic shock-like syndrome [73, 81]. Notably, there is a high incidence of pulmonary sequelae following HAdV pneumonia in children, especially bronchiectasis [82, 83].

5.2.2 Pharyngoconjunctival Fever

This HAdV syndrome is characterized by pharyngitis, conjunctivitis, and spiking fevers. Either one or both eyes can be involved, and lymphadenopathy is often observed. Diarrhea and coryza can sometimes occur, and tonsillar exudates can be observed. Pharyngoconjunctival fever is most commonly caused by species B HAdV-3 and HAdV-7 and species E HAdV-4 [68, 84]. The disease can be seen sporadically and be transmitted among families. However, this syndrome is best known as an epidemic disease in summer camps. Studies suggest that infection is transmitted by direct contact with water from contaminated swimming pools and small lakes; virus is likely introduced into the eye or upper respiratory tract [68]. Outbreaks of pharyngoconjunctival fever have been specifically associated with inadequate chlorination of swimming pools [85].

5.2.3 Acute Respiratory Disease (ARD)

ARD epidemics can occur under the special conditions of fatigue and crowding present in military training camps [13, 86]. Symptoms typically include fever, sore throat, and cough, sometimes with coryza, headache, or chest pain. Malaise is characteristic and lasts for approximately 10 days. Pneumonitis can also occur, resulting in rare fatalities [87, 88]. ARD epidemics have been associated with species E HAdV-4 and species B serotypes 3, 7, 11a, 14, and 21. Outbreaks in military training camps usually peak at about 3–6 weeks after the onset of training, resulting in morbidity rates as high as 6–17/100 per week.

Introduction of live, oral HAdV-4 and HAdV-7 vaccines for US military recruits in the early 1970s significantly reduced the incidence of ARD [14]. After the manufacture of HAdV vaccines stopped in 1996, however, there was a prompt rebound in high rates of HAdV infections [89, 90].

Rare new fatalities were reported in military recruits due to probable HAdV pneumonia with or without encephalitis [91]. In a study of 584 clinical isolates from military recruits collected between 2004 and 2006, 93 % were HAdV-4 [36]. HAdV transmission among new military recruits was studied using active surveillance for illness and enrollment and end-of-study viral throat cultures and serology [86]. Febrile respiratory infections due to HAdV-4 were identified in 25 % (67/271) of new recruits, and the percentage of recruits seropositive of HAdV-4 increased dramatically from 34 to 97 % during the first 4 weeks of training. The authors proposed that introduction of recruits with asymptomatic viral shedding into new training groups was likely a primary cause of continual transmission of HAdV-4 in the camp. In 2006, species B adenoviruses became more prevalent, including serotypes 3, 7, 14, and 21 [92].

Species B HAdV-14, which was first identified in the Netherlands in 1955 and caused sporadic outbreaks in Europe, emerged in US military bases in 2005. Since the initial reports, HAdV-14 has caused several outbreaks of ARD in both military recruits and civilians [88, 93, 94]. In a report of 140 cases, 38 % were hospitalized, 17 % were admitted to intensive care units, and 5 % died [95]. An analysis of 99 isolates from military and civilian cases in the United States revealed that all isolates were identical and suggested that they arose from recombination between HAdV-11 and HAdV-14 strains [54].

Due to the increasing incidence of ARD in military recruits, live, oral HAdV-4 and HAdV-7 vaccines were redeveloped by a new manufacturer and licensed in the United States in 2011 [96, 97].

5.2.4 Epidemic Keratoconjunctivitis (EKC)

In contrast to the benign course of pharyngoconjunctivitis, certain species D serotypes (8, 19, and 37) can cause a more serious keratoconjunctivitis [98, 99]. This disease is characterized by conjunctivitis, followed by the development of corneal infiltrates that cause pain, edema of the eyelids, photophobia, and lacrimation. One or both eyes may be involved, and preauricular lymphadenopathy is common. Although this disease does not usually result in permanent corneal damage, it can cause severe pain and blurry vision lasting up to 4 weeks.

A number of outbreaks of EKC have occurred in medical facilities, in particular ophthalmology offices. Infections can be spread from contaminated instruments, surfaces, or hands [100, 101]. Adenoviruses are relatively resistant to disinfectants, so heat sterilization of ophthalmology instruments (in particular, tonometers) is preferred. Hand washing with soap and water does not efficiently remove adenoviruses, so gloving is important. In one investigation of a HAdV-8 epidemic, almost 50 % of patients diagnosed with EKC carried virus on their hands, and the virus remained viable on inanimate surfaces for up to 35 days [102].

5.2.5 Gastroenteritis

Species F serotypes 40 and 41 are responsible for about 5–10 % of acute diarrheal illnesses in infants and young children. In one study of over 400 cases of acute infantile gastroenteritis, enteric adenoviruses were the sole recognizable cause of diarrhea in 7.2 % of cases [103]. Outbreaks have occurred in day-care centers and pediatric healthcare facilities. In a review of an outbreak in several day-care centers, 38 % of 247 young children tested had positive stool specimens for HAdV-40 or HAdV-41, although only half were symptomatic [104]. These fastidious enteric adenoviruses require special cell lines for growth but can be readily detected by enteric adenovirus antigen assays. The species A HAdV-31 is a less common cause of infantile diarrhea [105]. Most other serotypes have not been clearly associated with diarrhea, but are commonly shed in stool for months after infection. However, non-enteric species C HAdVs have been associated with mesenteric adenitis, which may mimic appendicitis and occasionally cause intussusception in infants and young children [106, 107].

5.2.6 Uncommon Syndromes

HAdVs can cause acute hemorrhagic cystitis in children (species B serotypes 11 and 21) [108]. Rarely, HAdVs have caused urethritis in adults (species D serotypes 19 and 37), and sexual transmission has been postulated [109, 110].

Meningitis and encephalitis have been reported occasionally in association with HAdV infections [111]. Neurologic involvement usually occurs in association with severe pneumonia, especially with HAdV-7.

HAdVs have been associated with acute myocarditis in children [112]. In one study, 38 myocardial tissue samples from 34 children with acute myocarditis were tested by PCR for a panel of viruses [113]. HAdV was detected more commonly (15 samples) than enterovirus (8 samples) and was not detected in control samples.

HAdVs have been occasionally associated with polyarthritis syndromes [114, 115]. Reye's syndrome has also been reported in association with HAdV infections in infants [116, 117].

5.2.7 Immunocompromised Hosts

HAdVs can cause severe, life-threatening infections in immunosuppressed persons, especially in the pediatric population [118–122]. Disease can be caused by primary infection or reactivation of latent infection. In transplant recipients, HAdV infections can also rarely be transmitted from the donated organ or bone marrow. Severe neonatal HAdV infections occur primarily in premature infants, and vertical transmission may play a role [123].

Pediatric hematopoietic stem cell transplant (HSCT) recipients have the highest incidence of HAdV disease and mortality [124, 125]. In one study of 204 pediatric HSCT recipients, 15.1 % had HAdV infections and 8.8 % developed

severe disease [126]. In contrast, in one study of 1,050 adult HSCT recipients, 4.8 % had HAdV infections and only 0.9 % had invasive disease [127].

The clinical spectrum of HAdV infections in HSCT recipients can range from asymptomatic shedding to fatal disseminated disease. A wide range of clinical syndromes has been reported, including pneumonia, colitis, hepatitis, hemorrhagic cystitis, tubulointerstitial nephritis, encephalitis, and disseminated disease. Disease is most frequently associated with the common species C serotypes 1, 2, and 5. Interestingly, there is also a preponderance of urinary tract infections due to species B serotypes 11, 34, and 35, which are infrequently isolated in the general population [127–129]. One hypothesis is that these types frequently cause latent infections of the genitourinary tract that can reactivate following severe immunosuppression.

In contrast to the HSCT population, HAdV disease typically involves the donor organ in solid organ transplant recipients. For instance, hepatitis is the most common manifestation of invasive adenoviral disease in pediatric liver transplant recipients. In one large study of 484 liver transplant recipients, 14 (3 %) developed HAdV hepatitis [130]. HAdV-5 was the most common isolate, and 43 % of patients died. In another study, examination of pre- and posttransplant sera from recipients and donors suggested that virus was transmitted from the donated organ [131].

In renal transplant recipients, HAdV can cause acute hemorrhagic cystitis, sometimes complicated by interstitial nephritis [132]. The incidence has not been well defined but is low, and this disease is exclusively associated with species B serotypes 11, 34, and 34. The prognosis is generally good, although infection occasionally results in fatal disseminated disease [133]. In one study of 339 adult renal transplant recipients, 17 (5 %) developed HAdV-related hemorrhagic cystitis [134]. Symptoms included dysuria, hematuria, fever, and bilateral testicular pain and lasted a mean duration of 2 weeks (range, 0.5–9.6 weeks). Reversible allograft dysfunction occurred in ten patients. One patient developed disseminated HAdV disease and died from bacterial sepsis.

In a study of pediatric cardiac transplant recipients, HAdVs have been implicated as a cause of graft loss and coronary vasculopathy [135]. HAdVs was detected by PCR in myocardial biopsies from 24 of 149 patients (16 %) and was associated with reduced graft survival.

Severe, frequently fatal neonatal infections have been described [123, 136]. In addition to the usual routes of transmission, neonates can acquire HAdV infection from exposure to cervical secretions at birth [137]. Rare cases of intrauterine infection have also been described [138]. Primary HAdV infections can also cause severe disease in children with immunodeficiency syndromes such as severe combined immunodeficiency disease (SCID) [139].

HAdVs are an uncommon cause of morbidity and mortality in HIV-infected individuals. However, a number of serotypes have been isolated from AIDS patients, including species B serotypes 11, 34, and 35 in urine and rare species D serotypes and intermediate strains in stool samples [140, 141]. Occasional fatal cases of adenoviral infection in AIDS patients have been reported, especially in the pediatric population [142, 143].

6 Mechanisms and Routes of Transmission

Transmission of HAdVs primarily occurs by the fecal-oral and respiratory routes. Fecal-oral transmission is common in households with young children [144]. Moreover, prolonged fecal shedding can sustain transmission in households and day-care centers. HAdVs can be transmitted via inhalation of droplets dispersed in the air by coughing and via direct contact with infected secretions or contaminated surfaces. The respiratory route is an important means of transmission in epidemics of ARD in military training camps. In one study, 50 % of air samples from recruit barracks were positive for HAdV DNA [86]. This study also detected viral DNA from 14 to 39 % of surfaces, suggesting that environmental contamination of living quarters is a possible contributing factor. Direct contact with contaminated pool water plays a major role in causing outbreaks of pharyngoconjunctival fever in summer camps [68].

Nosocomial transmission has been well documented [145, 146] and can be challenging to prevent because HAdVs are resistant to a number of common disinfectants and can survive on surfaces for weeks [100, 147]. In one investigation of a large community outbreak of EKC, HAdV-8 was isolated from multiple ophthalmic solutions from one physician's office [148]. In another report, HAdV-8 conjunctivitis occurred in 7 premature infants who had undergone ophthalmological examination in a neonatal intensive care unit; infection was also transmitted to 9 staff and 12 family members [149]. There were 11 deaths from HAdV-7 infections among 61 residents of a long-term care pediatric facility during an 8-week period; 23 staff members had febrile respiratory illnesses during this period, suggesting sustained transmission between patients and staff [150].

Occasionally, neonatal infections have been caused by vertical transmission of HAdV, especially with species B HAdV-11 and HAdV-35 [136, 151]. Intrauterine infections have rarely been described, and ascending viral infection from the cervix has been proposed as one mechanism [137].

7 Pathogenesis

HAdVs are lytic DNA viral pathogens that usually cause self-limited localized disease but can disseminate in immunocompromised hosts and rarely in healthy children and

adults, causing significant morbidity and mortality. HAdVs cause pathology during the process of viral replication and lysis of susceptible cells. Additionally, investigations of replication-defective adenoviruses in animal models and clinical studies have revealed that HAdVs can cause significant inflammation in the absence of viral replication. Thus, the clinical manifestations of HAdV disease appear to result from both the direct effects of the infection and the host inflammatory responses.

7.1 Tissue Tropism

Although certain HAdV serotypes are associated with distinct clinical manifestations, the basis for these differences is not well understood. For example, the species D serotypes 8, 19, and 37 can cause a more severe eye disease than other types. The species E HAdV-4 and species B serotypes 3, 7, 14, and 21 have been associated with severe respiratory disease. In contrast, the species B serotypes 11, 34, and 35 primarily cause hemorrhagic cystitis. It is likely that differences in the fiber and penton capsid proteins that mediate cell receptor binding and cell entry contribute to serotype-specific differences in clinical manifestations. For instance, HAdV species display different cell receptor preferences that are mediated by the fiber. Most serotypes from species A, C, D, E, and F bind to CAR (the coxsackie adenovirus receptor), which is a member of the immunoglobulin superfamily expressed on multiple cell types [152]. Most species B viruses bind to a ubiquitously expressed membrane complement regulatory molecule CD46 [153], whereas the species B HAdV-3 and HAdV-7 bind to the related molecules CD80 and CD86 [154]. Members of the group D viruses can also utilize ubiquitous sialic acid receptors [155, 156]. Following viral attachment, penton base protein binds to cellular $\alpha v\beta 3$/$\alpha v\beta 5$ integrins [157], thus facilitating virus internalization via clathrin-coated vesicles into endosomes for further processing [158].

7.2 Pathology

In a natural infection of the human host, epithelial cells are the primary targets of adenoviral cytopathology [159]. The respiratory epithelial cells affected during adenoviral pneumonitis can develop acidophilic intranuclear inclusions. Infected cells with enlarged nuclei containing amphophilic or basophilic inclusion bodies surrounded by thin rims of cytoplasm referred to as "smudge cells" have also been described. There are no syncytia or multinucleated cells, as seen in herpes virus infection. In the rare case of fatal illness, the virus has been recovered from most body organs [160]. In such cases, extensive pathology is found in the lungs, with microscopic necrosis of tracheal and bronchial epithelium characterized as necrotizing bronchiolitis. Rosette formation, mononuclear cell infiltrates, and focal necrosis of mucous glands appear to be characteristic. Typical intranuclear virus particles have been observed in alveolar lining and bronchiolar cells by electron microscopy [72]. In infants who recover from adenovirus pneumonia, severe sequelae may follow, including bronchiectasis, radiolucent lung syndrome, persistent lobar collapse, and bronchiolitis obliterans [161].

HAdVs can also cause pathology in the absence of replicating virus. For example, replication-defective HAdVs can trigger innate immune responses, primarily by recognition of capsid proteins via pathogen recognition receptors (PRRs) with activation of dendritic cells and macrophages [162]. Capsid proteins can also activate the complement system via both classical and alternative pathways [163, 164]. This results in a proinflammatory response with the release of multiple cytokines. The viral capsid proteins also trigger humoral and cell-mediated immune responses that further exacerbate the developing proinflammatory response (see Sect. 8, below). For instance, antiviral antibodies can increase Fc receptor-dependent viral internalization in macrophages and amplify intracellular innate pathways [165]. The ability of this virus to induce an inflammatory response in the host in the absence of replication has implications for the clinical use of replication-deficient adenovirus vectors. For further discussion, see Sect. 11, below.

7.3 Immune Evasion Mechanisms

In natural infections, HAdVs have evolved several mechanisms to evade or downregulate the host immune response, which can help counteract the above inflammatory responses. The viral early region 3 (E3) encodes several small proteins (range 6.7–19 kDa) that play a prominent role in evading host innate and acquired immune defenses [166]. The E3 promoter also has NFkB binding sites that can be induced by cytokines such as TNF-α, and as a result, E3 protein expression is directly upregulated during an inflammatory response [167]. The E3-19K glycoprotein can block the transport of major histocompatibility complex (MHC) class I antigens to the cell surface, thereby inhibiting the recognition of virus-infected cells by cytotoxic T lymphocytes (CTLs). E3-19K evokes two distinct mechanisms to inhibit MHC class I molecule presentation of viral peptides to CTLs. First, E3-19K directly binds to class I antigens in the endoplasmic reticulum (ER) and inhibits their egress from the ER to the cell surface [168, 169]. Additionally, E3-19K can directly bind to TAP (transporter associated with antigen processing) and block class I/TAP association [170]. As a result of this interaction, the transfer of viral peptides processed in the cytosol to class I antigens is also inhibited.

Other E3 proteins enable the virus to evade apoptosis by inhibiting signaling from death receptors. CTLs express Fas

ligand on their cell surface and induce apoptosis upon interaction with the Fas ligand receptor CD95 on target cells. Similar apoptotic pathways are triggered by TNF-α and its ligand TRAIL (TNF-related apoptosis-inducing ligand). However, in the presence of the E3-10.4K and E3-14.5K proteins, these pathways are inhibited. Two units of E3-10.4K and one unit of E3 14.5K hetero-trimerize to form the RID complex (receptor internalization and degradation), which stimulates the degradation of receptors for Fas ligand and TRAIL via endocytosis and lysosomal degradation [171–173]. Thus, RID inhibits apoptosis through the TNF receptor 1 (TNF-Rl), Fas, and TRAIL-R1 pathways. The E3-14.7K protein is also a potent inhibitor of apoptosis mediated by TNF-α [174].

HAdVs also can counteract host antiviral immunity by interfering with the antiviral activity of type I interferons (IFNs). About 1 % of the viral genome is transcribed into noncoding virus-associated RNA (VA RNA). The synthesis of VA RNA begins during the early phase of the infectious cycle and accelerates during the late phase. VA RNA interferes with IFN-dependent phosphorylation of cellular proteins that inhibit viral peptide chain initiation [175, 176]. As a result, the viral polypeptide chain synthesis proceeds uninhibited. E1A proteins also inhibit the function of type I IFNs by blocking signal transduction pathways via IFN-stimulated gene factor (ISGF3). Conserved regions of E1A bind directly to STAT 1, the transcription factor that mediates IFN-stimulated transcription [177].

7.4 Viral Persistence

Although most HAdV illnesses are acute and self-limited, infection may be prolonged, and asymptomatic infections are common. Viral shedding from the gastrointestinal tract may persist for weeks to months, thus increasing the risk for horizontal transmission. By devoting about a third of the genome towards gene products that counteract host defense mechanisms, HAdVs have evolved strategies (discussed above) to help facilitate persistence after primary infection. HAdVs can be isolated from at least 50 % of surgically removed tonsils [178], occasionally from the kidney [131] and also from lymphocytes [58], suggesting that infection may remain latent for a very long time, possibly for life. Mechanisms for maintaining persistent and latent HAdV infections are not well understood. For further discussion, see Sect. 12.2 below.

8 Host Immune Responses

Adenoviruses are highly immunogenic and elicit strong innate and adaptive immune responses. In natural infections, the immune responses to HAdVs are moderated by multiple mechanisms related to expression of E1 and E3 region proteins, as well as VA RNA (as described above). However, these immune evasion mechanisms are not activated by infection with replication-defective E1-deleted adenovirus vectors.

8.1 Innate Immune Responses

The innate response to adenovirus acts as a first line of defense and serves to control infection locally and recruit effector leukocytes, such as granulocytes and monocytes/macrophages, to the site of infection. The viral capsid proteins are primarily responsible for inducing innate immune responses and for activating and recruiting Kupffer cells, endothelial cells, neutrophils, splenic macrophages, and dendritic cells [162, 179, 180]. Binding of capsid proteins to complement, pattern recognition receptors (PRRs), erythrocytes, and other blood factors further enhances the ensuing immune response [181, 182]. For example, recognition of HAdVs via Toll-like receptors (TLRs) triggers activation of NFκB and signal transduction via the mitogen-activated protein kinases (MAPKs), resulting in the transcription of host chemokine and cytokine genes [183]. Overall, the inflammatory response generated from leukocyte recruitment provides additional local control of infection and facilitates antigen presentation by infiltrating cells such as macrophages and dendritic cells. A robust innate response is thus essential for the development of adaptive immunity.

Capsid proteins induce the production of proinflammatory cytokines and chemokines such as TNF-α, IL-6, IL-1B, IL-8, IL-12, RANTES, MIP-1, and MCP-1 [162, 184, 185]. While the primary role of these cytokines is to locally enhance the antiviral activity (via recruitment of appropriate effector cells) and enhance the immune cascade, overproduction may result in acute toxicity. In one study, 38 children hospitalized with HAdV infections were found to have high levels of IL-6, IL-8, and TNF-α without evidence of bacterial infection. Very high levels of IL-8 were found in all 16 fatal cases of HAdV infection, comparable to the levels seen in septic shock in adults [186]. Similarly, TNF-α was more frequently detected in the fatal group. Thus, an association between high proinflammatory cytokine levels and the severity of a natural HAdV infection was noted in infected children.

Virus-induced innate responses are also clinically relevant with regard to gene therapy using adenovirus vectors. The inflammatory response to replication-deficient adenovirus vectors significantly reduces gene transfer efficiency and vector persistence in both animal and clinical studies [180, 187, 188]. Moreover, one of the initial gene therapy clinical trials to treat ornithine transcarbamylase deficiency using a replication-deficient, E1-deleted HAdV-5 vector resulted in the unfortunate death of an 18-year-old patient.

In this case, mortality coincided with the induction of a cytokine storm [189]. There was a massive release of proinflammatory cytokines, including IL-6 and IL-10, causing a systemic inflammatory response syndrome. The patient developed disseminated intravascular coagulation and multiple organ system failure, leading to death 98 h following gene transfer. This case highlights the need to develop strategies to moderate HAdV vector-induced innate immune responses. In contrast, for the purposes of vaccine development or cancer immune therapy, the innate immune response to adenovirus capsid proteins can have a desirable adjuvant effect to enhance the host immune response or cause a bystander effect [179, 190]. For further discussion, see Sect. 11, below.

8.2 Adaptive Immune Responses

The development of an adaptive immune response is critical in the resolution of HAdV infections. Virus-specific antibodies (mainly secretory IgA) are present in the upper respiratory tract within 3 days of infection. Approximately 7 days postinfection, antibodies can be detected in serum, and nasal secretions contain both secretory IgA and IgG [191, 192]. Serotype-specific neutralizing antibodies (Nabs), predominantly directed against the hexon, fiber, and penton base, are generated following the first exposure to each HAdV serotype [193, 194]. Anti-fiber and anti-penton Nabs prevent cellular entry of the virion, while anti-hexon antibodies prevent virus uncoating and nuclear entry of viral DNA [195, 196]. Nabs inhibit HAdV transduction of cells by a variety of methods, including prevention of cell attachment and facilitation of virus aggregation and clearance [197]. In addition, anti-hexon Nabs that allow virus entry but prevent virus gene expression have been identified [198]. Nabs generated against hexon target hypervariable regions (HVRs), which account for 80–95 % of virus-specific Nabs, appear to be most critical for virus clearance. Studies have shown that the presence of Nabs prevents reinfection with the same serotype [66, 86], and Nabs have been demonstrated 10 years after documented infection [199]. However, the protective effect of Nabs is serotype specific and does not allow for broad protection against multiple HAdV serotypes.

The severe HAdV infections observed in patients with a suppressed cellular immune system reflect the importance of cell-mediated immunity in limiting HAdV replication and preventing dissemination of infection [118, 128, 200]. Adenovirus-specific memory CD4+ T cell responses can be detected in the vast majority of healthy adults [201, 202]. These CD4+ T cell responses are Th1 type, based on the cytokine secretion pattern [203] and, unlike Nabs, are cross-reactive against different serotypes. Several CD4+ T cell epitopes have been mapped from the hexon, including a highly conserved epitope located in the COOH terminus of hexon that is restricted by a HLA class II allele present in 75 % of the population [204]. Lower frequencies of adenovirus-specific CD8+ T cells can be detected in most healthy adults. Hexon is also recognized by CD8+ T cells, and multiple cross-reactive hexon epitopes have been identified [205–207]. In addition to the hexon, conserved regions of HAdV early proteins like the E2 DNA polymerase and DNA-binding protein (DBP) have been identified as CD8+ T cell targets and are recognized by both healthy and acutely infected adults [208]. Thus, cross-reactive virus-specific memory CD4+ and CD8+ T cell responses can be detected in most individuals.

Cross-reactive memory T cell responses to HAdVs pose a challenge to the development of adenovirus vector applications (see Sect. 11, below). However, virus-specific memory T cells from HSCT donors have potential use for immunotherapy of severe HAdV infections in HSCT recipients. Several reports have demonstrated an association between recovery of HAdV-specific T cells and resolution of acute HAdV infections following HSCT [209, 210]. Specifically, HSCT recipients recovering from HAdV disease can mount CD4+ and CD8+ T cell responses to hexon, as well as CD8+ T cell responses to the above early protein targets [208, 211]. Therefore, passive transfer of virus-specific donor T cells is being explored as an adjunctive therapy for severe HAdV infections in HSCT recipients [212, 213]. For further discussion, see Sect. 9 below.

9 Treatment

The majority of HAdV infections are self-limited and do not require specific therapy. There are no agents licensed specifically for treatment of HAdV disease.

9.1 Antiviral Agents

Of the available antiviral agents, only cidofovir has reproducible in vitro activity against adenoviruses [214, 215]. Cidofovir has been most commonly used to treat invasive infections in immunocompromised patients [126, 216, 217]. Treatment with cidofovir has been associated with clinical responses and declines in viral loads in some HSCT recipients with invasive HAdV disease [218, 219]. Early treatment and immune reconstitution appear to be important factors associated with improved outcomes [220]. Although some pediatric HSCT programs perform active HAdV surveillance using blood PCR assays and treat preemptively [221, 222], the nephrotoxicity of cidofovir is often dose limiting. Less nephrotoxic lipid-ester derivatives of cidofovir are being investigated for the treatment of serious HAdV infections

[223, 224]. Disseminated adenoviral disease was successfully treated with the cidofovir prodrug CMX001 in a pediatric stem cell transplant recipient [225].

9.2 Other Therapies

Pooled intravenous immune globulin has high titers of Nabs against common species C HAdV and is commonly used as adjunctive therapy for severe HAdV infections in immunocompromised patients [226, 227]. A benefit from immune globulin was demonstrated in an immunosuppressed mouse model where passive transfer of mouse adenovirus (MAV)-specific IgG caused a marked delay in mortality after MAV infection and survival correlated with levels of MAV-specific antibodies [228].

Additionally, adoptive transfer of virus-specific donor T cells has been investigated in a small number of pediatric HSCT recipients. In one study, virus-specific donor T cells were isolated and infused into nine children with systemic adenoviral infections [212]. Viral clearance was demonstrated in 5 of 6 evaluable patients. In another study, patients were treated with donor lymphocytes stimulated in vitro with HAdV [213]. Reductions in viral loads were documented in all three patients with active infection, and one patient with adenoviral pneumonia had a clinical response. Methods to optimize recovery and in vitro expansion of donor virus-specific T cells for immunotherapy trials are being investigated [211, 229].

10 Prevention

Prevention of transmission of adenoviral infections is challenging. Transmission is common in households with young children and day-care centers. HAdVs can be intermittently shed in stool for weeks to months and pose an ongoing source of infection. Nosocomial transmission can also occur, as discussed above. In an outpatient study, 126 (7 %) of 1,870 ophthalmology patients developed EKC due to HAdV-8 [101]. Inadequate disinfection of instruments and finger-to-eye transmission by healthcare workers were implicated in this outbreak.

Adenoviruses are nonenveloped viruses that can remain viable on environmental surfaces for weeks and are relatively resistant to commonly used disinfectants. In one study, only bleach (1:10 dilution) and 2.4 % glutaraldehyde were effective disinfectants against HAdV-8 under all test conditions [230]. The disinfectants 70 % ethanol and 65 % ethanol plus 0.63 % quaternary ammonium compound also demonstrated at least a 3-$\log_{10}$ reduction in titers, but their virucidal activity was significantly reduced in the presence of organic matter. Other common disinfectants, including 70 % isopropyl alcohol, 0.63 % quaternary ammonium compound alone, 4 % chlorhexidine gluconate, and 10 % povidone-iodine, were significantly less active. Additionally, one study found that HAdVs are not completely eliminated from hands after washing with soap and water [102]. These viruses are also relatively resistant to UV light [231] but can be inactivated by heat.

Infection control measures can reduce the risk of HAdV transmission in some settings. For instance, adequate chlorination of swimming pools can help prevent pharyngoconjunctival fever outbreaks [68, 85]. The spread of EKC in ophthalmology offices can be prevented by heat sterilization of instruments, the use of single-use ointments and solutions, and the use of gloves and strict hand hygiene practices. However, during a large community outbreak of EKC where over 100 nosocomial cases occurred at a large ophthalmology center, transmission continued to occur despite the institution of strict hand washing, gloving, and bleach disinfection of equipment [232]. Transmission was stopped only after patients were rigorously triaged and cohorted, highlighting the difficulties in preventing the nosocomial spread of HAdV infections.

In healthcare facilities, the Centers for Disease Control and Prevention recommends to use contact precautions (gloves and gown) for children with suspected or documented adenoviral conjunctivitis or gastroenteritis (if incontinent or in diapers). Both contact and droplet precautions (surgical mask) are recommended when caring for children with suspected or documented adenoviral respiratory tract infections. Although there are no specific recommendations regarding adults, isolation precautions should also be considered for adult patients with HAdV disease [146].

Immunization with live, oral, enteric-coated HAdV-4 and HAdV-7 vaccines was used safely and effectively for years in military training camps. After the sole manufacturer stopped production in 1996, outbreaks of ARD reappeared [90]. Efforts to control the spread of HAdVs and prevent epidemics in new military recruits were largely unsuccessful. In response, new live oral HAdV-4 and HAdV-7 vaccines were produced [96] and were relicensed in 2011 for military use [97].

11 Adenovirus Vectors

A large number of studies have investigated replication-defective, E1-deleted adenovirus vectors for gene therapy. Species C HAdV-5 has been the primary platform for the construction of vectors. Adenovirus vectors can infect a variety of cell types, including nondividing as well as dividing cells, and can be prepared readily in large quantities in tissue culture. These vectors can accommodate large inserts (up to 8 kb) and express higher levels of recombinant proteins than most other viral vectors.

A major obstacle to utilizing adenovirus-mediated gene therapy is the fact that adenovirus vectors are highly immunogenic, as discussed above. As a result, in vivo transgene expression is transient in both animal and clinical studies and is associated with substantial inflammatory responses [233–235]. Additionally, most individuals have serotype-specific Nabs to HAdV-5 and exhibit cross-reactive memory T cell responses to HAdVs, which further limit transgene expression from HAdV vectors [205, 236]. Therefore, a number of strategies to reduce immunogenicity in order to prolong transgene expression have been investigated, including (1) making additional vector deletions to reduce adenovirus protein expression [237], (2) preparing "gutless" or helper-dependent vectors [238, 239], and (3) inserting or upregulating proteins that inhibit immune responses such as Fas ligand or the adenovirus E3 region [240, 241]. Additionally, alterations in the fiber protein, which mediates virus attachment to cells, have been engineered to enhance binding to cell types that are negative for CAR, the major HAdV cell receptor [242].

Since 1993, about 400 clinical protocols have been implemented using adenovirus vectors. Most clinical trials have focused on the administration of E1-deleted HAdV vectors by direct injection into tumor masses. HAdV vectors expressing the tumor suppressor p53 have shown modest activity in patients with head and neck cancer and non-small cell lung cancer [243]. HAdV vectors expressing the herpes simplex virus thymidine kinase have been used as a suicide gene therapy in patients with glioblastoma or mesothelioma [244]. Additionally, HAdVs engineered with E1 mutations that preferentially allow viral replication and cell lysis in tumor cells, so-called "oncolytic" adenovirus vectors, have had modest activity in combination with chemotherapy in patients with head and neck cancer [245, 246].

Additionally, both live and E1-deleted replication-defective adenoviruses are being investigated as vaccine vectors for immunization against other infectious pathogens. A large phase II trial (the STEP study) of a replication-defective HAdV-5 vector expressing HIV-1 gag, pol, and nef proteins failed to prevent HIV-1 infection or to reduce early HIV replication after infection [247, 248]. However, priming with recombinant protein or DNA, followed by boosting with an adenovirus vector, may improve vaccine efficacy by evading preexisting memory immune responses to adenoviruses [249]. For instance, an influenza matrix protein 2 DNA prime, followed by a recombinant adenovirus boost, conferred broad protection against influenza A infection (including H5N1 influenza) in mice [250]. Other strategies under investigation to help evade preexisting immune responses include (1) administration via the intranasal route [251, 252], (2) use of vaccines based on animal adenoviruses or rare HAdV serotypes [253, 254], (3) insertion of immunostimulatory proteins [255], and (4) incorporation of novel antigens into adenovirus capsid proteins [256]. For instance, in one study, sublingual administration of a HAdV-5 vector expressing HIV Gag in HAdV-5-immune mice elicited a broad CTL response in both systemic and mucosal compartments [257].

12 Unresolved Issues

12.1 Typing Nomenclature

Typing of HAdVs has historically been accomplished by establishing their immunologic distinctiveness by quantitative neutralization with hyperimmune animal antisera. Designation and numeric assignment of a new serotype require demonstration of either no cross-reactions with other serotypes or a homologous-to-heterologous titer ratio of ≥16 in both directions. For a HAdV with a borderline SN titer ratio, distinctiveness is assumed if the hemagglutinin can be distinguished by HI or if substantial biophysical, biochemical, or phylogenetic differences exist. As noted above, naturally occurring intermediate strains that possess hemagglutinins of one or more serotypes and neutralizing antigens of another have been designated with the SN component first and the HI component following a slash (e.g., HAdV-11/H14) [20]. Other intermediate strains that are doubly neutralized by two prototype antisera have been described and molecularly characterized [258, 259].

Because of the lack of immunotypic clarity with some HAdV strains, the challenging requirements of virus cultivation and antisera preparation, and the limited access to reference prototype antisera, alternative typing schemes like genome restriction analysis have been proposed as noted above. With the increasing availability of cost-effective methodologies in DNA sequencing and computational analysis, full genomic sequencing has become the agreed upon standard for future classification of adenoviruses [63]. However, the criteria used for assigning new numbers based solely on genomic sequences have been unclear [260], and in the last few years, a plethora of new HAdV numeric "types" have appeared in the literature (types 52–65) [259, 261, 262], many of which were previously described intermediate strains. To facilitate better integration into the existing system, others have proposed retaining the preeminence of the hexon gene as the primary identifier and the fiber gene as the major determinant of tropism in designating a new virus type [263]. However, the degree and character of sequence divergence necessary to consider a candidate virus as a new numeric type has yet to be agreed upon.

12.2 Mechanisms of Latency

HAdVs were originally isolated from tonsil and adenoid explants. Using a sensitive real-time PCR assay, Garnett et al. [264] detected a high prevalence of adenoviral DNA in

human tonsil tissues from children, but infectious virus was isolated from only 13 of 94 donors (11 %). The average amount of viral DNA was 280 copies per cell, and all species C serotypes were identified. Notably, adenoviral DNA replication could be induced in most samples by lymphocyte stimulation in culture. In another study, analysis of lymphocyte populations from tonsil tissue indicated that adenoviral DNA was associated with T cells, not B cells [58].

There is also evidence for HAdV reservoirs in lymphocytes from other tissues and other cell types. HAdVs are frequently shed in feces, suggesting that the gastrointestinal tract may be a source of persistent infection. In one study, intestinal tissue from surgical specimens and the lymphocytes isolated from these specimens were tested using a nested adenoviral PCR assay [265]. Intestinal tissue from 21 of 58 specimens and intestinal lymphocytes from 21 of 24 evaluable specimens were positive for adenoviral DNA. Surprisingly, species E serotype 4 sequences were most commonly detected – this virus has rarely been isolated from stool samples in civilian epidemiologic studies or from clinical specimens in immunocompromised hosts. Species B and C sequences were also detected. Rare reports implicating HAdV transmission from donor organs (liver and kidney) suggest that these viruses can maintain reservoirs in other tissue types [131, 133]. Additionally, adenoviral DNA was commonly detected by PCR assay in brain tissue specimens in one study [266] (see Sect. 12.4, below).

What are mechanism(s) of latency in lymphocytes? Although HAdVs infect lymphocytes and monocytes very inefficiently in vitro, one group found that a subset of B and T cell lines supported short-term viral replication [267]. Another study found that adenovirus genomes were maintained at varying levels in different B and T lymphocyte cell lines in association with downregulation of CAR expression [268]. Additionally, viral DNA was maintained as a monomeric episome in the lymphoma cell line BJAB. There is also one report of a spontaneous persistent HAdV infection of an EBV-positive B cell lymphoma in a HSCT recipient [269]. These studies suggest that HAdVs can exist in a latent form as episomal DNA in lymphocytes and can be induced to replicate upon certain activation signals.

12.3 Role in Obesity

Several animal and clinical studies have identified an association between obesity and species D HAdV-36 infection. HAdV-36 increases adiposity in experimentally infected mice, chickens, and marmosets [270–272]. In one study of over 500 adult volunteers, HAdV-36 antibodies were associated with increased body weight and lower serum lipids [273]. In another study of 124 children, the prevalence of antibodies to HAdV-36 was significantly higher in obese children (15 of 19, 78 %) compared to nonobese children (15 of 67, 22 %) [274]. However, a study in military personnel did not confirm a correlation between HAdV-36-specific antibodies and obesity but rather identified differences in HAdV-36 seroprevalence related to race and sex [275].

12.4 Oncogenicity

All HAdVs can transform cultured rodent cells, a cell type in which infection is highly restricted. Species A HAdVs such as HAdV-12 and HAdV-18 and, to a lesser extent, species C viruses can induce tumors in newborn hamsters [276]. This transformation process is mediated by the adenovirus E1 transactivating region [277]. However, there is no definite evidence for oncogenicity in humans. In one study using a highly sensitive quantitative PCR assay to test over 500 pediatric tumor specimens, including leukemias, lymphomas, and solid tumors, there was no evidence of HAdV DNA in any tumor cell types except in brain tumors [266]. Although HAdV DNA was detected in 25 of 30 glioblastomas and 22 of 30 oligodendrogliomas, HAdV DNA was also detected in most control brain tissue samples. Predominantly, species B and D HAdV DNAs were identified in both malignant and nonmalignant brain tissue specimens. These data suggest that the brain may represent another reservoir of latent HAdV infection.

Alphaviruses: Equine Encephalitis and Others

7

Scott C. Weaver and Ann M. Powers

1 Introduction

Arthropod-borne viruses (arboviruses) are an ecologically defined set of viruses that share a common mode of transmission involving arthropod vectors that transmit to vertebrate hosts. Most are biologically transmitted, requiring replication in both arthropod and vertebrate host with transmission between vertebrate animals by the bite of mosquitoes, ticks, sandflies, or midges [1]. The vast majority of arboviruses belong to one of five families: *Togaviridae, Flaviviridae, Bunyaviridae, Reoviridae*, and *Rhabdoviridae*. Information on their isolation, morphology, sensitivity to inactivation by chemicals, arthropod vectors, vertebrate hosts, laboratory propagation, serological reactions, geographic distribution, clinical manifestations, and epidemiology is found in the *International Catalogue of Arthropod-Borne Viruses*, compiled by the American Committee on Arthropod-Borne Viruses [2]. This exhaustive reference source has been used freely in preparing this chapter.

The biological transmission of arboviruses is characterized by their replication in the arthropod. The period from ingestion of an infectious blood meal until the virus replicates, reaches the salivary glands, and can be transmitted is called the extrinsic incubation period. After being fed upon by an infected arthropod that secretes saliva to block hemostatic responses and often to limit pain, the vertebrate host becomes infected and usually viremic. This part of the transmission cycle takes from 1 day to more than a week and constitutes the intrinsic incubation period. Biological transmission should be distinguished from mechanical transmission in which the virus contaminates the mouthparts of the arthropod and can be transmitted immediately to a new vertebrate host without replication in the invertebrate. Also, nonviremic transmission has been described for a few arboviruses whereby virus inoculated via the saliva is sufficient in amount to generate an immediate, nonreplicative viremia [3, 4].

Arboviruses are usually maintained in a reservoir cycle that consists of both arthropod and vertebrate hosts. Both are needed to maintain the virus in nature [5]. A subset of arboviruses, including members of the family *Togaviridae* [6, 7], is transmitted vertically through the egg of the arthropod. In these cases of transovarial transmission, the arthropod alone may be the reservoir of the virus and may maintain the virus in the absence of a vertebrate animal (for a limited duration assuming the rate of vertical transmission is <100 %).

2 Sources of Mortality Data

Mortality data are collected systematically but passively by national governments for the encephalitic alphaviral infections and other diseases such as epidemic polyarthritis. Data are published in the *Morbidity and Mortality Weekly Report* of the US Centers for Disease Control and Prevention, in the *Weekly Epidemiological Report* of the Pan American Health Organization, and the *Weekly Epidemiological Report* of the World Health Organization. The mortality data are underreported, but may serve as a comparative database, since underreporting may be uniform throughout much of the world.

The information flow to the World Health Organization is sometimes facilitated by informal networks of scientists and interested citizens. Nevertheless, the organization is constrained from action until official reports are received. This constraint can mean a delay in control of a disease of regional or world importance.

3 Sources of Morbidity Data

The same sources supply morbidity data as supply mortality data. In the USA, of the arboviral diseases, only encephalitis is reportable. An observed trend of increased nonspecific encephalitic cases during years of arbovirus epidemics may be due to increased physician requests for more diagnostic tests, leading in turn to diagnosis in a higher percentage of cases in these years. If so, this implies underdiagnosis in other years [8].

4 Serological Surveys

Alphaviruses are distributed focally nearly throughout the world [9]. The distribution of any given arbovirus is ecologically limited by the range of the vector and vertebrate hosts. Serological surveys are ideally suited for arboviruses to determine the point prevalence in different geographic areas. Often distribution of the antibody will give clues to the ecological conditions necessary for maintenance of the virus. Surveys of different age groups will show if the virus is more prevalent as the population ages, typical of an endemically transmitted agent. Another prevalence pattern in which antibody is present only in persons born before a certain year may indicate an epidemic in that year. Alternatively, a relatively constant percentage of antibody in each age group may indicate a recent introduction of the virus causing a virgin soil epidemic.

Broadly based serological surveys of large populations can provide extensive information about virus distribution in different geographic areas, rural versus urban populations, different age and sex groups, and different occupational types. However, arbovirus serosurveys have limitations. Cross-reactions occur among viruses of the same serogroup using certain tests. This is especially true of the hemagglutination inhibition (HI) test and enzyme-linked immunosorbent assay (ELISA). The neutralization test is more specific and should be used where feasible. Surveys with HI or ELISA must be interpreted with caution unless one is certain that only one virus is extant in the region, or unless the results have been confirmed by neutralization test with a portion of the negative and positive sera.

The serosurvey usually will not indicate when the infection responsible for the antibody occurred. If the antibody is suspected to be of recent origin, the IgM antibody-capture ELISA is useful for detection of infections originating within recent months.

5 Laboratory Methods

The laboratory is an all-important resource in the study of the epidemiology of arbovirus diseases. Diagnosis can rarely be made with certainty by clinical examination. Isolation of virus from arthropods, wild or domestic animals, and people is essential to determine the natural history of infection with these agents.

Positive findings on survey sera are greatly bolstered by virus isolations from the vector, nonhuman vertebrates, or humans. Virus isolation procedures for serum specimens require inoculation of a small amount of serum into laboratory animals or cell cultures or both. Mice are observed daily, or more than once a day, for evidence of illness. A subpassage may be made to attempt to enhance the virulence of the virus, and when one is assured that a virus has been isolated, a stock pool of virus is established and hyperimmune mouse serum or ascitic fluid is prepared if needed. In fatal cases, 10–40 % suspensions of the tissue—brain, liver, lung, or spleen (purified by centrifugation)—may be inoculated as for serum.

Cell culture systems (vertebrate or insect cells) can also be used for virus isolation. For certain alphaviruses and certain cell cultures, the cell culture systems, are as sensitive as laboratory animals (considering an equal volume of total inoculum). Intracerebral inoculation of infant mice will serve to isolate a much wider total range of arboviruses than will any single cell culture system. Conversely, in the investigation of a specific virus, a cell culture system that has been predetermined to be suited to the virus can be easier, cheaper, involve fewer regulatory hurdles, and atleast as reliable than techniques that require laboratory animals.

In the study of material derived from patients, it is highly desirable to have a pair of serum specimens to work with. The first should be taken early in the course of illness and can serve as material both for virus isolation and for the determination of baseline serum antibody levels before the patient has developed antibodies to the infecting virus. A second serum should be obtained at least 3 weeks after onset of illness or as late as several months after onset. A seroconversion (four-fold or greater rise in antibody titer) demonstrable between the early and later specimens is a strong evidence of a recent virus infection. Demonstration of IgM in ELISA permits a presumptive diagnosis with a single serum as long as two etiologic agents that produce similar disease are not circulating during the same time period [10, 11].

Details of the techniques of CF, HI, and virus neutralization relating specifically to alphaviruses are available in current references [11]. Fluorescent antibody (FA) techniques; antigen detection ELISA, often coupled with monoclonal antibody; and RT-PCR are widely used for antibody, antigen, and RNA detection, respectively. Additional specialized assays for the serotype determination and genetic characterization of specific alphavirus groups are detailed below.

6 Biological Characteristics of the Viruses That Affect the Epidemiologic Pattern

A prerequisite for the survival of arboviruses in nature is a period of viremia in a vertebrate host at a level sufficient to infect the arthropod vector. Even with alphaviruses that generate high-titer viremias and highly susceptible vectors, a viremia titer in excess of 10,000 infectious doses of virus per milliliter of blood is frequently required to sustain transmission. Such high levels of viremia are generally found in the natural host and often are attained in the more commonly used laboratory animals such as mice, hamsters, guinea pigs, chicks, and monkeys. For some alphaviruses, however, the natural hosts or natural vectors, or both, are either unavailable or not known, so that the postulate of a level of viremia in the vertebrate adequate to infect a susceptible vector remains undemonstrated.

7 Epidemiology

The epidemiology of arbovirus infections in humans is influenced by three major determinants: (1) the behavior of the arthropod vector, including the ecological setting in which its larval habitats occur, its pattern and range of mobility, its biting habits and species preferences for feeding, its longevity, and the factors affecting the infection, replication, dissemination, and secretion into the saliva of virus within the arthropod host; (2) the frequency, nature, and duration of exposure of humans to the infected arthropod vectors, as influenced by the presence, level, and specificity of humoral antibody and by use in the population of insecticides, insect repellents, and protective clothing; and (3) the requirements for the presence of a necessary and/or amplifying vertebrate host for the virus, such as horses, birds, or rodents, and of the availability of humans as alternative hosts.

8 Epidemic Behavior

Outbreaks of alphavirus infections in the USA involving humans occur periodically and unpredictably, as evident from the activity from 1955 through 1987. Only 182 cases of eastern equine encephalitis (EEE) were reported during this time, of which 12 cases and 6 deaths were in 1968; during the same period, 1,030 cases of western equine encephalitis (WEE) were reported, of which 172 occurred in 1965, with four deaths, and 133 in 1975, with six deaths (http://www.cdc.gov/ncidod/dvbid/arbor/arbocase.htm). In contrast, from 1988 to 2010, 159 EEE cases were reported, while only five WEE cases occurred. Venezuelan equine encephalitis (VEE) produced its first outbreak in Texas, USA, in 1971, with no epidemic activity in the USA since that date.

9 Geographic Distribution

Alphavirus infections are nearly worldwide in distribution and may occur whenever the appropriate mosquito vectors occur in sufficient numbers in proximity to humans and a suitable amplifying host. Table 7.1 includes the geographic distribution of alphaviruses.

10 Temporal Distribution

In the USA, mosquito-borne alphaviruses produce human infections primarily in late summer and fall. Tropical alphavirus infections tend to occur during rainy seasons when mosquito vectors are most abundant. However, chikungunya virus (CHIKV), which occurs both in enzootic, sylvatic primate-amplified and urban, human-amplified cycles, can cause human disease throughout the year.

11 Age and Sex

Infections with alphaviruses can occur at any age. The age distribution depends on the degree of exposure to the particular transmitting mosquito relating to age, sex, and occupational, vocational, and recreational habits of the individual or group of individuals. For most alphaviruses, there is not a strong association between these groups and markedly higher rates of exposure. However, once humans have been exposed and infected, the severity of the disease may

[a]Recommended for species designation [12] but not yet approved by the International Committee on the Taxonomy of Viruses

also be influenced by age. For example, WEEV and VEEV tend to produce the most severe clinical infections in young persons.

12 Mechanism and Route of Transmission

By definition, arboviruses must be transmitted by arthropod vectors. There is often a high-level virus–vector specificity associated with biological transmission, usually manifested at the initial infection of the mosquito alimentary tract. This biological transmission may be supplemented under some circumstances by mechanical transmission.

The duration of the necessary period of virus replication within the arthropod host before it becomes infectious varies from virus to virus and vector to vector and is also directly temperature dependent. For some alphaviruses, the extrinsic incubation period can be as little as 2 days under average summer temperature conditions [13, 14]. However, mosquitoes generally must develop their eggs and oviposit before a subsequent blood meal, resulting in transmission, occurs; this gonotrophic cycle length may limit the minimum time until transmission if it is longer than the time for virus to reach and replicate in the salivary glands after an infectious blood meal. Once infected, vectors often remain infected and able to transmit for life, which can be many weeks or even months.

Transmission of alphaviruses transovarially in mosquitoes, often referred to as "vertical transmission," has been demonstrated for CHIKV [6] Sindbis [15] and Ross River virus [7].

13 Pathogenesis and Immunity

Most alphavirus infections are transmitted by the bite of a mosquito vector, so that the skin represents the sole portal of entry. With early wide dissemination throughout the host, multiplication follows in generally poorly determined target cells and tissues. Viremia in the host then provides the seedbed for infection of succeeding cohorts of biting arthropods. The incubation period is usually 3–15 days.

The site of replication of most arboviruses remains undetermined but is presumed to be in the vascular epithelium and the reticuloendothelial cells on the lymph nodes, liver, spleen, and elsewhere. Liberation of virus from these organs constitutes the "systemic phase of viremia," resulting after 3–7 days of symptoms such as fever, chills, and aching. A number of arbovirus infections have two phases—this early phase and then a second phase with or without a few days of freedom from symptoms. The second phase may be attended by encephalitis, joint involvement, rash (sometimes hemorrhagic), and involvement of the liver or kidneys. In most arbovirus infections, only the first phase occurs, and the disease is "nonspecific." In other instances, the early phase may be missed, and only the severe manifestations occur. The early phase is often accompanied by leukopenia and the second phase often by leukocytosis [16]. Tissue injury may be the direct effect of viral multiplication in susceptible cells, as is the case with lymphodepletion following VEEV infection.

Humoral antibodies regularly appear early in the course of alphavirus infection and constitute the major basis of immunity. Such immunity may be lifelong. The role of cell-mediated immunity in alphavirus infections has been poorly studied but can protect mice deficient in antibody production from lethal VEEV infection [17]. It is possible that it may be important in controlling virus persistence and in determining the immunopathological lesions suspected in certain manifestations of infection.

14 Patterns of Host Response

14.1 Clinical Features

Inapparent and subclinical human responses predominate in most alphavirus infections, with the exception of CHIKV and VEEV. For example, infection with EEEV and WEEV results principally in mild and inapparent infections; the reasons for these differences are unknown.

14.2 Diagnosis

Cases of alphavirus infections in the USA are not likely to be diagnosed unless there is a high degree of clinical suspicion. Outbreaks of encephalitis in horses during the summer, caused by EEEV, WEEV, or VEEV, serve to focus attention on febrile illness in humans associated with symptoms or signs indicating involvement of the CNS. Recognition of the arbovirus infection acquired by the traveler outside the USA also depends on the alertness of the examining physician. Rapid jet transport now permits exposed overseas travelers to reach home and fall ill even within the short incubation period of such infections. This trend was exemplified by the 35 CHIKV-infected patients diagnosed after their return from epidemic regions of the Indian Ocean and Asia during 2006 [18]. The physician must maintain a high degree of suspicion when seeing CNS infections or influenza-like illnesses occurring in travelers recently returned from areas endemic for alphaviruses. Testing for alphavirus infection is not widely available, so special testing must often be done through arrangements with regional, national, or international public health agencies and/or reference centers. It

should be noted that arbovirus infections constitute only a small fraction of the encephalitis cases seen in the USA with the majority of cases of undetermined etiology.

The laboratory diagnosis depends on the isolation of the virus from the blood, a fourfold antibody rise in titer between acute and convalescent sera, or the presence of specific IgM taken during the acute phase. Often, the suspicion of an alphavirus infection in individual cases, especially in cases of neurologic disease that occurs several days after the onset of illness, arises too late for virus isolation from the blood. Under these circumstances, the presence of a high antibody titer in a single serum may be significant if the infection is an uncommon one in that region and particularly if antibody surveys reveal a low antibody prevalence or if prior surveys have demonstrated the absence of antibody in that community. The appropriate procedure in suspected cases is to (1) notify the health department and seek background epidemiologic and clinical data and (2) send acute and convalescent serum samples to the nearest public health laboratory (usually a state laboratory), with a request for antibody tests for alphaviruses. Some state laboratories may not have all necessary testing available, at which point a request for transshipment of sera to the CDC for additional testing might be included.

14.3 Control and Prevention

Major control methods include (1) control of the arthropod vector, which may be by elimination of aquatic larval sites or their treatment with insecticides or by direct control of adult female mosquitoes that are responsible for transmission, through insecticide applications such as malathion; (2) avoidance of exposure to mosquito vector bites by screening of houses, by using protective clothing, by staying indoors during times of peak host seeking by vector mosquitoes, and by applying insect repellents when outside in high-risk areas. Control of mosquito vectors through biological approaches ranging from larvicidal bacteria, predatory fish, and the introduction of genes deleterious to the vector population [19] or of *Wolbachia* bacteria that render adult female mosquito vectors refractory to transmission [20] is receiving much attention as an alternative control strategy.

15 Characteristics of Selected Arboviruses

15.1 Alphaviruses of Importance in the USA

Of the alphaviruses found in North America, only eastern (EEE), western (WEE), and Venezuelan equine encephalitis (VEE) viruses are important human pathogens. The former two viruses are enzootic within the USA, Canada, and Mexico, while VEE is enzootic and endemic only to Mexico but has spread into the USA on at least one occasion.

15.2 Eastern Equine Encephalitis Virus

15.2.1 Natural History/Transmission

In North America, most human and equine EEEV infections occur near enzootic foci of transmission, which occur in hardwood swamps populated by the principal mosquito vector, *Culiseta melanura*, and passerine birds that serve as amplification hosts (Fig. 7.1). These habitats occur along the Atlantic and Gulf coasts but also at inland locations in the upper Midwest (Fig. 7.2).

However, southeastern USA foci in locations where this mosquito is not abundant suggest the involvement as enzootic vectors of ornithophilic *Culex* spp. mosquitoes including *Culex erraticus* [21]. Because *Cs. melanura* feeds primarily on avian hosts, bridge vectors, probably including *Aedes vexans, Coquillettidia perturbans*, *Ae. canadensis*, and *Cx. salinarius,* have been assumed to transmit from birds to humans and horses [21, 22] (Fig. 7.3).

However, some studies suggest that *Cs. melanura* may bite mammals at sufficient frequency to implicate them in human and other mammal infections [23, 24]. Passerine birds that inhabit swamps are considered the principal enzootic amplification hosts in North America. However, recent serological and experimental infection data from the southeastern USA suggest that amphibians and reptiles could be involved in enzootic circulation [25, 26]. Although a wide variety of domesticated mammals and birds suffer severe and often fatal disease after EEEV infection, none is believed to be efficient at amplification via mosquito transmission because viremia levels are generally low [27–29]. Thus, unlike VEE outbreaks that can spread far from their origin due to efficient equine amplification, cases of EEE rarely occur far from enzootic foci, which tend to occur in relatively remote locations.

Presumably because they receive greater exposure to mosquito feeding, equids suffer a higher incidence of EEE than humans in North America. EEE epizootics in horses and pheasants often precede human cases, and the former are thus useful sentinels for detecting epizootic circulation [30]. Human and equine outbreaks are associated with excessive rainfall [31, 32] and usually peak in early fall in temperate regions of North America.

EEEV strains closely related to North American strains isolates have also caused equine outbreaks in the Caribbean [33] and northern Mexico [34]. Because there is no clear evidence of enzootic circulation in these locations, these outbreaks may represent introductions followed by epizootics of limited duration. Similarly, it remains unknown if the detection of epizootic

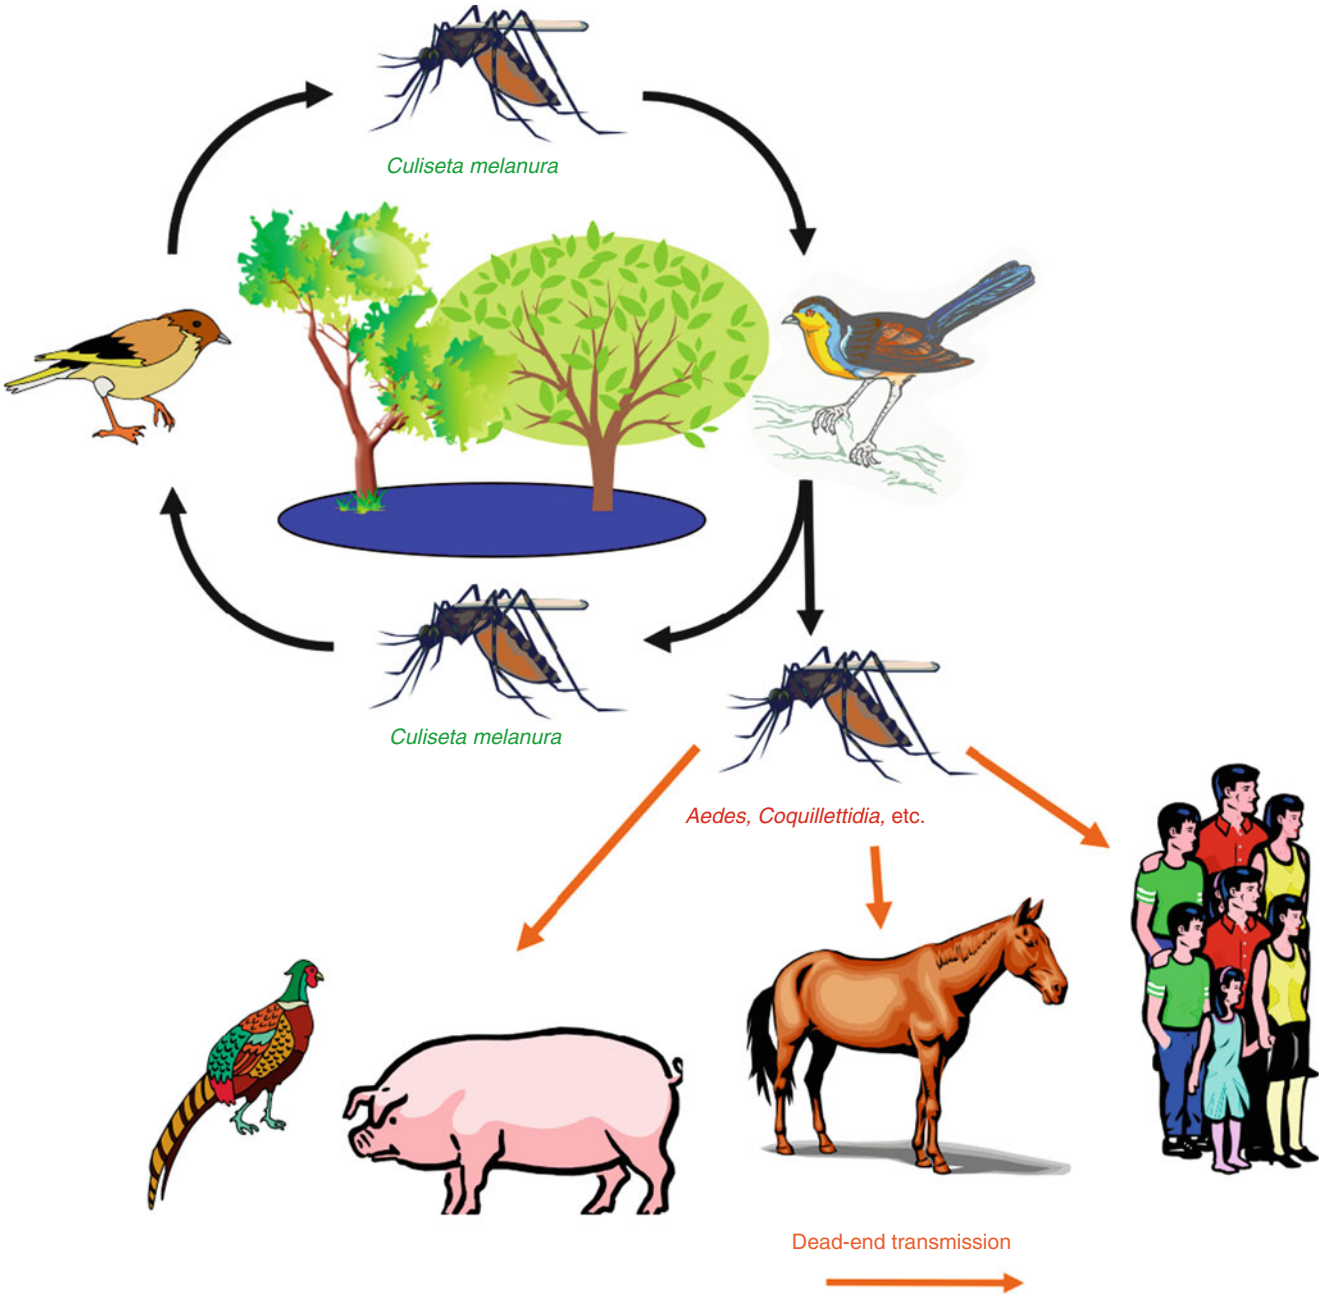

Fig. 7.1 Enzootic transmission cycle of eastern equine encephalitis virus in North America and epidemic or epizootic spillover to humans and domestic animals, respectively

EEEV circulation as far north as northern Maine in 2009 [35] represents stable enzootic circulation or a temporary introduction. In Central and South America, strains recently assigned to the species *Madaringa virus* (MADV have been isolated repeatedly from mosquitoes, principally members of the subgenus *Culex* (*Melanoconion*), as well as from equids suffering from neurologic disease. The most important reservoir hosts in South America remain unclear but may involve both small mammals and possibly birds [36]. Prior to 2010, despite clear evidence of their exposure during epizootics and by living in areas of enzootic transmission, only three cases of human EEE were reported in Latin America [37–39]. Genetic and antigenic distinctions between EEEV strains that circulate in North versus South American strains (MADV), as well as differences in sensitivity to and induction of interferons, suggest fundamental differences in human virulence [40, 41]. However, a 2010 EEE outbreak in Panama, involving both horses and humans, may reflect a change in human virulence there [10].

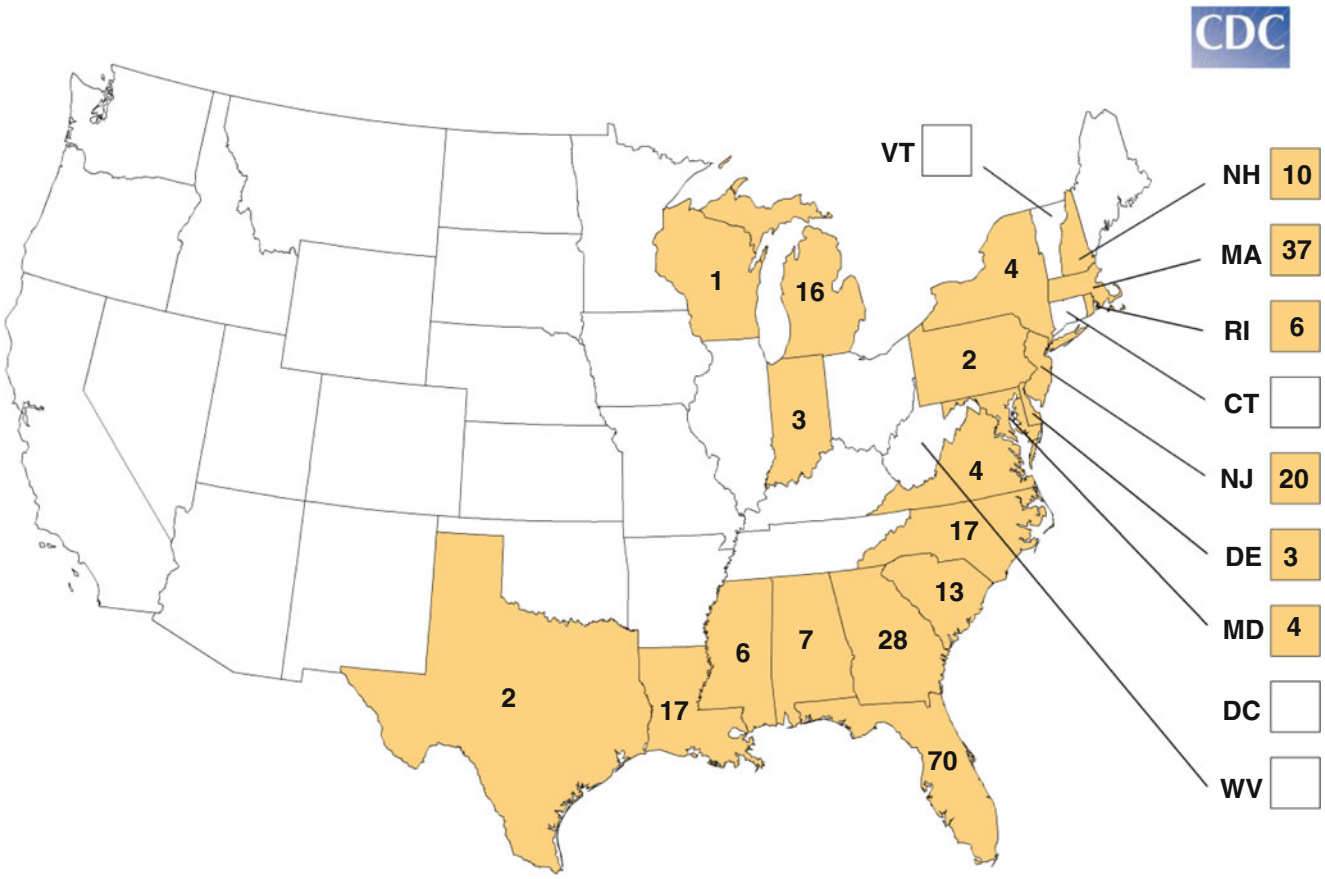

Fig. 7.2 Eastern equine encephalitis virus neuroinvasive disease cases reported by state, 1964–2010 (Adapted from http://www.cdc.gov/easternequineencephalitis/tech/epi.html)

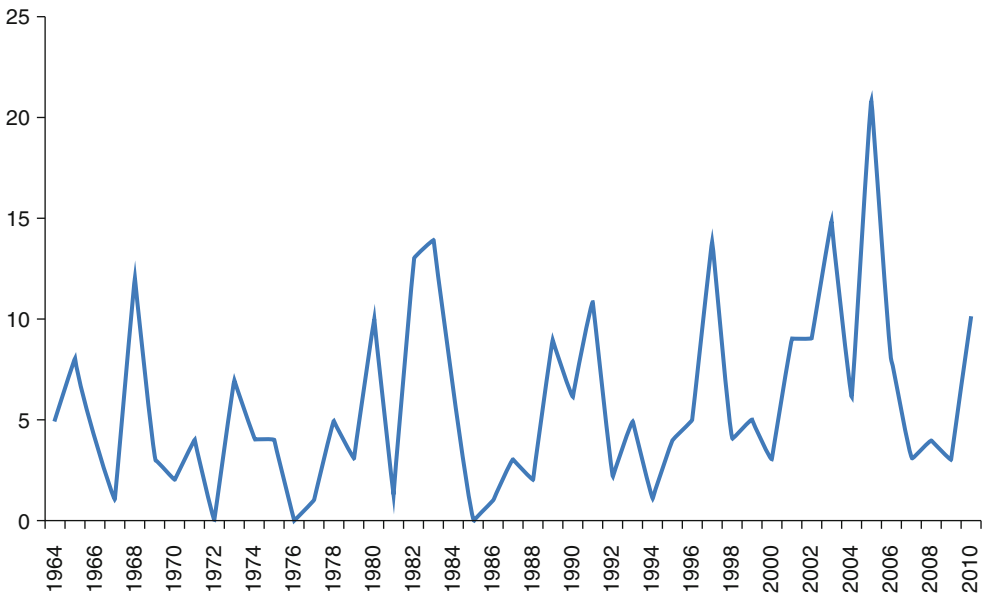

Fig. 7.3 Eastern equine encephalitis virus neuroinvasive disease cases reported as encephalitis, meningoencephalitis, or meningitis, by year, 1964–2010 (Adapted from http://www.cdc.gov/easternequineencephalitis/tech/epi.html)

15.2.2 Impact on Human and Animal Health

Clinical EEE in humans has remained sporadic with little evidence of any overall change in incidence during the past several decades. Although some epidemics from the 1930s to the 1950s involved more than 30 people [42], an average of only five to ten human cases has been documented annually in the USA since the 1970s (Fig. 7.3). Historic records suggest that the principal enzootic vector of EEE virus (EEEV),

Cs. melanura, may have become more abundant along the Atlantic seaboard following reforestation during the twentieth century, leading to increased virus circulation and periodic epidemics. Although the average number of human cases remains low, the high EEE case-fatality rate, usually exceeding 50 %, leads to fear in the affected populations and considerable expenditures for mosquito vector control to reduce the risk of infection [16]. Because EEE survivors often suffer permanent, debilitating neurologic sequelae, health care and institutionalization costs were estimated at $3 M per case in 1994 ($4.7 M in 2012 dollars) [43]. EEE occurs predominantly in eastern and Gulf Coast states and in northeastern inland states in the USA and Canada (Fig. 7.2).

15.2.3 Human Disease

The incubation period in human beings is short, usually 4–10 days [16, 44]. Gender is not a major factor in risk for disease [45], but patients <10 years of age are more likely to suffer severe sequelae than older age groups. The ratio of inapparent or mild infections to severe infections has been described as low in some studies based on very low human seroprevalence after epidemics [44]. However, following the 1959 New Jersey epidemic, 3.1–3.6 % of persons surveyed exhibited complement fixing antibodies, suggesting many inapparent infections [46], with inapparent (no recognized central nervous system disease)—apparent ratios of 8–26 % in different age groups, or 23 % overall [47]. Abrupt onset of severe fever, nausea, myalgias, and intense headache are followed by encephalitis in 1–2 days. Infants and children often present with convulsions. The encephalitis rapidly progresses to a coma, particularly in small children. Between 30 and 70 % of clinical cases are fatal. Patients with a short prodrome are more likely to develop encephalitis than those with a long prodromal illness accompanied by nonspecific signs and symptoms [48] a pattern observed in some animal models [49]. Pathological features include diffuse encephalitis with evidence of scattered neuronal destruction. Intensive supportive care is essential, since there is no specific treatment for EEE. Immunity is probably lifelong, with no reinfections being described.

15.2.4 Diagnosis

EEEV infection is typically suspected based on the proximity of the patient to known swamp habitats that support enzootic circulation in the eastern USA. Differential diagnoses include a wide variety of noninfectious (e.g., tumor, stroke, Alzheimer's disease, long-term alcohol abuse, and other dementias, although these conditions are not usually accompanied by fever) as well as infectious (herpes simplex virus, enterovirus, influenza virus, adenovirus, lymphocytic choriomeningitis virus, respiratory syncytial virus, rabies, or Epstein–Barr virus infection, bacterial meningitis, mycoplasma, *Bartonella henselae*, Rocky Mountain spotted fever, leptospirosis, Lyme disease, HIV, syphilis, tuberculosis, and other mycobacterial or fungal diseases) etiologies. After initial clinical suspicion, diagnosis is ideally established by virus isolation from the serum, cerebrospinal fluid (CSF), or brain tissue or the detection of viral RNA from these samples through reverse-transcription polymerase chain reactions [16]. However, human viremia is not typically of high titer, so serological diagnosis is more common, including demonstration of seroconversion (a fourfold or greater rise in antibody titers between acute and convalescent serum) or the finding of high-titer IgM in serum. Because the background prevalence of EEE in endemic areas is very low, a single serum demonstrating high-titer antibodies is highly suggestive of etiologic infection. Evidence of an outbreak of disease involving birds and mosquitoes, and more particularly equids or other domesticated animals in the region, should alert clinicians.

15.2.5 Prevention and Control

Because there are no licensed human vaccines or treatments, prevention of exposure to infected mosquitoes is the only way to prevent the disease. Passive surveillance relies on the finding that equine or avian disease usually precedes human infections. More active approaches include the use of chickens to detect EEEV circulation through seroconversion and monitoring mosquito populations for infection; [50] early season detection of the latter is predictive of late season epizootics and human cases [51]. When high levels of EEEV circulation are detected, the control of adult female mosquito populations is often attempted using aerial insecticide applications. Avoidance of mosquito contact relies on wearing long pants and long-sleeved shirts, applying repellents to exposed skin, and remaining indoors during the evening and nighttime when mosquito vectors are most active. An inactivated virus vaccine has been administered to laboratory personnel at risk through the US Army Special Immunizations Program [52]. Equids and other domesticated animals can be immunized with commercially available inactivated vaccines [53]. However, these vaccines are poorly immunogenic, requiring annual boosters, and can carry the risk of disease from residual live, virulent virus [54]. Several recently developed vaccine candidates have shown promise in preclinical trials [55–57], but because of the small numbers of natural human infections, they are unlikely to attract a commercial market.

15.2.6 Viral Genetics and Evolution

Genetically, aside from the recombinant portion of WEEV that was derived from an ancestral EEEV strain, EEEV is most closely related to VEE complex alphaviruses [58, 59]. Antigenically, it is also most closely related to the latter group. In North America and the Caribbean, EEEV is highly conserved genetically across time and space, with only less than 2 % nucleotide sequence divergence among all strains isolated since 1933 [60] (Fig. 7.4).

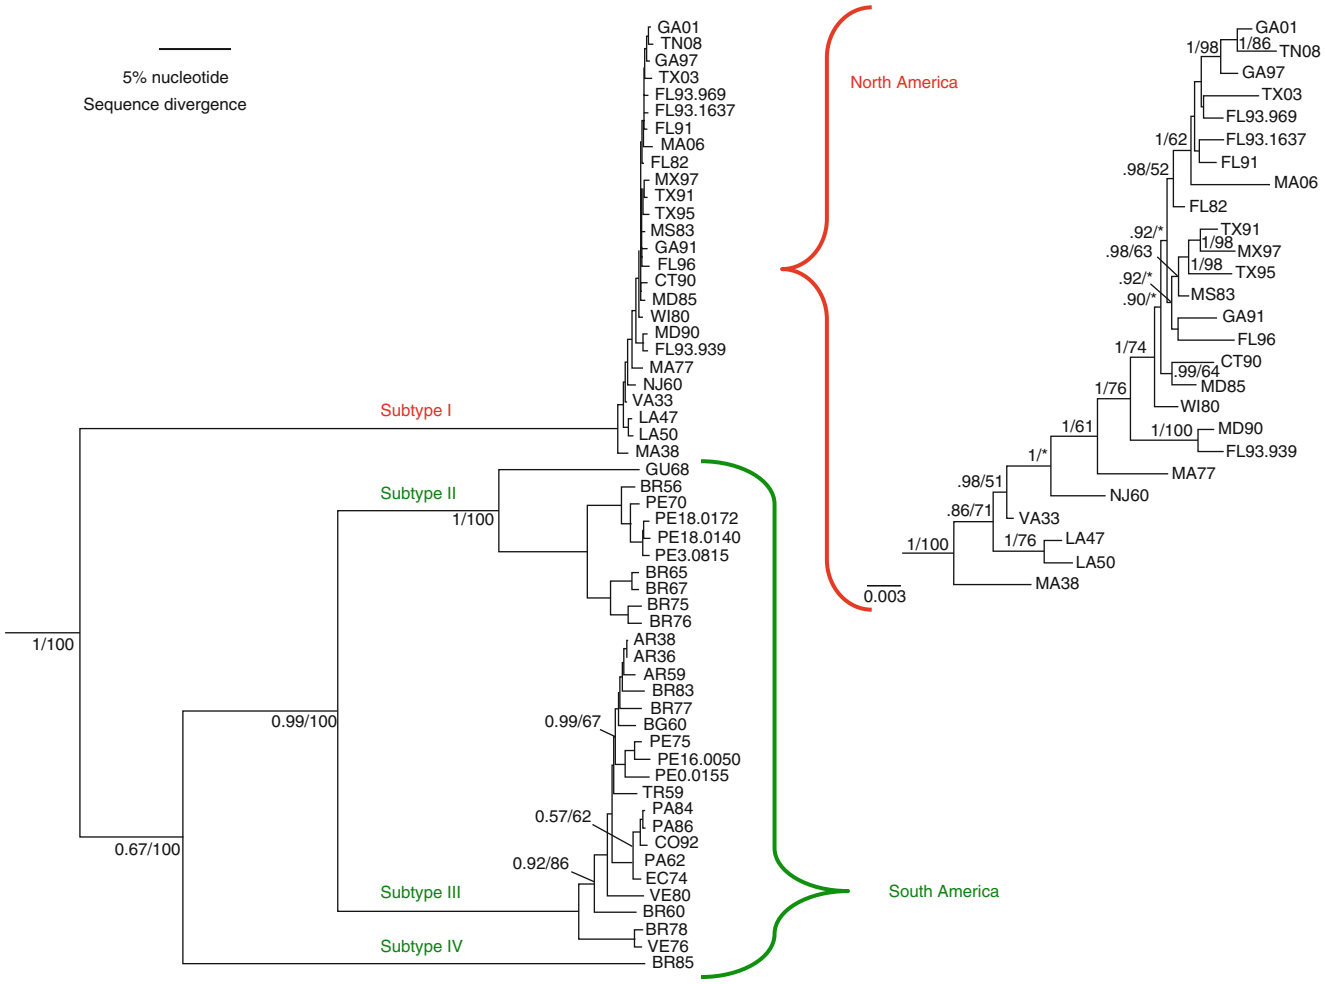

Fig. 7.4 Phylogenetic analyses of EEEV isolates using Bayesian methods, with the complete structural polyprotein open reading frames. (**a**) *Left*, tree of NA and SA EEEV. Bayesian posterior probability (PP) values and maximum parsimony (MP) bootstrap values are noted for all major nodes of lineage divergence (PP/MP values). Within each SA EEEV (MADV) lineage, values for PP/MP are shown only if either value is less than or equal to 0.90 (PP) or 90 (MP) for the adjacent node. *Scale bar* shows a genetic distance of 5 % nucleotide sequence divergence. (**b**) Magnified version of NA EEEV phylogeny. Values for PP/MP are shown only if either value is greater than or equal to 0.90 (PP) or 90 (MP) for the adjacent node. *Asterisks* indicate a polytomy in MP bootstrap analysis. *Scale bar* shows a genetic distance of 0.3 % nucleotide sequence divergence (Adapted from) [60]

This conservation and the evolution of EEEV as a single ongoing lineage in North America presumably reflect the efficient transport of strains via infected birds [61, 62], leading to periodic selective sweeps. However, phylogenetic groupings of strains isolated from temperate foci over several years also suggest that EEEV overwinters in the northeastern USA, where transmission does not occur during the winter because *Cs. melanura* survives only in the larval stage [62, 63]. In South America, EEEV strains (MADV) are much more diverse genetically and antigenically, with regionally defined viral clades that suggest the use of vertebrate amplifying hosts with limited dispersal potential [34, 60]. There is no evidence of mixing of EEEV strains between the continents. However, as with North American strains, two distinct lineages have been identified in the same location at the same time [64], suggesting that EEEV population structure is not completely spatially defined.

15.3 Venezuelan Equine Encephalitis

15.3.1 Natural History/Transmission

Venezuelan equine encephalitis (VEE) virus (VEEV) is one species in the VEE antigenic complex of alphaviruses, which comprises several species, subtypes, and varieties that can be distinguished genetically and antigenically [9, 65]. Most of these viruses, including VEEV subtypes ID and IE, circulate in enzootic transmission cycles involving rodent

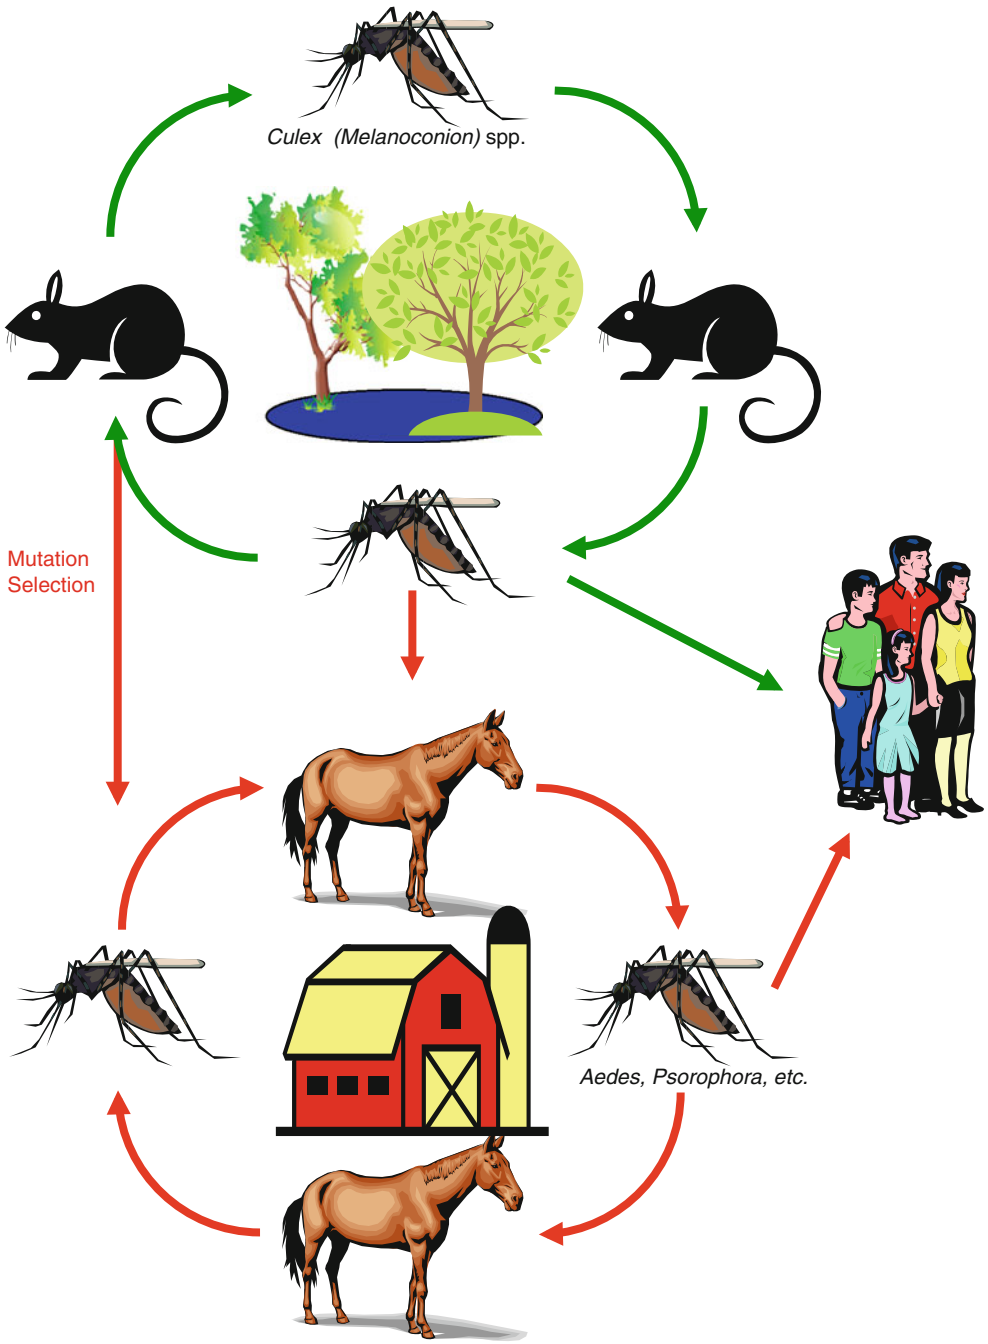

Fig. 7.5 Enzootic (*above*) and epizootic/epidemic (*below*) transmission cycles of most VEE complex alphaviruses (enzootic) and VEEV subtypes IAB and IC (epizootic/epidemic). *Arrows* show transition from the enzootic VEEV subtype ID strains to the epizootic/epidemic VEEV subtype IAB or IC strains via adaptive mutations that enhance equine viremia or from enzootic subtype IE strains in Pacific Coastal Mexico to an epizootic subtype IE phenotype that infects more efficiently *Aedes* (*Ochlerotatus*) *taeniorhynchus* mosquito vectors

reservoir/amplification hosts and mosquito vectors in the subgenus *Culex* (*Melanoconion*) (Fig. 7.5).

Exceptions include the VEE complex alphaviruses Tonate and Bijou Bridge, which appear to utilize birds as vertebrate hosts in South and North America, respectively. Although many members of the VEE complex have only been isolated in one or a few locations and at one or a few time points when surveillance activities were implemented (Fig. 7.6), they are probably widespread in South America.

Enzootic strains of VEEV, subtypes ID and IE, have been more intensively studied and are important causes of endemic disease among people who live in regions where they circulate in forested or swamp habitats [66–70]. Studies of dengue-like illness suggest that they may cause a burden of

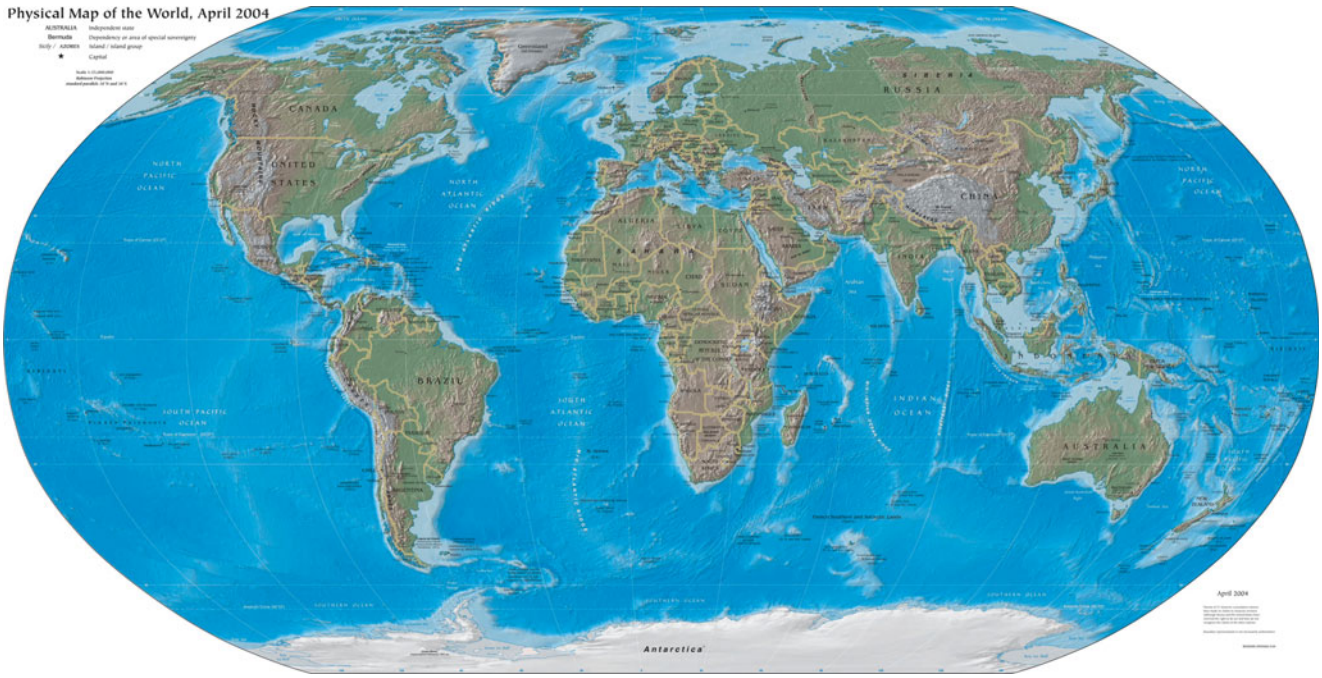

Fig. 7.6 Known distributions of alphaviruses in the VEE antigenic complex

disease that is approximately 1/10 that of dengue in Latin America and that fatal human infections occur regularly [66]. Everglades virus, which is only found in Florida, occasionally causes human disease [71] but has never been associated with equine outbreaks.

In addition to the enzootic strains that circulate continuously and in a widespread manner, VEEV variants in subtypes IAB and IC, often called "epizootic" or "epidemic" strains, arise periodically from the enzootic strains to cause major outbreaks of disease in people and equids [72, 73]. Phylogenetic and reverse genetic studies indicate that these strains arise when enzootic forms adapt via positive selection to increase their viremia and virulence in equids, leading to highly efficient amplification in rural locations [74], and/or to mosquito vectors that undergo seasonal expansions [75]. However, most of these epizootic/epidemic strains are short lived, presumably due to their reliance on equids for amplification and the limited population turnover of these relatively long-lived hosts.

15.3.2 Impact on Human and Animal Health

VEE complex viruses have a severe impact on both human and animal health. The former is affected both by spillover of enzootic transmission cycles and by equine-amplified epidemics, while equids and other domesticated animals are affected primarily during epizootics [72]. Because equids remain important for agriculture and transportation in areas of Latin America where epidemics occur, epizootics also have significant economic effects. Epidemics, which usually involve VEEV subtypes IAB and IC, typically affect hundreds to hundreds of thousands of people, with low rates of fatality but with many long-term effects on survivors due to high rates of permanent sequelae, especially among infected children. Endemic human VEE due to spillover directly from enzootic cycles is rarely diagnosed because most infections closely resemble dengue fever, which is endemic in most of Latin America [66, 67, 69]. However, if estimates that about 3 % of dengue-like illness are caused by VEEV in Iquitos, Peru [67], can be extended to other parts of Latin America, there could be tens of thousands of human cases annually, with hundreds of fatalities assuming a case-fatality rate of about 0.5 % [66].

15.3.3 Human Disease

Infection with VEEV or many VEE complex alphaviruses typically leads to an undifferentiated acute febrile illness characterized by an abrupt onset of headache and fever, often accompanied by gastrointestinal signs and symptoms [16]. Unlike those of many other arboviruses such as EEEV, most human VEEV infections are symptomatic and attack rates during outbreaks can exceed 50 % [65]. A small fraction of infections, primarily those in children, progress to central nervous system disease typically including convulsions, disorientation, and drowsiness and occasionally to coma and death. Children who survive neurologic disease often experience lifelong sequelae that affect motor function and cognition. In addition to its direct effects, VEEV is lymphotropic and causes immune suppression, which leads to secondary infections at elevated rates for up to months after infection.

There is no evidence that different strains of VEEV differ greatly in human virulence, although virulence differs markedly in equids [76, 77].

15.3.4 Diagnosis

Diagnosis of VEEV infection largely follows the procedures outlined above for EEEV [16]. However, in addition to the basic diagnosis that generally relies on virus isolation, IgM detection, or seroconversion (fourfold or greater ride in IgG measures by ELISA or other assay), it is important to determine the serotype circulating because subtypes IAB and IC can spread rapidly due to equine amplification. Virus isolation followed by complete or partial genome sequencing with a focus on the E2 envelope glycoprotein is most informative [78], but more rapid, ELISA-based methods are also available to diagnose the serotype of infection [79]. Human viremia usually lasts 3–4 days and is relatively high in titer, so virus isolation or viral RNA detection by RT-PCR is useful for definitive diagnosis. Once viral clearance from the blood has occurred, usually 5–6 days after infection, a blocking ELISA can still be used to determine the VEEV serotype of infection [80].

15.3.5 Prevention and Control

Prevention of endemic VEE caused by spillover of enzootic strains is challenging because the enzootic cycle involving rodents and forest-dwelling mosquitoes would be difficult to control due to its relatively remote location and widespread occurrence in the neotropics [66]. Prevention of exposure to enzootic vectors, which generally are active during crepuscular time periods or during the nighttime, relies on wearing appropriate long-sleeved shirts, long pants, and other garments to reduce skin exposure, applying repellents, and staying inside during the evening and night. Prevention of equine-amplified epidemics can be achieved by vaccinating equids with the live-attenuated TC-83 VEEV strain, which received its first widespread use during a 1971 Texas epidemic, where it may have limited spread of VEEV to other parts of the USA [81]. However, TC-83 has several deficiencies including reactogenicity in experimentally vaccinated laboratory workers and poor immunogenicity in many people and its reliance on only point mutations for attenuation [82]. Because it can be transmitted from vaccinated horses by mosquitoes, which occurred in 1971 [83], reversion to virulence could occur and might allow equine vaccination to initiate an epidemic. An inactivated version of TC-83, called C84 in human formulations, is administered to laboratorians and horses in the USA. Several other vaccines have been developed during the past decade, and one, live-attenuated strain V3526, was tested in Phase I clinical trials but was associated with some reactogenicity and thus has been developed as an inactivated formulation [84, 85]. Other DNA and live-attenuated vaccines appear promising in preclinical trials [86–90].

15.3.6 Viral genetics and Evolution

Among the alphaviruses, VEEV and related VEE complex viruses have received extensive study since the 1980s. Initial studies focused on determining the relationships between enzootic and epizootic/epidemic strains to determine the origins of the latter. RNA fingerprinting [91] followed by partial and complete viral genomic sequencing [78, 92, 93] first supported the hypothesis that epizootic/epidemic strains evolve periodically from enzootic precursors. Sequencing studies also suggested that several outbreaks caused by subtype IAB VEEV were initiated by incompletely inactivated equine vaccines made from early isolates [94]. Later, reverse genetic studies demonstrated that a single mutation in an enzootic subtype I strain was sufficient to transform the ID serotype and equine amplification incompetent phenotype to an IC epizootic phenotype [74] (Fig. 7.5). Another mutation found in recent Mexican subtype IE strains appears to have adapted the virus to more efficient transmission by the mosquito vector, *Ae.* (*Ochlerotatus*) *taeniorhynchus*. Phylogenetic studies have also revealed spatially partitioned genetic lineages of VEEV within serotypes, presumably reflecting the limited mobility of rodent and mosquito hosts.

15.4 Western Equine Encephalitis

15.4.1 Natural History/Transmission

Western equine encephalitis virus (WEEV) is one species in the WEE complex of alphaviruses [95]. Others include Highlands J Fort Morgan and Aura viruses in the New World and Sindbis virus in the Old World [96]. Western equine encephalitis virus was first isolated from a horse in California in 1930 [97], and the first human isolate was made nearby in 1938 [98]. Subsequent field studies determined that WEEV is mosquito-borne and that birds are the principal amplification hosts, especially house finches (*Carpodacus mexicanus*) and house sparrows (*Passer domesticus*) [95, 99, 100]. In most North American locations, *Cx. tarsalis*, which is often abundant in irrigated farmland, is the most important enzootic and epizootic vector mosquito, and human and equine infections generally occur in agroecosystems from June to August (Fig. 7.7) [99]. A secondary enzootic cycle involving leporids and other rodents and *Ae. melanimon* mosquitoes as vectors in arid habitats has also been described (Fig. 7.7). In South America, *Ae. albifasciatus* appears to be an important epizootic vector [101, 102].

Genetic studies (see below) indicate that WEEV is readily transported between North and South America but that local overwintering and regionally defined evolution occur in temperate regions of North America. However, experimental infections of birds have not generated chronic infections that could facilitate long-distance transport or

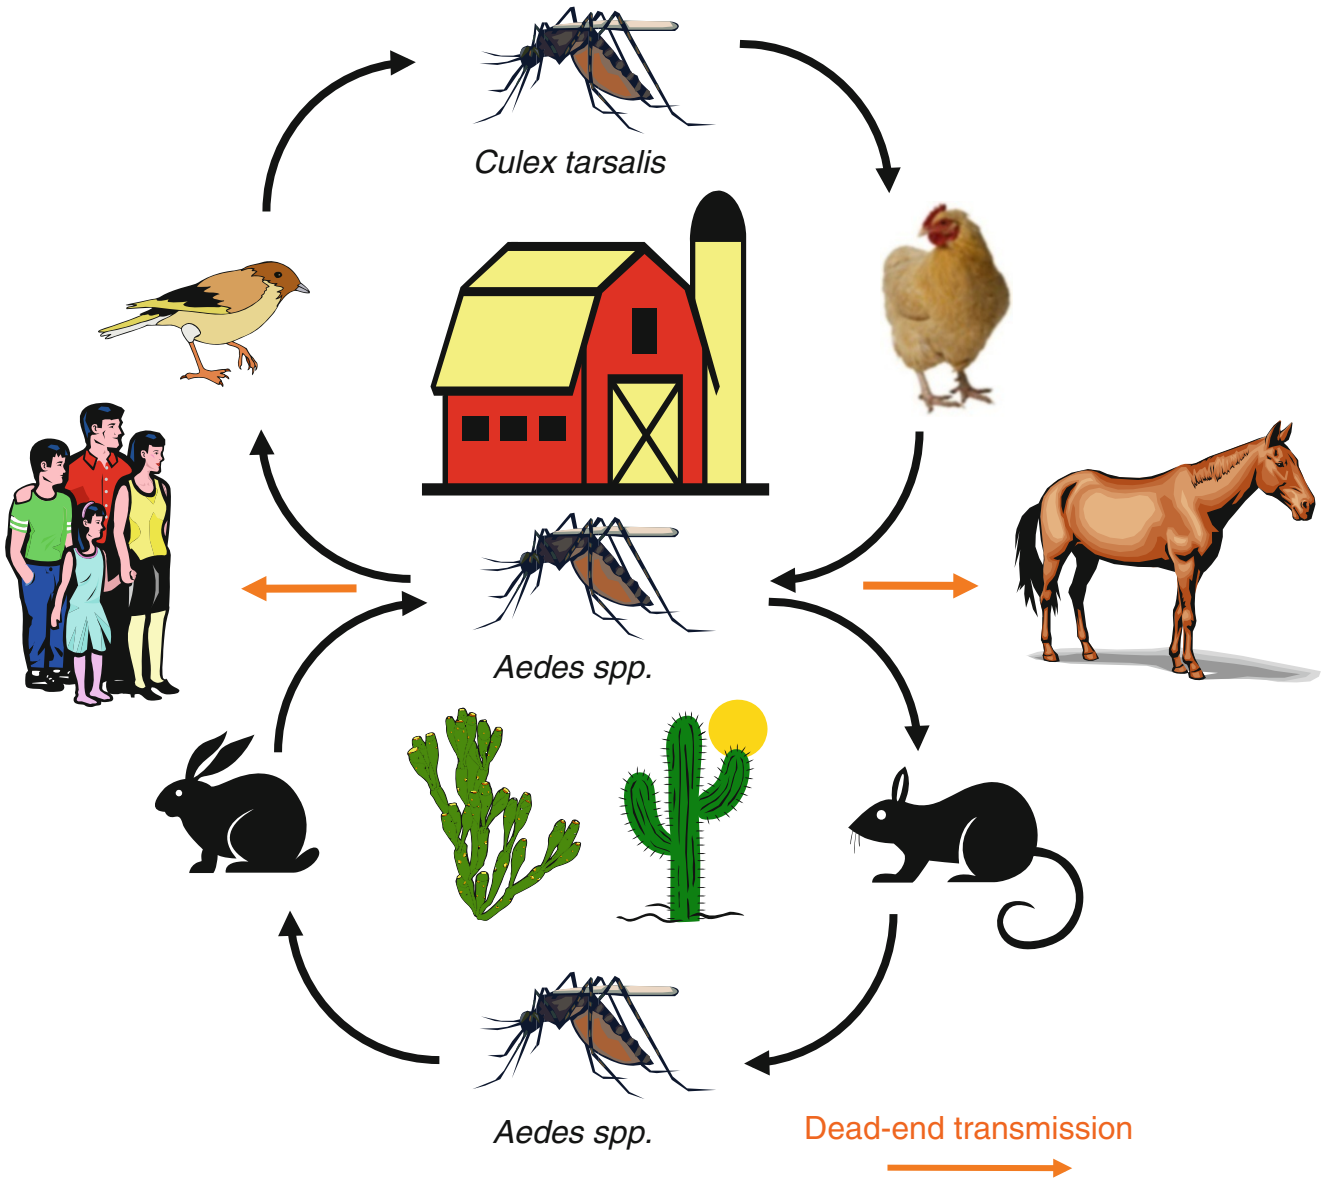

Fig. 7.7 Transmission cycles of western equine encephalitis virus in North America and epidemic or epizootic spillover to humans and domestic animals, respectively

overwintering of the virus [103, 104]. Overwintering of WEEV in infected mosquitoes undergoing reproductive diapause has been suggested by some laboratory studies but not confirmed by virus isolation from field-collected, overwintering *Cx. tarsalis* [105].

15.4.2 Impact on Human and Animal Health

During the mid-twentieth century, WEEV caused major epidemics and equine epizootics in the USA and Canada involving up to thousands of people and tens of thousands of equids during a single summer transmission season [99, 100]. Major epizootics occurred in the USA in 1930, 1937, 1938, 1941, 1944, and 1947 [95]. From 1937 to 1938, more than 300,000 equids were affected in the USA, and in 1941 alone, 2,242 human cases were documented in the Dakotas, Nebraska, and Minnesota (Fig. 7.8).

Human attack rates during this epidemic were as high as 171/100,000 persons [95]. However, the last documented human WEE case in North America occurred in 1999 in Minnesota, and only one other case has occurred since 1988 (in Colorado, 1989). Compared to the previous period from 1964 to 1988, when an average of 26 documented human cases occurred each year, this suggests a dramatic reduction in severe human disease caused by WEEV. The most recent

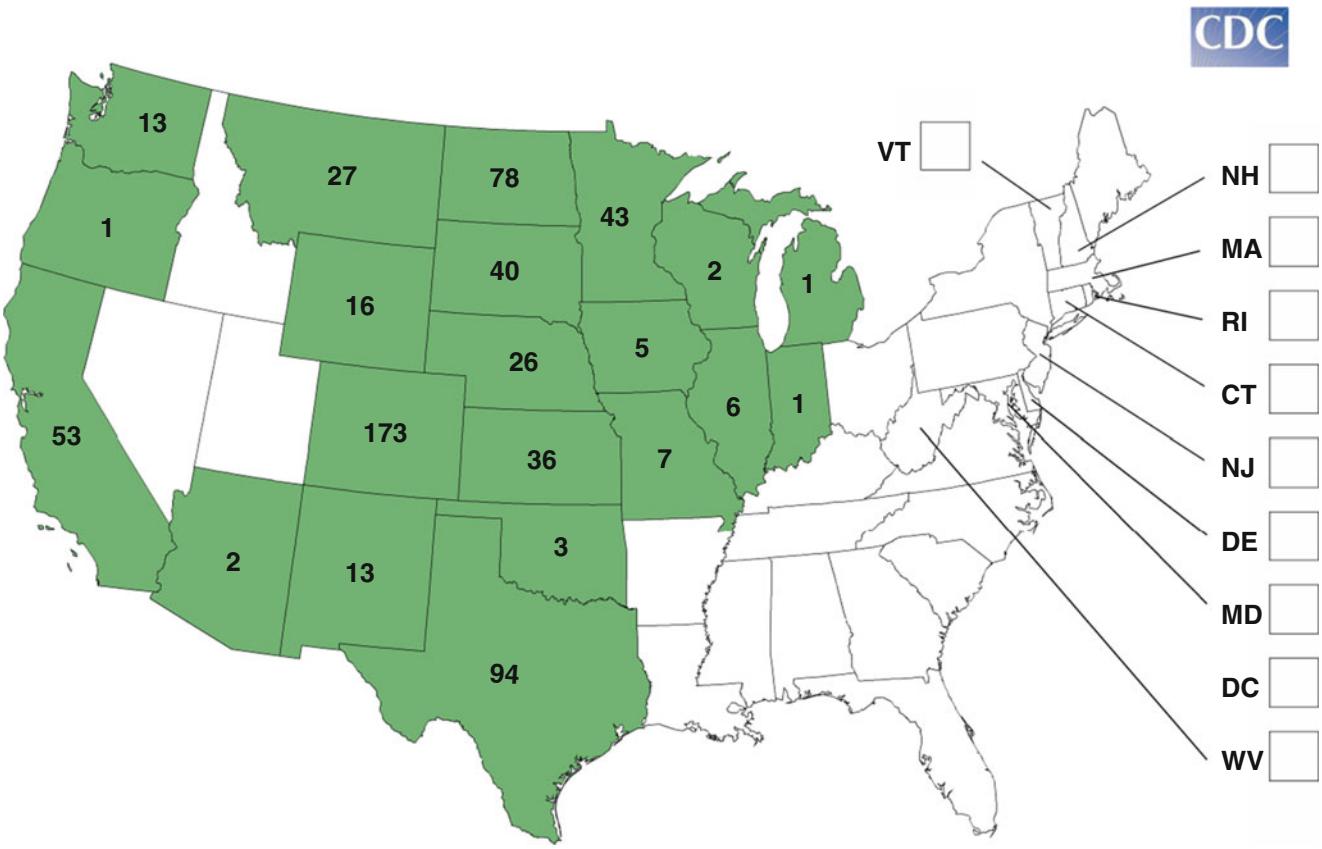

Fig. 7.8 Western equine encephalitis virus neuroinvasive disease cases reported by state, 1964–2010 (Adapted from http://www.cdc.gov/ncidod/dvbid/arbor/arbocase.htm)

estimates of human seroprevalence available from consistently enzootic regions of California were <3 %, indicating infrequent exposure [106, 107]. In Latin America, seroprevalence studies have indicated that WEEV circulation is widespread from Mexico [108] to Argentina [109], and equine epizootics have been described in Argentina since the 1930s. Human cases, which are occasionally fatal [110], have also been detected.

15.4.3 Human Disease

After an incubation period of 5–10 days, human WEE disease ranges from inapparent infection (by far the most common outcome, especially in adults where the apparent–inapparent ratio can be as low as 1:150,000) to a nonspecific flu-like illness to fatal encephalitis. The highest incidence and most severe infections generally occur in the youngest age groups, especially in infants <1 year of age. Males are more likely to be infected than females, possibly due to greater outdoor exposure in rural locations where the risk of infection is highest [95, 99, 100]. Symptomatic infections are typically accompanied by a sudden onset of fever, headache, chills, nausea, and vomiting. A minority of adult cases progress, usually one week from onset, to central nervous system disease characterized by generalized weakness and tremulousness, especially of the hands, tongue and lips. Some cases present with lethargy, drowsiness, nuchal rigidity, and photophobia, which can be followed by coma and death. Overall case-fatality rates usually range from 3 to 4 %. Children often exhibit muscular rigidity, involuntary movements, and paralysis. Survivors of encephalitis often experience lifelong neurologic sequelae, including fatigue, irritability, progressive mental and physical debilitation, headache, and tremors, which can also follow infection in utero [95, 99, 100]. Because no specific treatment is available for any alphavirus infection, patient management focuses on supportive care and treatment of acute complications, such as increased intracranial pressure and seizures, as well as management of long-term sequelae [16].

15.4.4 Diagnosis

A diagnosis of WEEV infection is usually based on the suspected exposure to rural locations where WEEV transmission occurs, often accompanied by knowledge of equine cases, which often precede those in humans. The diagnostic

approach and methods outlined above for EEEV and VEEV generally apply equally to WEE diagnosis. Like EEEV but unlike VEEV, WEEV is rarely isolated from blood or CSF at onset of symptoms because viremia titers are generally low and the incubation period is long, but can be isolated from brain samples taken at autopsy or from biopsies [95, 99, 100]. Antibodies are often detectable at first presentation due to the relatively long incubation period preceding signs and symptoms.

15.4.5 Prevention and Control

As for EEEV and VEEV described above, there are no licensed vaccines or antiviral drugs to prevent or treat WEE, so avoidance of contact with potentially infected mosquito vectors, especially in rural, agricultural settings, is critical.

15.4.6 Viral Genetics and Evolution

Initial sequencing and phylogenetic studies of WEEV revealed at least four major lineages [111]. Two of these were restricted to South America (Argentina and Brazil, respectively), while the others were widely distributed in both North and South America, suggesting that the latter are readily transported between the continents, probably via migratory birds. Enzootic WEEV strains from northern Argentina include an antigenic subtype [96] that is more attenuated in certain laboratory animal models than others [112]. More detailed studies of WEEV in California suggest that introductions from outside the state are not common, and little mixing of viral lineages occurs north versus south of the Tehachapi and San Bernardino Mountains, indicating regionally independent evolution [113]. However, within southern California, WEEV appears to disperse more freely. Finally, all WEEV strains are descendents of a recombinant alphavirus that derived its nonstructural protein and capsid protein genes from an ancestral EEEV and the envelope glycoprotein genes from an ancestral Sindbis virus strain [111, 114]. All other members of the WEE complex of alphaviruses, including Highlands J and Fort Morgan viruses, but not Aura virus, are also descendents of this ancient recombination event [111].

16 Alphaviruses of Public Health Importance Outside of the USA

16.1 Chikungunya Virus

16.1.1 Natural History/Transmission

Chikungunya virus (CHIKV) is transmitted in two distinct cycles. The enzootic maintenance cycle utilizes forest-dwelling mosquitoes such as *Ae. furcifer/taylori* and *Ae. africanus* and nonhuman primates. This cycle has only been identified in Africa [115]. In contrast, the epidemic transmission cycle occurs when humans are bitten by infected *Ae. aegypti* or *Ae. albopictus*. In this cycle, no other vertebrate reservoir is required (Fig. 7.9).

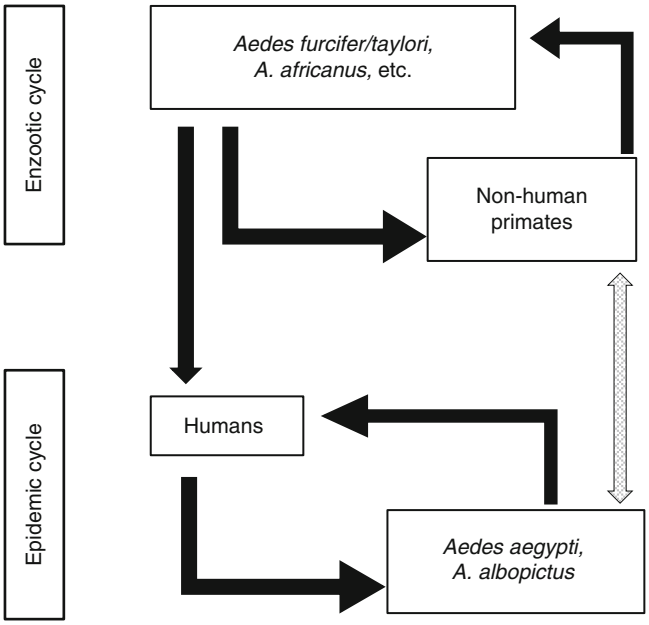

Fig. 7.9 Enzootic and epidemic transmission cycles of chikungunya virus

This is the only cycle that has been detected in Asia to date, where a limited number of field studies have failed to identify an independent enzootic cycle. It is possible that appropriate enzootic vectors are not present in Asia to establish a zoonotic cycle such as that found in Africa.

16.1.2 Impact on Human and Animal Health

The first detection of CHIK fever occurred in 1952–1953 during a small epidemic in what is now Tanzania [116]. While there were periodic human infections in population centers of East Africa, the first major urban outbreaks were recorded in Bangkok and India in the 1960s and 1970s [117–119]. During the next 30 years, there were sporadic emergences of CHIKV resulting in febrile illness, but major epidemic activity returned only after the turn of the century. At this time, reports of human cases began to increase in frequency in areas with historical activity such as Indonesia, while reports of the virus in new areas such as Central African Republic were also occurring [120, 121]. A major reemergence began in coastal Kenya in 2004 and moved to the islands of Comoros and Reunion off the coast of Tanzania in 2005/2006 [122–124]. Over 1/2 million cases were estimated in these three areas in less than 2 years. The virus then spread from Africa to India (over 1 million cases) and throughout Southeast Asia (Fig. 7.10).

A viremic traveler also transported the virus from India to Italy, where autochthonous transmission was detected for the first time in a temperate region [125]. This dramatic

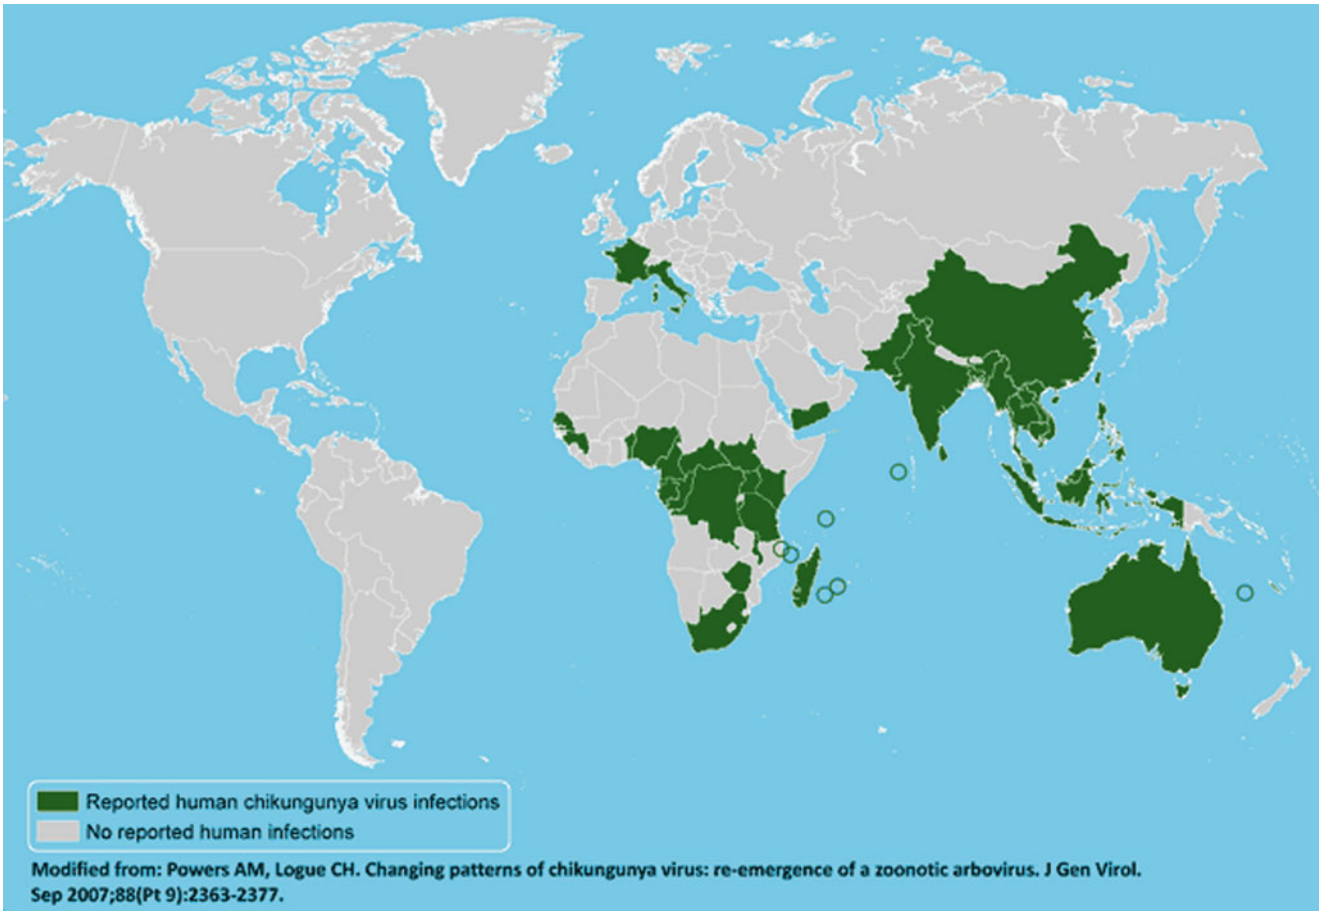

Fig. 7.10 Approximate known geographic distribution of CHIKV, 2007–2012 (Map obtained from CDC: http://www.cdc.gov/chikungunya/map/index.html)

geographic spread in less than 5 years with an estimated two million cases led to serious concern that a global epidemic could ensue. Significantly, during this massive and lengthy epidemic, the severe and chronic nature of CHIKV infection was revealed, as was the tremendous economic drain on affected countries [126].

16.1.3 Human Disease

Clinical disease begins between 3 and 7 days postinfection with the abrupt onset of a high fever (>101 °F). The fever typically lasts several days but usually subsides within 2 weeks. Shortly after fever onset, additional signs and symptoms appear which almost always include a severe bilateral arthritis of the small joints and may include a maculopapular rash. The rash, if present, lasts only a few days, while the arthralgia may be highly incapacitating and can persist for weeks or even months. Occasional reports of chronic joint pain (>1 year) have been documented, but these are atypical and may be associated with comorbidities.

Most CHIKV infections are symptomatic (75–97 %) and involve only the signs and symptoms noted above. However, recent outbreaks have revealed occasional, more serious conditions associated with infection including meningoencephalitis, hepatitis, myocarditis, and uveitis. Additionally, mortality was associated with infection for the first time in 2006, and intrapartum transmission was shown to result in neonatal complications [127].

16.1.4 Diagnosis

Because the symptoms associated with CHIKV infection are so nonspecific (fever, joint pain, rash) and similar to those caused by other sympatric pathogens (including dengue and malaria), laboratory diagnosis is critical for confirmation of infection. Fortuitously, viremia in humans is reasonably high (up to ~10^7 pfu/ml of blood) and persists for up to 1 week, allowing easy detection of the virus by either isolation or RT-PCR methods [18]. For serum samples collected more than 1 week after the onset of illness, serological assays such as ELISA or plaque-reduction neutralization tests (PRNT) can be used to detect anti-CHIKV-specific antibodies. Typically, both acute and convalescent samples must be tested, and a fourfold change in titer (for PRNT) or a change from negative to positive (in ELISA) must be detected for definitive diagnosis [128]. Commercial CHIKV diagnostic assays are now

available in limited markets, but their quality and utility are not universally accepted [129, 130]. Because CHIKV has such a broad geographic range, a complete travel history should also be considered with samples submitted for laboratory testing.

16.1.5 Prevention and Control

Like all mosquito-borne viruses, infection prevention can be accomplished using a limited number of approaches. These include mosquito control, personal protective measures, or vaccination. In general, mosquito control is extremely challenging as efforts must be broadly distributed, sustained, and coordinated with surveillance efforts. While there is historic evidence to show that CHIKV vector mosquitoes can be controlled and/or eliminated with intensive efforts, the mosquitoes rapidly return when control measures are discontinued [131]. Similarly, encouraging the use of personal protection such as repellents or long-sleeved shirts and pants presents challenges because most individuals do not maintain rigorous efforts to prevent mosquito bites. This is particularly difficult in the primarily tropical habitats where CHIKV circulates because repellents may not be widely available and the wearing of long sleeves is uncommon because of the hot and humid climate.

The ideal approach to control CHIKV would be by the use of a vaccine. However, there are no commercially available options at this time. A live-attenuated vaccine developed by the US Army was evaluated as an investigational new drug [132], and several newer vaccine candidates have been generated by genetic engineering. These include virus-like particles, chimeric viruses, genetically modified attenuated strains, DNA vaccines, and adenovirus-vectored options and others [133–136, 137]. To date, none of these have advanced into commercial development.

16.1.6 Viral Genetics and Evolution

Three distinct genotypes of CHIKV have been identified that, prior to the 2004 outbreak, were primarily aligned geographically (Asian, East/Central/South African (ECSA), and West African genotypes). Strains within each genotype are up to ~22 % genetically divergent from the others, while strains within a genotype are much more similar genetically, with a maximum of ~5 % divergence [138, 139].

The large number of complete CHIKV genome sequences publically available allowed close monitoring of the movement of the virus during the 2004–2009 outbreak. All strains from the 2004 to 2009 epidemics were the ECSA genotype, thus expanding the distribution of this genotype into Oceania, India, and Southeast Asia [139]. Studies of these novel isolates also allowed identification of mutations associated with altered vector infectivity and provided insights into the microevolution of the virus [140–143].

16.2 O'nyong-nyong Virus

16.2.1 Natural History/Transmission

O'nyong-nyong virus (ONNV) is unique among the alphaviruses in its transmission cycle; this virus is transmitted by anopheline mosquitoes (primarily *Anopheles gambiae* and *An. funestus*) during epidemics. Similarly, the few interepidemic isolates have also come from anophelines, suggesting the virus is maintained enzootically by this genus as well [144]. A single isolate of the virus was obtained from *Mansonia uniformis*, but this species was not abundant to determine its role in epidemic transmission [145]. The vertebrate reservoir host for ONNV has not been determined, but serosurveys suggest a role for domestic livestock and several species of rodents.

16.2.2 Impact on Human and Animal Health

The history of epidemic ONNV is one of the most intriguing of all alphaviruses. The virus was identified during the first recorded outbreak that lasted 3 years beginning in 1959. The magnitude of the outbreak was staggering, with an estimated two million cases spanning the duration of the epidemic across Uganda and other parts of East Africa [146]. With significant absenteeism due to the debilitating nature of infections, the outbreak had major impact on both the economies and public health resources of the numerous affected countries.

After this first epidemic subsided, there was virtually no detection of ONNV for ~40 years with the rare exception of isolates from mosquitoes or febrile humans. A subtype of ONNV, designated Igbo-Ora, was identified in West Africa, expanding its known geographic range [147]. However, no epidemic activity has been reported due to this strain. The next major epidemic of ONN fever occurred in Uganda in 1995–1996. Like the earlier outbreak, the virus moved rapidly through affected communities, impacting up to 70 % of the population [148]. No significant epidemic activity has been reported since 1996, although serological evidence of infection in vertebrates has been documented.

16.2.3 Human Disease

Like its close relative CHIKV, ONNV causes a febrile arthralgic syndrome. However, there are some distinctions from CHIKV infection such as the more prominent and frequent appearance of cervical lymphadenopathy in ONN cases. Additionally, the rash associated with ONNV infection is reported to be highly irritating but to cause little discomfort in CHIKV cases [149]. No mortality has ever been reported to be associated with ONNV infection and long-term sequelae appear to be rare.

16.2.4 Diagnosis

As noted for CHIKV, laboratory diagnosis is critical due to the lack of specific symptomology associated with ONNV infection, which precludes diagnosis based on clinical criteria. Diagnosis is primarily accomplished by serological testing, which includes testing for CHIKV infection since the two viruses have shared a close antigenic relationship and cross-reactions can be distinguished in only one direction, i.e., CHIKV immune serum inhibits the formation of ONNV plaques to the same extent as CHIKV plaques, but the inverse reaction is weaker [150]. Thus, when performing PRNT assays for detection of ONNV, additional test using CHIKV antigen must be performed. To confirm ONNV infection based upon these results, the neutralization titer for ONNV must be higher than that of CHIKV, and typically, the CHIKV titer will be lower or undetectable. Molecular techniques including RT-PCR approaches may also be used on acute samples. However, the duration and level of viremia in infected individuals is not well characterized, so the timing of the sample collection may preclude this as a feasible diagnostic option.

16.2.5 Prevention and Control

Prevention and control strategies are virtually the same for ONNV as described above for CHIKV. However, there may be fewer options for prevention of ONNV infection when compared with CHIKV. Mosquito control includes many of the same challenges but may be even more problematic for ONNV because the natural larval habitats of anopheline larvae are generally more diverse than those of CHIKV vectors. Personal protective measures include some of the same options as for CHIKV (repellent and long sleeves) but are likely to be used to a more limited degree in resource-poor settings typical of ONN epidemics. One personal protection approach that can be used to protect against ONNV infection is insecticide-treated bednets, as biting by anopheline mosquitoes primarily occurs at night. No vaccines have been developed to protect against ONNV. However, there is evidence that a recently developed CHIKV vaccine may induce cross protection against ONN disease [151].

16.2.6 Viral Genetics and Evolution

ONNV is genetically most closely related to CHIKV, with 28 % divergence at the nucleotide level [138, 139]. Antigenically, these viruses are also closely related, but a unique unidirectional relationship exists: antisera raised against CHIKV neutralize both viruses, but ONNV-antisera neutralize only the homologous virus as described above. Evolutionarily, this suggests that ONNV emerged from a CHIKV-like ancestor, followed by the evolution of unique surface epitopes.

Among the very few strains of ONNV that are available for evaluation, the degree of genetic diversity appears to be limited. Isolates obtained from the original outbreak have fewer than 100 amino acid differences from isolates obtained during the second Ugandan outbreak over 40 years later [152]. This indicates that the virus may be maintained in a zoonotic cycle involving efficient virus dispersal, which would retain a high degree of sequence similarity across a broad geographic range.

8 Arenaviruses: Lassa Fever, Lujo Hemorrhagic Fever, Lymphocytic Choriomeningitis, and the South American Hemorrhagic Fevers

Daniel G. Bausch and James N. Mills

1 Introduction

The family *Arenaviridae* (genus *Arenavirus*) derives its name from the Latin "arena" for "sand," referring to the grainy appearance of infected host cell ribosomes seen on electron microscopy (Fig. 8.1) [1]. Arenaviruses are zoonotic, maintained in nature, with a few possible exceptions, by chronic infection in rodents of the superfamily Muroidea [2]. The viruses are grouped serologically, phylogenetically, and geographically into Old World/lymphocytic choriomeningitis (i.e., Africa, Europe, Asia, and Oceania) and New World/Tacaribe (i.e., the Americas) complexes. Over 40 arenaviruses have been identified, although less than half of these are clearly recognized as human pathogens (Table 8.1 and Figs. 8.2 and 8.3). Arenaviruses continue to be discovered, and at a quickening pace in recent decades [3–11]. Factors in disease emergence and the increased incidence of human cases often relate to anthropogenic disturbance of natural habitats, such as conversion of forest to cultivated fields, resulting in loss of biodiversity and selection for opportunistic rodent species that are frequently hosts for zoonotic pathogens [12]. Conversion to agriculture also prompts incursion of reservoir rodents from the surrounding bush seeking food in croplands, with resultant increased human exposure to rodents [13, 14]. Some reservoir species may also enter towns and homes, further increasing risk to humans.

Arenaviruses are perhaps best known as agents of viral hemorrhagic fever (HF), an acute systemic illness classically involving fever, a constellation of initially nonspecific signs and symptoms, and a propensity for bleeding and shock [15, 16]. A few arenaviruses have been associated with aseptic meningitis and other central nervous system (CNS) diseases, including congenital malformations when transmitted in utero. Many arenavirus infections are asymptomatic or result in a nonspecific febrile illness difficult to distinguish from many more common diseases.

Seven arenaviruses have been clearly established as causative agents of HF via natural infection (i.e., excluding laboratory infections), Lassa and Lujo in Africa and Junín, Machupo, Guanarito, Sabiá, and Chapare in South America (Table 8.1). Similar HF syndromes are caused by members of the virus families *Bunyaviridae*, *Filoviridae*, and *Flaviviridae* (see Chaps. 10, 15, and 17). As with other HF viruses, arenaviruses are generally named after the geographic location of the first recognized case or place of first virus isolation. For the New World arenaviruses, the

Table 8.1 Arenaviruses known or suspected to cause human disease

Virus	Associated human disease	Annual incidence of human disease	Human disease-to-infection ratio	Human-to-human transmissibility	Case fatality
Dandenong	Fever with encephalopathy and multiorgan system failure	3 cases recognized	Unknown	All known cases infected through organ transplantation	100 % of three known cases
Lassa	Lassa fever	Poor surveillance. Estimated 30,000–50,000	1:5–10	Moderate	25 %
Lujo	Lujo fever	5 cases recognized	Unknown	Moderate to high	80 % of five known cases
Lymphocytic choriomeningitis	Nonspecific febrile illness/ aseptic meningitis	Poor surveillance. Estimated hundreds to thousands	Unknown but appears to be low	Congenital transmission as well as transmission through organ transplantation	<1 %
Chapare	Chapare HF	Unknown	Unknown	Unknown	1 fatality among a "small cluster" of cases. Few details reported
Flexal	Nonspecific febrile illness	2 laboratory infections	Unknown	Unknown	2 known infections were nonfatal
Guanarito	Venezuelan HF	<50	1:1.5	Low	30–40 %
Junín	Argentine HF	50–100	1:1.5	Low	15–30 %
Machupo	Bolivian HF	<50	1:1.5	Low	15–30 %
Pirital	Nonspecific febrile illness	1 laboratory infection	Unknown	Unknown	Only known case was nonfatal
Sabiá	Brazilian HF	1 natural and 2 laboratory infections known	1:1.5	Low?	33 % of three known cases
Tacaribe	Febrile illness with mild CNS symptoms	1 laboratory infection	Unknown	Unknown	Single nonfatal case
Whitewater Arroyo	Pathogenic potential unclear. Three putative cases with fever and some signs of hemorrhagic fever	Unknown	Unknown	Unknown	Unknown

diseases are often named after the country where they were first detected, with the virus named after the town or some other local geographic feature. For example, Junín virus was first isolated from a human in the town of Junín, in central Argentina, and subsequently designated as the causative virus of Argentine HF. Two Old World arenaviruses, lymphocytic choriomeningitis virus (LCMV) and an LCMV variant named Dandenong virus, are typically associated not with HF but rather with febrile illness and CNS disease [17]. Whitewater Arroyo virus has been detected in three sick persons in California but its role as a pathogen is controversial. Tacaribe, Pirital, and Flexal viruses have caused nonspecific febrile illnesses after laboratory accidents but no natural infections have been recorded. Numerous arenaviruses are thought to be nonpathogenic in humans, or at least pathogenicity has yet to be recognized. Pichinde and Pirital viruses are frequently used in animal models (guinea pig and hamster, respectively) of arenaviral HF.

Because of their potentially high lethality, risk of secondary spread (although this is often overestimated), and tendency to cause public panic and social disruption, some HF-causing arenaviruses are considered "Select Agents" that could possibly be used as bioweapons. Attempts to weaponize various arenaviruses were reportedly made by the Soviet Union during the Cold War era [18]. Many arenaviruses are classified as biosafety level four (BSL-4) or "maximum containment" agents [19].

2 Biological Characteristics

2.1 Physical Properties

Arenavirus virions are pleomorphic, ranging from 60 to 300 nM, and have a lipid envelope. On electron microscopy, host cell ribosomes show a grainy appearance inside the cell, with surface glycoproteins seen as club-shaped projections or spikes protruding from the envelope membrane (Fig. 8.1) [1].

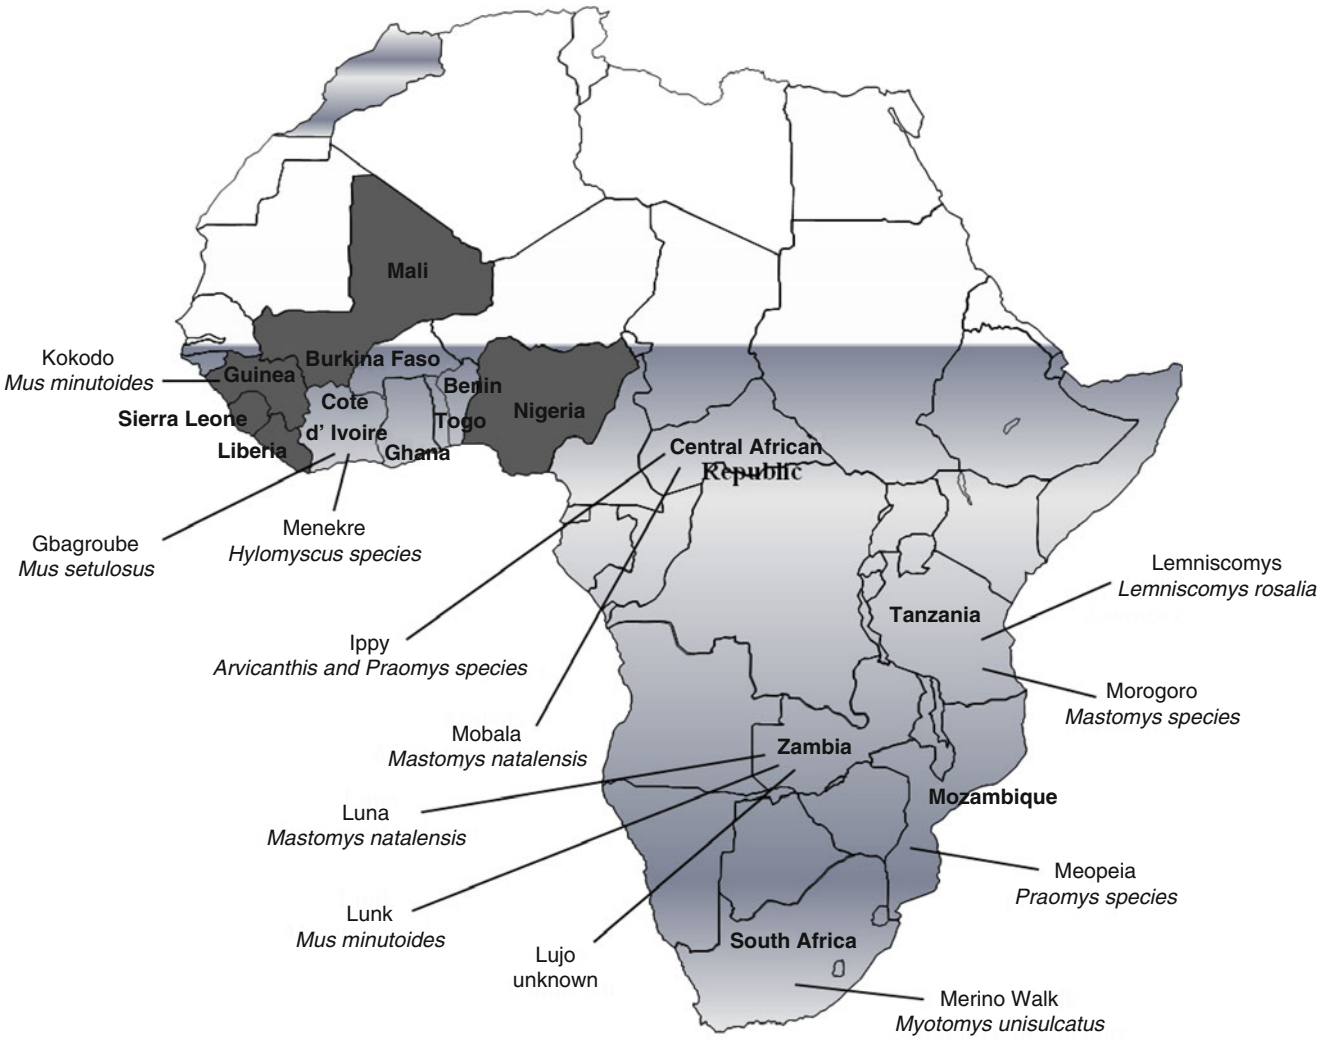

Fig. 8.2 Geographic distribution of Old World arenaviruses. The virus name and known or suspected rodent reservoir are listed. Although the virus has been isolated from the animal listed, the status of that animal as the natural reservoir is not established in all cases. Countries where Lassa fever, the major arenaviral disease in Africa, has been definitively shown are depicted in *dark gray* and the distribution of rodents of the genus *Mastomys* is shown in *light gray*. Only Lassa, Lujo, lymphocytic choriomeningitis, and Dandenong viruses have been definitively associated with human disease. The distribution of the virus and incidence of associated disease may vary significantly within each country. With the exception of Lassa and lymphocytic choriomeningitis viruses, most Old World arenaviruses have been isolated on single or very few occasions and the precise distribution of the virus beyond the place of first identification is unknown. Not shown on the map: lymphocytic choriomeningitis virus (reservoir *Mus musculus*), which has a worldwide distribution, and Dandenong virus (unknown reservoir), which is thought to be found in Eastern Europe

2.2 Gene Organization, Replication, and Transcription

Arenaviruses are bisegmented with a ~11 kb genome comprised of two single-stranded RNA segments denoted small (S) and large (L) of 3.4 and 7.2 kb, respectively [20, 21]. The S RNA encodes the viral nucleoprotein (NP) and a precursor glycoprotein (GPC) that is posttranslationally cleaved into GP1 and GP2 by the cellular subtilase SK1-1/S1P. Proteolytic processing of GPC is necessary for arenavirus infectivity. GP1 is a peripheral membrane protein while GP2 is transmembrane. Both are involved in receptor binding and cell entry. The L RNA encodes the viral polymerase (L protein) and a small zinc-binding protein (Z), which appears to play a regulatory role in virus replication, particle formation, and budding, as well as having a structural function as a matrix protein. The genes on the two RNA segments are separated by an intergenic region that folds into a stable secondary structure.

Arenavirus genes are oriented in both negative and positive senses on the two RNA segments, a coding strategy called ambisense. Through this mechanism, GPC and NP gene expression are independently regulated. Viral RNA must be transcribed before GPC can be expressed, which

Fig. 8.3 Geographic distribution of New World arenaviruses. *Left Panel*: the virus name and known or suspected rodent reservoir are listed, with viruses associated with natural infection and disease in humans in *bold*. Although the virus has been isolated from the animal listed, the status of that animal as the natural reservoir is not established in all cases. Countries with arenaviruses definitively associated with human disease are shaded *gray*. The distribution of the virus and incidence of associated disease may vary significantly within each country. Many of the New World arenaviruses have been isolated on single or very few occasions and the precise distribution of the virus beyond the place of first identification is unknown. *Right Panel*: close-up of administrative regions in which Venezuelan, Bolivian, Chapare, and Argentine hemorrhagic fevers have been recognized. The distribution of the viruses and incidence of disease may vary significantly within the region

may be fundamental to the maintenance of persistent infection in the animal reservoir. Replication and transcription of the genome occur in the cytoplasm and require the association of viral proteins with the viral RNA in the form of ribonucleoprotein (RNP) complexes. The NP and L proteins, together with virus RNA, are the minimal components of the RNP complex and are sufficient for genome replication and transcription. Purified RNPs are competent for RNA synthesis in vitro and can initiate virus replication after transfection into cells. Naked RNA is not infectious.

During genome replication, a full-length copy of the genome is synthesized yielding the corresponding antigenomic S and L RNAs. Due to the ambisense coding strategy, both genomic and antigenomic RNA serve as templates for transcription of viral mRNA. The transcripts contain a cap but are not polyadenylated. The viral RNA species that are packaged into virions are defined as the genomic RNAs; however, smaller amounts of antigenomic RNA and Z gene mRNA are also packaged. In addition to viral RNA, ribosomal RNA is present within virions. Virions mature by budding from the plasma membrane.

2.3 Phylogenetics

Both Old and New World complexes are further divided into major lineages or clades (Fig. 8.4). Genetic diversity within virus species may vary with the host and geographic region. Sequence diversity is generally higher among strains obtained from rodents than from humans; that pattern is consistent with chronic infection and frequent intraspecific transmission among rodents [22, 23].

The Old World complex is grouped into two monophyletic lineages that correlate with monophyletic genera within the rodent family Muridae, subfamily Murinae (see Sect. 3). The most attention has been paid to characterizing Lassa viruses, which show considerable sequence heterogeneity across West Africa, with four recognized lineages—3 in Nigeria and 1 in the area comprising Sierra Leone, Liberia, Guinea, and Ivory Coast [24, 25]. There is also considerable genetic heterogeneity within lineages (up to 26 % on the nucleotide level of the L and Z genes), especially in Nigeria [26]. Nigerian strains appear to be ancestral to those found further west in Africa, with limited recombination in the evolution of Lassa virus.

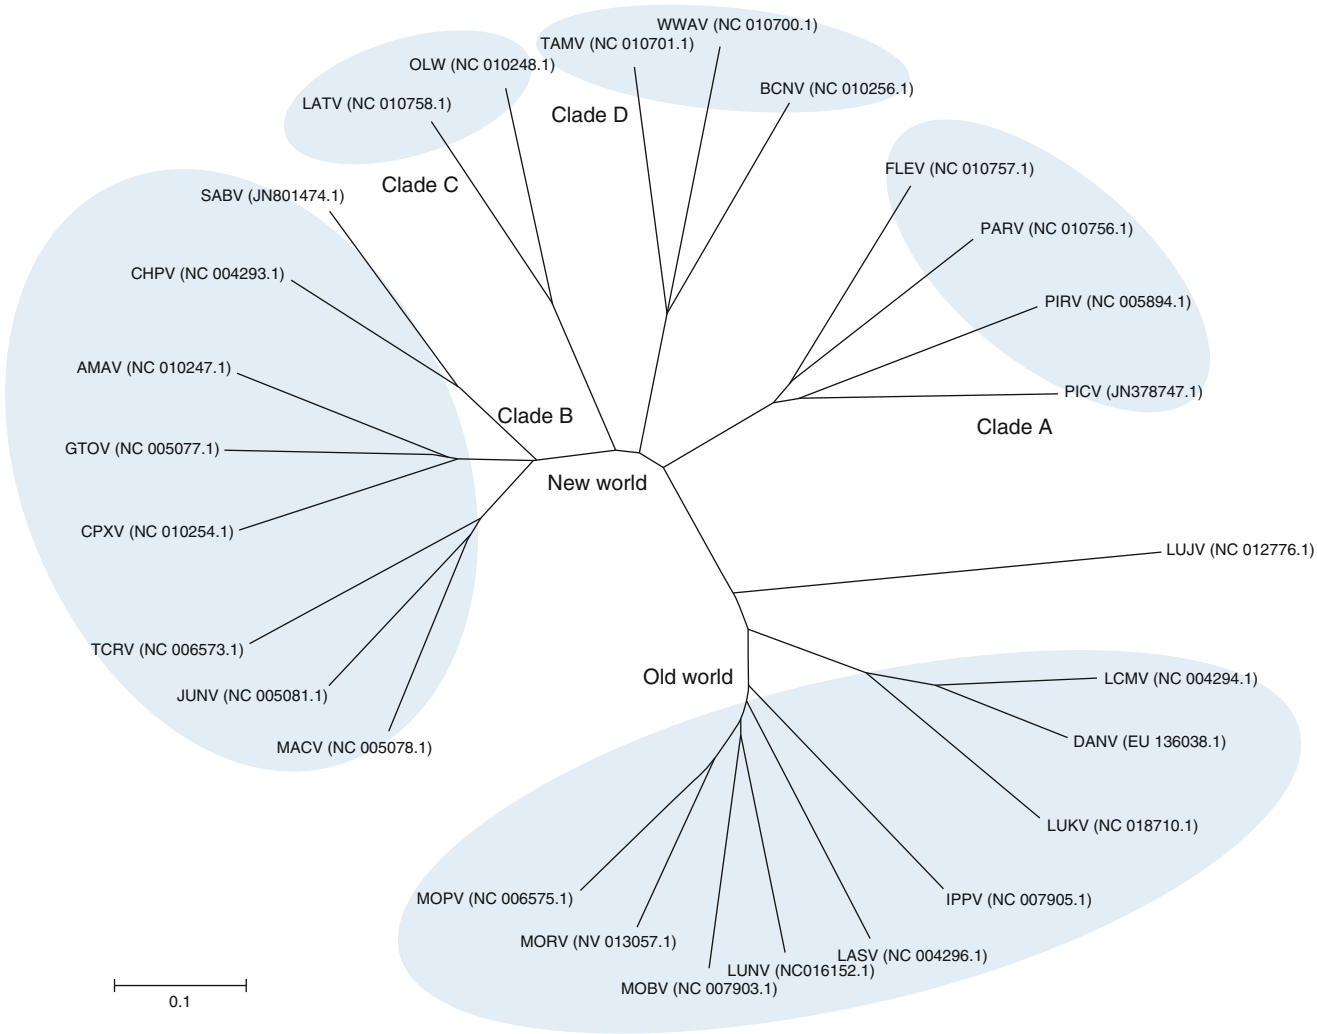

Fig. 8.4 Phylogenetic relationships of arenaviruses inferred based on full S segment nucleotide sequences. Phylogenies were reconstructed by neighbor-joining analysis applying the Jukes–Cantor model (1,000 replicates). The *A*, *B*, *C*, and *D* clades of the New World and Old World arenaviruses are delineated. Lujo virus (LUJV) falls between the two groups but appears to be closest to the Old World viruses, thus corresponding to its site of isolation in Zambia. The scale bar indicates substitutions per site. GenBank accession numbers are shown after each virus. Similar relationships are demonstrated based on L segment analysis (not shown). *Abbreviations*: *AMAV* Ampari virus, *BCNV* Bear Canyon virus, *CHPV* Chapare virus, *CPXV* Cupixi virus, *DANV* Dandenong virus, *FLEV* Flexal virus, *GTOV* Guanarito virus, *IPPV* Ippy virus, *JUNV* Junín virus, *LASV* Lassa virus, *LATV* Latino virus, *LCMV* lymphocytic choriomeningitis virus, *LUJV* Lujo virus, *LUKV* Lunk virus, *LUNV* Luna virus, *MACV* Machupo virus, *MOBV* Mobala virus, *MOPV* Mopeia virus, *MORV* Morogoro virus, *OLVV* Oliveros virus, *PARV* Paraná virus, *PICV* Pichinde virus, *PIRV* Pirital virus, *SABV* Sabiá virus, *TCRV* Tacaribe, *TAMV* Tamiami virus, *WWAV* Whitewater Arroyo virus. Viruses not shown due to incomplete sequence data: Allpahuayo, Big Brushy Tank, California Academy of Sciences, Catarina, Collierville, Gbagroube, Golden Gate, Kodoko, Lemniscomys, Menekre, Merino Walk, Ocozocoautla de Espinosa, Pinhal, Real de Catorce, Skinner Tank, and Tonto Creek

Field and laboratory data suggest variation in virulence among the four lineages and strains of Lassa virus. In laboratory experiments, the virulence of Lassa virus strains in guinea pigs roughly correlated with the severity of disease in the humans from whom the viruses were isolated [27]. Strains isolated from pregnant women and infants were benign in guinea pigs, suggesting that host factors such as immunosuppression play a role in human disease. Strains of Lassa virus from Nigeria may be more virulent than those from further west in Africa, but data to support or refute this theory are lacking. The virulence factors of the Lassa virus genome are not known, although for LCMV they are suspected to map to the L segment [28].

The New World complex is classified into 4 distinct lineages, A, B, C, and D, that generally correlate with monophyletic genera of the rodent family Cricetidae (see Sect. 3). All of the pathogenic New World viruses are in lineage B. Viruses of lineage D appear to be the product of recombination between viruses of lineages A and other arenaviruses and are thus also known as lineage A/Rec. Lineage A, B, and

C viruses are restricted to South America, while lineage D is exclusively North American.

There is also considerable genetic diversity among strains of LCMV, Guanarito, and Mopeia viruses, but no clear relationships between strain and pathogenicity in humans have been sought or recognized. Sequence diversity may also exist for other arenaviruses but the matter has not been extensively studied. Although pathogenic viruses generally cluster phylogenetically, recently identified Lujo virus illustrates the limitations in predicting clinical syndromes based on genetic sequence alone; Lujo and Lassa viruses cause almost identical HF syndromes, despite being genetically distinct (up to 38.1 % on the nucleotide level) [29]. Lujo virus is an outlier between New World and Old World arenaviruses but appears to be closest to the Old World viruses, corresponding to its site of isolation in Zambia.

2.4 Receptors

Arenaviruses enter cells by attachment of the GP1 to one or more cellular receptors [30]; α-dystroglycan, a protein found ubiquitously on primate and rodent cells, is a principal receptor for Old World viruses and pathogenic viruses of the New World clade C, while human transferrin receptor 1 protein is a receptor for the New World clade B arenaviruses [31]. Orthologs of transferrin receptor 1 protein appear to be the major receptors in the respective rodent host of each New World arenavirus and likely dictate species specificity [32].

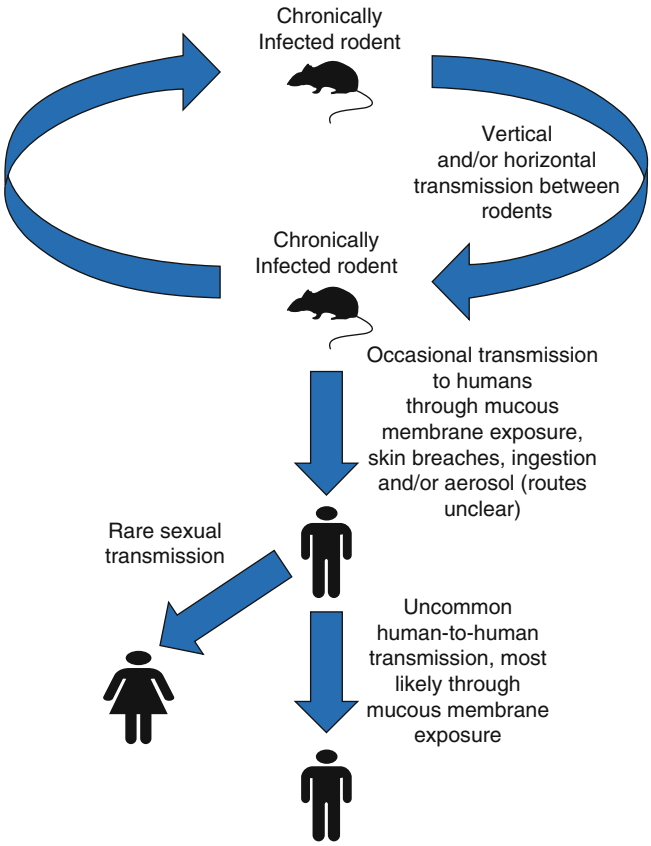

Fig. 8.5 Transmission cycle of arenaviruses illustrating chronic infection in rodents. Transmission between rodents may be vertical or horizontal depending upon the specific arenavirus. Humans are incidental hosts who play no role in virus maintenance in nature (Adapted with permission from Enria et. al. [17])

3 Reservoirs and Patterns of Host Response

Arenaviruses are generally maintained in nature by chronic infection in rodents of the superfamily Muroidea (Fig. 8.5) [2]. Transmission may be vertical (dam to progeny) or horizontal, depending on the specific arenavirus. Infected animals may chronically shed virus in urine, feces, and saliva. Old World arenaviruses are maintained in rodents of the family Muridae, subfamily Murinae, and New World arenaviruses in the family Cricetidae, subfamilies Sigmodontinae and Neotominae. There is a tight host–virus species pairing, thought to be the result of long-term rodent–virus coevolution [2]. Similar taxonomic classifications and host–virus relationships exist for the rodent-borne hantaviruses, suggesting a similar evolution. Occasional findings of a given arenavirus in species other than its recognized rodent host are usually considered to result from spillover infection (i.e., incidental transient infection of a non-reservoir host). These incidental and transient animal hosts are not thought to play a role in long-term virus maintenance.

The endemic area of each arenaviral disease is restricted to the geographic distribution of its rodent reservoir. Rodent populations are usually not uniformly infected across their entire geographic range; the distribution of the virus and disease is usually restricted to a small portion of the host range. The reasons for this are unclear but may relate to evolutionary bottlenecks in dispersal of the virus, rodent reservoir, or both. Landscape features are the most likely barriers to host migration. Humans are dead-end hosts who play no role in the natural maintenance of arenaviruses. There are generally few human cases relative to the frequency of infected rodents. The incidence of human infection may vary with changes in rodent abundance that relate to both climatic and seasonal weather changes and human-induced habitat alterations.

3.1 Old World Arenaviruses

3.1.1 Lymphocytic Choriomeningitis Virus

The common "house mouse" (*Mus musculus*) is the reservoir of LCMV, with infection maintained through vertical transmission [33]. Infection causes glomerulonephritis in mice and shortens their life-span by a few months, especially when

infected after birth. Renal deposition of virus–antibody complexes is believed to be the underlying cause of the kidney disease [34]. Although house mice and LCMV are phylogenetically of Old World origin, the rodent and virus have been disseminated worldwide as a result of rodent passage, usually on ships, over the last few centuries. Lymphocytic choriomeningitis virus may also transiently (but for months) infect laboratory mice and pet rodents, especially Syrian hamsters (*Mesocricetus auratus*) but also guinea pigs (*Cavia porcellus*), which can transmit the virus to humans [17, 35–41]. Whether Dandenong virus shares the same reservoir as LCMV is unknown.

As its name implies, the house mouse is frequently found living in association with humans within homes and other man-made structures in both rural and urban environments. The prevalence of LCMV and LCMV antibody in house mouse populations is highly variable (0–60 %) and focal [42]; in inner-city Baltimore, antibody-positive mice were clustered within residential blocks [43]; the prevalence of infected mice on four farms in California only several miles apart was 0–27 % [44].

3.1.2 Lassa Virus

Lassa virus is maintained in nature in the natal mastomys (*Mastomys natalensis*), also called the multimammate rat [45, 46]. Presumed spillover infection has been reported in other rodent species, including the reddish-white mastomys (*M. erythroleucus*), the roof rat (*Rattus rattus*), and the southern African pygmy mouse (*Mus minutoides*), although the animal species could not be definitively confirmed in all cases [47–50]. (L. Moses, manuscript in preparation). Reddish-white mastomys were reported to also be a natural host of Lassa virus but recent findings refute this. One explanation is the historical difficulty in identifying *Mastomys* to species; at least five morphometrically identical species exist in sub-Saharan Africa that, until recently, could only be distinguished through karyotyping, a technically cumbersome and perhaps error-prone technique. A reliable PCR-based assay to genotypically identify *Mastomys* to species has been recently developed and become the standard [51]. Studies using this technique have shown Lassa virus only in natal mastomys [50, 51].

Natal mastomys are almost always found in close association with humans in rural villages and surrounding cultivated fields and, less commonly, in grasslands and at the forest edge [52–54]. In highly endemic regions over 50 % of rodents caught in houses are natal mastomys, with the prevalence of Lassa virus infection ranging from 6 to 50 % [48, 50, 51, 54–56]. Because the incidence of Lassa fever is similar in men and women, and because children are frequently infected, peridomestic rodent exposure is thought to be most important [57]. Abundance of natal mastomys may be higher in houses than in surrounding agricultural fields or bush [48]. Open food storage and closed shutters during the day (a practice that favors prolonged rodent activity) may favor natal mastomys colonization of houses [48].

Despite the occurrence of *Mastomys* species throughout sub-Saharan Africa, for unknown reasons, Lassa virus and Lassa fever have been found only in West Africa (Fig. 8.2). Confusion over species identified in various regions as well as potential differences in the competency of *Mastomys* subspecies could account for this finding. Natal mastomys are not typically found in large urban centers, so the risk of rodent transmission of Lassa virus to humans in these environments is negligible.

Studies of transmission and maintenance of Lassa virus in natal mastomys are few. Consequently, many conclusions are based on extrapolations from experiments using LCMV in laboratory mice [58]. It is unknown how well this system represents Lassa virus. Available data suggest that Lassa virus is maintained in natal mastomys via vertical transmission. In addition, the age of the animal, host genotype, and route of inoculation affect the outcome of infection [59]; in the only published laboratory investigation of Lassa virus transmission in *Mastomys* species (reported to be natal mastomys), Lassa virus persistence was achieved when animals were infected as neonates, while most animals inoculated as adults cleared the virus [60]. Infected neonates did not produce Lassa virus antibody. Importantly, some laboratory strains of rodents identified as natal mastomys were later determined to be southern African mastomys (*M. coucha*), although it is unclear which species was used for the aforementioned study [61].

In wild-caught *Mastomys,* Lassa virus antibody and antigen are usually mutually exclusive [56]. Antibody-positive animals usually outnumber antigen-positive rodents, with a J-shaped curve of antibody prevalence (high at birth, decreasing in early adolescence, and then gradually rising as animals age). This pattern is consistent with transmission of maternal antibody to offspring, which is then lost as animals wean, to be regained by animals exposed to Lassa virus as they age. Although no pathology related to Lassa virus infection was observed in *Mastomys* infected in the laboratory, Lassa virus-infected wild natal mastomys were smaller in size and weight and had higher frequencies of myocardial and perivascular inflammatory lesions compared to their uninfected counterparts [62].

3.2 New World Arenaviruses

3.2.1 Junín Virus

Junín virus is maintained in the drylands vesper mouse (*Calomys musculinus*), also called the corn mouse. Occasional findings of antibody in (or even virus isolation from) species sharing the same habitat, including *Calomys laucha* and *Akodon azarae*, are likely due to virus spillover. Although drylands vesper mice are common and widely distributed in central and northwestern Argentina [63],

Junín virus is restricted to a small fraction of the host range (Fig. 8.3). The mice prefer more stable linear border habitats such as roadsides, fence lines, and railroad rights of way but may move into more mature and post-harvest crop fields in summer and early autumn to feed on abundant corn and soybeans [64, 65]. Unlike the natal mastomys, the drylands vesper mouse lacks peridomestic affinities and very rarely enters human habitations or peri-urban areas. Population densities of drylands vesper mice vary spatially and seasonally and appear to be dependent upon environmental conditions; the combination of a relatively mild winter followed by a cool, moist summer was followed by extremely high mouse abundance and a subsequent 14-year peak in cases of Argentine HF in 1990 [66]. The prevalence of Junín virus infection in reservoir populations is also highly variable temporally (0–50 % monthly prevalence over 3 years of surveillance) and spatially (0–8 % average long-term prevalence among sites within 30 km of each other) [67].

Field studies have shown that male drylands vesper mice are more frequently infected with Junín virus than females, that the prevalence of infection increases with age, and that infection is positively associated with the presence of scars [67]. These characteristics suggest that transmission between rodents is largely horizontal, between adult males, and may involve aggressive encounters and biting. In the laboratory, vertical infection resulted in highly deleterious effects on fitness [68]. Mice that were experimentally infected as adults showed a "split response"; half quickly developed antibodies and cleared the virus. The other half became chronically infected and persistently shed virus in urine and saliva [69], a characteristic that would facilitate horizontal transmission via aggressive encounters with biting, allogrooming, venereal contact, contact with infected nest materials, and perhaps inhalation of infectious aerosols.

3.2.2 Machupo Virus

The host for Machupo virus has been described as the big laucha (*Calomys callosus*), also called the large vesper mouse. Recent studies have shown, however, that *C. callosus* sensu lato (s. l.) is a clade of related but independently evolved taxa [70]. The "Beni Department clade" is one of those taxa and would be the host of Machupo virus [70, 71]. This new phylogenetic work helps to explain why Machupo virus and Bolivian HF are restricted to a small area of Beni Department, northeastern Bolivia, where *C. callosus* of the Beni Department clade are found, while *C. callosus* s. l. occurs in a much wider area of Bolivia, Brazil, Paraguay, and Argentina [72].

The big laucha is an opportunistic species that frequents disturbed habitats where forest and grasslands meet. They often seek higher ground during seasonal inundations, thus increasing contact with humans [73]. Unlike its congener *C. musculinus*, *C. callosus* will readily enter human habitations, sometimes in large numbers, and these events have been associated with devastating outbreaks of Bolivian HF [74, 75]. This same commensal characteristic contributes to relatively quick control of outbreaks by intensive trapping within and around homes in outbreak areas [73]. Both rodent abundance and prevalence of infection are highly variable over space and time, with the prevalence of Machupo virus infection in reservoir populations likely linked to population density. The prevalence of infection in rodents was 35 % in sites where human disease was present but much lower in disease-free areas [76]. No long-term studies of host or host–virus dynamics have been conducted. Therefore, the specific factors influencing population dynamics and Machupo virus transmission within host populations are unclear but likely include environmental factors such anthropogenic disturbance of natural ecosystems, which favors opportunistic species [12]; flooding, which concentrates host and human populations together on high ground [77]; and rainfall, which influences habitat quality and food availability.

In the laboratory, infection with Machupo virus in big laucha follows a similar pattern as Junín virus in drylands vesper mice; females inoculated at birth were chronically infected and sterile, indicating that vertical transmission would have a highly detrimental effect on the population. When infected as adults, again there was a split response, with half of the animals clearing the infection and half developing chronic infection and shedding virus in urine, feces, and saliva. It has been proposed that this split response is genetically controlled [78]. The mechanism of transmission among adult hosts in nature has not been studied, but presumably involves many of the same modalities described above for Junín virus and drylands vesper mice [78]. The split response caused by Machupo and Junín virus infections in their respective reservoirs has led to speculation that seasonal fluctuations in the incidence of Bolivian and Argentine HFs may be attributed to decreased populations of rodents caused by lowered fecundity in subsequent generations following chronic infection with these viruses.

3.2.3 Guanarito Virus

Guanarito virus is strictly hosted by the short-tailed zygodont mouse (*Zygodontomys brevicauda*), also referred to as the cane mouse, on the plains of northwestern Venezuela. A second *Sigmodontine* rodent species, Alston's cotton rat (*Sigmodon alstoni*), shares the same habitat with short-tailed zygodont mouse and hosts a second arenavirus (Pirital virus), yet spillover from one host to the other is rare [79, 80], illustrating the high specificity of rodent host–arenavirus relationships. It is not known whether this lack of cross-infection is due to a lack of physical interactions between the two species, despite their sharing the same habitat, or the poor ability of each virus to infect the other host. Within the endemic area for Venezuelan HF, both rodent species are commonly captured in crop fields, borders, and roadside habitats but

rarely in the peridomestic environment. Although the short-tailed zygodont mouse is a savanna species ranging from southeastern Costa Rica through most of Brazil north of the Amazon [81], the distribution of Guanarito virus (as determined by the occurrence of human cases) is restricted to a 9,000-km^2 area in Portuguesa and Barinas States in northwestern Venezuela [14]. Rodent community analysis [82] suggests that the development of intensive mechanized agriculture is associated with a relatively depauperate rodent assemblage dominated by the two arenavirus host species, the short-tailed zygodont mouse and Alston's cotton rat.

Laboratory studies [83] as well as detailed studies of tissue and fluid samples from wild short-tailed zygodont mice captured in the disease-endemic area [80] have provided a basic understanding of Guanarito virus infection dynamics in the host population. As with Junín and Machupo viruses, laboratory infection of newborn and juvenile rodent hosts resulted in chronic infection and persistent viral shedding in urine and saliva. There was no apparent detriment of infection to these animals after 3 weeks. Inoculation of adults again resulted in a split response, with some animals quickly clearing the virus and others developing a chronic infection, shedding virus in urine, saliva, and respiratory secretions. However, infection in adult females was associated with significantly reduced reproductive success [83]. In field-collected mice, infection was positively associated with host age, suggesting horizontal transmission. However, virus was restricted to lung tissue (not spleen or kidney), suggesting infection via the respiratory tract rather than wounding or venereal routes as suggested for Junín and Machupo viruses. Also unlike the Junín virus–drylands vesper mouse system, both sexes were equally infected, again arguing against infection by fighting among males [80]. Studies involving temporal patterns of host population dynamics and virus transmission and the influence of environmental factors on these processes are needed.

3.2.4 Whitewater Arroyo Virus

Numerous viruses antigenically and phylogenetically related to Whitewater Arroyo virus are widely distributed throughout the southwestern United States in association with several species of the genus *Neotoma*, including the southern plains wood rat (*N. micropus*), Mexican wood rat (*N. mexicana*), Stephen's wood rat (*N. stephensi*), and bushy-tailed wood rat (*N. cinerea*).

3.3 Other Arenaviruses

The reservoirs of Sabiá, Chapare, Lujo, and Dandenong viruses are unknown but are presumed to be muroid rodents. Most of the other arenaviruses from both the Old and New World complexes (Figs. 8.2 and 8.3) have been found in nature on relatively few occasions, often as a serendipitous result of field studies targeting other diseases. The animal from which the virus was isolated is assumed to be the natural reservoir, but systematic confirmatory field or laboratory studies have generally not been conducted. A few arenaviruses have been found only in animals other than rodents but the role of these animals as true natural hosts remains to be confirmed; Tacaribe virus has been isolated only once, from *Artibeus* species bats captured on the island of Trinidad [84]. However, a definitive role of these bats as the natural reservoir of Tacaribe virus is far from certain and placed in further doubt by failure to produce stable, nonlethal infection after laboratory inoculation of these bats with Tacaribe virus [85]. Three highly genetically divergent arenaviruses were recently discovered and putatively linked to inclusion body disease, a common infectious disease of captive snakes [86].

4 Rodent-to-Human Transmission

Transmission of arenaviruses to humans is believed to occur via exposure to rodent excreta, either from direct inoculation to the mucous membranes or broken skin or from inhalation of aerosols produced when rodents urinate [2, 45, 48, 87]. The relative frequency of these modes of transmission is unknown. Although the infectious dose for arenaviruses is thought to be low, transmission from rodents to humans appears to be inefficient, occurring infrequently even where infected rodents are common [56]. Transmission through aerosolized rodent urine or virus-contaminated dust particles is often mentioned in the scientific literature, but there are few data to support or refute its occurrence [88]. Although household clusters of arenaviral HF cases occasionally occur, single cases are much more common. This suggests that aerosol transmission to humans is not common, since it would logically often simultaneously infect multiple people in proximity to the aerosol source. Secondary aerosol generation, such as what might be produced through sweeping an area contaminated by rodent urine, is inefficient and is thus a less likely mechanism of infection. However, infectious and moderately stable aerosols of Lassa, LCMV, and Junín viruses have been artificially produced in the laboratory, so the possibility of primary aerosol transmission cannot be discarded [59, 89]. Regardless of their role in natural infection, the artificial production of infectious aerosols has obvious implications for the potential use of arenaviruses as bioweapons [19, 90].

Experimental data illustrate that arenavirus infection may also occur by the oral route, perhaps through a gastric portal [91, 92]. Lassa virus has been contracted when rodents are trapped and prepared for consumption, a common practice in some parts of West Africa, although it is rarely possible to determine whether infection resulted from exposure during

preparation or consumption [93]. Since arenaviruses are easily inactivated by heating, eating cooked rodent meat should pose no danger [2]. Various arenaviruses have been found in rodent saliva, although there are no reports of human infection from bites [60].

5 Transmission and Disease in Humans

With the exception of the LCMV reservoir, all arenavirus reservoirs occupy almost exclusively sylvatic rural habitats. Consequently, primary arenavirus infection in humans is seen almost exclusively in rural and often remote settings. Secondary human-to-human transmission may occur with some arenaviruses, most often to those caring for sick persons either at home or in healthcare centers. The combination of the remote and geographically restricted endemic areas (often in resource-poor countries), the apparent rarity of most arenaviral infections in humans, and the challenges to both clinical and laboratory diagnosis (see Sect. 8) make surveillance for arenavirus infection difficult. Consequently, reliable estimates of incidence are rare, except for Argentine HF, for which intensive surveillance with supporting laboratory diagnosis is applied in its circumscribed endemic area.

5.1 Old World Arenavirus Diseases

5.1.1 Lymphocytic Choriomeningitis and Other Central Nervous System Disease (LCMV and Dandenong Virus Infections)

Isolated during an investigation of encephalitis in St. Louis, United States, in 1933, LCMV was the first recognized arenavirus as well as the first recognized cause of aseptic meningitis in humans [94]. Ironically, despite being the prototype arenavirus, LCMV is one of the only pathogenic arenaviruses not associated with viral HF. Nevertheless, the virus has been extensively employed in mouse models to study arenavirus immunology. Given the great differences in associated clinical syndromes and pathogenesis, the applicability of these studies to other arenavirus infections is unknown [58].

Most human LCMV infections are thought to occur in homes, corresponding with the propensity of house mice to inhabit human dwellings [42]. Although cases are sporadically reported worldwide, accurate estimates of incidence are impeded by the usual presentation as a nonspecific febrile illness for which [95] diagnostic testing is not commonly requested or available. Most antibody surveys show a prevalence in humans of 5–10 % [36, 95–98]. The incidence of disease appears to have declined in recent decades, perhaps as housing construction and sanitation have improved, decreasing human exposure to house mice (although there is perhaps a bias toward data from more developed settings where cases are more likely to be noted, laboratory confirmed, and reported) [42]. Older reviews of patients with CNS disease showed LCMV infection in 8–11 % [42]. Infection with LCMV was the confirmed diagnosis in about 10 % of patients with febrile neurological syndromes admitted to a tertiary care hospital in Washington, DC, from 1941 to 1958, but the diagnosis was much less common recently [99, 100]. An investigation of cases of encephalitis in California (91 cases from 1998 to 2000) and England (2,574 cases from 1989 to 1998) revealed LCMV infection in zero and less than 1 %, respectively [101, 102]. Antibody surveys showing much lower prevalence in younger than in older patients support the notion of declining incidence, although this could also be explained by other factors that result in varied risk between age groups [97]. The incidence of LCMV infection peaks in the fall and winter in the northern temperate zones, presumably reflecting seasonal invasion of homes by house mice. The risk of infection is higher among rural dwellers and, in the United States, in low-income groups and, as expected, varies with the degree of rodent infestation in a home [36, 97, 103].

In 2003 and 2005, small clusters of LCMV infection and highly fatal (seven of eight cases died) neurological disease with organ failure occurred in solid-organ transplant recipients in the United States [104]. A third transplant-related cluster of three fatal cases occurred in Australia in 2009, leading to the discovery of the LCMV variant Dandenong virus [105]. The donor died of cerebral hemorrhage 10 days after returning to Australia from a 3-month visit to the former Yugoslavia, where he had traveled in rural areas. None of the donors in these outbreaks had a recent history of acute febrile disease and no virus could be identified in them, although the presence of IgG and IgM antibodies in the Australian donor confirmed recent infection. One donor in the United States had been exposed to a pet hamster from which LCMV was isolated and corresponded to the virus detected in the transplant recipients. With the exception of congenital transmission and through transplanted organs, there is no human-to-human transmission of LCMV.

5.1.2 Lassa Fever (Lassa Virus Infection)

Lassa fever is named after a village in northeastern Nigeria where the first case was recognized in 1969 [106]. However, hospital records and anecdotal reports describe cases consistent with Lassa fever in Nigeria as early as 1952 [107]. The disease is endemic exclusively in West Africa (Fig. 8.4). After first recognition in Nigeria, Lassa fever was noted in Sierra Leone, Liberia, and Guinea in the wake of hospital outbreaks and field studies in the early 1970s [57, 106, 108, 109]. Subsequent antibody prevalence studies and case reports indicate that Lassa virus is present in other West Africa countries [110, 111]. However, the risk of exposure to Lassa virus varies significantly across a given country and often between regions or even villages within endemic areas.

The highest incidence of disease appears to be in areas of eastern Sierra Leone, northern Liberia, southeastern Guinea, and central and southern Nigeria (Fig. 8.4) [48, 57, 112, 113]. Reasons for the extreme heterogeneity in incidence are not clear, especially considering that natal mastomys are often common in areas where little or no Lassa fever has been recognized. Varied intensity of surveillance may contribute to the apparent heterogeneous distribution, but cannot completely explain it.

Lassa fever is an extremely common infection among adults and children of both sexes in endemic areas of West Africa. An annual incidence of 300,000–500,000 Lassa virus infections with up to 5,000 deaths is often quoted in the scientific literature, but these figures are extrapolations from surveillance data collected in the 1970s and 1980s in eastern Sierra Leone where Lassa fever is clearly hyperendemic [48]. Estimating the true incidence and mortality is extremely difficult due to the nonspecific clinical presentation [57, 114], logistical impediments presented by civil unrest [115], unstable governments with underdeveloped surveillance systems [116], extensive human migration and perturbation of the physical landscape, and lack of reagents and laboratories for diagnostic confirmation in West Africa [117].

The incidence of Lassa fever is consistently highest during the dry season [57, 118]. The reasons for this are not clear but may relate to greater stability of Lassa virus at lower humidity [87] and seasonal fluctuation in host abundance and the prevalence of Lassa virus infection [54]. Natal mastomys may enter human habitations more frequently during the dry season, when food in agricultural fields is scarce, but stored rice and other staples in homes are abundant [54]. In a hospital in Guinea, the seasonal fluctuation in the incidence of Lassa fever mirrored the general pattern of other febrile diseases and hospital admissions, suggesting that nonbiological factors may be involved [57]. These may include cultural, economic, and other logistical impediments, such as poor road conditions, the need to attend to crops, and lack of funds prior to the seasonal harvest that often limit inhabitants' ability to seek medical care during the rainy season.

Mild or asymptomatic Lassa virus infection appears to be frequent. In a hyperendemic area of Sierra Leone in the 1980s, less than 20 % of persons who recently developed antibody reported recent febrile illness [48]. However, since antibody reversion (loss of antibody after infection) was also frequent, some of the seroconversions and asymptomatic infections may have represented re-exposure in persons with preexisting immunity from past Lassa virus exposure. The possibility of cross-reacting antibodies from previous infection with other nonpathogenic arenaviruses in West Africa, such as Kodoko, Gbagroube, or Menekre viruses, cannot be excluded (Fig. 8.4). Studies of the rate of asymptomatic transmission bear repeating with newer more sensitive and specific diagnostic modalities [119, 120].

Consumption of rodents and poor-quality housing, which may reflect ease of rodent access to the home, are risk factors for Lassa fever [93, 121]. In Sierra Leone, the incidence is consistently high in diamond mining areas, presumably due to increased contact with rodent excreta in the soil, although poor hygiene in mining camps and consumption of rodents may contribute. Large nosocomial outbreaks of Lassa fever have occasionally occurred in Africa following lapses in proper infection control, including reuse of non-sterilized needles and use of contaminated multiuse antibiotic vials, but secondary transmission associated with imported cases from returning travelers is extremely rare [122].

5.1.3 Lujo Fever (Lujo Virus Infection)

The name "Lujo" reflects the two geographic areas involved in the only outbreak recognized to date—*Lu*saka, Zambia, and *Jo*hannesburg, South Africa. The first recognized case was infected near Lusaka and subsequently medically evacuated to Johannesburg, initiating a chain of four nosocomial infections (a medical evacuation attendant, two nurses, and a cleaner) in South Africa in 2008 (Fig. 8.4). Four of the five (80 %) cases were fatal. The virus and disease have not been seen since and no antibody or ecologic surveys have been conducted to yield a greater understanding of the epidemiology or epizoology of Lujo virus.

5.2 New World Arenavirus Disease

5.2.1 Argentine Hemorrhagic Fever (Junín Virus Infection)

In 1959, the first of the HF-causing arenaviruses, Junín (named after a village about 240 km west of Buenos Aires), was described after a new disease, subsequently named Argentine HF, emerged in the central Argentine pampas, an area of intensive agriculture. Annual outbreaks of up to 1,500 cases continued in subsequent years. The endemic zone initially appeared confined to an area of approximately 16,000 km^2 but has steadily expanded to about 150,000 km^2 in parts of northern Buenos Aires, southern Santa Fe and Entre Rios, and southeastern Córdoba Provinces as agriculture expands (Fig. 8.5) [123]. The present endemic area is home to an estimated three million people. Transmission is typically high in the first few years of expansion into a new area and then declines.

The endemic area is largely a mosaic of crop fields and some cattle ranches crisscrossed by linear islands of relatively stable border habitats that are the preferred habitat of drylands vesper mice. As expected, the annual incidence is positively correlated with local population densities of this rodent. Young adult males are generally at highest risk due to their traditional involvement and exposure in agricultural activities [66]. Although cases occur throughout the year, the

incidence is usually highest from March to June, corresponding to periods of peak agricultural activity. In the early years the men affected worked in close contact with the land and harvested crops by hand, activities that presumably carried a high risk of exposure to rodents and their excreta. Later, mechanized agricultural practices became common, but cases continued to occur in field-workers, especially tractor drivers, probably through inhalation of infectious aerosols generated during the mechanized harvesting process.

An effective vaccine (see Sect. 10.6) was introduced in 1991, decreasing the incidence of Argentine HF from 837 cases that year to an average of 122 cases yearly from 1992 to 2009 [124]. The incidence has been steadily declining, with less than 100 cases in most years since 2000, despite increasing intensity of surveillance and quality of laboratory diagnosis. As young male agricultural workers in the high-risk provinces are increasingly protected by vaccination, the proportion of cases fitting this demographic is decreasing.

5.2.2 Bolivian Hemorrhagic Fever (Machupo Virus Infection)

An outbreak of what was subsequently named Bolivian HF occurred in Bolivia's El Beni Department in 1959. The etiologic agent, Machupo virus, named after a river in the region of the outbreak, was described in 1965. Community outbreaks of Bolivian HF continued during the 1960s but were eventually brought under control, in part by rodent trapping. There were then no reported cases for decades, followed by sporadic cases and small outbreaks reported again in the 1990s, which continue through the time of this writing in 2012.

Although Bolivian HF may be seen throughout the year, like Argentine HF, the incidence is usually highest during the dry season (June–August) at the peak of agricultural activity. Young men engaged in agricultural activities in rural areas are at highest risk. However, family and community clusters of Bolivian HF cases affecting both sexes and all age groups have also occurred in towns and hospitals, either as a result of epizootic conditions fostering high rodent population densities with invasion of towns and human dwellings [13] or through person-to-person transmission [125].

5.2.3 Venezuelan Hemorrhagic Fever (Guanarito Virus Infection)

In 1989, an outbreak of viral HF occurred in Guanarito District in the southern tip of Portuguesa State, Venezuela. Although originally thought to be dengue HF, in 1991 the disease was attributed to a new arenavirus named Guanarito, the causative agent of Venezuelan HF [126]. Outbreaks of Venezuelan HF have been reported every 4–5 years since its discovery, suggesting some cyclic climatic or social influence. Similar to Argentine and Bolivian HFs, epidemics appear to have a seasonal peak in November to January, coinciding with maximum agricultural activity, with highest incidence in male agricultural workers [14]. Recent surveys have demonstrated the presence of Guanarito virus genotypes (some closely matching genotypes from case patients in the disease-endemic area) in host populations over a wide area of the Venezuelan plains (western llanos), including areas in five states up to several hundred kilometers from the recognized disease-endemic area [22].

5.2.4 Brazilian Hemorrhagic Fever (Sabiá Virus Infection)

In 1990, a fatal case of HF was reported from outside of Sao Paulo, Brazil [127]. The victim was an agricultural engineer, although she worked primarily in the office. Although originally thought to be a case of yellow fever, a new arenavirus was subsequently isolated and named Sabiá after the community where the engineer was staying when she fell ill, although the name Brazilian HF has not been formally assigned. Only two cases of Sabiá infection, both nonfatal and due to laboratory accidents, have occurred since: one in Brazil and one in the United States. The case in the United States resulted from a centrifuge accident, illustrating the potential for aerosol transmission of arenaviruses in the laboratory. Despite the infected individual not reporting the incident for 12 days after the accident, no secondary transmission occurred.

5.2.5 Chapare Hemorrhagic Fever (Chapare Virus Infection)

The latest HF-causing New World arenavirus to be recognized is Chapare virus, discovered in 2003 after a small outbreak in Chapare Province in Cochabamba Department, Bolivia. Few details have been reported and no cases have been reported since then, although surveillance is limited.

5.2.6 Whitewater Arroyo Virus Infection

In 2000, in California, Whitewater Arroyo virus was detected via RT-PCR in three fatal cases with symptoms consistent with viral HF, with infectious virus isolated from one patient. However, not all laboratory results could be confirmed, leaving doubt about the pathogenicity of this virus. No further cases have been recognized. Nevertheless, findings from recent antibody surveys, including persons with significant increases in antibody titer associated with febrile illness, suggest a pathogenic role for Whitewater Arroyo or a similar arenavirus in the southwestern United States [128].

5.3 Human-to-Human Transmission

Most arenaviruses can be transmitted between humans through direct contact with infected blood or bodily fluids although, contrary to popular concept, secondary attack rates are generally low, probably on the order of 5 % or less as long as strict barrier nursing practices are observed. Tertiary

transmission is unusual. Large outbreaks are almost always fueled by nosocomial transmission, usually in resource-poor regions where barrier nursing practices may not be maintained [109, 118, 122, 129].

Viremia and infectivity of persons infected with arenaviruses generally parallels the clinical state, with highest infectivity late in the course of severe disease, especially when bleeding is present. Data on the precise modes of human-to-human transmission are lacking, but infection presumably results from oral or mucous membrane exposure, most often in the context of providing care to a sick family member (community) or patient (nosocomial transmission). Although aerosol spread of Lassa virus was speculated in the first recognized outbreaks in Nigeria, extensive field experience since then has not suggested aerosol transmission of arenaviruses between humans in natural settings [118]. African funeral rituals that entail the touching of the corpse prior to burial may also result in transmission of HF viruses, although this has not been specifically recognized with arenaviruses [130]. Arenavirus clearance from immunologically protected sites such as the kidney and gonads may be delayed for weeks to months, potentially resulting in transmission during convalescence [131–134]. Excretion may be intermittent [135]. Lassa virus has been isolated from human urine up to 67 days after onset of illness. Nevertheless, only a few incidences of transmission during convalescence have been reported, all consistent with sexual transmission of Lassa, Machupo, and Junín viruses months after recovery from acute disease [48, 136]. The risk of transmission during the incubation period or from asymptomatic persons is negligible.

New World arenaviruses appear to be less transmissible between humans than their Old World counterparts, although human-to-human transmission of Machupo virus has been reported in both community and nosocomial settings [137, 138]. Only one family cluster of Argentine HF is described, with the index case presenting with atypical skin lesions that may have facilitated transmission. Person-to-person transmission or nosocomial infection has not been observed with Guanarito virus despite the fact that patients with Venezuelan HF are usually admitted to open wards with minimal isolation precautions. It is unknown whether the perceived differences in transmissibility between the arenaviruses reflect true biological properties or varied cultural and infection control practices in the endemic areas of each virus.

Contrary to popular concept, the risk of imported arenavirus infections initiating outbreaks in industrialized countries, where barrier nursing techniques are usually maintained, is generally low. Because of the considerable travel between the United Kingdom and their former West African colonies, which also often happen to be the hyperendemic areas, Lassa fever is easily the most exported arenavirus infection. Foreign military personnel, peacekeepers, aid workers, and tourist in rural settings are occasionally infected, sometimes importing Lassa virus back to their countries of origin, most frequently the United Kingdom and Europe, but occasionally as far away as Japan [139]. Despite Lassa virus being one of the most communicable arenaviruses, in over 25 imported cases of Lassa fever reported since 1969 with at least 1,500 cumulative identified contacts, only a single putative and asymptomatic instance of secondary transmission has been noted [140]. Nevertheless, the risk is highlighted by the three secondary cases and one tertiary case following an index case of Lujo fever imported to South Africa; this transmission occurred in settings in which proper infection control practices may not have been maintained.

6 Clinical Presentation

6.1 Central Nervous System Disease

Despite the name, a minority of patients infected with LCMV manifest meningitis or CNS disease. Rather, most LCMV infections are asymptomatic or result in a nonspecific febrile illness [141].

The incubation period is about 1–2 weeks (typically 8–13 days). After 7–14 days of nonspecific illness (fever, headache, malaise), and often with a brief period of effervescence, CNS manifestations may ensue in a minority of patients, running a spectrum from aseptic meningitis (the most common) with headache, stiff neck, and photophobia to fulminant encephalitis with cranial nerve palsies, abnormal reflexes, focal seizures, polyneuritis, flaccid paralysis, and papilledema. CNS symptoms can also occur without recognized febrile illness. Rarer manifestations and complications of LCMV infection include hydrocephalus, transverse myelitis, Guillain–Barré syndrome, hearing loss, arthritis, parotitis, orchitis, myocarditis, mucosal bleeding, and pneumonia. Congenital infection has been associated with spontaneous abortion in early pregnancy and, when occurring later in pregnancy, a variety of neurological deficits, including psychomotor retardation, microcephaly and macrocephaly, hydrocephalus, chorioretinitis with visual loss, and seizures [17]. LCMV and Dandenong virus infection in immunosuppressed organ transplant recipients has resulted in a highly fatal syndrome with graft dysfunction, CNS symptoms, and multiorgan system involvement, in some cases resembling viral HF, within 3 weeks after transplantation, with case fatality approaching 90 % [104].

6.2 Arenaviral Hemorrhagic Fever

Although there are differences in the pathogenesis and clinical manifestations produced by the various arenaviruses, they are usually too subtle to allow for distinction on clinical grounds, at least in the early stages of disease. Nevertheless,

some notable distinctions can be made between the syndromes caused by Old World and New World viruses. The disease caused by the various New World arenaviruses is usually referred to simply as "South American HF." Asymptomatic transmission and milder nonspecific febrile illness appear to be relatively frequent in Old World arenavirus infections, at least for LCMV and Lassa virus, while infection with the pathogenic New World arenaviruses much more often results in disease that can ultimately be recognized as HF.

Arenaviral HF may be seen in both sexes and all age groups, with a spectrum ranging from mild disease to shock, multiorgan system failure, and death. Most patients present with nonspecific signs and symptoms difficult to distinguish from a host of other febrile illnesses common in the tropics. The incubation period is usually about 1 week (range 3–21 days). Illness typically begins with the gradual onset of fever and constitutional symptoms, including general malaise, anorexia, headache, chest or retrosternal pain, sore throat, myalgia, arthralgia, lumbosacral pain, and dizziness [57, 114]. The pharynx may be erythemic or even exudative in Lassa fever, a finding which has at times led to misdiagnosis of streptococcal pharyngitis [114]. Gastrointestinal signs and symptoms occur early in the course of disease and may include nausea, vomiting, epigastric and abdominal pain and tenderness, and diarrhea. Lassa fever has sometimes been mistaken for acute appendicitis or other abdominal emergencies. A morbilliform, maculopapular, or petechial skin rash is very frequent in South American HFs. Interestingly, although rash almost always occurs in fair-skinned persons with Lassa and Lujo fever, it rarely occurs in blacks. The reasons for this observation are unknown, but prior infection with partial immunity and genetic differences have been postulated. Conjunctival injection or hemorrhage is frequent but is not accompanied by itching, discharge, or rhinitis. A dry cough, sometimes accompanied by a few scattered rales on auscultation may be noted, but prominent pulmonary symptoms are uncommon early in the course of the disease. Jaundice is not typical and should suggest another diagnosis.

In severe cases, patients progress to vascular instability, which may be manifested by subconjunctival hemorrhage, facial flushing, edema, bleeding, hypotension, shock, and proteinuria. Swelling in the face and neck and bleeding are particularly specific but not sensitive signs in Lassa and Lujo fevers [114]. Despite the term "viral HF," clinically discernible hemorrhage is not always seen, being less frequent in disease produced by Old World than New World arenaviruses, and never in the first few days of illness [57, 114]. Hematemesis, melena, hematochezia, metrorrhagia, petechiae, epistaxis, and bleeding from the gums and venupuncture sites may develop, but hemoptysis and hematuria are infrequent. Significant internal bleeding from the gastrointestinal tract may occur even in the absence of external hemorrhage. Neurological complications are more common in the South American HFs and include disorientation, tremor, ataxia, seizures, and coma, particularly in the late stages, and usually portend a fatal outcome [142]. The cellular and chemistry profile in CSF is often normal. Pregnant women with arenaviral HF often present with spontaneous abortion and vaginal bleeding, with maternal and fetal mortality rates approaching 100 % in the third trimester [143]. Anasarca has been described in a single report of children with Lassa fever (termed the "swollen baby syndrome") but may have been related to aggressive rehydration [144]. Various clinical manifestations of arenaviral HF are illustrated in Fig. 8.6.

Typical clinical laboratory findings in arenaviral HF include early leukopenia and lymphocytopenia, sometimes with atypical lymphocytes, followed later by leukocytosis with a left shift; mild-to-moderate thrombocytopenia, hemoconcentration; elevated aspartate aminotransferase (AST), alanine aminotransferase (ALT), and amylase; electrolyte perturbations; and proteinuria [134, 145]. Unlike classic viral hepatitides, in arenaviral HF the AST is typically much higher than the ALT, suggesting that its source is not exclusively the liver. Since a broad range of tissues can release AST, it should be considered a marker of systemic organ damage [134]. Radiographic and electrocardiographic findings are generally nonspecific and correlate with the physical examination [146, 147].

7 Clinical Management

Although data from clinical trials are sparse, most arenaviruses show in vitro and in vivo sensitivity to the antiviral drug ribavirin, which should be considered in all severe arenavirus infections. Convalescent immune plasma has demonstrated efficacy in Argentine HF and may be indicated, when available, in other New World arenavirus infections, although it is associated with a late neurological syndrome in 10 % of cases. Detailed reviews of the clinical management of viral HFs are available elsewhere [17, 145].

8 Diagnosis

8.1 Clinical Diagnosis

Difficulties in diagnosing arenavirus infection, both clinically and in the laboratory, pose a major impediment to surveillance and control. Even if more clearly recognized HF or neurological syndromes eventually develop, most patients present with a nonspecific febrile syndrome difficult to distinguish from a host of other diseases that are usually more common in the area. The differential diagnosis of arenaviral HF includes a broad array of febrile illnesses, including malaria, typhoid fever, leptospirosis, bacterial septicemia, rickettsial infections, dengue fever, and other viral HF

Fig. 8.6 Clinical manifestations of arenaviral hemorrhagic fever. (**a**) Facial swelling and mild gum bleeding in Lassa fever (photo by Donald Grant), (**b**) conjunctival injection in Lassa fever (photo by Donald Grant), (**c**) maculopapular rash in Lujo hemorrhagic fever (photo by TH Dinh), (**d**) gum bleeding in Argentine hemorrhagic fever, (**e**) petechial rash in Argentine hemorrhagic fever (Photos used with permission from Blumberg et al. [210])

syndromes, depending upon the specific geographic region and patient history of exposures [145]. The classic presentation of LCMV infection is aseptic meningitis occurring in the fall, particularly if an initial prodromal period of fever, perhaps with a remission, occurs before the CNS phase. The differential diagnosis includes the arboviral meningitides and herpes encephalitis and, for congenital manifestations, the classic TORCH organisms (*to*xoplasma, *r*ubella, *c*ytomegalovirus, and *h*erpes virus). The presence of thrombocytopenia and leukopenia should enhance suspicion of arenavirus infection.

A diagnosis of arenavirus infection should be considered in patients with a clinically compatible syndrome who, within 3 weeks prior to disease onset, (1) live in or traveled to an endemic area (Figs. 8.2 and 8.3), (2) had potential direct contact with blood or bodily fluids of a person with arenaviral HF during their acute illness (this group most often is comprised of healthcare workers or persons caring for family members at home), (3) worked in a laboratory or animal facility where arenaviruses are handled, or (4) had sex with someone recovering from arenaviral HF in the last 3 months. Recognized direct contact with rodents in endemic areas, including laboratory mice and pet hamsters and guinea pigs if LCMV infection is suspected, should heighten suspicion but is rarely noted even among confirmed cases. Acts of bioterrorism must be considered if arenaviral HF is strongly suspected in a patient without any of the aforementioned risk factors, especially if clusters of cases are seen [19]. Even persons who meet the above criteria most commonly have a disease other than arenaviral HF, so alternative diagnoses should always be aggressively sought.

8.2 Laboratory Diagnosis

The difficulty in clinical diagnosis makes prompt laboratory testing imperative. Unfortunately, no commercial assays are available, a situation further complicated by the BSL-4 designation and Select Agent status of many arenaviruses that limit access and research potential even to many legitimate scientists. Various recombinant-protein- and virus-like-particle-based assays are being developed which may eventually relieve the diagnostic bottleneck, as well as improve sensitivity and specificity, although interpretation and validation of these assays are proving challenging [148, 149]. Meanwhile, various "in-house" assays have been developed and are performed in a few specialized laboratories. Common diagnostic modalities include cell culture (restricted to BSL-4 laboratories for most pathogenic arenaviruses), serologic testing by enzyme-linked immunosorbent assay or immunofluorescent antibody assay, and the reverse transcriptase polymerase chain reaction. Serum is the usual substance tested, but these assays may also be applied to cerebrospinal fluid in LCMV infection [38, 95, 150, 151]. Postmortem diagnosis of some arenavirus infections may be established by pathology examination with immunohistochemical staining of formalin-fixed tissue [152]. Although extensive standardization and validation of these assays has not been conducted, they generally appear to have high sensitivities and specificities when conducted by experienced technicians [119, 153]. Cross-reactions between antigenically similar arenaviruses may pose a problem with the serologic assays, which sometimes can be resolved using neutralization tests [59]. The diagnostic methodologies and their distinct advantages and disadvantages are reviewed elsewhere [154].

9 Pathogenesis and Immune Response in Humans

9.1 Central Nervous System Disease

Overt cell damage by arenaviruses is minimal or modest, but they alter cell function and induce mediators of shock, directly or by immunopathologic mechanisms. Immune cell activation is also the fundamental process in the pathogenesis of LCMV, although without the same effects on endothelial cell function and hemostasis as in HF (see Sect. 9.2) [17]. CNS involvement typically occurs a week or two after disease onset, after virus has cleared from the blood, and is thus thought to be immune mediated, although virus can still be recovered from the CSF at this time.

9.2 Arenaviral Hemorrhagic Fever

As with all viral HFs, microvascular instability and impaired hemostasis are the hallmarks of arenaviral HF. Unchecked viremia appears to be central to the pathogenesis of arenaviral HF [134]. Viremia is usually present at patient presentation (presumably starting with disease onset, although patients are rarely available for testing at this time), peaking between days 4–9 and clearing within 2–3 weeks in survivors. Cell-mediated immunity is thought to be the primary arm of recovery in Old World arenavirus infection, while the humoral arm is important in disease caused by New World viruses [155–157]. Antibody titers are significantly lower in fatal cases relative to survivors [119, 134, 158] Neutralizing antibodies may be produced in Old World arenavirus infection, but usually months after recovery and often at a low titer. The continued increase in antibody titer to Lassa virus months after infection suggests a sustained B cell response that might be attributable to low-level virus persistence; in vaccine experiments in monkeys, replication-competent virus was cleared within 14 days after Lassa virus challenge,

but detection of RNA up to 112 days suggested low-level viral persistence or the presence of defective interfering particles [159]. The delayed clearance of Lassa virus from immunologically protected sites could explain the finding.

In survivors, IgM antibodies begin to appear after about a week and progressively increase as virus clears, lasting at least some months [119]. There are conflicting reports regarding the timing of IgM antibody appearance; this discrepancy may reflect differences in the production of reagents and their target epitopes, variations in assay sensitivity and specificity, and experience of the persons conducting the assay [119, 134, 160]. IgG antibody begins to appear 2–3 weeks after onset and recovery and lasts for years, including being found in persons over 40 years after Lassa virus infection who left the endemic area for Lassa fever and had no opportunity for re-exposure [161].

A long-standing mystery of arenaviral HF, especially Lassa fever, is the extreme range of clinical severity. The reasons for this variation are unknown but may relate to heterogeneity in the virulence of infecting Lassa virus strains, route and dose of inoculation, genetic predisposition, underlying coinfections or premorbid conditions (e.g., malaria, malnutrition, or diabetes), or misclassification of reinfection as new infection due to waning of antibody. Most studies in nonhuman primates use challenge doses designed to produce uniformly fatal disease and thus are not particularly illustrative regarding the pathogenesis of the full spectrum of arenaviral HF. In a monkey model of Lassa fever using the WE strain of LCMV, intravenous inoculation resulted in fatal viral HF while monkeys inoculated via the gastric route mostly had an attenuated infection with no disease [92, 155]. Human genes encoding "like glycosyltransferase" (*LARGE*), dystrophin (*DMD*), and IL-21 have apparently undergone positive selection in populations in endemic areas for Lassa fever in Nigeria, suggesting a protective effect [162, 163]. Readers are referred to recent reviews for more details on arenavirus pathogenesis [21].

10 Prevention and Control

10.1 Rodent Control

In the absence of effective vaccines for most arenavirus infections, effective and sustainable control relies on avoidance of known reservoir host habitats or, when this is not feasible, implementation of measures to prevent direct contact with rodents and their excreta. Most successful control programs entail principles of integrated pest management, integrating biological and chemical control measures with education or regulation to change human behaviors that put them at risk [164, 165]. Structural improvements to homes may be important for arenaviruses whose rodent hosts invade houses [166].

For LCMV, Lassa, and Machupo viruses, whose hosts often colonize human dwellings, measures to improve "village hygiene" are advocated to discourage rodent invasion, including assuring proper waste disposal, eliminating unprotected storage of garbage and foodstuffs, reducing clutter and vegetation around houses that give rodents shelter, and sealing holes that allow entry into homes [55]. These measures may not always be possible with the rudimentary construction of houses in some regions, especially with regard to Lassa fever in areas of West Africa that have been ravaged by war or civil unrest.

Although complete elimination of rodents from the environment through trapping or poisoning is not feasible or desirable, considering their importance to overall healthy ecosystems, short-term intensive rodent elimination in defined areas may occasionally be useful to control outbreaks; an outbreak of Bolivian HF in 1963–1964 in the village of San Joaquin ended abruptly after 2 weeks of continuous trapping in homes during which 3,000 big laucha were captured [73, 167]. However, a single trapping session in houses in Sierra Leone did not diminish the incidence of human Lassa virus infection [55]. A sustained elimination program would be necessary for effective long-term control because rodents from surrounding fields and forests may quickly recolonize villages and homes. Rodent elimination programs are unlikely to control transmission of Junín and Guanarito viruses to humans because their reservoir hosts are widespread in agricultural fields, although targeting the linear habitats preferred by drylands vesper mice might be plausible [2]. Crop replacement or periodic burning of tall grassy areas that are in close proximity to agricultural fields and human habitation has been recommended to control these viruses, although the measures are untested [42].

10.2 Environmental Shedding and Disinfection

Little published literature exists on transmission dynamics or viability of arenaviruses after shedding into the environment, especially data applicable to settings other than research laboratories. However, the lipid envelope of all HF viruses, including arenaviruses, is easily disrupted, limiting their viability outside a living host. Little concern is required regarding HF viruses seeping into groundwater or posing any long-term risk through casual exposures in the general environment, where harsh thermal and pH conditions would likely readily inactivate them. The survival of HF viruses in animal excreta is likely affected by factors such as the animal's diet and urinary pH and the presence of protein. When shed naturally in animal excreta or human body fluids, which would then usually dry, infectivity appears to last from a few hours to days, varying with the specific virus and environmental conditions

such as temperature and light [168–170]. However, other non-arenavirus HF viruses have been isolated from samples kept for weeks at ambient temperatures if stored hydrated in a biological buffer, such as blood or serum. This would likely hold true for arenaviruses as well. The viruses are also stable when frozen or freeze-dried [171].

Routine environmental surveillance (i.e., in soil, water, or air) for the arenaviruses is generally not feasible or routinely conducted. However, concerns about bioterrorism have spurred interest in this area in recent years, especially around specific events attracting large crowds, such as sporting events, that might be potential bioterrorist targets. Detection of an arenavirus outside its usual endemic area should certainly raise suspicion about bioterrorism. The specificity of any test employed would have to be high to avoid the considerable alarm and expenditure of resources that a false-positive result would likely initiate.

When contamination is suspected, such as in homes or hospitals treating persons with arenaviral HF, disinfection is warranted and effective. Arenaviruses can be inactivated by exposure to temperatures above 60 °C for 1 h, acidic or basic pH, gamma irradiation, ultraviolet light (surface disinfection only), surfactant nanoemulsions, and a host of chemicals and detergents, including chlorine compounds, alcohols, phenols, quaternary ammonium compounds, formaldehyde, cupric and ferric ions, zinc finger-reactive compounds, photoinducible alkylating agents, and various proprietary detergent-containing lysis buffers [172–184]. Toxicity and corrosion may be concerns with some of these compounds depending upon the frequency of use and concentrations.

Sodium hypochlorite (i.e., household bleach) is the most readily available effective inactivation method [185]. Bleach solutions should be prepared daily; starting with the usual 5 % chlorine concentration, a 1:100 (1 %) solution should be used for reusable items, such as medical equipment, patient bedding, and reusable protective clothing before laundering. A 1:10 (10 %) bleach solution should be used to disinfect excreta, corpses, and items to be discarded. Workers cleaning areas potentially contaminated by the excreta of small mammals should let the area aerate before entering, then spray the area with the 10 % bleach solution and let it sit on the surface for at least 15 min before mopping or wet sweeping [186]. A site with appropriate security should be dedicated for waste disposal if routine autoclaving is not available.

Specific guidelines exist regarding handling and burial of corpses of victims of viral HF [185]. The question of the safety of exhuming remains of persons who died of arenaviral HF overseas for transport back home occasionally arises. No data regarding the viability of arenaviruses under these circumstances are available, but it is unlikely that the viruses would survive long under the harsh pH conditions of a decomposing corpse unless the ambient temperature is below freezing, which is unlikely in the endemic areas of most arenaviral diseases. If corpses are to be exhumed, the same protective measures used for burial of victims of viral HF, including placing the cadaver in a sealed body bag, should be used.

10.3 Occupational Exposure and Personal Protective Equipment

10.3.1 Healthcare Workers

Since transmission of arenaviruses between humans requires direct contact with blood and body fluids, infection can be prevented by the isolation of the patient and use of routine barrier nursing. However, due to the high fatality rates associated some arenaviral HFs, so-called viral HF precautions (surgical mask, double gloves, gown, protective apron, face shield, and shoe covers) are advised for added security [185]. Powered air-purifying respirators and other small-particle aerosol precautions should be used when performing procedures that may generate aerosols, such as endotracheal intubation. Items that were in direct contact with the patient should be decontaminated (see Sect. 10.2).

10.3.2 Laboratory Workers

Fortunately, since most arenavirus infections are rare in humans and routine laboratory safety procedures are generally adequate to prevent transmission, infection in hospital laboratories from clinical samples is extremely rare. Of more concern is the risk to laboratorians specifically working with cultured arenaviruses, especially the highly pathogenic agents of HF. However, these agents are largely restricted to work in BSL-4 laboratories. No arenavirus infections have been reported in laboratorians working in BSL-4 laboratories, although numerous accidents, sometimes fatal, have occurred in lower-level containment laboratories. Recognition of LCMV transmission associated with laboratory mice has led to guidelines and regulations in these settings that have markedly decreased risk [187].

10.3.3 Field-Workers

Field-workers such as agricultural workers, field biologists, and pest control workers are potentially exposed to rodents and their excreta in an occupational setting. Inadvertent exposure to contaminated rodent excreta by agricultural workers is difficult to prevent. Routine use of masks is probably not feasible or cost-effective, but should be considered when the risk of aerosols is high. Common dust or surgeon's masks will not protect against small-particle aerosols; specifically designed N-100 or P-100 face masks must be used for this purpose [188].

Field biologists and pest control workers who trap rodents merit special consideration; although the risk would seem to

be high, the limited evidence available suggests that arenavirus infection in this group is rare, even in the absence of the use of extensive personal protective equipment. Field biologists who handled rodents in North America showed a prevalence of exposure to HF viruses of less than 1 %, and not all infection could be clearly attributed to occupational exposure [189]. The risk may vary depending upon the prevalence of the pathogen in the animals and the specific procedure conducted. For example, simple elimination of pests via snap-trapping and disposal of intact dead animals would be less risky than live-trapping with subsequent euthanasia and necropsy to procure samples for scientific research.

In the absence of a clear consensus on the risk of infection, a wide variety of biosafety practices are employed by field-workers, ranging from no personal protective equipment to use of gloves, gowns, safety glasses, and HEPA filter respirators or even positive-pressure respirators [189]. While the inclination of those responsible for workers' safety is to err on the side of caution, and thus require the full complement of protective personal equipment, significant cost and practical implications must be considered. More research is needed to assess the true risk to field-workers and thus the cost–benefit balance of the various protective measures if a widely agreed-upon standard procedure is to be set. Because risk depends upon geographic location, pathogens expected to be encountered, species handled, specific tasks, and worker training, any such standards will have to address multiple situations. In the meantime, it seems prudent to follow established safely guidelines when handling known viral HF reservoir host species [190]. Full precautions, including positive-pressure respirators, are warranted when sample centrifugation or other potentially aerosol-generating procedures are performed.

10.3.4 Pet Store Workers and Pet Owners

Recognition of LCMV transmission associated with pet animals has led to guidelines and regulations in these settings [187]. Pregnant women and immunosuppressed persons in particular must be protected from infection because of the potentially severe consequences in these groups [36]. Serologic testing of individual pet rodents is generally unreliable and not recommended. Educational materials on safe handling of pet rodents should be made available at pet stores. Pet stores with potentially infected rodents in stock should contact public health authorities for additional information and guidance. Human infection with arenaviruses other than LCMV from pet contact has not been reported. However, although not an arenavirus, monkeypox virus, traced to the importation of infected Gambian rats from Ghana, has infected humans in the United States and highlights the risk to those importing and keeping exotic pets [191].

10.4 Case Identification and Patient Isolation

Control of most arenaviral HF relies on classic public health principles of identification and isolation of cases and monitoring of their contacts. However, the early nonspecific presentation of arenaviral HF poses a serious challenge to case identification. Fortunately, the low secondary attack rate affords a measure of reassurance even when cases go unrecognized as long as proper barrier nursing is maintained. Furthermore, since mild cases are not very infectious, missed or delayed diagnosis of these patients is unlikely to pose a problem from an infection control standpoint. All patients with a clinically compatible syndrome should be presumed infectious and kept under "viral HF isolation precautions" (see below) until a specific diagnosis is made [185]. If available, placement in a negative airflow room is prudent, but hermetically sealed isolation chambers are not required and may have severe adverse psychological effects on both patient and staff. Access to the patient should be limited to a small number of designated staff and family members with specific instructions and training on the implementation of viral HF isolation precautions.

Since the clinical status of patients with viral HF generally correlates with the level of viremia and infectivity, patients who have recovered from their acute illness can safely be assumed to have cleared viremia and can be discharged without concern of subsequent transmission. However, because of potential delayed virus clearance in urine and semen, abstinence or condom use is recommended for 3 months after acute illness. Although transmission through toilet facilities has not been noted, simple precautions to avoid contact with excretions in this setting are prudent, including separate toilet facilities and regular hand washing. Breastfeeding should be avoided during convalescence unless there is no other way to support the baby.

10.5 Contact Tracing

Persons with unprotected direct contact with a patient during the symptomatic phase of arenaviral HF should be monitored daily for evidence of disease for three weeks (the longest known incubation period) after their last contact. Contacts should check their temperature daily and record the results in a log. Despite the lack of evidence for transmission during the incubation period, exposed persons should avoid close contact or activities with household members that might result in exposure to bodily fluids, such as sex, kissing, and sharing of utensils. Hospitalization or other confinement of asymptomatic persons is not warranted, but persons who develop fever or other signs and symptoms consistent with arenaviral HF should immediately be isolated until the diagnosis can be excluded.

10.6 Vaccines

In Argentina, the use of a live attenuated vaccine for Argentine HF called Candid #1 began in 1991 and has resulted in a steady decrease in the incidence of cases, as described above. The vaccine may also protect against Bolivian HF, although it does not appear to cross-protect against other arenaviruses [192]. However, Candid #1 is generally not available or approved outside of Argentina, and even within Argentina supplies are insufficient to cover the population at risk. Furthermore, despite the efficacy and generally excellent safety profile of Candid #1 for Argentine HF, fear of reversion to virulence with live-virus vaccines is a major disincentive to exploring its application to other arenavirus infections.

Other arenavirus vaccines are in the experimental stages. A number of vaccine platforms have been explored in animal models of arenaviral HF, primarily aimed at preventing Lassa fever. Approaches include inactivated or attenuated viruses [193, 194], recombinant vaccinia viruses [159], RNA replicon vectors derived from an attenuated strain of Venezuelan equine encephalitis virus [195], recombinant *Salmonella* Typhimurium [196], arenavirus protein subunits [197], naked DNA [198], chimeric viruses using the yellow fever 17D vaccine strain [199, 200], reassortant Lassa/Mopeia viruses [201–203], viruslike particles [204], and recombinant vesicular stomatitis virus [205, 206]. The arenavirus GP1 appears to be the most important immunogenic protein.

The recombinant vesicular stomatitis virus platform is perhaps the most promising candidate, providing 100 % protection after a single dose in a monkey model of Lassa fever. Furthermore, this vaccine may be effective when given by the nasal or oral route, potentially facilitating its use in epidemics or as postexposure prophylaxis [207]. Although there are concerns over the safety of an unproven live-vector vaccine in populations in Africa with a high frequency of immunosuppressed persons due to HIV/AIDS or malnutrition, preliminary studies of the recombinant vesicular stomatitis virus vaccine platform in immunocompromised monkeys have not indicated problems, perhaps because the vector virus lacks the neurovirulence genes and properties of the wild-type virus [208]. The social, economic, and political barriers to development of arenavirus vaccines are at least as formidable as the scientific ones, considering that most arenavirus diseases exist in geographically restricted areas with resource-poor populations.

10.7 Postexposure Prophylaxis

Ribavirin has been used as postexposure prophylaxis for Lassa fever, although there are no data on efficacy, dose, or duration of administration of the drug for this purpose. Nevertheless, postexposure prophylaxis with oral ribavirin should be considered for persons with direct unprotected contact with blood or bodily fluids from a person with confirmed or highly suspected arenaviral HF. Persons who develop manifestations of arenaviral HF should be immediately converted to the intravenous form. Prophylaxis should not be given if the only exposure was during the incubation period. A review and specific guidelines have been published [209].

11 Unresolved Problems and Future Challenges

The progress in our understanding of the arenaviruses in recent decades has primarily been driven by concern over the use of these agents as bioweapons [19, 117]. The focus has been largely in the realm of the laboratory and basic sciences, with promising developments in treatments and vaccines. However, much remains to be elucidated regarding arenavirus epizoology and epidemiology if improved prevention and control are to be achieved. The ultimate goal is to understand the complex epizoologic, epidemiologic, and ecologic interactions of arenaviruses and predict and prevent their emergence and increased incidence of disease. Significant barriers exist, including inadequate surveillance and lack of commercially available diagnostic reagents. Population-based, longitudinal studies in both humans and rodents are necessary to understand transmission dynamics, including reasons for patchy endemicity and seasonality, and the genetic and evolutionary relationships between viruses and reservoirs. However, the often remote and sometimes politically unstable endemic areas and the difficulty in securing long-term funding are significant challenges to long-term studies. Laboratory studies on precise modes of arenavirus transmission between rodents and humans are needed, especially the role of aerosol transmission. While logical in terms of biosafety and biosecurity, the BSL-4 and Select Agent status of many arenaviruses poses a significant impediment to research. Little attention has been paid to community control, including the efficacy of measures such as regular rodent trapping or the use of rodenticides, perhaps timed to coincide with the breeding season, rodent-proofing of homes, and the introduction of predators, such as cats. Interdisciplinary programs bridging human, animal, and ecosystem health and conservation offer further opportunities to understand ecosystem regulation of arenavirus transmission and how human alterations of the environment and biodiversity loss affect the risk of infection. Lastly, major challenges include global economic distress that threatens to blunt research funding, the lack of economic incentive to invest in research on agents that are primarily endemic in resource-poor regions of the world, and the relatively weak research and training infrastructure in developing countries that continue to experience loss of their scientists to more lucrative jobs elsewhere.

Acknowledgments The authors thank Andrew Bennett, Cecilia Gonzales, Barbara Ellis, Claudia Guezala, Maria Silva, Ruben Valle, and Landon Vom Steeg for assistance in preparing the manuscript.

Bunyaviruses: Hantavirus and Others

9

Alexander N. Freiberg, Dennis A. Bente,
and James W. Le Duc

1 Introduction

The *Bunyaviridae* family is the largest family of RNA viruses with more than 350 named isolates [70]. Viruses in the family are divided into five genera (*Orthobunyavirus*, *Phlebovirus*, *Nairovirus*, *Hantavirus*, and *Tospovirus*) on the basis of serological, molecular, antigenic, and structural characteristics. The *Bunyaviridae* are a unique group of viruses whose members are able to infect invertebrates, vertebrates, and plants, and they can be found worldwide. Multiple members are significant pathogens with the ability to cause severe disease in humans, such as encephalitis, hepatitis, or hemorrhagic fever. Most bunyaviruses are spread through sylvatic transmission cycles between susceptible vertebrate hosts and hematophagous arthropods, including ticks, mosquitoes, and phlebotomine flies. Unique are the members of the *Hantavirus* genus, in that they are not infecting insect vectors but are maintained in nature through persistent infection of rodents. Human and animal pathogenic bunyaviruses can be found in four of the five genera, with tospoviruses being plant pathogens. The large family of bunyaviruses is a pool not only for many emerging and reemerging viruses, such as Rift Valley fever virus, Crimean-Congo hemorrhagic fever virus, and the hantaviruses, but also for recently emerged pathogens, such as the newly identified severe fever with thrombocytopenia syndrome and Heartland, Shuni, and Schmallenberg viruses. This chapter will discuss the most important human pathogens of the *Orthobunyavirus*, *Phlebovirus*, *Nairovirus*, and *Hantavirus* genera.

2 Overview of the *Bunyaviridae* Family

2.1 Morphology and Morphogenesis

The morphological properties among the viruses in each of the five bunyavirus genera vary; however, in general, virions appear to have a spherical to pleomorphic morphology, with diameters ranging from 80 to 120 nm. Embedded in the lipid bilayered envelope are the two surface glycoproteins, Gn and Gc, which can be up to 10 nm in length and form protrusions or spikes. Recent structural studies have revealed that the two surface glycoproteins of phleboviruses form the so-called capsomeres (built by Gn/Gc heterodimers) and are arranged on an icosahedral lattice with a triangulation number of 12 [86, 112, 176, 204, 223]. For hantaviruses each glycoprotein spike complex is arranged in a square-shaped assembly with fourfold symmetry [19, 111]. In contrast to most other negative-strand RNA viruses, bunyaviruses do not contain a matrix protein, which facilitates the interaction between the surface glycoproteins and the ribonucleoprotein (RNP) core. It has been demonstrated that the cytoplasmic tails of at least one of the glycoproteins mimic the function of a matrix protein [177, 194, 224]. The virion envelope is usually derived from cellular Golgi membranes but can occasionally also be derived from the cell surface membrane and contains 20–30 % lipids. The membrane encloses the viral tripartite single-stranded negative-sense RNA genome. The viral genomic RNA segments are only found encapsidated by the nucleoprotein (N) in the form of RNP complexes and

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_9, © Springer Science+Business Media New York 2014

not as naked RNA molecules, indicating that encapsidation and RNA synthesis occur concomitantly. The RNA-dependent RNA polymerase (L) is associated with the RNP complexes and they display a helical symmetry. At least one of each of the three segments must be contained in a virion for infectivity. Virions contain 2–7 % carbohydrate by weight, and asparagine-linked sugars on the glycoproteins Gn and Gc are largely of the high mannose type when viruses are grown in vertebrate cells.

2.2 Biochemical and Physical Properties

Bunyavirus buoyant densities in sucrose and CsCl gradients are 1.16–1.18 g/cm^3 and 1.20–1.21 g/cm^3, respectively. The molecular mass of the virions ranges from 300 to 400×10^6 and have a sedimentation coefficient of 350–500 S. Treatment with lipid solvents or nonionic detergents results in loss of infectivity due to the removal of the envelope [173]. Bunyaviruses are also sensitive to heat and formaldehyde.

2.3 Genome Organization and Viral Proteins

All members of the *Bunyaviridae* share a common tripartite single-stranded negative-sense RNA genome. The three RNA molecules are designated as S (small), M (medium), and L (large) segments (Table 9.1). Each genome segment can be divided into three regions, the 3′ noncoding region (3′ NCR), coding region, and 5′ NCR. The terminal nucleotides at the 3′ and 5′ NCRs of each viral RNA segment are highly conserved and invertedly complementary to allow base pairing, resulting in stable panhandle structures and non-covalently closed circular RNAs [105]. These terminal sequences are conserved among viruses within each genus but are different to members in the other genera. The 5′ NCRs of the genomic viral RNA segments are not modified. Viral mRNAs are not polyadenylated and are truncated relative to the 3′ NCR of their genomic RNA counterpart. The 5′ ends of viral mRNAs have methylated caps and 10–18 non-templated nucleotides which are derived from host cell mRNAs. The NCRs do contain signals not only for the N protein encapsidation but also for the viral promoters, mRNA transcription termination, and probably the RNP-packaging signals [65, 81, 175, 258].

The four bunyavirus structural proteins (Table 9.2) are encoded in the complementary sense RNA of the three viral segments. All bunyavirus L segments use conventional negative-sense coding strategies and encode for the RNA-dependent RNA polymerase. The two envelope glycoproteins, Gn and Gc, are encoded in a single, continuous open reading frame (ORF) in the mRNA, and the primary gene products are then co-translationally cleaved to give mature Gn and Gc proteins (referring to the amino-terminal or carboxy-terminal coding of the protein). Orthobunya- and phleboviruses encode an additional nonstructural protein (NSm) in the virion-complementary-sense RNA. Nairoviruses encode two proteins of unknown function, a mucin-rich protein and glycoprotein GP38, which are the products of posttranslational cleavage of glycoprotein precursor preGn. The N protein is encoded on the S segment. Orthobunyaviruses and some hantaviruses encode a nonstructural protein (NSs) in an overlapping ORF to that encoding the N protein in the 3′ half of the virion-sense S RNA. Phleboviruses encode a NSs protein in an ambisense ORF in the 5′ half of the virion-sense S RNA. The NSs proteins of orthobunya-, phlebo-, and hantaviruses have been shown to act as interferon antagonists (reviewed in [131]). The NSm protein of phleboviruses can act as an apoptosis antagonist [196, 240, 262].

Table 9.1 Sizes of viral RNA segments in the bunyavirus genera (sizes are given in kb)

	RNA segment		
Genus and virus	S	M	L
Phlebovirus	1.7	3.5	6.4
Nairovirus	1.7	4.9	12.2
Orthobunyavirus	1.0	4.5	6.9
Hantavirus	1.7	3.6	6.5
Tospovirus	2.9	4.8	8.9

2.4 Antigenic and Genetic Properties

One or both of the envelope glycoproteins display hemagglutinating and neutralizing antigenic determinants. Complement-fixing antigenic determinants are principally associated with the N protein.

Table 9.2 Sizes of structural proteins in the bunyavirus genera (sizes are given in kDa)

RNA segment: viral protein	Genus				
	Phlebovirus	*Nairovirus*	*Orthobunyavirus*	*Hantavirus*	*Tospovirus*
S: N	24–30	48–54	19–25	50–54	52
M: Gn	50–70	30–45	29–41	68–76	52–58
M: Gc	55–75	72–84	108–120	52–58	72–78
L: L	238–241	459	259–263	246–247	330–332

Viruses with segmented genomes have the ability to expand their genetic diversity through (a) slow genetic drift (i.e., accumulation of individual point mutations) or (b) sudden genetic shift (i.e., new arrangement of whole genome segments in progeny viruses produced during a coinfection event). Genetic reassortment occurs in nature and in the laboratory by exchange of genomic segments and genetic relationships within the same serogroup and can affect pathogenicity of RNA viruses. Genetic reassortment between closely related bunyaviruses has been demonstrated in experimentally coinfected tissue culture cells and arthropod hosts but also by analysis of naturally occurring virus isolates [20, 26, 28, 43, 104, 140, 198, 201, 208, 212]. High-frequency reassortment can occur when arthropod vectors are infected simultaneously with two viruses. This can either happen in the same blood meal or through interrupted feeding, when blood meals are taken within a relatively close time window of each other [21].

2.5 Biological Properties

Members of the *Orthobunyavirus*, *Nairovirus*, and *Phlebovirus* genera have the capability of replicating alternatively in vertebrate and arthropod hosts. While they are not causing any cytopathic effects in their invertebrate hosts, cytolytic effects are generally observed in their vertebrate hosts. Arthropod vectors can be mosquitoes, ticks, sandflies, and phlebotomine flies, and transovarial and venereal transmission has been demonstrated. Hantaviruses are the exception, since they are the only rodent-borne bunyaviruses and are transmitted via the aerosol route of aerosolized rodent excreta. In contrast to other bunyaviruses, hantaviruses routinely establish a persistent, non-cytolytic infection in susceptible mammalian host cells, primarily in endothelial cells. This observation is consistent with their nonpathogenic persistence in their natural rodent host.

3 The Viruses

3.1 *Orthobunyavirus* Genus

The *Orthobunyavirus* genus is the largest of the five genera within the *Bunyaviridae* family and contains more than 170 named viruses, including medically important viruses, such as Oropouche, La Crosse, and Jamestown Canyon viruses. Viruses within this genus are grouped into 18 serogroups (Anopheles A, Anopheles B, Bakau, Bunyamwera, Bwamba, Group C, Capim, California, Gamboa, Guama, Koongol, Minatitlan, Nyando, Olifanstlei, Patois, Simbu, Tete, and Turlock). This classification is based on serological studies, using neutralization, hemagglutination inhibition, and complement fixation assays, and each serogroup contains viruses that are antigenically distinct but related.

At least 30 members of the *Orthobunyavirus* genus have been associated with human disease, causing a range of symptoms such as encephalitis, hemorrhagic fever, or febrile illness. In livestock, orthobunyavirus infections are mainly associated with abortions or teratogenic effects.

The majority of the orthobunyaviruses are arthropod-borne viruses and have amplification cycles in a variety of vertebrate hosts. Infection of the different species can result in fundamentally different outcomes for the host cells. Mosquitoes (and derived cell lines) are persistently infected and shed virus.

3.1.1 Oropouche Fever

Oropouche virus (OROV) is a member of the Simbu serogroup and the causative agent of Oropouche (ORO) fever, an urban febrile arboviral disease widespread in South America [193]. OROV was first isolated in 1955 in Trinidad and Tobago from the blood of a febrile forest worker from a pool of *Coquillettidia venezuelensis* mosquitoes and named after the Oropouche River [8, 134]. Recurrent epidemics have involved tens of thousands of patients and are economically significant, owing to loss of working hours. Over the past 50 years, ORO fever has emerged as a major public health problem in tropical areas of Central and South America [11]. OROV is transmitted by culicoid midges and humans develop a high viremia for an orthobunyavirus infection, such that uninfected midges can acquire the virus after biting [101].

Descriptive Epidemiology

Members of the Simbu serogroup are distributed globally and transmitted by biting midges (*Culicoides*). Since the original isolation of OROV from a febrile patient in Trinidad and Tobago in 1955, the medical importance of the virus, particularly in the Amazon basin regions of northern Brazil and Peru, has become increasingly evident [193]. OROV has been shown to be associated with more than 30 epidemics reported in Brazil, Peru, Panama, and Trinidad and Tobago during 1960 and 2009, with more than 500,000 persons estimated to be infected [193, 202]. Most of these outbreaks occurred in relatively urban areas, leading to the suggestion that OROV is maintained in two distinct cycles, an epidemic urban and a silent sylvatic cycle [61, 200]. High antibody prevalence in populations in endemic areas suggests that human infection can be common in such areas [12, 202, 257]. The principal urban vector in Brazil appears to be the tiny biting midge, *Culicoides paraensis* [190, 200]. Isolates have also been made from mosquitoes such as *Culex pipiens quinquefasciatus*, but its vector competence is poor [61, 107]. The favorite larval breeding habitats of *C. paraensis* midges are rotting banana tree stumps and cacao husks [192]. These decomposing plant materials remain moist even during dry

periods and serve as an excellent growth medium for the microorganisms on which the *C. paraensis* larvae feed. Adult midges feed predominantly in the early evening hours and are quite anthropophilic. It is assumed that humans entering the jungle become infected with OROV and develop viremia sufficiently high to transmit the virus to uninfected midges and appear capable of serving as the vertebrate amplifying host during the urban cycle [192]. When they return to their village or town, temporary urban transmission can occur, resulting in an epidemic. Serological data also suggest that forest animals (primates or sloths or even birds) may be potential vertebrate hosts in the sylvatic cycle. Factors such as deforestation, urbanization, and agricultural development are probably contributing to the emergence of ORO fever as a human pathogen in South America. Phylogenetic studies indicate that distinct OROV genotypes are present in different geographic areas: Genotype I viruses include the prototype strain from Trinidad and Tobago and Brazilian strains from the states of Acre, Amazonas, Maranhão, Tocantins, and Pará; Genotype II contains the Peruvian strains isolated between 1992 and 1998 and strains from the Brazilian states of Amapá, Pará, and Rondônia; Genotype III includes virus strains isolated in Panama and the Brazilian states of Acre, Minas Gerais, and Rondônia; and Genotype IV is formed by the Brazilian strains isolated in Amazonas state [11, 171, 207, 250, 251].

Clinical Features

Several thousand cases of acute febrile illness can occur during OROV epidemics observed throughout the Amazon basin regions of Brazil and Peru. Humans acquire the infection by bite from infected midges. In addition to large outbreaks, OROV can also cause sporadic infections in humans [243]. The incubation period is approximately 4–8 days, followed by an abrupt onset of fever, with arthralgia, generalized myalgia, anorexia, nausea, vomiting, weakness, dizziness, severe headache, chills, photophobia, and prostration. Occasionally, ORO fever patients also exhibit rash, meningitis, or meningismus [161, 191]. Most of the symptoms resolve within 3–5 days, although a period of asthenia, myalgia, and dizziness may persist for up to 9 months. Viremia is detectable in the majority of patients 2–3 days post onset of illness. No fatalities have been reported with the disease, and lifelong immunity follows recovery. Approximately half of the patients can exhibit recurrence of some disease symptoms 1–10 days after they become afebrile [252]. A recent study identified the presence of OROV in the cerebrospinal fluid of three samples from 110 meningoencephalitis patients, demonstrating the involvement of the central nervous system in OROV infections (Bastos et al. [17]). Two of the three patients presented with other diseases affecting the immune system and central nervous system (HIV and neurocysticercosis). The findings suggest that OROV should be investigated in cases of meningoencephalitis of unknown etiology in affected areas and that previous blood-brain barrier damage might facilitate the entry of OROV into the central nervous system. OROV is also suspected to be infectious by aerosol, based on reported laboratory infections [190].

Diagnosis

The diagnosis of OROV is performed by virus isolation from the blood of infected patients and by serological assays. The serological response is strongest in the acute phase against the N protein, and recombinant expressed N protein has been used to develop an enzyme immunoassay for the diagnosis of ORO fever [206]. Further, RT-PCR-based assays are available for the detection of OROV [158, 259].

Treatment and Prevention

There is no specific treatment for ORO fever and the disease is normally self-limiting. However, treatment of symptoms with anti-inflammatory drugs might be recommended. This consists of drinking plenty of fluids to prevent dehydration, as well as prescribing pain analgesics. A recent study indicated that ribavirin does not have antiviral activity on OROV [144]. With the ORO fever disease in Brazil and Peru, avoiding the buildup of rotting organic debris such as banana tree stalks or cacao husks in agricultural areas may help curtail population levels of *C. paraensis* and reduce the risk of seasonal epidemics [192]. Avoiding exposure (treated netting, DEET repellents) to these midges during their early evening feeding hours is also recommended.

3.1.2 California Serogroup

The California serogroup has great relevance from a human infection perspective, as they have been associated with influenza-like illness in central Europe and are an important cause of encephalitis in the United States. Other members of the genus are of veterinary importance. The California serogroup includes 14 viruses and subtypes. All members of the group are transmitted by mosquitoes. Although serological studies and analysis of genomic sequences have demonstrated their relationship, each virus is only prevalent in a specific geographic area delimited by the presence of its mosquito vector and mammalian host. Hammon and Reeves isolated California encephalitis virus from *Aedes melanimon* mosquitoes in 1943 in Kern County, California [100, 199]; serological studies subsequently showed high incidence of seropositivity. Nevertheless, California encephalitis virus has not been recently implicated with any human disease in California [199]. California serogroup viruses sequentially replicate in striated muscle, cause viremia, and invade and replicate in the central nervous system causing encephalitis in their mammalian hosts. Each of these viruses has a limited geographic range, and members have been isolated from several continents including North and South America, Europe, and Africa.

La Crosse Virus

In 1960, La Crosse virus (LACV) was isolated from a fatal case of a 4-year-old girl who suffered encephalitis in La Crosse, Wisconsin [245]. LACV was shown to be closely related but distinct from California encephalitis virus, and it was quickly recognized as an important virus causing human infections over a wide area of the Midwestern United States. Testing mosquitoes and more widespread serological diagnosis of individuals with encephalitis identified a number of other arboviruses that were related to California encephalitis virus and LACV, and together these were designated as the California serogroup.

Descriptive Epidemiology

Approximately 80–100 cases of LACV encephalitis occur every year; however, the disease is gravely underreported and underdiagnosed. The disease is primarily reported in the upper Midwestern states (Minnesota, Wisconsin, Iowa, Illinois, Indiana, and Ohio) from late spring through early fall; however, infrequently cases are also reported in winter in the Gulf states. Recently, more cases have been reported from mid-Atlantic and southeastern states (West Virginia, Virginia, Kentucky, North Carolina, and Tennessee) [99]. LACV is transmitted to humans through the bite of an infected mosquito. LACV is maintained in nature by infections of two alternate hosts: mosquitoes and small mammals, particularly chipmunks and squirrels. The main vector is a woodland mosquito, *Aedes triseriatus* (the eastern tree hole mosquito), which preferably breeds in tree holes and in discarded tires and feeds during the day [133]. In the United States, *Aedes triseriatus* is present in areas east of the Mississippi River, where numbers peak from June through September [57]. *Aedes albopictus*, a mosquito introduced into the United States from Asia, has been shown to be a competent vector, at least in experimental studies. LACV can be transmitted transovarially to the next generation or venereally from infected males to uninfected females [22]. In endemic areas, a high proportion of chipmunks and squirrels have been found to be seropositive. Studies have shown that these two species generate high enough viremia levels to subsequently infect mosquitoes after feeding on the experimentally infected animals [267]. Incidence of California serogroup virus neuroinvasive disease has ranged from fewer than 40 to over 160 cases per year since 1964. The highest numbers of cases reported are from Ohio, West Virginia, Wisconsin, and North Carolina, with an average annual incidence above 1.0 per 100,000 population in some endemic counties ([98]; www.cdc.gov/lac/tech/epi.html, accessed Sept 2012).

Clinical Features

LACV causes acute encephalitis preceded by a nonspecific febrile illness [47]. Based on experimental studies it is estimated that the incubation period ranges between 6 and 15 days. After mosquito bite, multiplication probably occurs in vascular endothelial and reticuloendothelial cells; dissemination occurs in the blood and lymph [203]. The symptoms of the central nervous system disease include stiff neck, lethargy, nausea, headache, and vomiting in milder cases and seizures, coma, paralysis, and permanent brain damage in severe cases. Severe disease occurs most commonly in children under the age of 16. Death from LACV encephalitis occurs in less than 1 % of clinical cases. A small proportion of patients may develop persistent paresis or learning disabilities and other cognitive deficits [203]. The cerebrospinal fluid demonstrates elevated protein in 20 % of the cases. Unlike most viral encephalitis, many of the cells found in the cerebrospinal fluid are polymorphonuclear neutrophils [97].

Diagnosis

Diagnosis is based on clinical features and patient exposure history. Laboratory testing is available in many state or local public health laboratories and in some referral hospitals and is accomplished by testing serum or cerebrospinal fluid to detect virus-specific IgM antibodies. Virus may also be detected by nucleic acid amplification and in fatal cases by histopathology and virus-specific immunohistochemistry. Virus isolation may also be useful.

Treatment and Prevention

There are no vaccines against LACV infection or specific antiviral treatment. Treatment is supportive. Prevention is based on avoidance of vector mosquitoes through use of insect repellants, wearing protective clothing, keeping screens in good repair, and effective vector control.

3.1.3 Ngari Virus

An orthobunyavirus, originally designated Garissa virus, was isolated from human hemorrhagic fever cases during a large disease outbreak in 1997 and 1998 in East Africa (Kenya and Somalia) [28]. The disease was characterized by acute onset of fever and headache, followed by hemorrhage (with gastrointestinal and/or mucosal bleeding). During the investigations, a previously unidentified orthobunyavirus was isolated from two hemorrhagic fever cases. The genetic analysis of fragments of the virus S, M, and L genome RNA segments revealed that the virus was subsequently recognized as being the same as the previously identified Ngari virus and characterized as a naturally occurring reassortant between Bunyamwera virus (S and L segment donor) and Batai virus (M segment donor) [30, 93]. Interestingly, these two viruses do not cause a hemorrhagic febrile illness. During the outbreak in 1997–1998, an estimated 89,000 human infections occurred with over 250 deaths. Of 231 febrile patients for which clinical records existed, half met the case definition of hemorrhagic fever [28]. Initially, it was thought that the

hemorrhagic fever outbreak was associated with Rift Valley fever virus (RVFV) infections [263], a human pathogenic phlebovirus endemic in Africa. Of the hemorrhagic fever cases, 23 % had evidence of acute RVFV infection, whereas 27 % had evidence of acute Ngari infection.

3.2 *Phlebovirus* Genus

The genus *Phlebovirus* comprises over 70 antigenically distinct serotypes, which are divided into two groups, the *Phlebotomus* fever viruses (sandfly group, transmitted by sandflies) and the Uukuniemi group (transmitted by ticks). Eight of these serotypes contain viruses known to cause disease in humans (Alenquer, Candiru, Charges, Naples, Punta Toro, Rift Valley fever, Sicilian, and Toscana viruses). Recently, two new human pathogenic tick-borne phleboviruses have been identified, severe fever with thrombocytopenia syndrome virus and Heartland virus [152, 266].

3.2.1 Rift Valley Fever Virus

Rift Valley fever virus (RVFV) is a member of the genus *Phlebovirus*, endemic in sub-Saharan Africa and introduced to Egypt and the Arabian Peninsula periodically. It is the causative agent of the mosquito-borne disease Rift Valley fever (RVF) in humans and ruminant animals. Infections with RVFV generally result in self-limiting febrile disease but can also manifest in more severe illness, such as hemorrhagic fever, encephalitis, or retinitis. Currently, there is no commercially available vaccine for human use.

Descriptive Epidemiology

The geographic distribution of RVFV covers much of Africa, ranging from Egypt to South Africa and from Senegal to Madagascar. The first confirmed outbreak of RVFV outside Africa was reported in 2000 in Saudi Arabia and Yemen [3, 255]. RVFV has the potential to infect a remarkable number of different vectors, including mosquitoes, ticks, and flies. However, mosquitoes, especially floodwater *Aedes* mosquitoes, are thought to be the principal vector and play an important role in RVFV epizootics, which frequently occur at times of unusual high precipitation [141]. In general, the vectors can be classified into two groups: (1) reservoir vectors (*Aedes* species (spp.)) and (2) amplifying vectors (*Culex* spp.) [82, 83, 91]. RVFV persists in the environment through vertical transmission in mosquitoes and horizontal transmission by mosquitoes among animals [174]. Dambos are thought to play a central role because they flood during heavy rainfall. During interepidemic periods RVFV was isolated from unfed mosquitoes, demonstrating that the virus can be maintained between epidemics through transovarial transmission in mosquitoes [142]. Heavy rainfall and flooding increases the hatching of eggs and explosive population growth in floodwater *Aedes* mosquitoes [234], which can initiate an epizootic leading to viremic livestock that then act as amplifying hosts and a source of the virus for feeding mosquitoes [234]. Once livestock is infected, the classical hallmark of RVF epizootics is the large number of abortions observed among pregnant ruminants. Usually 1–2 weeks after these abortions, initial human infections can be detected, especially in groups that are in close contact with livestock, such as farmers, veterinarians, and abattoir workers. RVFV infection can be acquired either through the bite from an infected mosquito or more importantly through direct contact with infected livestock. People involved in the birth or abortions of livestock, butchering process of animals, or abattoir workers are at high risk of infection during epizootics [2, 39]. Aerosol exposure has been demonstrated to be another potential route of infection, especially in a laboratory setting [14, 31, 84, 109, 159, 160, 229].

Clinical Features

RVFV is one of the most severe human pathogen among the phleboviruses and infections can result in a wide range of clinical features, varying from an asymptomatic (30–60 %), to a weeklong undifferentiated febrile illness, to the severe development of hemorrhagic fever, encephalitis, retinitis, and potentially death (the overall case fatality rate is estimated to be between 0.5 and 2 %). The most frequent course of the disease is a self-limiting febrile illness; less than 2 % of human infections result in severe disease (hemorrhagic fever, encephalitis, or retinitis). During the 1977–1978 outbreak in Egypt, approximately 200,000 human cases with 600 deaths were estimated to have occurred [153], and an estimated 27,500 RVFV infections occurred during the 1997–1998 outbreak in the Garissa district of Kenya [263].

Infected patients can develop a mild form of RVF, which is characterized by a feverish syndrome with a sudden onset of flu-like fever, muscle pain, joint pain, and headache. Additional symptoms can include neck stiffness, photophobia, loss of appetite, and vomiting. These symptoms normally last from 4 to 7 days. However, in a small percentage of patients, the development of one or more of the three distinct syndromes can occur: ocular disease (0.5–2 %), meningoencephalitis (less than 1 %), or hemorrhagic fever (less than 1 %). Ophthalmologic complications remain very important sequelae of human RVF disease and can result in long-lasting visual disturbance in affected patients [129]. It has also been described that in its most severe form, RVF can lead to acute renal dysfunction [69].

A majority of RVF patients suffer from a self-limiting and mild to often subclinical febrile illness, with an incubation time of typically 4–6 days [55, 80, 119, 147, 162, 232]. Symptoms typically include severe chills, weakness, malaise, throbbing headache, and dizziness [80, 120]. Further, the development of a sensation of fullness over the liver region

has been described [80]. Following these symptoms, patients present with fever, decreased blood pressure, proximal large-joint arthralgia (particularly shoulders, elbows, and knees), and anorexia followed by nausea and vomiting. A lowering of the body temperature can be observed between the 3rd and 4th day after onset of symptoms, which then returns back to a normal level. However, some patients can either maintain their fever as long as 10 days, or within 1–3 days after the recovery, a recurrence of high fever can be observed [80, 162]. This biphasic febrile phase is normally combined with a severe headache. During the febrile period, viremia can be detected, as well as neutralizing antibodies, which appear around day 4 after onset of symptoms [80, 205]. Patients can also develop a massive coronary thrombosis after the febrile phase [162, 219].

Patients who develop one of the severe forms of RVF (jaundice, hemorrhagic fever, or neurological disease) are at increased risk of fatality [130, 147]. Hemorrhagic manifestations are typically characterized by a sudden onset of illness, including fever, throbbing headache, lethargy, malaise, vomiting, nausea, vague mid-epigastric discomfort, and body pain. Further, these patients may present with a low blood pressure, hematemesis, diarrhea, jaundice, macular rash over the entire trunk, subconjunctival hemorrhage, and bleeding from the gums and/or gastrointestinal mucosal membrane [120, 237, 264]. Elevated aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and alanine aminotransferase (ALT) and reduction of platelet count and hemoglobin level are typical [5, 237]. Death can occur within 3–17 days after onset of these symptoms, and fatal RVF cases show diffuse hepatic and gastrointestinal necrosis [1, 237].

RVF patients developing encephalitis may present with a sudden onset of fever, rigor, retro-orbital and throbbing headache, mild arthralgia of the knees and elbows, and bilateral retinal hemorrhage [6, 120, 145]. After onset of the illness, patients eventually experience neck rigidity, confusion, hypersalivation, fatigue, malaise, stupor, and coma, and temporal or permanent vision loss has been described as well [6, 145, 249]. Indicative of a possible development of meningitis or meningoencephalitis was the increased number of white blood cells (mainly lymphocytes) in the cerebrospinal fluid (CSF). Patients with a developing RVF-induced encephalitis can also present with a decreased level of consciousness [6]. Histopathological lesions in the brains of these patients were characterized by focal necrosis associated with infiltration of lymphocytes and macrophages and perivascular cuffing [249].

As described previously, in some cases, RVF patients can develop a maculopathy or retinopathy (0.5–2 %), which can affect either one or both eyes and can occur either very early or months after infection [59, 210, 228]. Patients reported to experience a blurry vision and noticed floating black spots within their visual fields or even the loss of central vision. While in some cases a partial improvement in vision over time is established [210, 218, 226, 227], in many patients, no complete recovery of vision occurred and chorioretinal scarring remained in macular and paramacular areas [4, 10, 59, 85, 210, 226, 227].

While there is much documentation of the symptoms of severe RVF illness, much more work is still needed to better describe specific manifestations of RVF in humans. This will be necessary to allow clinicians to recognize the disease in its early stages and to be able to limit and ultimately prevent its spread.

Diagnosis

RVFV belongs to a large group of RNA viruses endemic in Africa, which have the potential to cause viral hemorrhagic fever (VHF), including Lassa, Ebola, Marburg, Crimean-Congo hemorrhagic fever, and yellow fever viruses. Infections by RVFV and other VHF viruses are clinically difficult to recognize, if no hemorrhagic or specific organ manifestations are present. Diagnosis of RVFV infection is often performed by combining the analysis of clinical signs of disease and available diagnostic testing. RVF may be suspected when there is an occurrence of abortions in domestic ruminants and death of young animals, associated with an outbreak of febrile illness in human with headache and myalgia. In the laboratory, the diagnosis of RVF is achieved by a variety of techniques, such as virus isolation from whole blood, serum, or tissue samples [7]; viral antigen detection [154, 168]; detection of specific antibodies [138]; and amplification of viral nucleic acids [64, 89, 115], which are preferable due to the rapid and reliable analysis of samples for RVFV. Multiplexed PCR, reverse transcription (RT)-PCR enzyme hybridization assays, quantitative (q)RT-PCR, and real-time detection PCR are very useful techniques, since detection can be performed simultaneously for many hemorrhagic fever viruses [25, 64, 89, 102, 115, 211]. Further, the real-time RT-loop-mediated isothermal amplification (RT-LAMP) assay demonstrated its practicability in a field laboratory, since it does not rely on thermocycler equipment and only requires a one-step, single-tube reaction [132, 188]. To prevent potentially false-negative results due to the rather short viremic phase during which RVFV genomes can be detected, diagnosis should be combined with the detection of RVFV-specific antibodies. Viral antigen (such as the RVFV nucleoprotein) can rapidly be detected in blood and tissue samples by the use of immunohistochemistry staining of tissue samples or enzyme-linked immunosorbent assays (ELISA) [117, 154, 168, 268]. Shortly after exposure to RVFV, serological tests, such as detection of type-specific IgG and IgM antibodies, can also be performed [182, 183, 185, 186]. Additional serodiagnostic tests for the detection of RVFV are hemagglutination inhibition, indirect immunofluorescence, and virus neutralization test (VNT)

[184, 185, 239]. However, VNT as a diagnostic tool has to be handled with care, because RVFV induces a long-lasting neutralizing immunity and previously infected individuals will also give a positive result.

Treatment and Prevention

Currently, no licensed vaccines and specific treatments are available for RVF in humans. Studies in monkeys and other animal models for RVF infection have demonstrated promise for ribavirin as an antiviral drug for future use in humans [187]. However, ribavirin might have unexpected side effects. Further, studies have suggested that interferon, immune modulators, and convalescent-phase plasma may also help in the treatment of patients with RVF [187].

A formalin-inactivated vaccine (TSI-GSD-200) is the only RVFV vaccine presently available for use in humans [195] but, currently, only for military personnel, veterinarians working in endemic areas, high-containment laboratory workers, and others at high risk for contracting RVFV. Another strategy of controlling RVF outbreaks is vaccination of livestock to prevent epizootics. The currently used live Smithburn vaccine is only partially attenuated and leads to high abortion rates or teratology (10–25 %) of pregnant animals [50, 121, 235] and exhibits pathogenicity in European cattle [27]. In addition, the risk of reversion to full virulence precludes its use in countries where RVFV is not known to be endemic [235]. A live attenuated vaccine (RVFV MP-12) is efficacious in livestock. However, RVFV MP-12 may have similar safety concerns associated with the Smithburn strain, since RVFV MP-12 can be teratogenic in sheep [114]. RVFV MP-12 was recently tested in human clinical trials, to determine adverse effects in humans using a single injection dose, with promising results [24]. A 95 % seroconversion rate was reported with a high titer in a plaque reduction neutralization test. In addition, a genetic analysis of RVFV MP-12 isolated from vaccinated individuals showed no reversions of vaccine virus in attenuated regions compared to wild-type RVFV. Overall, many promising RVFV vaccines (including subunit and DNA vaccines, as well as viruslike particles) and therapeutic concepts are currently employed to generate an urgently needed safe and efficacious countermeasure against RVFV.

Infection with RVFV can be prevented by decreasing the chance of contact with mosquitoes and other bloodsucking insects through the use of mosquito repellents and bed nets. An important protective measure for persons working with animals in RVF-endemic areas is avoiding exposure to blood or tissues of animals that may potentially be infected.

3.2.2 Sandfly Fever Viruses

Sandfly fever viruses are transmitted in the Mediterranean area by the sandflies *Phlebotomus papatasi, P. perniciosus* and *P. perfiliewi*. Human infections with Naples and Sicilian sandfly fever viruses cause self-limiting disease of unknown epidemiology. However, infection with Toscana virus is the third most frequent cause of aseptic meningitis between May and October in central Italy, where it was originally isolated from sandflies in 1971. Toscana virus has since been detected in many countries close to the Mediterranean area, such as France, Spain, Slovenia, Greece, Cyprus, and Turkey. In all Mediterranean countries Toscana virus should be included in the differential diagnosis of viral meningitis during the warm summer season.

Descriptive Epidemiology and Clinical Features

Toscana Virus

Toscana virus (TOSV) is an arthropod-borne bunyavirus, which is transmitted to humans by *Phlebotomus*, *Sergentomyia*, and *Lutzomyia* genera, in particular by *Phlebotomus perniciosus* and *P. perfiliewi*. The virus was isolated in 1971 from *P. perniciosus* in Monte Argentario (Tuscany) [235–255], but it was first recognized as a causative agent of neurological disease in humans only in 1983, when it was isolated for the first time from a young woman with lymphocytic meningitis [167]. Transmission of the virus occurs transovarially in the insect vectors, and it has been suggested that the reservoir of TOSV is most likely the vector itself. However, a progressive decline of vector infected rates over many generations suggests that TOSV cannot be maintained exclusively by vertical transmission [48, 49, 242], but its animal reservoir has not been identified yet. TOSV isolation from the brain of an insectivorous bat (*Pipistrellus kuhlii*) has so far been the only evidence of the possible involvement of this species in the ecology of the virus [49, 254, 255].

TOSV is the major cause of aseptic meningitis (95 %) and meningoencephalitis (4.5 %) and influenza-like illness during the summer season, with a peak of incidence in August [103, 214]. Most cases of the TOSV infections have been reported in either residents or travelers in central Italy or Spain. However, over the last years, an increased number of cases have also been recorded in other countries in the Mediterranean area, such as Portugal, France, Cyprus, Turkey, and Greece [67, 179, 189, 213, 215]. It has also been described that TOSV can result in asymptomatic infection and infection without involvement of the central nervous system, such as febrile erythema or influenza-like illness [103, 197]. Recent reports of TOSV infections included unusual clinical manifestations or severe sequelae, such as hydrocephalus, epididymo-orchitis, and ischemic complications [13, 103, 150, 197, 213].

Serological analysis conducted in Italy (particularly in Tuscany) revealed a TOSV seroprevalence of 77.2 % in forestry workers, compared to 22.7 % of seropositivity in the urban population [247]. Moreover, this serological analysis underlined the presence of asymptomatic infections of TOSV in exposed people. Preexisting immunity also seems to play

an important role in limiting TOSV-caused illness, and cases with reinfection have not been detected so far [52, 53].

A recent retrospective study on the antibody prevalence rates of TOSV among adults and children was performed in a population (n=2,737) living in Tuscany during 1999 to 2006 [241]. This study revealed that the seroprevalence rate was 19.8 % in adults and 5.8 % in children, showing an age-dependent increase in TOSV-specific immunity. Furthermore, the study indicated that asymptomatic TOSV infection is more frequent in young people (91 %) than in adults (31.4 %). A correlation of the seroprevalence to the clinical profile showed that a higher incidence of severe signs of neurological disorders was found in adults, but it is still unclear why this occurs.

Interestingly, a seroprevalence study conducted in volunteer blood donors in France showed that 12 % of sera from healthy donors and 18.9 % of sera from patients hospitalized for CNS infection were IgG positive for TOSV. These findings confirmed that TOSV circulates in southeastern France and that a significant proportion of healthy blood donors have a history of TOSV infection [56]. This indicates that a potential risk of transmitting the virus to naïve subjects is possible and can raise concerns about potential implications for blood donors.

Sandfly Fever Sicilian and Naples Viruses

The sandfly fever Sicilian virus (SFSV) and sandfly fever Naples virus (SFNV) serotypes have the widest geographic distribution which is related to the distribution of the vector (*P. papatasi*), and these viruses have been isolated from sandflies in Africa, Central Asia, and Europe [18, 51, 54, 60, 79, 116, 128, 179, 209, 244]. Serological investigations performed on the indigenous populations and tourists visiting temperate regions demonstrated that sandfly activity normally peaks during the summer months when the human population in these areas is exposed to sandfly-transmitted diseases [32, 40, 62, 66–68, 71, 72, 113, 231]. SFSV and SFNV were first described in Italy in 1943–1944 during outbreaks of influenza-like illness in US soldiers [244].

SFSV and SFNV cause the so-called 3-day fever or pappataci fever. Infected patients present with influenza-like symptoms, including fever, myalgia, malaise, and retro-orbital pain [29, 256]. Usually, these patients recover fully within 7 days. Even though infections with these viruses are mild and self-limiting, patients are highly incapacitating during the course of the illness.

Newly identified SFVs include the sandfly fever Turkey virus [33, 127], which is an SFSV variant; Punique virus, a related virus to SFNV [273]; and Massilia virus, which is a new member of the SFNV complex [41].

Diagnosis

The direct diagnosis of SFVs can be performed by virus isolation or RT-PCR from the blood or CSF but is only possible during early stages of infection (i.e., within the first 2 days after onset of symptoms and before the IgM seroconversion occurs). In most cases, the diagnosis is based on serological investigation of acute and early convalescent sera. ELISA for the detection of SFV antigen can be performed in reference laboratories. Within the SFSV and SFNV antigenic complexes, serological cross-reaction exists. VNT using early convalescent sera still remains the reference method to specifically identify the viruses or to assess the antibody response specificity.

Treatment and Prevention

There is no specific therapeutic available for infections with SFV and treatment is symptomatic. Individual protective measures such as insect repellents and insecticide-impregnated mosquito bed nets are recommended.

3.2.3 Severe Fever with Thrombocytopenia Syndrome Virus (SFTSV)

Recently, a new member of the *Phlebovirus* genus has been identified in China (Hubei and Henan provinces), after a heightened surveillance of acute febrile and life-threatening illness in China. The novel virus was isolated from patients who presented with fever, thrombocytopenia, leukocytopenia, and multiorgan dysfunction and termed severe fever with thrombocytopenia syndrome virus (SFTSV) [266]. The clinical symptoms were initially considered to resemble those of human anaplasmosis [270]; however, neither bacterial DNA nor antibodies could be detected in blood samples.

Descriptive Epidemiology

The majority of affected patients were farmers living in wooded and hilly areas, and they were working in the fields before onset of clinical signs of disease. SFTSV RNA was detected in ticks of the Ixodidae family (species *Haemaphysalis longicornis*) that were collected from domestic animals where the patients lived, and these ticks may be a candidate vector for SFTSV. High seroprevalence of SFTSV was detected among goats (up to 83 %) and cattle (up to 32 %) but also in pigs (up to 5 %), dogs (up to 6 %), and chicken (1 %) in SFTSV-endemic regions [272]. SFTSV caused cytopathic effect in DH82 cells after inoculation with white blood cells isolated from a 42-year-old patient were subsequently isolated. In cell culture, SFTSV can infect a variety of cells, such as Vero E6, Vero, and L929 cells; however, cytopathic effect could only be detected in DH82 cells. Phylogenetic analysis of six isolated SFTSV strains indicated that all isolates cluster together and that they were nearly equidistant from the sandfly fever group and the Uukuniemi group, suggesting that SFTSV is the prototype of a third group within the genus *Phlebovirus*.

Clinical Features

The major clinical symptoms include fever (temperatures of >38 °C), fatigue, conjunctival congestion, thrombocytopenia (platelet count of <100,000 per cubic millimeter),

gastrointestinal symptoms, abdominal pain, diarrhea, proteinuria, hematuria, and leukopenia. Frequently, regional lymphadenopathy was observed. In most patients, multiorgan failure develops rapidly, indicated by elevated levels of AST, ALT, CK, LDH, and CRP [58, 88]. The appearance of CNS symptoms (including apathy, lethargy, convulsions, muscular tremor, and coma) as well as hemorrhagic fever (bleeding from the mouth mucosa, lungs, and gastrointestinal lumen) has been described [87, 88, 266, 269]. Dynamic profiling of laboratory findings in SFTS patients showed that clinical progression of the disease occurs in three stages [88]. The first stage or fever stage (days 1–7 after onset of illness) is characterized by marked thrombocytopenia and leukopenia and low platelet counts and peripheral white blood cell counts. Lymphocyte levels substantially decrease during the first 9 days, suggesting that these cells are mainly involved in leukopenia. Coagulation tests indicated that prolonged aPTT occurred on days 5–9. Cardiac and liver enzymes, such as ALT, AST, LDH, CK, and CK-MB, were elevated, indicative for heart and liver impairment. The second stage (or multiorgan dysfunction stage) of the disease is defined to occur between days 7 and 13 after disease onset and characterized by development of multiorgan dysfunction. In survivors viral load decreases, while it remains elevated (up to 10^8 viral RNA copies/mL) in patients with fatal outcome. Further, in fatal cases, platelet counts continued to decline, and serum tissue enzymes further increased, reaching maximum levels before death. A recent study by Deng and colleagues analyzed the cytokine and chemokine profile in 57 patients and found that levels of TNF-α, IP-10, and IFN-γ were elevated in patients with severe disease [58]. These findings suggest that a cytokine-mediated inflammatory response, mediated through an imbalance in cytokine and chemokine production, might result in a severe disease progression. The third stage or convalescent stage describes the recovery phase for surviving patients after day 13 and is characterized by the return of clinical parameters to normal physical levels. In summary, the key risk factors contributing to a patient's death have been identified as increased viremia; elevated AST, ALT, LDH, CK, and CK-MB levels past the fever stage; and the appearance of CNS symptoms and manifestation of hemorrhagic tendency, DIC, and multiorgan failure. The average case fatality rate is 12 % but can be as high as 30 % [266].

Initially, no epidemiologic evidence of human-to-human transmission of SFTSV was detected [266]. However, recent publications indicated that the virus can be transmitted from person-to-person through personal contact with the index patient, while no exposure to suspected animals or vectors was reported [16, 87, 143].

Diagnosis

Direct diagnosis of SFTSV RNA in patient serum can be performed by real-time PCR from the blood or by quantitative real-time RT-PCR assay [233]. Patient sera can also be tested for the presence of antibodies to SFTSV by indirect fluorescence assay (IFA), and sera reactive at a dilution of ≥1:64 were considered to be positive [143]. Virus neutralization assays (modified microneutralization assay) can be performed to detect IgG-specific antibodies to SFTSV [16, 266]. High levels of neutralizing antibodies are generated during the convalescent phase of the illness.

Treatment and Prevention

There is no specific treatment available for infections with SFTSV. Clinical management is directed toward a symptomatic treatment. Individual protective measures such as insect repellents and avoidance of areas where ticks may be common are recommended.

3.2.4 Heartland Virus

Recently, a new pathogenic phlebovirus has been identified in northwestern Missouri (USA), named the Heartland virus. Two patients were independently hospitalized in 2009 with fever, diarrhea, headache, anorexia, nausea, elevated hepatic aminotransferase levels, thrombocytopenia, moderate neutropenia, and leukopenia [152]. Both patients were bitten by ticks approximately 5–7 days prior to onset of signs of illness. After discharge from the hospital, both patients reported fatigue and difficulties with short-term memory. Blood was negative for *Ehrlichia* and *Rickettsia* and electron microscopy identified viruses isolated from patient leukocytes to be consistent with members of the bunyavirus family. Next-generation sequencing then revealed that the viruses were new members of the genus *Phlebovirus*. Isolates from both patients were highly identical, indicating that both patients were infected independently with the same virus strain. Further, phylogenetic analysis identified that the Heartland virus is closely related to the recently identified tick-borne phlebovirus SFTSV in China [266]. Interestingly, serum samples were strongly positive for IgG antibodies 2 years after the onset of illness. Future studies will need to be performed to identify the vector and potential hosts of Heartland virus, as well as epidemiologic and ecological studies.

3.3 *Nairovirus* Genus

The *Nairovirus* genus was named after Nairobi sheep disease, an acute hemorrhagic gastroenteritis in sheep, which was first recognized in the early twentieth century in Nairobi, Kenya. The genus consists of at least 34 strains/serotypes that have been divided into seven species/serogroups. All viruses in the *Nairovirus* genus are exclusively transmitted by ticks, although a few isolations have been made from *Culicoides* flies and mosquitoes.

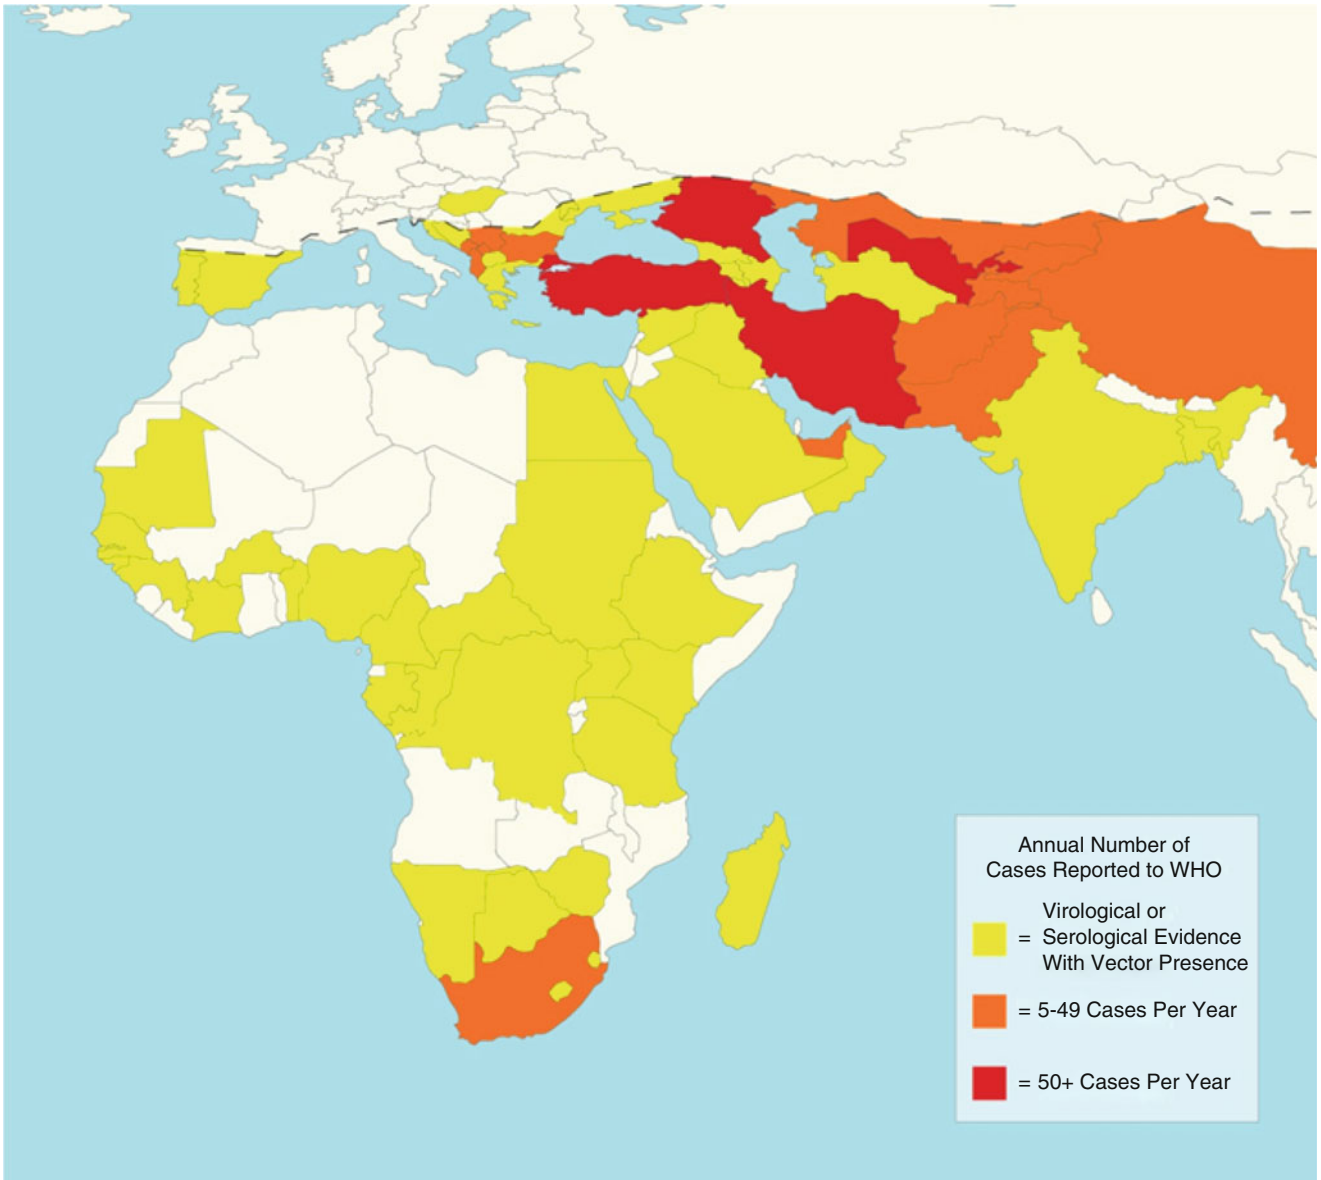

Fig. 9.1 Geographic distribution of CCHF. Countries in red report more than 50 human cases annually to the WHO, and those in orange report fewer than 50 cases. Countries in *yellow* have not reported human cases, but CCHFV has been isolated, or its presence has been inferred from serological studies, and a transmission-competent tick vector is also present. The northernmost limit of *Hyalomma margin-atum* and *Hyalomma asiaticum* is demonstrated by a *gray*, *dashed line*. The figure is based upon that created by the WHO (http://www.who.int/csr/disease/crimean_congoHF/en/) and on tick distribution maps at www.kolonin.org and http://www.efsa.europa.eu/en/efsajournal/pub/1723.htm

3.3.1 Crimean-Congo Hemorrhagic Fever Virus

The most important human pathogen in this genus is Crimean-Congo hemorrhagic fever, a zoonosis, which does not cause disease in its animal host, but results in a severe hemorrhagic syndrome in humans.

Descriptive Epidemiology

Crimean-Congo hemorrhagic fever (CCHF) is an acute, often fatal, tick-borne zoonosis and is among the most important emerging viral hemorrhagic disease of man. Crimean-Congo hemorrhagic fever virus (CCHFV) is extensively distributed in wild and domestic mammals, birds, and ticks throughout at least 30 countries in Western Asia, Southeast Europe, Middle East, and Africa regions [108, 23] (Fig. 9.1).

The distribution pattern approximates that of the predominant tick vector of the genus *Hyalomma* and is the largest among the tick-borne viruses, second of all medically important arboviruses only to that of the dengue viruses [90, 261]. The incidence of CCHF cases has increased over the past decade, including reports of cases for the first time in some countries such as

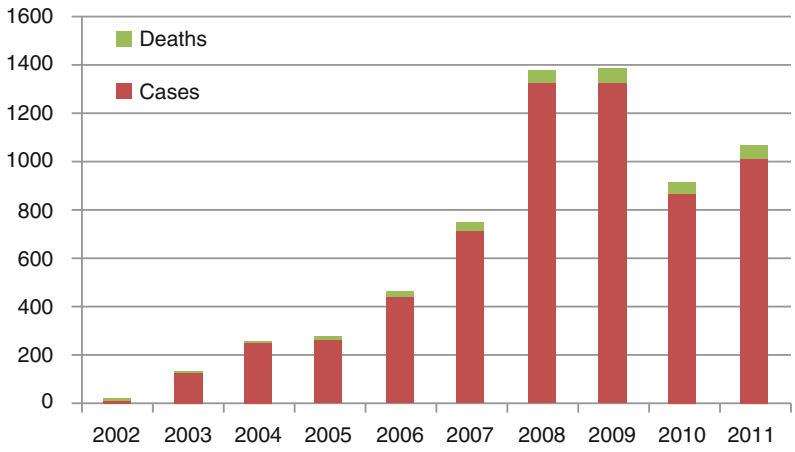

Fig. 9.2 Confirmed CCHFV cases in Turkey since 2002 (Source: Turkish Ministry of Health)

Turkey or India [123, 181]. This has been attributed to anthropogenic factors such as habitat fragmentation as well as possible climate change. In affected countries, typically a few dozen confirmed cases are reported, but annual spikes three to four times higher occur sporadically with no apparent pattern or synchrony between countries. Presumably, a combination of biological factors, both intrinsic and extrinsic, may trigger these spikes [75]. Interestingly, the emerging epidemiologic characteristics of CCHF in Turkey, where the disease was first diagnosed in 2002, appear to differ from those reported previously. Since 2002, the case numbers have increased exponentially and still continue to remain high with a total of over 6,330 cases in the last 10 years (Fig. 9.2). It is suspected that difference in ecology of the disease might have contributed to this emergent trend [76].

Clinical Features

CCHF viral apparent infection has been well documented with an onset of a mild febrile illness that may progress to severe and often fatal hemorrhagic disease [148]. CCHF has a distinct course of infection in humans with four different phases: incubation, prehemorrhagic, hemorrhagic, and convalescence period [73]. The length of the incubation period for the illness varies and precise data is difficult to obtain. The incubation period appears to depend on the mode of acquisition and the dose of the virus. Following infection via tick bite, the incubation period is usually short, ranging on average between 3 and 7 days. The incubation period following contact with infected blood or tissues is usually 5–6 days, with a documented maximum of 13 days [73]. Clinical manifestations in the prehemorrhagic period include fever, malaise, myalgia, dizziness, and, in some patients, diarrhea, nausea, and vomiting lasting for an average of about 3 days. The hemorrhagic phase usually begins on days 3–5 after the onset of illness and is usually short, lasting on average 2–3 days. The first evidence of disease is usually a flushing of the face and the pharynx and a skin rash that progresses to petechiae and ecchymoses, hemorrhage of the mucus membranes and conjunctiva, hematemesis, melena, epistaxis, hematuria, and hemoptysis [73]. Cerebral hemorrhage, gingival bleeding, and bleeding from the nose, vagina, uterus, or urinary tract may occur, as well as internal bleeding in abdominal muscles. Cerebral hemorrhage and massive liver necrosis indicate a poor prognosis. Hepatomegaly and splenomegaly may occur in up to 40 % of the patients. Deaths generally occur on days 5–14 of illness and are attributed to hemorrhages, hemorrhagic pneumonia, or cardiovascular disturbances. Lethal cases typically do not develop an antibody response. The mortality rate has been reported to average around 30 %, but may range from about 5 % to more than 80 % [261]. The variation in rates is believed to reflect the difference in diagnostic capabilities or treatment of patients between outbreak areas as well as the genetic variation of CCHFV strains resulting in different levels of virulence. The convalescence period usually begins 10–20 days after the onset of illness and recovery can take up to a year. Patients may experience generalized weakness, tachycardia, temporarily loss of all their hair, poor appetite, difficulty breathing, polyneuritis, loss of hearing and memory, and impaired vision [236]. In contrast, convalescing patients during recent outbreaks in Turkey and Iran did not present with any of the latter symptoms [148]. The mortality rate is among the highest of all the viral hemorrhagic diseases, ranging from about 5 % to more than 80 %.

Diagnosis

Preliminary diagnosis is based on clinical features and relevant travel or exposure history. Laboratory diagnosis can be made serologically by the detection of IgM-specific antibodies and detection of viral nucleic acids or through virus isolation; however, appropriate biocontainment precautions should be taken. Virus-specific immunohistochemical testing of autopsy tissues may aid in confirming the diagnosis [23].

Treatment and Prevention

At present, there is no internationally licensed vaccine, and treatment is only supportive [74]. Ribavirin has been used for treatment; however, efficacy has not been clearly established [230]. Research has been hampered due to the need of

a maximum biocontainment laboratory (BSL-4) to study the virus and lack of an animal model.

3.3.2 Other Nairovirus Infections

Dugbe Virus

Dugbe virus (DUBV) was first isolated in 1964 in Nigeria from *Amblyomma variegatum* ticks [35]. Serologically, DUBV is related to Ganjam virus, first isolated in 1954 in India from *Haemaphysalis intermedia* ticks and later also from man. DUBV has since been recovered on many occasions in Western Africa from ticks, domestic cattle, mosquitoes, and *Culicoides*. Despite the large number of isolations, serosurveys did not reveal widespread human infections, and isolations from blood of humans were only made occasionally, mainly children, with benign febrile illness including a laboratory infection. One patient had transient meningitis and virus was isolated from the cerebrospinal fluid [92, 157].

Nairobi Sheep Disease

Nairobi sheep disease (NSD) is a noncontagious, tick-borne infection of sheep and goats characterized by hemorrhagic gastroenteritis, abortion, and high mortality caused by NSD virus (NSDV). Antibodies against NSDV have been detected in human serum, but it is not known if these antibodies are the result of an NSDV infection or have been caused by a yet unidentified agent. An apparently naturally acquired clinical case was reported from Uganda in which a young man from which the virus was isolated experienced transient clinical signs [125]. However, no serological conversion was demonstrated.

Erve Virus

Erve virus (ERVEV) was isolated in 1982 from the tissues of a white-toothed shrew (*Crocidura russula*) collected in the Erve river valley in northern France and is only distantly related to the other nairoviruses [42]. The virus has been described in the Czech Republic, Germany, France, and the Netherlands. ERVEV has been suspected to cause severe headache and intracerebral hemorrhage in humans [42]. Due to the lack of commercial diagnostic test, only very little is known about the involvement in human disease.

3.4 *Hantavirus* Genus

Many distinct hantaviruses have been associated with human illness since the isolation of prototype Hantaan virus in 1978 and recognition of the new genus *Hantavirus* within the family Bunyaviridae [138, 217]. Hantaan virus is the causative agent of Korean hemorrhagic fever (KHF) in Korea and epidemic hemorrhagic fever (EHF) in China. Hantaviruses likely occur around the world; however, to date they are best known in Asia, Europe, and the Americas. Human disease caused by hantaviruses in Asia and Europe is characterized by acute fever, a tubular renal lesion, and in some instances a life-threatening capillary leak syndrome, often accompanied by hemorrhagic manifestations. Hantaviruses found in the Americas cause hantavirus pulmonary syndrome, also known as hantavirus cardiopulmonary syndrome, a severe acute disease associated with the onset of febrile illness that rapidly progresses to life-threatening respiratory failure and shock.

3.4.1 Descriptive Epidemiology

Hantaviruses are maintained in nature through chronic infection of small mammals, primarily rodents, although a number of novel hantaviruses have recently been found associated with shrews and moles [122]. Transmission to humans is by aerosol following exposure to infectious rodent excreta and occasionally by bite [94, 246]. Human infection is often seasonal, occurring in temperate zones during the fall when rodents may invade households, during warmer months when summer cabins may be first occupied, and through rural occupational exposure as seen among farmers, hunters, and field-deployed military. Hantaviruses are natural parasites of small mammals, and this genus is apparently unique in the *Bunyaviridae*, which otherwise are uniformly biologically transmitted by arthropods. Routes of transmission among small mammals are not known, although laboratory experiments have clearly documented the susceptibility of laboratory rats to aerosol exposure [172], and a strong correlation exists among free-living urban rats between increased evidence of wounding and rising antibody prevalence rates, suggesting that transmission by bite may be important [94]. Depending on the virus and host, transmission may occur in rural, urban, or occupational (such as from laboratory rats) settings. Person-to-person transmission is not known to exist among Old World hantaviruses; however, the New World cause of HPS, Andes virus, has been associated with person-to-person transmission [260]. Other New World hantaviruses do not appear to be transmitted in this manner. At least 20 genetically and antigenically distinct hantaviruses are known to cause human disease (Table 9.3), and many other hantaviruses with unknown pathogenic potential for humans have been found associated with various species of small mammals including shrews and moles.

Systematic population-based surveys to establish antibody prevalence rates for hantavirus infection have not been widely attempted; however, sufficient examination of selected "at-risk" populations has been conducted to offer a good indication of the global distribution of the hantaviruses. Methods employed include immunofluorescent antibody (IFA) assays, most often using prototype Hantaan virus-infected cell cultures as antigen; enzyme immunoassays (EIA); and radioimmunoassays (RIA). Populations surveyed are generally rural, frequently with high potential for occupational exposure to rodents (farmers, woodcutters,

Table 9.3 Old and New World hantaviruses causing hemorrhagic fever with renal syndrome (HFRS) or hantavirus pulmonary syndrome (HPS) and their known distribution and hosts

Distribution and subfamily of rodent host	Virus	Distribution	Primary host species	Human disease
Old World	Hantaan virus	China, Korea, Russia	*Apodemus agrarius*	HFRS
Murinae	Dobrava (Belgrade) virus	Balkans	*Apodemus flavicollis*	HFRS
	Seoul virus	Global	*Rattus sp.*	HFRS
	Saaremaa virus	Europe	*Apodemus agrarius*	HFRS
	Amur virus	Far East Russia	*Apodemus peninsulae*	HFRS
Arvicolinae	Puumala virus	Europe, Russia	*Myodes (Clethrionomys) glareolus*	HFRS (nephropathia epidemica)
New World	Sin Nombre virus	North America	*Peromyscus maniculatus*	HPS
Sigmodontinae	Monongahela virus	North America	*Peromyscus leucopus*	HPS
	New York virus	North America	*Peromyscus leucopus*	HPS
	Black Creek Canal virus	North America	*Sigmodon hispidus*	HPS
	Bayou virus	North America	*Oryzomys palustris*	HPS

	Juquitiba virus	Brazil	*Oligoryzomys nigripes*	HPS

Condensed from Jonsson et al. [118]

foresters, and others); patients with clinically compatible or interchangeable disease (e.g., leptospirosis); or unselected blood donors. About 12,000 sera from the European parts of the Russian Federation were examined by RIA, with antibodies found in a geographically focal pattern, generally increasing in prevalence with age, and most common in oil production and forestry workers or tractor and truck drivers [163]. Men were more likely to have antibodies than women (1.3:1 to 2:1), and this ratio increased in the clinically ill to 3:1. In a subsequent study in Bashkortostan, antibody prevalence among over 9,000 persons reached over 16 % in some adult age groups. Seropositive children have been infrequently identified in virtually all serological surveys.

The distribution pattern that has emerged from various surveys suggests that Hantaan virus is most abundant in Asia, including China, where the endemic areas are thought to be expanding, and the Korean Peninsula. Puumala virus, cause of nephropathia epidemica, is most abundant across a broad band from Norway, northern Sweden, Finland, and through the Russian Federation to the Ural mountains. Antibody prevalence rates in these endemic areas approach or exceed 10 % [169, 170, 221]. Elsewhere in Western Europe, antibody prevalence rates are lower, but clinical cases and positive serological results have been found in most European countries; and in areas such as France, Belgium, and Germany, where active research programs exist and clinicians recognize the disease, NE is increasingly diagnosed as an important cause of acute disease [248]. Incidence of human infection with Puumala virus increases following mast years, and recent studies in Germany demonstrated multiple local outbreaks of distinct virus clades associated with simultaneous increases in densities and infection rates of voles in different regions [77]. Seoul virus, cause of a less severe form of HFRS, is thought to be nearly global in its distribution based on serological surveys of peridomestic rodents [135, 136], but extensive tests for this specific virus in humans have not been widely attempted outside of China. In the United States, however, surveys were conducted among residents of Baltimore, Maryland, where inner-city rats are known to be heavily infected with a Seoul-like virus [44, 45, 46]. An antibody prevalence rate of 0.25 % was found among 6,060 persons with no known risk factors for hantavirus infection except residence in Baltimore [96]. This rate was significantly different from the rate found among patients with proteinuria (1.46 %; OR, 3.23; $p<0.05$) and the rate among dialysis patients with end-stage renal disease (2.76 %; OR, 5.03; $p<0.05$). Overall, 6.5 % of patients with end-stage renal disease due to hypertension were seropositive for a hantavirus, suggesting that hantavirus infection may be associated with hypertensive renal disease. Canadian blood donors had 1.4 % prevalence of antibodies to hantaviruses (3.5 % in the Maritime Provinces), but the exact strain of infecting virus was not determined [139].

3.4.2 Clinical Features

Hemorrhagic Fever with Renal Syndrome (HFRS)

Acute hemorrhagic and nephropathic clinical syndromes were described and variously named decades before their causative agents were identified. As cited by Casals et al. [34], records of severe, often fatal, hemorrhagic fever have been discovered in Vladivostok, Eastern Siberia, as early as 1912, and it seems likely that similar syndromes, albeit often confused with other causes of fever and hemorrhage, were known in Asia and Europe several centuries prior to this time. Modern scientific descriptions are credited to Soviet and Japanese scientists working in Siberia and Manchuria in the 1930s [163]. English-speaking physicians first encountered this disease during the Korean conflict in the early 1950s and named it Korean hemorrhagic fever (KHF). Modern Chinese and Japanese authors prefer the term "epidemic hemorrhagic fever" (EHF). A milder form of illness, with minor hemorrhage and lower mortality, was recognized in Scandinavia, also in the early 1930s, and termed "nephropathia epidemica" (NE) [164]. Today, hemorrhagic fever with renal syndrome (HFRS) is generally used to refer to the diseases caused by Old World hantaviruses.

Mortality in HFRS generally ranges from <5 to 15 % and is reduced by recourse to dialysis and proper management of patients who experience renal shutdown [34]. Between 1950 and 2007, over 1.5 million cases of HFRS and over 46,000 deaths (3 %) were reported in China with the highest case fatality rates above 14 % in 1969; however, for the last decade mortality rates for HFRS in China have maintained at approximately 1 % [271]. Case fatality rates of 10–15 % were reported from the Russian Federation for the periods 1978–1992, with peak annual incidence rates of over 11,000 cases (8.0 per 100,000 population) (World Health Organization 1993) and annual incidence rates of 50 cases per 100,000 in Bashkortostan [170]. Mortality in the former Yugoslavia during an outbreak in 1989 was 6.6 % (15 deaths of 226 cases) [95]. Dobrava virus is found in Greece, Bulgaria, Albania, the former Yugoslavia, and some foci elsewhere in Europe where it occurs relatively infrequently but produces an especially severe form of HFRS with mortality rates as high as 30 % in some areas [9, 95, 135, 136]. Incidence rates have dropped in recent years for prototype Hantaan virus in Korea to reports of a few hundred cases annually. Less severe NE-like disease occurs in several hundred patients each year in Scandinavia, and increasing numbers of cases are now recognized in Western Europe. The highest incidence rates in Sweden exceeded 20 cases/100,000 population in endemic areas [169, 221], while the prevalence of serum IgG antibodies ranged from about 2 % in non-endemic areas to around 8 % in endemic regions [168] [169]. The incidence of clinical cases and antibody prevalence in an endemic area of Sweden were compared, and the antibody prevalence rate in the oldest age groups was found to be 14–20 times higher than the accumulated life risk of being hospitalized with NE, suggesting that mild or asymptomatic infections are not uncommon [124]. The case fatality rate for NE due to Puumala virus in Sweden was estimated at about 0.2 % [220]. In the Balkan region of Europe, the viruses that cause both severe HFRS and relatively mild NE coexist, although the total disease burden generally does not exceed several hundred cases annually. More than 100 clinical and subclinical infections associated with occupational exposure to laboratory rats infected with Seoul virus have been recognized in Japan, and additional cases have occurred in Korea, the former Soviet Union, Belgium, and the United Kingdom. HFRS caused by Hantaan, Dobrava, or Amur virus is more severe, while Puumala and Seoul virus infections are generally milder.

Clinical HFRS in its classic severe form is highly distinct. By far the best description of the disease in English is that written by a medical commission during the Korean conflict [222]. Distinct phases of evolution were described, and although not all patients exhibited each of them, the pattern accurately reflected significant physiological changes that characterized Hantaan virus infection (Table 9.4). The incubation period of HFRS has been variously estimated at 10–35 days. The longer intervals, in particular, are of significance both in terms of pathogenesis and for their implications with respect to occurrence of unusual illness among travelers who may be infected on one continent and sick on another.

Hantavirus Pulmonary Syndrome (HPS)

In May 1993, an outbreak of an apparently new disease characterized by unexplained adult respiratory distress syndrome occurred among residents of rural southwestern United States. This disease became known as hantavirus pulmonary syndrome (HPS) or sometimes hantavirus cardiopulmonary syndrome (HCPS). The original outbreak was centered in the Four Corners region, where the states of New Mexico, Arizona, Utah, and Colorado join, and primarily affected young, previously healthy adults. By October 1993, 42 cases had been confirmed, including one retrospectively diagnosed from July 1991. Median age of patients was 32 years (range 12–69 years) and 52 % were males. American Indians accounted for 55 % of the cases; of the remainder, 36 % were non-Hispanic whites, 7 % were Hispanic, and 2 % were black. The mortality rate was 62 %, and cases were identified from 12 states [36, 37]. Epidemiologic investigations quickly determined that small rodents in the outbreak area were especially abundant in the spring and early summer of 1993, and virological examinations of captured rodents found *Peromyscus maniculatus* to be the species most frequently infected. Route of transmission from rodents to humans was assumed to be by the aerosol route, similar to other hantaviruses. The examination of PCR-amplified products from human cases and from *P. maniculatus* captured in and around patient's homes found identical hantaviral sequences at a given site but surprisingly high levels of

Table 9.4 Characteristic course of clinical disease for hemorrhagic fever with renal syndrome

Phase	Duration	Predominant signs and symptoms	Laboratory findings
Febrile	3–7 days	Fever, malaise, headache, myalgia, back pain, abdominal pain, nausea, vomiting, facial flush, petechiae (face, neck, trunk), conjunctival hemorrhage	WBC = normal or ↑ Platelets = ↓ Hematocrit = ↑ Urine = proteinuria 1 + → 3+
Hypotensive	2 h–3 days	Nausea, vomiting, tachycardia, hypotension, shock, visual blurring, hemorrhagic signs, ± oliguria (late)	WBC = ↑ with left shift Platelets = ↓↓ Bleeding time = ↑, PT may be ↑ Hematocrit = ↑↑ Urine = proteinuria 4 + hematuria 1 + Hyposthenuria BUN and creatinine = increasing
Oliguric	3–7 days	Oliguria ± anuria BP may ↑; nausea and vomiting may persist; 1/3 with severe hemorrhage (epistaxis, cutaneous, GI, GU, CNS)	WBC = normalizes Platelets = normalize Hematocrit = normalizes, then ↓ Urine = proteinuria 4 + Hematuria 1 + → 4 + BUN and creatinine = ↑↑ Na^{+}↓, K^{+}↑, Ca^{2+}↓
Diuretic	Days to weeks	Polyuria = 4 + (3–6 l daily)	BUN and creatinine = Normalize electrolytes Possibly abnormal (diuresis)
			Urine = normalizes
Convalescent	Weeks to months	Strength and function regained slowly	Anemia and hyposthenuria = may persist for months

From McKee et al. [151] Reproduced with permission
Phases as seen in KHF. All phases may not be present in a given patient

genetic diversity among samples taken from different sites [166]. Investigators using the same PCR techniques on preserved tissues of *P. maniculatus* captured in 1983 in California likewise found infected rodents, indicating that this virus is not "new" or recently mutated [222]. *Peromyscus maniculatus* is one of the most common and widely distributed rodents in North America. Subsequently, many other hantaviruses have been identified from small mammals throughout the Americas, from Canada to Argentina and Chile, many of which cause HPS-like clinical disease, often resulting with fatalities. Each recognized hantavirus appears to be predominantly associated with a particular species of small mammalian host and occupies a distinct ecological habitat.

Hantavirus pulmonary syndrome is found in the New World and characterized by rapid onset of pulmonary edema, soon followed by respiratory failure and cardiogenic shock. Many New World hantaviruses are capable of causing HPS, with the most severe disease typically associated with Sin Nombre virus, isolated during the original North American outbreak in 1993, and Andes virus, recognized predominantly in Chile and Argentina; however, many other New World hantaviruses found elsewhere in the Americas are known to cause serious human infection similarly associated with severe morbidity and high mortality rates. Case fatality rates for HPS are usually about 40 %. New World hantaviruses infect lung microvascular endothelium causing microvascular leakage that is characteristic of HPS [146]. Incubation period is 9–33 days, with most onsets occurring between 14 and 17 days post exposure to small mammal reservoir hosts [265]. A detailed examination of HPS in Brazil was characteristic of HPS as seen elsewhere in the Americas and reported a typical clinical course associated with a febrile prodrome with fever, myalgia, and worsening thrombocytopenia, headache, backache, and other symptoms, followed by dyspnea, cough, and tachycardia along with low blood pressure, leading to shock in about a third of patients. More than half the patients developed renal failure and about half had mild hemorrhagic disturbances. Reduced platelets, metabolic acidosis, hemoconcentration, and leukocytosis were documented in more than half the patients seen. Diffuse bilateral rales were seen in the majority of cases. Patients were typically admitted 3–6 days post onset of symptoms, and fatalities occurred within a day or two after admission. Survivors typically remained hospitalized for more than a week [118].

3.4.3 Diagnosis

The serological diagnosis of hantaviral infection in humans is typically done by detection of IgM- and IgG-specific antibodies, often using recombinant N protein as antigen, which is the most abundant viral protein and induces a strong humoral response. Both traditional indirect IgG and IgM enzyme-linked immunosorbent assays (ELISAs) and IgM capture ELISAs are used routinely. Virtually all patients are

IgM positive by the onset of acute illness [137]. Rapid strip immunoblot assays have also been developed [106]. Immunoblot and neutralization tests have been used for serological diagnosis, and focus reduction neutralization assays and plaque reduction neutralization assays have been used for virus-specific serological diagnosis and classification of hantaviral isolates. Molecular diagnostics such as reverse transcription PCR can rapidly detect hantaviral genomic sequences in clinical specimens early in infection and even prior to onset of acute illness [78, 178]. Direct isolation of hantaviruses from acute human specimens or from tissues of suspect small mammalian hosts is difficult and time-consuming. Hantaviruses are slow to adapt to growth in cell culture, and indeed only a few cell lines are known to support hantaviral growth. Most infected cell cultures do not exhibit cytopathic effect, the exception being HEK293 cells [149]; consequently, the presence of infectious virus must be established by demonstration of specific viral antigen or nucleic acids, typically by direct IFA assay or polymerase chain reaction (PCR). Primary isolation has been most successful when a combination of techniques was employed [126]. A note of caution: Although asymptomatically infected, laboratory animals may shed infectious virus in their excreta and saliva. Consequently, isolation attempts and experimentation that utilizes laboratory animals should only be carried out under appropriate biocontainment conditions that minimize the risk of aerosol transmission between animals and humans. BSL-2 practices, containment equipment, and facilities are recommended for laboratory handling of sera from persons potentially infected with hantaviruses, and potentially infected serum or tissue samples should be handled in BSL-2 facilities following BSL-3 practices and procedures. Cell culture-virus propagation and purification should be carried out in a BSL-3 facility using BSL-3 practices, containment equipment, and procedures. Experimentally infected rodent species known not to excrete the virus can be housed in ABSL-2 facilities using ABSL-2 practices and procedures. Primary physical containment devices including BSCs should be used whenever procedures with potential for generating aerosols are conducted. All work involving inoculation of virus-containing samples into rodent species permissive for chronic infection should be conducted at ABSL-4 [38].

3.4.4 Treatment and Prevention

The pathogenesis of both HFRS and HPS is complex and is associated with an intense immune activation that leads to changes in vascular permeability. Aggressive supportive care and careful clinical management of fluid levels are essential to the successful treatment of critically ill patients. HPS cases may quickly progress to respiratory failure and shock that requires extracorporeal membrane oxygenation (ECMO) and careful monitoring of cardiac output and respiratory function [155]. Beneficial effect of treatment with the antiviral drug ribavirin has been reported for HFRS patients in China when administered early in the course of illness [110]; however, due to the rapid progression of HPS and the fact that the diseases are rarely recognized until after the onset of cardiopulmonary involvement, ribavirin has not had a beneficial effect on the treatment of HPS patients [156]. A role for antiviral drugs in the prophylaxis of intimate contacts of patients infected with Andes virus could be beneficial, but has yet to be demonstrated. A number of hantavirus vaccines have been tested in humans, including both rodent brain-derived and cell culture-derived formalin-inactivated vaccines. Most have targeted Hantaan or Seoul virus, either individually or in combination, although at least one candidate DNA vaccine has included Puumala virus. In addition, vaccinia-vectored vaccines expressing Gn, Gc, and N viral proteins and plasmid DNA delivered by gene gun have been tested (reviewed in [216]). Hantavax® is a commercially available suckling mouse brain-derived formalin-inactivated vaccine marketed in Korea; however, its efficacy has not been demonstrated [180]. Inactivated vaccines for Hantaan and Seoul viruses have also been produced in China with neutralizing antibody produced in over 90 % of those receiving three doses [63].

4 Unresolved Problems

The bunyaviruses exist in nature through silent transmission cycles that typically involve an animal vector (arthropod or rodent) and only occasionally result in human infection, often occurring in rural environments where human contact with potentially infectious vectors is more likely to occur. Those exposed are frequently residents of less developed regions of the world who may lack access to modern medical facilities and resources leading to a definitive diagnosis or effective treatment. Populations at greatest risk are often those least able to afford preventive vaccines, diagnostic tests, or effective therapeutics should they be available for these low incidence diseases, and as a result few economic incentives exist for commercial investment in the development of the critical tools needed to address the diseases caused by bunyaviruses. Inexpensive, accurate diagnostic tests are needed to better define the incidence of human infection. With the availability of better diagnostics, a greater appreciation of the full impact of bunyavirus infections on human and animal health will become apparent and may lead to investments in vaccine production or discovery of therapeutic interventions.

Much remains to be learned regarding the natural history of the bunyaviruses, including how they exist in nature and interact with their vector; the molecular mechanisms developed by the vector to limit virus spread; and why some vectors efficiently maintain and transmit these viruses, while

other closely related species do not. Critical information is still needed to better understand how these viruses survive adverse environmental conditions and the key role played by vectors in maintaining these pathogens in nature in some cases over a long period of time. Further, a better understanding of the behavior of vector species could lead to improved prevention, development of intervention strategies, and control of human and animal disease.

Bunyaviruses cause a wide range of clinical illness from febrile disease to frank hemorrhagic fever, encephalitis, and death, yet the pathogenesis of human bunyavirus infection is not well understood. This is due in part to the relatively rare access to acutely ill patients, thus limiting the opportunity for in-depth clinical evaluations and interventions, and also to the absence of robust animal models that faithfully replicate human infection. Furthermore, core questions (e.g., through genomic or proteomic studies) will need to focus on the identification of pathogenic determinants and virulence markers, defining host and tissue specificity.

The bunyaviruses represent one of the most geographically diverse families of viruses known, existing under virtually all climatic conditions and being maintained in nature through a wide variety of vectors. As such, they are often seen as the cause of "new" or emerging infectious diseases, often encountered as humans occupy previously uninhabited regions of the world or become exposed through the modification of the environment that allows the introduction of potentially infectious vectors. Comprehensive determination of bunyavirus genome sequences will be fundamental for a better understanding of their relationship and help developing taxonomic schemes, ultimately supporting diagnostics. We can expect greater interaction between humans and the bunyaviruses in the future as populations increase, our environment changes, and we experience more rapid and frequent travels over greater distances, bringing these "exotic" infections to our doorsteps.

Coronaviruses

10

Arnold S. Monto, Benjamin J. Cowling,
and J.S. Malik Peiris

1 Introduction

Coronaviruses of humans have been classified as a subfamily of the Coronaviridae family. The viruses are roughly spherical, enveloped particles 120–160 nm in diameter. Their name derives from the characteristic "crown"-like projections on their surface, approximately 20 nm long. They are positive-sense, single-stranded RNA viruses, are sensitive to heat and lipid solvents, and have a distinct replication strategy common to other viruses in the order Nidovirales [1–3]. Coronaviruses have in the past been divided into three groups. In part, because of increasing work on coronavirus discovery in the wake of the outbreak of severe acute respiratory syndrome (SARS) in 2003, a number of new coronaviruses of humans (hCoVs) have been identified. This has resulted in the three groups being reclassified as genera of the Coronavirinae subfamily. Before the SARS outbreak, while it was recognized that the coronavirus infected many different species, particularly domestic and laboratory animals, their extreme diversity in nature was not fully appreciated. Although severe diseases of differing characteristics were known to occur in animals, in humans the viruses were thought to cause only acute respiratory infection which were generally mild. All this changed with the recognition that SARS was caused by a coronavirus (SARS-CoV). This signaled that coronaviruses could produce lethal disease and encouraged more broadly based research on the agent and its prevention and control. In the process, two new respiratory or endemic coronaviruses have been identified as causing human infections, which appear to resemble in epidemiologic characteristics those previously known. Very recently, MERS (Middle East respiratory syndrome) coronavirus, a novel human betacoronavirus lineage C virus, has been discovered zoonotically infecting humans in Middle Eastern countries.

In light of the differences between the endemic respiratory and the SARS coronaviruses in terms of epidemiology and clinical expression, they will be covered separately in much of this chapter.

2 Historical Background

Coronaviruses were first identified from domestic and laboratory animals before they were identified in humans. Infectious bronchitis virus of chickens was actually isolated in embryonated eggs in the 1940s. The late recognition of these viruses was, in large part, because of difficulty in recovering the human viruses using standard cell culture techniques [4]. The first human coronaviruses were identified by different techniques in the United Kingdom and the United States at approximately the same time. The British Medical Research Council's Common Cold Research Unit had been studying fluids collected from persons with natural respiratory infections by standard cell culture isolation methods and by inoculating them into human volunteers. Rhinoviruses or other cytopathogenic agents could be recovered from a portion of the fluids [5]. There was an additional, substantial portion from which no agents could be isolated but that could still cause colds in the volunteers. Organ cultures of human embryonic trachea or nasal epithelium were then used in an effort to detect the recalcitrant viruses present. A specimen, B814, that had been collected in 1960 from a boy with a common cold had not yielded a virus on inoculation into cell culture. After the specimen had been passaged serially three times in human tracheal organ culture, it could still cause colds on inoculation into volun-

teers, which indicated that replication had taken place [6]. In Chicago during the winter of 1962, five agents were isolated in primary human kidney cell cultures from specimens collected from medical students with common colds. The viruses were ultimately adapted to WI-38 cultures and exhibited a type of cytopathic effect (CPE) not previously seen. A prototype strain, 229E, was selected for characterization and was found to be RNA containing, ether labile, and 89 nm in diameter but distinct serologically from any known ortho- or paramyxoviruses. Sera collected from the five medical students all exhibited a fourfold rise in neutralization antibody titer against 229E [7]. It became clear that these "novel" viruses were of more than passing significance when organ culture methods were added to standard cell culture techniques in a study of acute respiratory infections of adults conducted at the National Institutes of Health (NIH). Six viruses were found that grew in organ but not cell culture and were ether labile; on electron microscopy, the agents were shown to resemble avian infectious bronchitis virus (IBV) in structure, and these represented a distinct family of viruses [8]. The B814 and 229E strains were soon also demonstrated to have a similar structure on electron microscopy and to develop in infected cells by budding into cytoplasmic vesicles [9, 10]. As a result of the similarity of the human agents to IBV and also to mouse hepatitis virus (MHV), they were collectively considered to represent a group of vertebrate viruses distinct from the myxoviruses antigenically and structurally [11]. The name coronavirus was eventually adopted for the group to describe the fringe of projections seen around them on electron microscopy [1]. Except for 229E, none of the human coronaviruses had been successfully propagated in a system other than organ culture. McIntosh et al. reported successful adaptation of two of the NIH isolates, OC (organ culture) 38 and OC43, to the brains of suckling mice [12]. These strains were shown to be essentially identical antigenically but quite distinct from MHV. Only OC38 and OC43 could be so adapted; the other four OC strains resisted such attempts. The IBV was known to exhibit hemagglutination under certain conditions, but no such phenomenon had been demonstrated for the human strains until OC38 and OC43 were adapted to mice. Kaye and Dowdle found that the infected brain preparations would directly and specifically agglutinate red cells obtained from chickens, rats, and mice [13]. This technique greatly expanded the ability to do sero-epidemiologic studies, since it was simple and reproducible.

Subsequent developments included adaption of OC38 and OC43 to growth in cell monolayers; either mouse brain or organ culture material could be used as sources of virus [9]. Not only was CPE available for reading of neutralization tests, but also the OC38 and OC43 viruses were found to hemadsorb red cells of rats and mice, making available a more precise means of evaluating endpoints in tests involving these organ culture-derived strains [14]. The other OC strains and B814 that could not be adapted to mouse brain resisted adaptation to cell culture as well; these distinct viruses have since been lost and may actually have been rediscovered recently.

Work on the coronaviruses of humans proceeded slowly, with debate about how frequently the viruses caused lower rather than upper respiratory disease. The methodological problems of working with them were a major impediment, as was their apparent involvement only in a relatively mild disease. All this changed when in 2002 SARS appeared first in China and then in other countries of the world. The near panic resulted because of its transmission characteristics, case fatality, and the fact that the agent was initially unknown. That last aspect was solved quickly with the identification of the causative agent as a new coronavirus. The knowledge that the virus emerged from a zoonotic reservoir spurred investigation of its possible source. Small mammals (civet cats) in live game-animal markets in Guangdong were identified carrying closely related viruses. This led to the identification of these animals as amplifier hosts and to the game-animal wet markets as an interface where zoonotic infection of humans was being initiated [15]. The natural reservoir was later identified to be Chinese horseshoe bats [16, 17]. The SARS epidemic ended following the use of various population control measures and unexpectedly has not recurred. However, increased attention to the coronaviruses continued globally. New coronaviruses were identified in various animal hosts, and two additional coronaviruses were identified in humans, the first since 229E and OC43. NL63 was identified in Amsterdam in 2004 from a 7-month-old child with febrile bronchiolitis [18]. The same virus was also isolated at almost the same time by the group in Rotterdam from an 8-month-old child with pneumonia [19]. The second virus, HKU1, was detected in a specimen collected from a 71-year-old man from China with pneumonia and then from another adult with the same diagnosis [20]. With the development of real-time PCR techniques for all four human respiratory coronaviruses, it has now become possible to identify them in many situations. Such identification is now typically done not only for these viruses but also for a variety of other respiratory agents. This has meant that coronaviruses are now detected as much in clinical settings as in epidemiologic studies.

3 Methodology

3.1 Sources of Mortality Data

Until the occurrence of SARS, coronaviruses of humans were not thought to cause death, except, possibly, in those with underlying conditions. This was in contrast to the situation in animals, where infections were sometimes fatal, depending on the particular virus. Since the SARS episode, the major change which has affected data on the respiratory coronaviruses has been more ready detection using the polymerase chain reaction (PCR) technique, so that infections are

now recognized in those who might previously have not been studied. This has especially been the case in hospitalized individuals, particularly those who will likely experience severe outcomes, such as the immunocompromised. It is also known from earlier studies that coronavirus frequently infects small children and reinfects adults, including persons with chronic respiratory disease [21]. It would be logical to assume that deaths could occur in these most susceptible segments of the population, but they are probably not very frequent.

A problem during SARS was in defining the specificity of infection, whether inapparent, mild, or fatal. This was related to the lack of a readily available diagnostic test in many areas where outbreaks occurred. To a large extent, cases were classified using a clinical case definition. In some cases that survived, there was an attempt at serological confirmation.

3.2 Sources of Morbidity Data

Since the coronaviruses of humans, other than the SARS virus, usually produce illnesses indistinguishable from those caused by other respiratory viruses, it is not possible to define morbidity in the absence of laboratory identification. Before PCR became available, it was difficult directly to identify the infecting virus; thus, besides anecdotal reports, most of the epidemiologic studies were based on identifying rises in antibody titer. In contrast, since development of the PCR technique, direct identification has become relatively simple. However, this seeming advance has often been accompanied by the use of the method to determine the incidence of infection in population groups and to define characteristics of associated disease or even seasonality. The major problem is the short duration of many of the available studies and the concentration on hospitalized individuals. As a result, while it is possible to say these viruses can sometimes cause hospitalization and to infer the particular clinical diagnoses they produce, it is difficult to estimate what proportion of overall illnesses are severe. A small number of studies have been population based and have produced the only data available for determining the overall impact of illness [22–24]. While the older population-based studies were limited to 229E, OC43, or both, they are useful since there are few recent investigations that give the same information. They were conducted in different settings but in some cases contemporaneously which allows direct comparison. In fact, almost no studies include all four recognized coronaviruses and cover more than a single year. This makes it difficult to discuss year-to-year variation in frequency of activity as well as seasonality, as was possible with the older data. Such studies are therefore of continuing interest, at least as background, in determining the long-term occurrence of the viruses. These original investigations were typically broadly based, with coronavirus infection forming part of overall evaluations of the role of viruses in general in respiratory illnesses. As indicated in the selected listing in Table 10.1, a variety of different open and closed populations were used for these studies. The 229E strain was originally isolated from medical students in Chicago as part of a long-term study of respiratory illnesses in young adults [7, 25]. Employee groups were the source of specimens in the NIH [26, 27] and in the studies at Charlottesville, Virginia [30]. Infection was also evaluated in children's homes [28] and boarding schools [5], among military recruits [34], and among children hospitalized for severe respiratory illnesses in various parts of the world [26]. Serological methods were used to detect occurrence in persons with acute exacerbations of asthma [33] or chronic obstructive respiratory disease [21]. Patterns of coronavirus infection were identified among the general population residing in the Tecumseh, Michigan, community as part of a longitudinal study of respiratory illness [31, 32]. Also included in Table 10.1 are more recent studies using PCR to identify infection. The previous studies, based on serology, often did not characterize infections identified clinically; in fact, challenge studies of volunteers were employed early, to determine characteristics of illnesses, because of problems associated with direct isolation [35, 36]. The more recent studies were able to characterize the illnesses clinically but have other limitations as indicated above.

Table 10.1 Selected longitudinal studies on the epidemiology of coronavirus infection in humans

Location	Population	Virus studied	Years
Chicago, IL [25]	Medical students	229E	1961–1967
Washington, DC [26, 27]	Hospitalized children	229E, OC43	1962–1967
Bethesda, MD [26, 27]	Adult employees	229E, OC43	1962–1967
Atlanta, GA [28, 29]	Institutionalized children	229E, OC43	1960–1967
Charlottesville, VA [30]	Working adults	229E, OC43	1962–1970
Tecumseh, MI [31, 32]	General community	229E, OC43	1965–1970
Denver, CO [33]	Hospitalized asthmatic children	229E, OC43	1967–1969
N. and S. Carolina [34]	Military	229E, OC43	1970–1972
Nashville, TN, and Rochester, NY	Hospitalized children <5 years of age	4 viruses	2001–2003
Melbourne, Australia [23]	Preschool children	NL63	2003–2004
Edinburgh, Scotland [22]	Medically attended illnesses—general population	4 viruses	2006–2009

3.3 Serological Surveys

Relatively simple serological technique was available for the first two coronaviruses identified (229E and OC43), and surveys of antibody prevalence were carried out in various parts of the world. Many surveys formed a part of studies directed mainly toward determination of incidence of infection. Information on the prevalence of antibody was available for populations in the United States [27, 30, 31], the United Kingdom [36], Brazil [37], and other parts of the world. A special situation was determining the meaning of the presence in man of antibody against coronaviruses of animals. The finding of mouse hepatitis antibodies in military recruits and in children and adults from the general population was surprising when first described in 1964 [38]. It is now recognized that this did not indicate past experience with MHV but rather with human coronavirus strains known to cross-react with it. Similarly, antibodies in human sera against the hemagglutinating encephalomyelitis virus of swine and the coronavirus of calf diarrhea also appear to represent cross-reactions with OC43 or related strains [29, 39]. In contrast, in a survey of antibodies to avian IBV, none could be found in a military population. Low-level antibodies were detected only in a portion of subjects who had close contact with poultry [40]. The virus is not known to cross-react with the human strains. More recently, following a gap in active work on the epidemiology of coronaviruses, ELISA methods have been developed for at least some of the viruses [41, 42]. These have not been as much used as the older techniques, given the availability of PCR, and may not be as specific to the particular strain.

3.4 Laboratory Methods

3.4.1 Viral Identification

Laboratory diagnosis can be achieved by identification of the virus in clinical specimens, using virus isolation or antigen or molecular detection techniques. Identification of infection can also be accomplished by detecting a host antibody response. Relevant specimens for virus detection are typically respiratory specimens, such as nasopharyngeal aspirates, washes or swabs, nose or throat swabs, and, when available, endotracheal aspirates or bronchoalveolar lavages. In the case of SARS, in which disseminated infection may occur, viral RNA could also readily be detected in the feces and in the serum or plasma.

Although PCR-based methods are becoming the "gold standard" in diagnosis, virus isolation is indispensable for characterizing virus, studying pathogenesis, determining susceptibility to antivirals, and developing novel antivirals and vaccines. The human coronavirus 229E was originally isolated in cell culture and later adapted to roller culture monolayers of human embryonic lung fibroblast cells such as WI-38 and MRC-5. A cytopathic effect of small, granular, round cells appears at the periphery of the cell monolayer [7]. Although these cells can be used for the cell-adapted prototype 229E virus strain, primary isolation of new 229E-like agents remains difficult. The human embryonic intestine (MA177) semicontinuous cell line has been used for the primary isolation of other 229E-like viruses [26]. Human coronaviruses OC38 and OC43, not related to 229E, were originally isolated in organ cultures of human trachea or lung [6, 8, 43, 44]. These two strains are similar and have been further adapted to replicate in suckling mouse brain and to primary monkey kidney and BS-C-1 cell cultures [9, 12, 14]. Another cell system, LI32, a heteroploid human lung line, has been reported to be suitable for primary isolation of 229E, a related virus (LP), and the B814, the first-described organ culture agent [45, 46]. This last finding has not been confirmed by other workers [9]. Similarly, MRC-C cells have been used for 229E-like viruses and human rhabdomyosarcoma cells for propagating 229E and OC43 [47, 48].

Human coronavirus NL63 was initially isolated in African green monkey kidney cells (LLC-MK2) [18]. Human colon carcinoma cells (CaCo-2) have recently been shown to be more susceptible to NL63 infection and show more prominent cytopathic effect [49]. HKU1 was initially discovered in 2005 by "broad-range" (primers designed to detect all known coronaviruses, rather than being specific for known coronavirus types) reverse transcriptase PCR (RT-PCR) [20], and new isolates remain difficult to grow reproducibly in the laboratory. However, it has been successfully cultured in human ciliated airway epithelial cells (HAE) [50].

SARS-CoV was initially isolated in 2003 on African green monkey kidney epithelial cells (VeroE6) and in fetal rhesus kidney cells [51, 52] during the SARS epidemic in 2003. VeroE6 cells, which are deficient in interferon induction, continue to be the cells of choice for culturing SARS-CoV at present. Following isolation of this novel agent, electron microscopy and molecular methods (random primer PCR and virus detection arrays) followed by partial genetic sequencing led to its identification as novel coronavirus.

Recently, MERS, a novel human coronavirus of the betacoronavirus lineage C, has been detected in patients from Middle Eastern countries with severe pneumonia and renal dysfunction. Vero and VeroE6 cells are suitable for primary isolation of this virus from clinical specimens [53].

Continuous transformed cell lines do not mimic the physiological state of cells in tissues in vivo, and this may be the reason why many coronaviruses are difficult to culture in vitro. The use of primary cells from the relevant species, cells differentiated in vitro in air–liquid interface cultures and ex vivo organ cultures (as was used in the early days of virology), may be needed for the isolation of more fastidious viruses, since some animal viruses are more readily isolated

in culture although they are species-specific in their in vitro growth characteristics, especially on primary isolation [54–57]. Embryonated egg culture has been used as a host system for avian coronaviruses [58]. However, none of the plethora of bat coronaviruses detected by RT-PCR have been readily cultured in vitro to date, even in primary bat epithelial cell lines [59].

3.4.2 Antigen Detection

Immunofluorescence tests on cells from the respiratory tract (e.g., nasopharyngeal aspirates or swab) using commercially available reagents [60] or polyclonal [61] or monoclonal antibodies to 229E and HKU1 [62, 63] have been reported, but these are not widely used. Such antigen detection tests can also be used for the diagnosis of SARS-CoV infection [62]. Several ELISA systems have been developed to detect coronaviruses including coronavirus 229E [64] and the nucleocapsid (N) or spike (S) proteins of SARS-CoV in respiratory samples [65, 66].

3.4.3 Molecular Diagnostic Methods

Since the majority of human coronaviruses cannot be readily cultured in vitro, reverse transcriptase PCR (RT-PCR) and real-time quantitative RT-PCR have become the methods of choice for detecting and quantifying coronaviruses in clinical samples and for discovering novel viruses. RT-PCR methods were used for the detection of 229E and OC43 viruses in clinical specimens [67]. There are now a number of commercial assays that detect a range of respiratory pathogens (including coronaviruses) by the use of a combination of PCR amplification together with nucleic acid hybridization in Luminex bead assay formats. These methods provide the opportunity for the rapid detection of a panel of over 15 respiratory viruses including a number of coronaviruses in a clinical specimen. However, the sensitivity is generally less than that provided by individual RT-PCR methods [68, 69].

Apart from detection of known coronaviruses, RT-PCR is useful in virus discovery and further characterization. This includes a wide range of coronaviruses in bats detected solely by such broad-range RT-PCR methods because these viruses cannot at present be cultured [70]. For example, the first identification of HKU-1 as a cause of human disease was initially based on detection of viral RNA in clinical specimens by broad-range RT-PCR with primers designed to detect all viruses within the coronavirus family [20]. NL63 was discovered using the VIDISCA (virus-discovery-cDNA-amplified restriction fragment length polymorphism) method [18]. Amplified sequences from RT-PCR permit viral genome sequence analysis, which sheds light on virus structure, characteristics, biological properties, phylogeny, host and tissue tropism, epidemiology, cross-species transmission, and drug design [53, 71–75].

3.4.4 Serological Tests

The demonstration of rising antibody titers between acute and convalescent sera to a specific viral antigen provides evidence of recent infection, while the detection of antibody in seroepidemiologic surveys provides evidence of past infection. Methods that can be used for serodiagnosis have included the complement fixation test, neutralization test, indirect immunofluorescent (IF) assay, and enzyme-linked immunosorbent assay (ELISA). Hemagglutination-inhibition (HI) and gel-diffusion tests are less frequently used nowadays.

Neutralization test can also be used on coronaviruses that only grow in organ cultures [8]. Neutralizing antibodies could be detected as early as 5–10 days after symptom onset during SARS infection [76]. The seroprevalence for SARS-CoV in asymptomatic children and adults living in high- and low-risk regions in Hong Kong in 2003 showed that subclinical infection was rare [77, 78]. Pseudotyped virus expressing the SARS spike protein can also be used for detecting neutralizing antibody to SARS-CoV without the need for handling the live SARS-CoV, which has to be carried out in BSL-3 containment [79].

Indirect immunofluorescence tests use virus-infected cells fixed to inactivate virus infectivity as the solid-phase antigen to bind antibody in serum specimens. Anti-SARS-CoV antibodies present in the serum would bind to the viral antigens expressed on the infected VeroE6 cells; these primary antibodies could then be detected by adding secondary antihuman antibodies labeled with FITC [80]. IgM subclass antibodies to SARS-CoV, though declining in titer, can be detectable for more than 6 months after onset of disease. There is less of a decline in titers of IgG antibodies and neutralizing antibodies to the virus. Such assays can also be adapted to detect low- and high-avidity IgG antibodies both for discriminating early from late antibody responses and for distinguishing anamnestic cross-reactive antibody responses from primary specific responses. This may be useful in some clinical situations [81].

ELISA assays have been also developed for detecting antibodies to coronaviruses [82, 83] and have been used to investigate the epidemiology of coronavirus infections [84]. The elicited antibodies detected by ELISA predominantly react with the viral surface proteins rather than the ribonucleoprotein [85], and infections of 229E- and OC43-like viruses can be distinguished in ELISA assays [86]. ELISA has been used to study the seroprevalence of HKU1, showing an increase from 0 % in age <10 years old to a plateau of 21.6 % in the age group of 31–40 years old [87]. Recombinant protein-based ELISA assays for detecting antibody to SARS-CoV have been developed [88, 89]. The duration of antibodies by ELISA to the SARS-CoV spike protein was long-lived and paralleled neutralizing antibody responses, while those to the nucleoprotein was less long-lived [90].

A protein-based line immunoassay which individually detects antibody to HCoV 229E, NL63, OC43, HKU-1, and SARS-CoV nucleocapsid protein has been evaluated [91]. Paired sera from confirmed OC43 or 229E infections and 49 convalescent sera from SARS patients showed that there was considerable cross-reactivity between the two betacoronaviruses OC43 and HKU1 and between the two alphacoronaviruses 229E and NL63. However, 229E- or OC43-infected patients did not develop cross-reactive antibody to SARS-CoV. It is important to keep in mind such cross-reactions when evaluating the results of serological assays. It is also relevant that immunofluorescent assays appear to manifest the greatest cross-reactivity. Neutralization tests are likely to be the most specific although this has not been systematically studied with the recently discovered coronaviruses.

Historically CF or HI tests were used in epidemiologic studies of coronaviruses [7]. By this method, the CF test detected antibody in low titer and for only a short time after infection. However, if the antigen was highly concentrated, antibody could be detected at a higher titer, and this antibody persisted in the population so that the CF method could be employed in surveys of prevalence [92]. An indirect HI test for 229E virus using tanned sheep erythrocytes has been described which appears to be highly sensitive with no cross-reactions with OC43 virus [93]. CF tests can be satisfactorily performed with OC43 virus using infected suckling mouse brain as antigen [27]. The same mouse brain material can also be used in the HI test for OC43 antibody. In this test, the hemagglutination titer has been higher for rat than for chicken erythrocytes but sufficient with the chicken cells so that HI testing could generally be employed; this is of particular importance in view of the wider availability of chicken erythrocytes and the spontaneous agglutination that often complicates working with rat erythrocytes. Serum to be tested did not require treatment with receptor-destroying enzyme but rather standard heat inactivation at 56 °C. The agglutination took place equally at various temperatures including room temperature [94]. It has also been possible to demonstrate precipitin lines on gel-diffusion tests with coronavirus antigens concentrated 10- to 50-fold. Two or three precipitin lines were observed by Bradburne [92] in tests with hyperimmune animal or human serum, but others have identified only one such line [94].

The neutralization, CF, HI, gel-diffusion, and immunofluorescent techniques have been used in the antigenic analyses of the older strains of 229E and OC43 [36, 95]. Cross-reactive antibody responses among hCoVs have been reported. When sera from individuals experimentally infected with 229E- and OC43-like coronaviruses, including organ culture viruses, were tested, they are found to cross-react within each group but not across groups. Thus, it is possible that the ELISA test with 229E and OC43 antigens may be able to detect infection with most, if not all, human 229E and OC43 coronaviruses [86]. However, persons with antibody to 229E and OC43 (most of the adult population) did not have cross-reacting antibody to SARS-CoV even in immunofluorescent tests, allowing these serological tests to be reliably used for diagnosis and seroepidemiology of SARS. Patients who had OC43 infections without prior exposure to SARS-CoV had increases of antibodies specific for the infecting OC43 virus but not to SARS-CoV. However, antibody responses to SARS-CoV antibody were sometimes associated with an increase in preexisting IgG antibody titers for human coronaviruses OC43, 229E, and NL63 by immunofluorescent assays. This probably reflects anamnestic cross-reactive antibody responses to coronaviruses to which the patient has had prior exposure (i.e., similar to the concept of "original antigenic sin") [96, 97]. The cross-reactivity is less when purifying nucleocapsid proteins are used in ELISA or Western blot assays.

4 Biological Characteristics

4.1 Classification

All human coronaviruses (hCoVs) are enveloped, positive-strand RNA viruses and belong to the subfamily *Coronavirinae* in the family *Coronaviridae*, order *Nidovirales*. The subfamily *Coronavirinae* is further divided into three genera, *Alpha-*, *Beta-*, and *Gammacoronaviruses*, corresponding to the previous informal classification groups I, II, and III, respectively; there is also a recently recognized *Deltacoronavirus* genus [98, 99] (Fig. 10.1). The genus *Betacoronavirus* consists of four separate lineages, designated from A to D, which correspond to the former subgroup 2A to D. As viruses sharing more than 90 % amino acid (aa) sequence identity in the conserved replicase pp1ab domain are treated as the same species, *OC43* and *human enteric coronavirus* (*HECV*) are thus now regarded as one species (*Betacoronavirus 1*).

At present, only members of alpha- and betacoronaviruses are known to infect humans. They differ from each other in nsp1 protein, which is distinct in size and sequence (gammacoronaviruses have no nsp1). In addition, alphacoronaviruses commonly share an accessory gene designated as ORF3. The type species for alpha- and betacoronaviruses are *Alphacoronavirus 1* (equivalent to *porcine transmissible gastroenteritis coronavirus*, *TGEV*, in older literature) and *murine coronavirus* (equivalent to *mouse hepatitis virus*, *MHV*), respectively. The viruses that are human pathogens are the alphacoronaviruses *229E* and *NL63*, the betacoronavirus lineage A viruses betacoronavirus 1 (which comprises *OC43* and human enteric coronavirus which are now regarded as variants of the same species) and HKU1, and the betacoronavirus

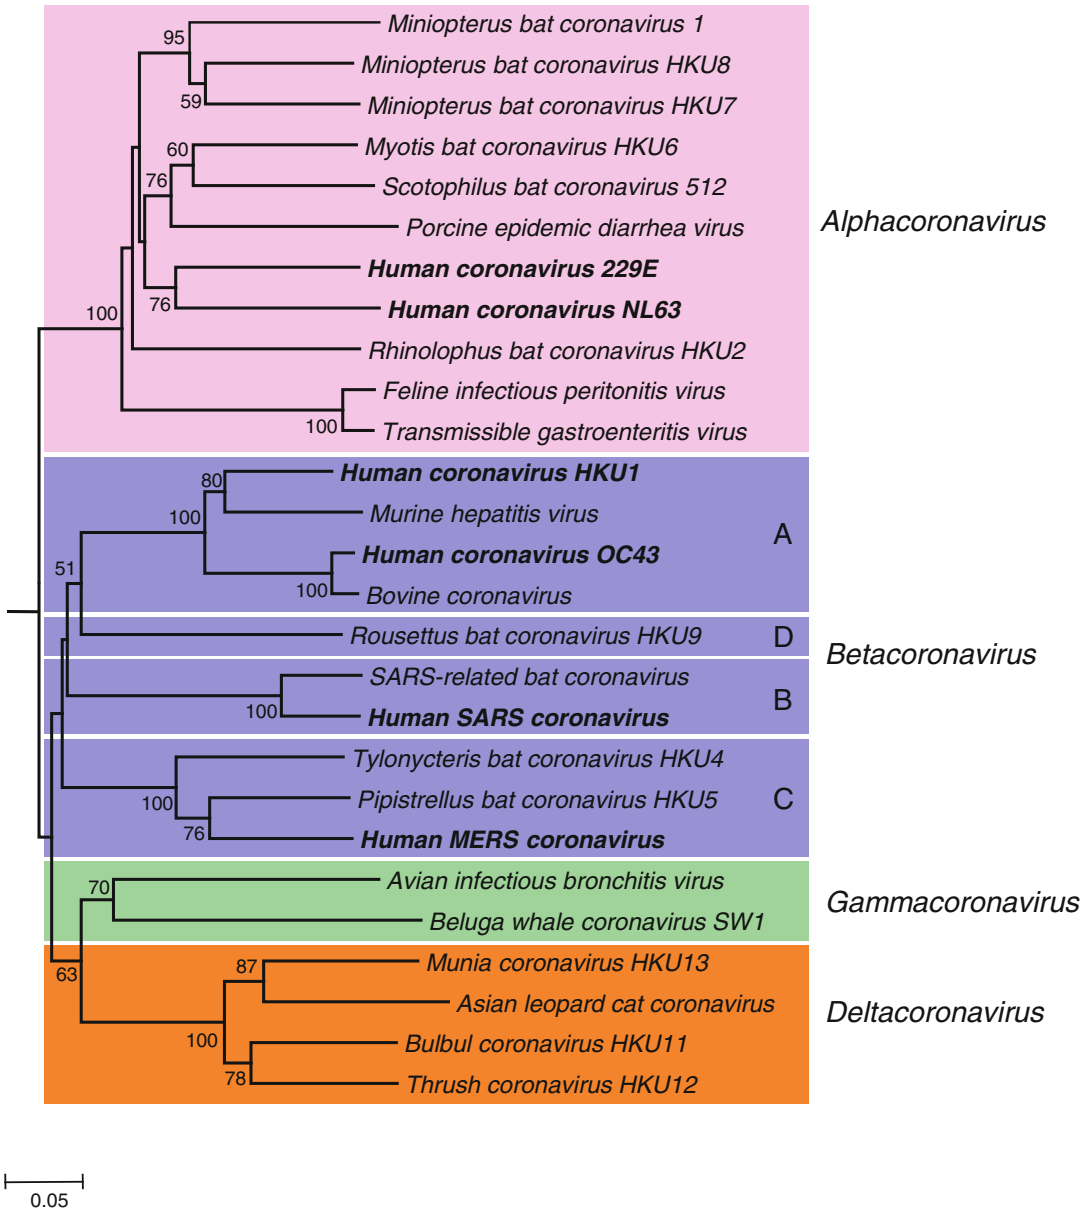

Fig. 10.1 Phylogenetic relationships of *Coronavirinae*. A rooted phylogenetic tree generated from nucleotide alignments of RdRp gene by neighbor-joining method with equine torovirus Berne as an out-group. Four genera of coronaviruses are indicated by different colors, *Alpha-* (*pink*), *Beta-* (*blue*), *Gamma-* (*green*), and *Deltacoronavirus* (*orange*). The distinct betacoronavirus lineages A through D were denoted. Human coronaviruses are denoted in *bold* (Figure is based on Refs. [1–3] and includes novel human betacoronavirus coronavirus 2c)

lineage B virus SARS-*related coronavirus* [98]. Recently, MERS (Middle East respiratory syndrome) coronavirus, a novel human coronavirus in lineage C, has been isolated. Phylogenetically, it is closely related to bat viruses previously detected in China and in Europe [53].

4.2 Genome and Structure

The name coronavirus comes from its appearance under the electron microscope with large 20 nm petal-shaped surface projections ("spikes") on a 120–160 nm spherical or

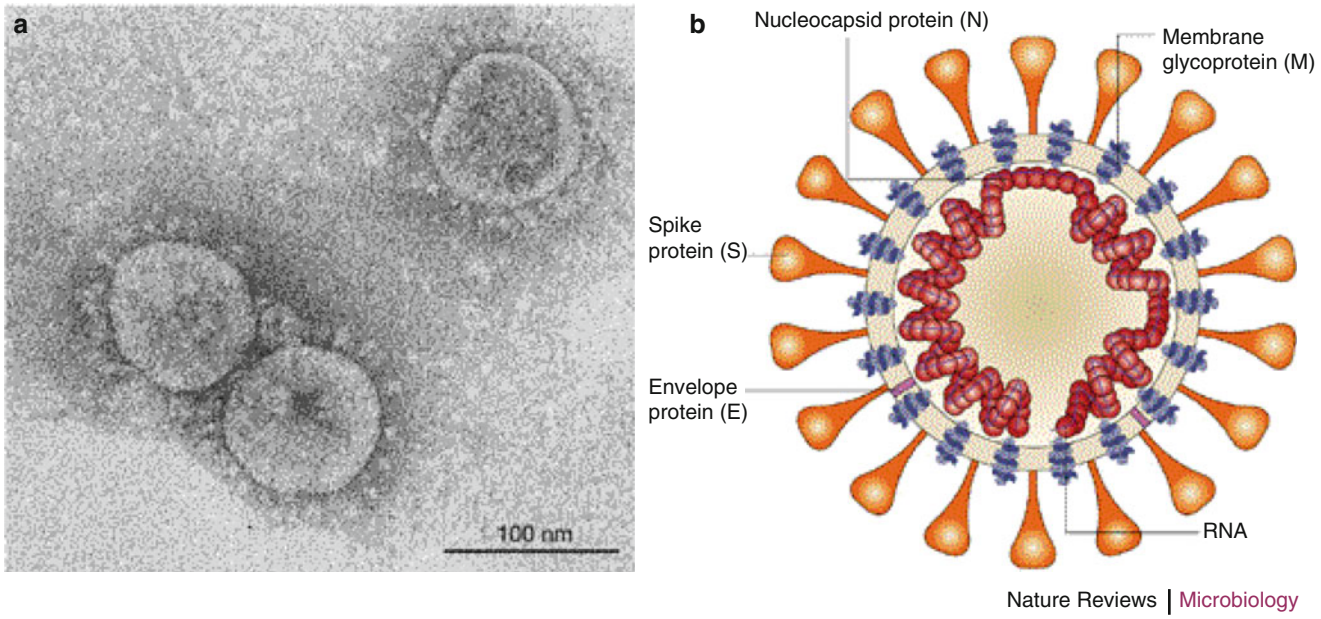

Fig. 10.2 Morphology of coronaviruses. (**a**) Electron micrograph of *severe acute respiratory syndrome-related coronavirus* (*SARS-related CoV*) cultivated in Vero cells. Large, club-shaped protrusions (*spike protein*) form a crown-like corona that gives the virus its name (Image courtesy of Dr L. Kolesnikova, Institute of Virology, Marburg, Germany). (**b**) Schematic representation of the virus. A lipid bilayer comprising the spike (*S*), membrane (*M*), and envelope (*E*) protein cloaks the helical nucleocapsid, which consists of the nucleocapsid (*N*) protein that is associated with the viral linear positive-stranded RNA. The lipid envelope is derived from intracellular membranes of the host cells [100]

pleomorphic body resembling a solar corona [100] (Fig. 10.2). Lineage A betacoronaviruses display an additional surface projection, the 5–7 nm homodimeric hemagglutinin-esterase (HE) glycoprotein. The interior ribonucleoprotein looks like either a long strand with 1–2 nm diameter or a helix condensed into coiled structures with 10–20 nm diameter. The virions are sensitive to heat, lipid solvents, nonionic detergents, formaldehyde, oxidizing agents, and UV irradiation [98].

The genome of coronaviruses consists of a linear positive single-stranded RNA between 26 and 32 kilobases and is the largest RNA virus genome to cause infection in humans [101]. The infectious genome has multiple open reading frames (ORFs), six of which are conserved across the subfamily and are arranged (in 5′–3′order) as ORF1a and 1b (which encode for two huge polyproteins, pp1a and pp1ab) and the ORFs for structural proteins, spike (S), membrane (M), envelope (E), and nucleocapsid (N). The two polyproteins pp1a and pp1ab from ORF1a/b are autoproteolytically cleaved into about 16 nonstructural proteins (nsp) which subsequently form into the replicase. Between the structural proteins S, M, E, and N lies the ORFs coding for the accessory proteins whose function is not essential for virus replication in vitro and the functions of many of them in vivo are still unknown.

As a positive-sense RNA genome, genome of coronaviruses serves as template for both replication and viral protein synthesis. Following entry into the cell by receptor-mediated endocytosis and uncoating of the virus genome, ORF1a/b of the genome is first translated to generate replicase proteins. These replicases use the positive viral genome as the template to generate full-length negative-sense RNAs, which in turn serve as templates for generating additional full-length genomes (i.e., replication). In viral protein synthesis, the 3′ proximal genes of the viral genome are first transcribed to segmented subgenomic negative-sense RNAs by discontinuous minus-strand RNA synthesis. The process is initiated at the 3′ end of the genome and proceeds until they encounter one of the transcriptional regulatory sequences (TRS) that reside upstream (5′) of most ORFs. Through base-pairing interactions, the nascent transcript is transferred to the complementary leader TRS, and transcription continues through the 5′ end of the genome. Therefore, all mRNAs of a coronavirus characteristically contain a common 5′ leader sequence fused to a downstream gene sequence. These subgenomic RNAs then serve as templates for positive-sense mRNA production and subsequent translation into viral proteins [101].

Three structural proteins S, E, and M are found on the viral lipid-membrane envelope; these are acquired as the virus buds into the endoplasmic reticulum, intermediate compartment, and/or Golgi complex of the host cell [98]. The spike protein (S) is a large homotrimeric type I membrane glycoprotein (1,128–1,472 aa). The S protein carries the receptor binding domain and is a class I fusion protein that triggers fusion between viral and host cell membranes

within the endocytic vesicle, thereby releasing the genome into the cytoplasm. The envelope protein (E) is a pentameric integral membrane protein (74–109 aa) that acts as ion channel for preferential transport of different ions into the virion. Although present in low copy number in a virion, E is significantly involved in virus budding, morphogenesis, and intracellular trafficking [102]. The membrane protein (M) is an integral type III triple-spanning membrane protein (218–263 aa). Being the most abundant protein in the viral envelope, it is essential in virus assembly within the infected cell. It could also interfere with host immune responses by inhibiting type I interferon production [103, 104]. The nucleocapsid protein (N) is a phosphoprotein that encapsidates the RNA viral genome to form ribonucleoprotein complex and regulates viral replication and translation (349–470 aa). It has RNA chaperone activity and also functions as an interferon antagonist [105]. In addition to these, the group A betacoronaviruses (includes OC43/HECV and HKU1) express an extra accessory homodimeric type I envelope glycoprotein, hemagglutinin esterase (HE), on its surface. It is related to subunit 1 of the influenza C virus hemagglutinin-esterase fusion protein (HEF) and mediates reversible virion attachment to *O*-acetylated sialic acids [106].

5 Descriptive Epidemiology

5.1 Incidence and Prevalence of Respiratory Coronaviruses

Coronaviruses are of major importance in common respiratory infections of all age groups. Before the identification of the newer endemic human coronaviruses, NL63 and HKU-1, it was recognized from the earlier studies that other unidentified human coronaviruses existed. It is still unknown if additional unidentified viruses exist, so that it is still useful to discuss burden in terms of both the individual virus and coronaviruses in general. Incidence of infection with 229E and OC43 exhibited a marked cyclical pattern, and reported rates can be expected to vary based on the number of seasons of high viral activity included in a particular study, again indicating the need for long-term evaluation. Table 10.2 presents a summary of results obtained in four studies which established the patterns of infection and illness [25, 28, 30, 31].

Another approach toward developing a minimal estimate of the total role of coronaviruses in respiratory illnesses comes from a study involving exhaustive laboratory examination, including organ culture, of specimens from 38 common colds. Coronaviruses were isolated from 18 % of the specimens, but an additional 13 %, which were negative in the laboratory, produced colds when given to volunteers [108]. Based on these results, which came from a limited age group, it has been estimated that coronaviruses could be responsible for at least 14 % of all respiratory illnesses in a general population [109].

Table 10.2 Reported frequency of infection or respiratory illness with 229E and OC43 in four locations

	Mean incidence of infection with	
Study	229E	OC43
Chicago medical students [25]	15/100/year	—
Tecumseh, MI [31, 32]	7.7/100/year	17.1/100/year
	Proportion of illnesses associated with	
	229E	OC43
Charlottesville, VA, employees [10]	1.7 % of illnesses	2.4 % of illnesses
Atlanta, GA, children [28, 108]	4.3 % of illnesses	3.3 % of illnesses

5.1.1 Incidence and Prevalence of 229E Virus

The frequency of 229E illness and infection was determined in several long-term investigations. The activity of 229E was found to be high in three out of 6 years of a study among Chicago medical students. The mean annual incidence of infection during the total period was 15 % where the criterion for identification was a reproducible twofold seroconversion determined by CF. There was marked year-to-year variation in infection frequency, ranging from a high of 35 % of those tested in 1966–1967 to a low of 1 % in 1964–1965. However, nearly 97 % of the infections occurred during the months from January to May, often at a time when isolation of rhinoviruses was at a low and seroconversions for 229E were only rarely accompanied by a rise in titer against another respiratory agent [25].

The serological study of 229E activity in the community of Tecumseh, Michigan, initially covered 2 years, which included one period of high prevalence. As with the study in Chicago, routine blood specimens were collected so that infection rates could be determined; however, the study group was composed of individuals of all ages living in their homes. Over the 2 years, infections were detected in 7.7 % of individuals tested by CF, as shown in the curve in Fig. 10.3. However, this appeared to be an underestimate of the actual activity of the virus. Serum specimens had been collected on a regular basis, 6 months apart; rises in titer by CF occurred most frequently in those pairs in which the second specimen was collected in April 1967, clearly indicating the peak period of viral dissemination. Both CF and the more sensitive N test results were combined to give an overall infection rate for the population studied; this rate, 34 %, was remarkably similar to the 35 % observed in Chicago at the same time. Because of the limited period of viral activity, it was possible to compare illness rates of those infected with persons not infected matched by age and sex; it was estimated that 45 % of the infections had

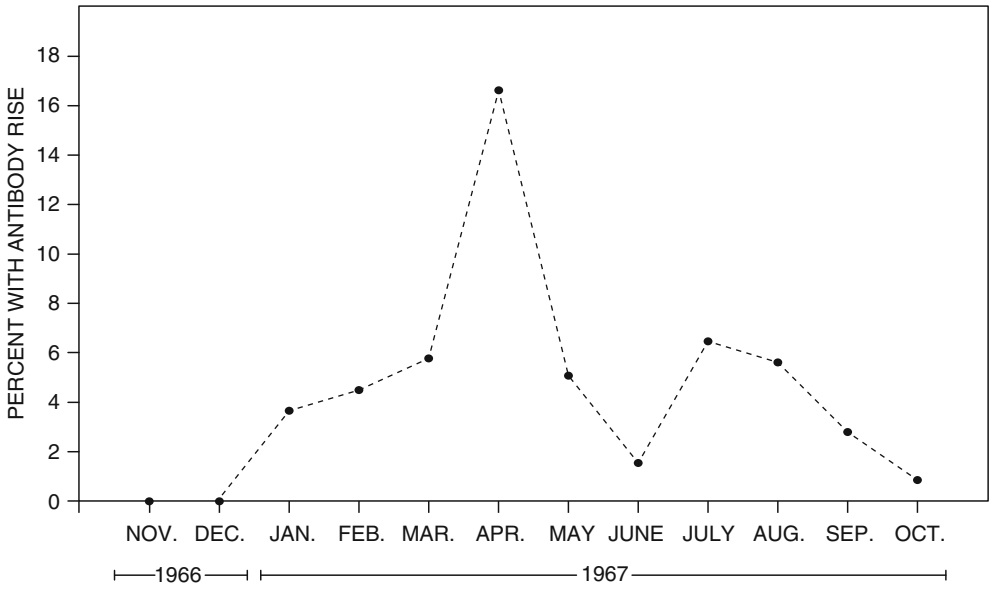

Fig. 10.3 Serological incidence by CF of infection with 229E virus in Tecumseh, Michigan, 1966–1967

produced clinical disease. Thus, the rate of 229E-associated illnesses during the outbreak was 15 per 100 persons studied. Activity in all age groups was apparent, including those under 25 years of age [31].

In other investigations of 229E activity, attention has been directed mainly toward study of associated illnesses; in such studies, sera have been collected before and after the illness rather than continually on a routine basis as done to determine infection rates. Employees at State Farm Insurance Company, in Charlottesville, Virginia, were studied during an 8-year period for rises in titer for both 229E and OC43. By CF, 229E infection could be related to 3 % of the colds that occurred in the winter–spring and to 0.4 % of colds that occurred in the summer–fall. There was some year-to-year variation in activity, but differences in the number of specimens tested from various years did not permit complete identification of cyclical patterns [30]. Employees of the NIH with respiratory illness were studied by both isolation and serology for 229E infection over a 6-year period. Again, attention was specifically directed toward certain segments of the 6 years, and no specimens were tested during other segments. Of particular interest once more is the segment from December 1966 to April 1967. Isolation of rhinoviruses and myxoviruses was uncommon at this time, but respiratory illness continued to occur. During this period, 24 % of those persons with colds studied had rises in titer for 229E. As part of the same investigation, paired blood specimens collected from infants and children admitted to the hospital with acute lower respiratory disease during the 1967 period of 229E activity were tested for rise in antibody against the virus, but none was found [26, 27]. Healthy children institutionalized in Atlanta, Georgia, were studied from 1960 to 1968; antibody response to 229E was determined by the indirect hemagglutination test. The investigation involved collection of serum specimens related to illness and also routine collection of sera from some non-ill individuals. Frequency of infection showed marked variation from year to year. Overall, 4 % of colds could be associated with 229E infection, with greatest association in autumn, winter, and spring [28]. A more recent study took advantage of specimens sent from medical facilities in Edinburgh, Scotland, for laboratory identification of infection to study the incidence of a number of respiratory viruses identified by PCR. Overall, 229E was found in only 0.3 % of those sampled, lowest of any of the four coronaviruses studied. This may reflect that the source of the specimens was from illnesses seen in hospitals and primary care facilities, and coronaviruses are mainly involved in milder illnesses [22].

Surveys of prevalence of 229E antibody have been carried out to document past history of infection, often as parts of longitudinal studies. A general finding is that antibody is present in a significant portion of adults who, despite possessing this antibody, can subsequently experience reinfection and illness. Reports of antibody prevalence in adults in the United States have varied from 19 to 41 %, depending on the type of test used to determine antibody and the time of collection of serum [27, 30, 110]. Children under 10 years of age exhibited lower mean antibody titers than older children or adults [27, 31]. Individual sera from normal healthy adults collected serially in Britain from 1965 to 1970 were tested by Bradburne and Somerset. It is of interest that the proportion of sera positive by CF increased from approximately 17 % in specimens collected in October–December 1966 to 62 % in those collected in July–September 1967. This suggests that the spring 1967 outbreak that occurred in several parts of the United States may have taken place in Britain as well.

5.1.2 Incidence and Prevalence of OC43 Virus

Populations employed to study infection and illness caused by OC43 virus were generally been the same ones employed to study the occurrence of 229E virus. Kaye et al. [107] used the group of institutionalized children in Atlanta, Georgia, to identify infection by means of their HI test. Infections with the agent were detected in all years of the study, but with definite cyclical variation. Seasons most involved were the winter and spring. Overall, 3 % of the illnesses recorded in the 7-year period could be associated with OC43 infection, with a high of 7 % in 1960–1961. Interestingly, testing of the sera collected routinely from non-ill individuals indicated that an additional equal number of OC43 infections were occurring without the production of symptoms [107]. The Charlottesville study of adult employees was of both OC43 and 229E infections. Here, too, the emphasis was on illness, and in all years studied OC43 was associated with 5 % of colds in the winter–spring and with no illnesses in the summer–fall. Again, there was cyclical variation from year to year in the number of rises in titer detected [30].

The original isolations of OC38 and OC43 were made in December and January 1965–1966 as part of the study carried out among NIH employees with colds. Testing of sera collected from these employees indicated that during this period, up to 29 % of the colds studied were accompanied by rise in titer for OC43. In the children hospitalized with lower respiratory disease, up to 10 % of illnesses during this period were associated with such a titer rise. However, it was impossible to show that the relationship to disease was truly etiologic. This finding was in contrast to that seen with 229E, in which no rises in titer were detected in such cases [27, 111]. In the Tecumseh study, occurrence of OC43 infection was determined in the community population over a 4-year period: CF and HI tests were used on all specimens, and N tests were used as an aid in evaluating these results in selected specimens. During the total period, OC43-related infection was detected in 17.1 % of the 910 persons studied for 1 year. Most of the infections took place in the winter–spring months of 1965–1966, 1967–1968, and 1968–1969. The only winter–spring period without such activity was in 1966–1967, when the 229E outbreak had taken place. The 1968–1969 outbreak of OC43 infection was nearly as widespread as the prior 229E outbreak, with 25.6 % of the population studied showing evidence of infection. Of special note was the fact that children under 5 years of age had the highest infection rates [32, 112]. More recently, in the Edinburgh study involving medical care, OC43 was the most commonly identified coronavirus but only was identified by PCR in 0.85 % of specimens. This again may be a reflection of the source of the specimens. Surveys of antibody prevalence have been conducted in several settings using OC43 antigens. McIntosh et al. [27] found that children began to acquire antibody to this virus in the first year of life. By the third year of life, more than 50 % had antibody present. Among adults, 69 % could be demonstrated to have antibody; this indicates, in view of the high incidence of infection with the agents in all age groups, the frequency with which such infections must represent reinfection. The high prevalence of antibody has been confirmed in other studies [28, 30, 112]. In Britain, Bradburne and Somerset followed prevalence of antibody for OC43 over time, as they also had done with 229E [36]. Each year, the greatest prevalence of antibody was found in the winter–spring period. The single highest point in antibody prevalence was in January–March 1969, at the same time the OC43 outbreak was occurring in some parts of the United States [30, 38].

5.1.3 Geographic Distribution

Occurrence of coronavirus infection has now been documented, by isolation, PCR, or serology, throughout the world. In earlier studies, in the United States, in addition to the studies listed in the first part of Table 10.1, a 229E-like virus was isolated in California, and OC43 and 229E have been demonstrated to be present in many regions of the country [21, 113]. Extensive studies have been carried out by the Common Cold Research Unit, which have demonstrated the presence of the agents in Britain. The activity of 229E virus has been documented in Brazil in an early study of children and adults with and without respiratory illness. Significant rises in antibody titer accompanied respiratory infection in the nonhospitalized children. Prevalence of antibody was determined by CF, and like the situation in some studies in the north temperate zone, children had little antibody, whereas 26 % of adults were antibody positive [37]. Later investigations have confirmed the worldwide distribution of these agents [112, 114]. In particular, the widespread use of PCR has now allowed easy documentation of the activity of all the coronaviruses. In fact, one of the four viruses now recognized, HKU1, was first identified in the subtropical city of Hong Kong [20]. These findings suggest that coronaviruses are worldwide in distribution and cause similar types of illness in different localities [115], as has been noted with many other respiratory viruses [116, 117].

The newly recognized human MERS coronavirus infections have only occurred in Middle Eastern countries (Jordan, Qatar, Saudi Arabia, the United Arab Emirates) with limited secondary transmission being reported in France, Italy, Tunisia, and the United Kingdom. The infection is probably of zoonotic origin although other scenarios cannot be completely excluded at present. Persons with immunosuppressive conditions and other underlying diseases appear to be particularly susceptible to infection. While there have been significant clusters of infection in some health-care facilities, MERS coronavirus appears to have limited capacity for human-to-human spread at present [118–120].

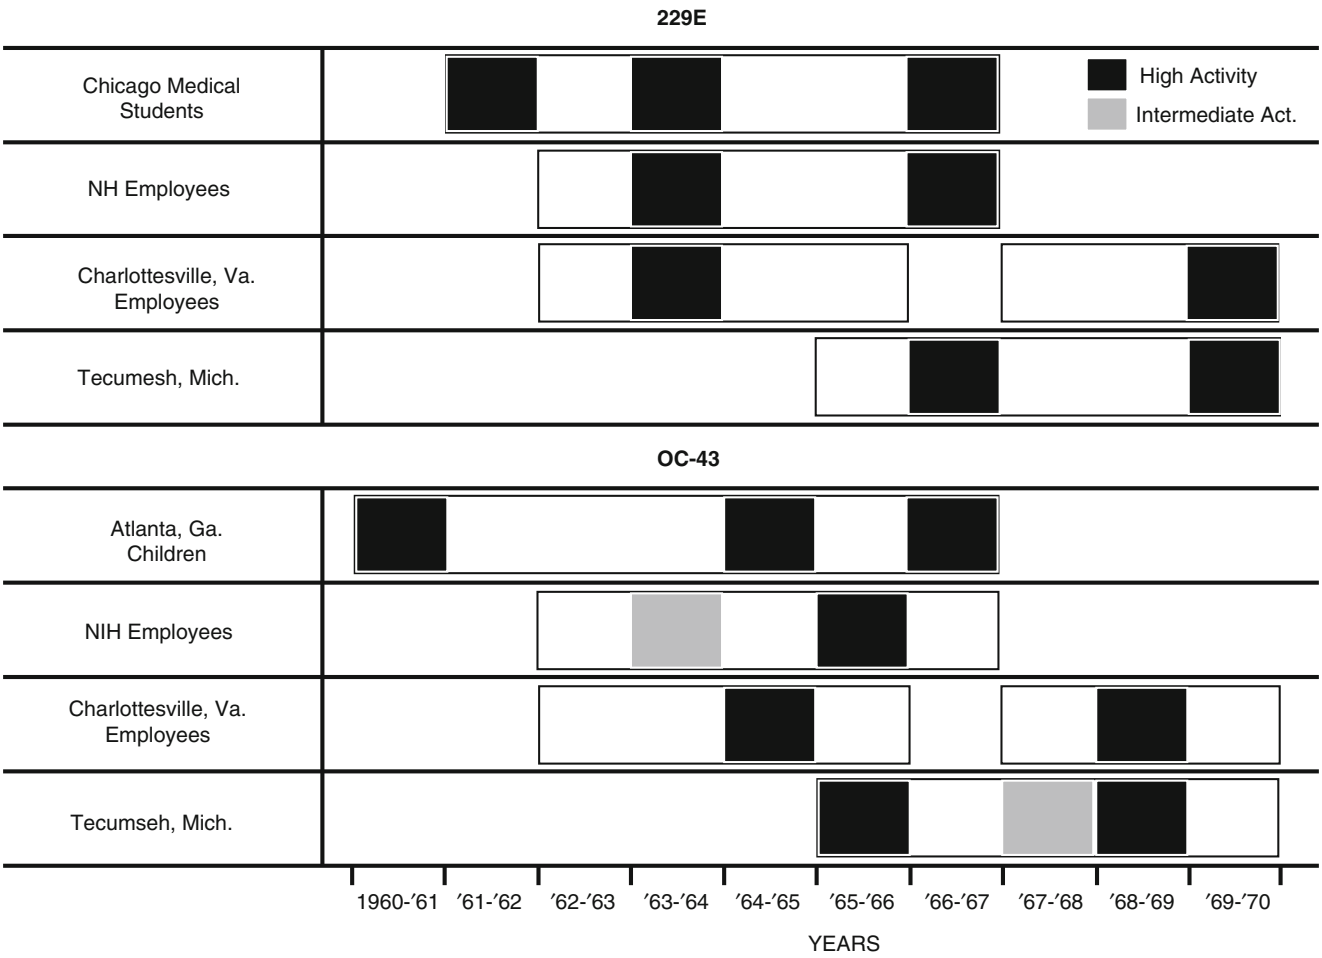

Fig. 10.4 Cyclic behavior of 229E and OC43 viruses observed in five longitudinal studies

5.1.4 Temporal Distribution

Because most illnesses caused by coronaviruses are similar to those caused by other respiratory viruses, it is impossible to identify epidemic behavior of the viruses clinically. In early epidemiologic studies, there was, however, evidence of variation in the frequency of infection on both a seasonal and a cyclical basis. In these investigations, isolation and rises in antibody titer for all types of coronaviruses were rare events outside the period from December through May. This is the portion of the year in which isolation rates for rhinoviruses often reach their lowest level. An exception to this rule was a study in which frequent rises in titer were detected by ELISA in summer as well [84]. More recent studies identifying the viruses by PCR have largely confirmed the winter seasonality of the viruses in the north temperate zone; one study observed that the timing of coronavirus identifications was similar to that of influenza in winter–early spring [22]. As expected, the seasonality appears to differ in places like Hong Kong, based on accumulating data [121].

In the earlier multiyear, population-based studies, a cyclical pattern could also be seen in the occurrence of individual virus types. In Fig. 10.4, data are summarized from five longitudinal studies of coronavirus activity carried out in different parts of the United States. In all studies, some sporadic activity did occur in nearly all years studied, but rises in antibody titers were concentrated in certain years in which they far exceeded the means for the entire studies. Those periods are indicated as solid black boxes in the figure. The times during which specimens were collected in each investigation are indicated in the figure by the white boxes. Activity of 229E was detected in all four studies at the same time, even though two were in the Midwest and two in the eastern United States. It seems possible, on the basis of these data, to postulate a 2- to 3-year cycle for this agent. The greatest number of infections in Chicago was seen in 1967, after the absence of the agent for 3 years; that pattern suggests a role of herd immunity in determining the time of reappearance of the agent.

With OC43, the situation is quite different. As with 229E, in no investigation did 2 years with high rates of infection or illness follow one another. A possible exception was in the Tecumseh study. However, the agent that caused the rises in titer in 1967–1968 did not appear as closely related

serologically to OC43 as the agent involved in the other two outbreaks. This observation indicates a problem in identifying cycling of OC43 using the serological test employed.

More recent studies using PCR have mainly not been population based or have focused on a limited number of the four known respiratory coronaviruses, so that comparable observations across all of the viruses are not possible. However, it is possible to conclude that, in any winter season, all four viruses may be identified in a single geographic area [122, 123]. There are likely to be increases of one or more in specific years, but it is unlikely that any coronavirus disappears completely; this is somewhat similar to our growing realization, with better surveillance, of the long-term occurrence of influenza types and subtypes [22].

5.1.5 Age

There is little available evidence that the respiratory coronaviruses behave differently than other respiratory viruses: infections are most common in children and decrease with increasing age. However, it is unclear whether the drop-off is modest or more extreme, as is the case with respiratory syncytial virus [124]. In the Tecumseh study, a total population group was followed. During the 1968–1969 OC43 outbreak, infection rates were relatively uniform for all age groups, varying from a high of 29.2 per 100 person-years in the 0–4 age group to 22.2 in those over 40 years of age [32]. The reversal of the pattern of age-specific infection rates customarily associated with the respiratory viruses becomes complete with 229E. Infection with this virus has been more difficult to demonstrate in small children than in adults. In Tecumseh, during the 1966–1967 outbreak, highest age-specific infection rates by CF were found among those 15–29 years of age, following a steady increase in infection frequency from the 0- to 4-year-olds. However, when neutralization tests were used to detect infection, the 15- to 19-year-olds still had high infection rates, but the serial increase to that point among younger age groups was much less steep [31]. This suggests that the apparent sparing of small children with 229E may be an artifact resulting from the relative insensitivity of the young to the serological procedures commonly employed. It would be surprising if two different coronavirus serotypes behaved so differently [125].

5.1.6 Other Factors

There is little evidence for or against a sex differential in infections with the coronaviruses. In Tecumseh, adult females experienced higher infection rates with OC43 than adult males, which is in conformity with the usual patterns of all respiratory illnesses [126]. Similarly, female volunteers appeared to be more susceptible to infection with 229E-like strains than males in artificial challenge studies [127]. In the study by Candeias et al. of antibody prevalence, the results were examined by sex, but no significant differences could be observed [43]. There are no data available on occupational or racial susceptibility to infection or on the role of socioeconomic status in influencing rates. Occurrence of infection in closed or special populations, such as military recruits or residents of children's institutions, has been reported [5, 26, 34]. The role of the school-age child in dissemination of coronavirus has not yet been clearly defined, but it would be surprising if these infections differed in their transmission pattern so markedly from that documented with the other agents. Because of the high frequency of infection in older children and adults, other sites of dissemination may also be of significance. It has been possible to show that the family unit is of importance in transmission, since clustering of 229E and OC43 infections in families was observed in the Tecumseh and Seattle studies [31, 128].

Although nutritional and genetic factors have not been associated with susceptibility to coronavirus infections, there are clear indications that the viruses are associated with exacerbations of chronic obstructive respiratory disease. Such a finding is hardly surprising in view of the high infection rates that have been observed in unselected older adults [129]. It has not yet been demonstrated whether this represents true increased susceptibility to infection or simply a more severe form of expression of the infection when it occurs in an already compromised host. In addition to the situation in older individuals, there is evidence that both OC43 and 229E may trigger acute attacks of wheezing in young asthmatics; in fact, in one study, coronaviruses were the most common agent involved in episodes of wheezy bronchitis [21, 33, 117, 130]. Recent studies using the PCR technique also associate the viruses with illnesses including pneumonia in immunocompromised patients [63, 115, 131]. One study identified all the viruses over the course of a year but the newer viruses, NL63 and HKU1, most commonly. Again, this may be a reflection of these viruses being most common at that point in time; it should be noted that shortly after the first identification of NL63 in one city in the Netherlands, it was again identified in another, which may indicate increased circulation at the time [18, 132].

5.2 Epidemiology of Severe Acute Respiratory Syndrome

In late 2002, the SARS coronavirus emerged in humans in southern China as a zoonotic pathogen [133]. Infection spread in Guangdong province for approximately 3 months before an infected individual visited Hong Kong in mid-February 2003. That case infected a number of tourists, sparking a global outbreak, and also went on to initiate a large outbreak in Hong Kong [73]. The subsequent global outbreak lasted around 4 months and had a substantial impact on global travel, trade, and economy [134]. Sustained epidemics have not occurred since 2003, although there have been a few sporadic events or minor outbreaks in Singapore,

Taiwan, and mainland China in 2003–2004, with most of them linked to laboratory releases and only four cases from mainland China perhaps of animal origin [135].

SARS patients initially developed influenza-like prodromal nonspecific symptoms including fever in the first week and usually presented cough, dyspnea, and diarrhea within 14 days. Severe illness developed rapidly progressing to respiratory distress and oxygen desaturation requiring intensive care and potentially resulting in death [136]. The World Health Organization (WHO) defined a suspected SARS case as a person with high fever (>38 °C) and cough/breathing difficulty, who either had close contact with a suspect or probable case of SARS or resided in or traveled to an area with recent local transmission of SARS in the 10 days prior to onset of symptoms. A suspected case became a probable case when (1) the patient's chest X-ray (CXR) presented infiltrates consistent with pneumonia or respiratory distress syndrome (RDS), (2) he/she was positive for SARS-CoV by laboratory assays, or (3) his/her autopsy findings were consistent with the pathology of RDS without an identifiable cause [137].

5.2.1 SARS Epidemiology in Time, Place, and Person

In total, 8,096 "probable" SARS cases were reported to the World Health Organization by August 2003 [138]. The most affected areas were Hong Kong, with 1,755 "probable" cases among a population of 6.8 million, and mainland China, with 5,327 "probable" cases among a population of 1.3 billion. Taiwan, Canada, and Singapore also experienced notable epidemics, with 346, 251, and 238 probable cases, respectively, while altogether cases were reported in more than 25 different countries and administrative regions. Reported cases of SARS globally and in Hong Kong by time of symptom onset are shown in Fig. 10.5.

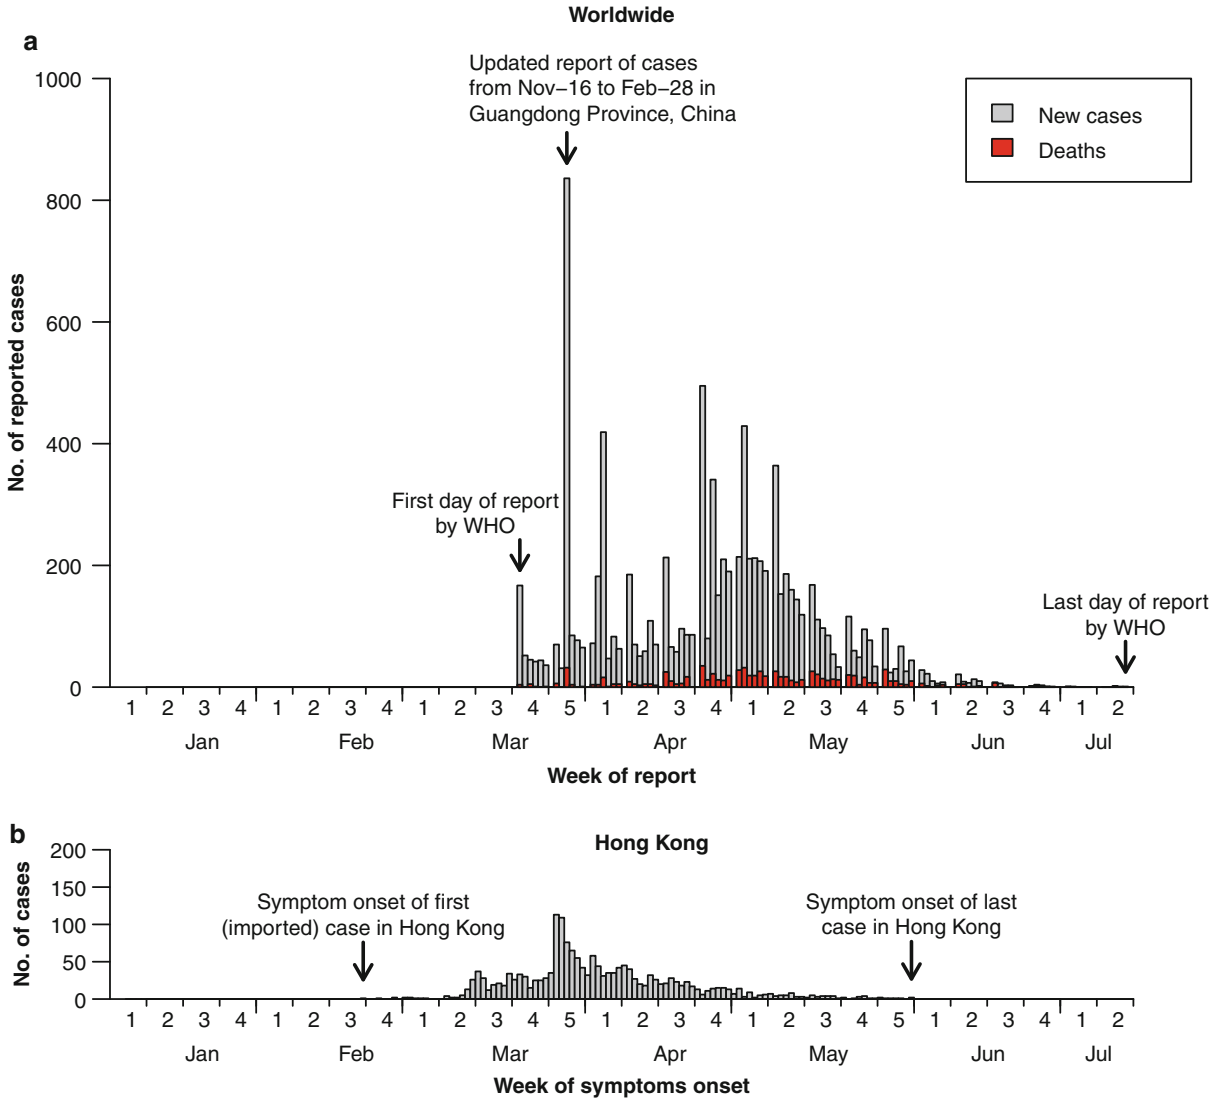

Fig. 10.5 Probable cases of SARS by week of onset (Source: [138]). (**a**) Cases worldwide, (**b**) Cases in Hong Kong

A common feature of SARS outbreaks in different regions was the central role of hospitals and transmission among patients and health-care workers [139–143]. A peak in infectiousness was thought to occur around 10 days after illness onset [144], by which time cases would have been hospitalized, and certain medical procedures were particularly prone to generating transmission [145]. Hospital transmission played a prominent role in the initial epidemic in Hong Kong, with more than 250 cases attributed to an outbreak at the Prince of Wales Hospital in early March 2003 [146, 147]. The Canadian outbreak began when a case returning from Hong Kong was admitted to hospital, and 72 % of cases were subsequently attributed to nosocomial transmission [143, 148].

Old age and the presence of comorbidities including diabetes mellitus, hypertension, coronary artery disease, and chronic obstructive pulmonary disease increased the risk of death or adverse outcomes, such as admission to an ICU requiring mechanical ventilation and development of ARDS [149, 150]. Sex (male), high lactate dehydrogenase concentration at presentation, and higher SARS-CoV viral load have been found contributing to higher case fatality rate as well [151]. Genetic factors may contribute to host susceptibility to SARS infection [78, 152, 153]. To date, there have been no studies on the relationship of race, socioeconomic status, occupation, or nutrition to susceptibility to SARS infection.

5.2.2 SARS Transmission Dynamics

Concerted efforts were made during the SARS epidemic to determine the transmission dynamics and thereby support control [154, 155]. Contact tracing exercises provided information to estimate the incubation period at around 5 days, with around 95 % of infections leading to illness onset within 10–14 days [156–158]. Early in the epidemic, delays between illness onset and admission to hospital were typically 5–7 days, and a measure of the success of public health control measures was the reduction in onset-admission intervals to just 1–2 days by the end of the epidemic [150, 157]. On average, patients remained in hospital for around 3–4 weeks [157].

The basic reproductive number, R_0, an estimate of the average number of secondary cases resulting from one infected case in a completely susceptible population, was estimated to be in the range 2–3 [154, 155, 159]. The average time between successive cases was around 8.4 days [155]. Due to these features taken together, in the early stages of outbreaks, the number of cases approximately doubled every week.

One issue of early controversy was the case fatality risk. Early in the epidemic, technical errors led to underestimation [160]. For example, on March 25, the World Health Organization reported the case fatality risk to be around 4 %, based on 49 deaths among more than 1,000 cases at that time [161]. This estimate was erroneously low because cases had not yet recovered, and some cases would subsequently succumb to the disease [160]. After the epidemic, the case fatality risk was estimated to be 9.6 % with 744 deaths among the 8,096 probable cases [135]. However, this masks substantial variability between affected regions, from around 7 % in Beijing to around 17 % in Hong Kong [150]. Reasons for variation remain unclear but could partly be attributed to case definitions, partly to case mix including age and underlying heath conditions [150] and partly to case management [162].

Few cases are thought to have been asymptomatic or subclinical. Serological studies were conducted in various groups including health-care workers, close contacts of cases, other patients, and the general community in affected regions, and a review of these studies found that the average seropositivity rate was just 0.1 % among more than 20,000 individuals [163].

5.2.3 Successful Control of the Global SARS Epidemic

Despite a basic reproductive number in the range 2–3, higher than influenza, the global epidemic of SARS was effectively controlled by appropriate nosocomial infection control measures. A range of interventions contributed to containment [164], including the use of engineering controls such as negative-pressure isolation rooms [143]; improved adherence to the use of personal protective equipment such as gowns, gloves, and masks [165]; as well as administrative measures including patient triaging and isolation, visitor restrictions, and establishment of dedicated SARS teams of staff [166]. The importance of strict infection control was illustrated particularly well by the experiences in Taiwan and Toronto, where control of the initial outbreaks was followed by complacency and subsequent second waves [167, 168]. Despite the importance of infection control strategies, there are also examples of individuals with SARS who were hospitalized where infection control practices were lax and yet their infection did not result in outbreaks [169]. Patient factors may also have had a role in the risk of transmission [170].

6 Mechanism and Route of Transmission

The four endemic respiratory coronaviruses are presumably transmitted by the respiratory route. It has been possible to induce infection experimentally in volunteers by inoculating virus into the nose [35, 44]. The virus is most stable at pH 6.0, and low temperature appears to protect it against varied relative humidity [171, 172]. No other route of transmission for coronaviruses seems involved in man, although animal coronaviruses are infectious by the fecal–oral route [57]. There is currently no direct evidence to aid in identifying the main mechanisms of transmission. However, it is possible to compare the epidemiologic behavior of the coronaviruses with that of other respiratory agents, the transmission mechanisms

of which have been more directly studied. Large-scale outbreaks of coronavirus infections have taken place, as in Tecumseh in 1967 [31]. This is much more analogous to the situation seen with influenza than to that with the rhinoviruses [173]. Rhinoviruses are thought to be transmitted by large droplet and may at times spread via fomites [174].

Unlike the situation with the SARS coronaviruses, there is no evidence that any animal reservoir or vector is involved in the maintenance of infection or transmission of the other respiratory human coronaviruses. There has been a report of antibody to avian IBV in the sera of poultry workers but not of controls, but no evidence of any further transmission [40].

The SARS coronavirus was thought to spread through a number of different modes, most commonly via direct close contact. Health-care workers involved in direct patient care duties often had the highest attack rates [175, 176], while contact precautions were effective in preventing transmission [165]. SARS coronavirus was capable of surviving on dried, inert surfaces and was found on some hospital surfaces [177], and indirect contact was implied in the infections of some nonmedical staff [178]. Although there is substantial evidence to support the role of transmission through droplet and direct contact and some evidence to support transmission by indirect contact, there is relatively little evidence for airborne transmission [179]. In one large community outbreak in Hong Kong, a computational fluid dynamics model was used to demonstrate that airborne transmission was consistent with the observed pattern of infections [180], although this hypothesis was not formally compared with other possible explanations. However, lacking other evidence of airborne transmission despite unprotected extended exposures in health-care settings [169, 181, 182], the World Health Organization classified SARS as a disease with "opportunistic airborne" transmission to indicate that the disease naturally spreads by non-airborne routes but under special environmental conditions may spread by the airborne route [183, 184]. Diseases that are spread by opportunistic airborne transmission do not require special airborne infection isolation measures, for example, negative-pressure isolation rooms, but special precautions are recommended for high-risk procedures.

7 Pathogenesis and Immunity

7.1 Etiology and Immunity

Data that demonstrate the etiologic role of coronaviruses in respiratory infections are derived from laboratory and field studies. Coronaviruses interfere with the action of cilia in tracheal organ culture, which suggests that they could have the same effect in vivo. Epidemiologic studies also have demonstrated association of 229E infection with disease. During the 1967 outbreak of 229E infection in Tecumseh, Michigan, illness was significantly more common among those with infection than among matched subjects without infection [31]. Similarly, 229E infection among Chicago medical students was statistically associated with illness when those with rises in titer were used as their own controls [25]. Furthermore, experimental inoculation of volunteers with strains of 229E and OC43 isolated in the laboratory has resulted in clinical illness, fulfilling Koch's postulates modified by Rivers [185] for attributing an etiologic role to a microbe as a cause of disease [35, 36, 47].

SARS-CoV has also fulfilled the Koch–Rivers postulates for association with the disease of SARS. The virus was detected in patients with SARS but not in those without disease, and the virus was detected at the site of the pathology, that is, lung [51]. The virus was isolated in pure culture from the lung biopsy of a patient with SARS, and experimental infection of cynomolgus macaques with this virus produced a comparable disease. A specific immune response to the virus was demonstrated, and the virus was successfully re-isolated from the site of pathology in the infected animal [186]. Fulfilling Koch–Rivers postulates for more recently discovered human coronaviruses has been more challenging because of the lack of suitable animal models that recapitulate the disease in humans [187], and their etiologic association with disease lies largely on epidemiologic grounds.

An important characteristic of the respiratory coronaviruses is their apparent high rate of reinfection, which in volunteers has now been documented to be possible within a year of prior infection [188]. In the Tecumseh study, 81.5 % of those infected with OC43 actually possessed prior N antibody [189]. Possession of circulating OC43 HI antibody among the Atlanta children did not appear to play a role in modifying severity of a subsequent illness [28]. With 229E virus, Hamre and Beem [25] demonstrated that the frequency of rise in titer detected by N was inversely proportional to preinfection levels of N antibody, which would indicate that this antibody exerted some protective effect. However, the importance of this N antibody could not be confirmed when infection was detected by CF. Thus, circulating N antibody as measured at present may bear a relationship to modification of infection, but this association is not a very strong one. Since coronavirus infections involve mainly the surface of the respiratory tract, it is likely that secretory IgA antibody plays a more direct role in protection; this had in fact been demonstrated with a swine coronavirus [190] and subsequently with 229E in humans experimentally infected [191].

7.2 Virus Tropism and Pathogenesis

Interaction between coronavirus spike proteins and host cell receptors determines specifically the host range, tissue

Table 10.3 Human coronaviruses and their major receptors

Human coronavirus	Major receptor	Receptor expression
229E	Aminopeptidase N (APN) [4]	Epithelial cells of kidney, intestine, and respiratory tract; granulocytes; fibroblasts; endothelial cells; cerebral pericytes at blood–brain barrier; synaptic junctions; macrophages; and dendritic cells [4, 193, 194]
Betacoronavirus 1 (OC43/ HECV)	9-*O*-Acetylated sialic acid-containing receptors [195]	Erythrocytes, neural gangliosides, gut mucins [193, 196]
SARS-related CoV	Angiotensin-converting enzyme 2 (ACE2) [197]	Lung alveolar epithelial cells, enterocytes of small intestine, arterial and venous endothelial cells, arterial smooth muscle cells [198]
NL63	ACE2 [199]	Same as above
HKU1	Unknown	Not known
MERS coronavirus	DPP4 (CD26)	Found in many tissues including the respiratory epithelium [200]

From the wide range of receptor expression, one could appreciate that coronaviruses could cause illness in many parts of the body, including the respiratory and gastroenteric systems [101, 201]

tropism, and pathogenesis [192]. Coronaviruses have a wide spectrum of susceptible host cell range, determined by the expression of the relevant receptors (Table 10.3). Related coronaviruses may use the same or similar receptors for entry, and major receptors for hCoVs include aminopeptidase (APN) and ACE2. Most alphacoronaviruses bind to APN with the exception of NL63 and SARS-CoV which binds to ACE2. Some of the betacoronaviruses (including OC43) attach to 4- or 9-O-acetylated sialic acids via the virus S and HE proteins. The HE protein also has enzymatic activity to cleave sialic acid linkages and thus serves to release virus from infected cells after replication is completed. Some human coronaviruses have other binding receptors that allow virus attachment to host cells, but these are not sufficient as functional receptors to mediate viral entry by themselves. These include calcium-dependent (C-type) lectins such as L-SIGN (**l**iver/lymph node-**s**pecific **i**ntercellular adhesion molecule-3-**g**rabbing **n**onintegrin), which may serve as a receptor for 229E and SARS [202, 203]. Recognition of a receptor from the same family in another host species is possible and may allow cross-species transmission. For example, 229E can use either human or feline APN but not porcine APN [201], and human and palm civet ACE2 serve as receptors for epidemic strains of SARS-CoV, but mouse and rat ACE2 do not [204, 205].

The receptor for MERS coronavirus has been identified to be DPP4 (also known as CD26), a protein that is widely conserved across mammalian species and found on the surface of several cell types, including the human upper airways. As with APN and ACE2, DPP4 is an ectopeptidase that cleaves amino acids from biologically active peptides [200].

The human coronavirus OC43 and bovine coronaviruses share close genetic similarity suggesting that they arose from a common ancestor less than 150 years ago [206]. Coronaviruses can undergo dramatic changes in tissue tropism and virulence within the same host. For example, porcine enteric transmissible gastroenteritis virus caused a severe enteric disease in pigs. A spontaneously occurring genetic mutation (deletion) occurring in the spike gene led to a change in virulence and was associated with a switch of virus tropism from the gastrointestinal tract to the respiratory tract [207].

7.3 Pathology and Pathogenesis

There is limited data on the pathology of coronaviruses other than SARS-CoV because these infections are generally mild. Electron micrographic changes from the nasal mucosa of a child with a coronavirus infection showed minimal pathological changes [208].

Although the clinically major pathology of SARS was that seen in the respiratory tract, SARS-CoV caused a disseminated infection with virus being found in the feces, urine, and plasma or serum [209]. Early disease was associated with desquamation of the alveolar epithelium and disseminated alveolar damage with hyaline membrane formation in the alveolar spaces. Viral antigen was demonstrated in alveolar and bronchial epithelial cells and alveolar macrophages [210]. In intestinal biopsy specimens of patients with SARS, virus infection of intestinal epithelium was demonstrated by electron microscopy with minimal cytopathic effect which is consistent with the watery diarrhea seen in these patients [211]. High serum levels of pro-inflammatory chemokines (CXCL10, IL-8) and cytokines (IL-1 and IL-6) suggested a role for immunopathology although it is uncertain whether these inflammatory responses are causally relevant or an epiphenomenon in the pathogenesis [212].

8 Patterns of Host Response

8.1 Disease Characteristics

The incubation period of coronavirus colds is relatively short. In studies involving volunteers, the mean period from inoculation of virus to development of symptoms was from

3.2 to 3.5 days, depending on the strain (range, 2–4 days) [35, 44]. Following exposure, the virus apparently multiplies superficially in the respiratory tract in a manner similar to that in which multiplication occurs in vitro. Nasal airway resistance and temperature of the nasal mucosa increase [213]. Virus excretion usually reaches a detectable level at the time symptoms begin and lasts for 1–4 days. The duration of the illness is from 6 to 7 days on the average but with some lasting up to 18 days. Serological response either to induced or to naturally acquired infection has been quite variable depending on the infecting strain and the serological test employed. For example, among those experimentally infected with OC38 or OC43 virus who had a cold produced, only 46 % had rises in titer by HI and 23 % by CF. Fewer than half of those infected with 229E showed a CF rise. It is not clear how the existence of titer or preinfection antibody affects the magnitude of the response detected by these tests. Rises in N antibody titer are easier to detect and have been found with sensitive techniques in all volunteers experimentally infected [36, 92]. The use of the ELISA test has given added sensitivity in antibody detection; it is not as yet clear if decreased specificity should be a concern.

The respiratory coronaviruses cause cold-like illness that on an individual basis is difficult to distinguish from illness caused by other respiratory viruses. They have also been reported to cause pneumonia and other severe respiratory infections, such as croup and bronchiolitis [115, 123, 214]. Most of the evidence of their involvement in severe disease comes from reports from hospitals of the identification of the viruses by PCR. It is thus impossible to say what proportion of infections, which appear to be common, that result in hospitalization are in fact caused by these viruses. Another problem recently encountered is the frequent identification by PCR of other viruses in those in whom a coronavirus is found [22]. This complicates determining the primary etiology. In induced infections in volunteers, the most prominent findings have been coryza and nasal discharge, with the discharge being more profuse than that customarily seen with rhinovirus colds [35]. Sore throat has been somewhat less common and in children has been associated with pharyngeal injection [215]. Experimental colds caused by B814 virus were about as severe as those caused by 229E; however, natural OC43 infections caused illnesses with considerably more cough and sore throat than did 229E infections [216]. The mean duration of coronavirus colds, at 6.5 days, was shorter than that seen in rhinovirus colds, at 9.5 days [35].

Clinical disease occurred in no more than 45 % of those infected with 229E in Tecumseh during the 1967 outbreak [31]. In Atlanta children, OC43 virus produced illness in about 50 % of those infected [28]. It is likely that with increase in age and concomitant experience with these agents, the ratio of clinically apparent to inapparent infection will decrease. As with other respiratory agents, a continuum of severity of symptoms exists among those in whom infection results in disease, and this may also be related to past experience with the viruses.

The mechanisms that lead to recovery from coronavirus infections have not been well defined. In volunteer studies, in persons infected with 229E-like strains, it is clear that symptomatic reinfection can occur after a period of about 1 year. It is not clear whether this is due to waning immunity or antigenic drift. Immunocompromised patients shed virus for a prolonged period and may sometimes be associated with a fatal outcome.

The novel MERS coronavirus initially presents with fever and myalgia, sometimes with gastrointestinal symptoms, rapidly progressing to severe viral pneumonia leading to respiratory failure, with renal dysfunction observed in some patients. Virus was detectable in the respiratory tract as well as the stool [119].

8.2 Viral Antigens Associated with Immunity

Virus-neutralizing antibodies are those that react with the virus S (and, where present, HE) protein although some antibodies against the virus M protein can also neutralize the virus in the presence of complement. Virus-neutralizing antibodies mainly bind to the N-terminal S1 part of the protein, which is also the part of the protein that manifests the greatest amino acid sequence variation. The removal of glycans from the S protein greatly reduces the binding of neutralizing antibodies. Antibodies to the S protein have also been associated with enhanced pathogenesis in feline infectious peritonitis virus, but such immunopathology has not so far been convincingly demonstrated with human coronaviruses. The nucleocapsid protein contributes to cell-mediated immune protection [209].

Neutralizing antibody responses to SARS-CoV appear in the second week of illness and peak at around 30 days of illness and antibodies remain detectable for many years. The major neutralizing epitope is in the region of the S protein amino acid residues 441–700 [98, 99, 209].

9 Control and Prevention

It is premature at present to think in terms of control of respiratory coronavirus infection by vaccination. Thus, preparation of vaccines using conventional types is impossible. The frequency of reinfection observed is so high that control by vaccination may not be practical, but it is possible that future studies may allow further characterization of truly protective antibodies. Work on vaccines for the animal viruses is in

progress, and these studies may help in understanding issues of protection. Chemoprophylaxis and related measures may be a more practical approach; it has been shown that recombinant α-interferon can prevent infections artificially produced in volunteers [217], and other approaches have been under investigation [25, 217–219]. There remains environmental control of infection; such efforts have rarely been useful for other respiratory agents, but they may be more efficacious if a practical barrier to transmission can be devised [220].

The situation is quite different in terms of the SARS-CoV, because of the severity of the disease produced. Here, the work on vaccines moved forward in the years immediately after 2003. Some of this activity of specific vaccine development continues but at a slower pace. Even when human cases were occurring, it was unclear how such a vaccine, if available, should be used, given the distribution of infection and occurrence of clinical disease. With disappearance of human cases, it has become even more difficult to decide on the appropriate vaccine target populations, except for those who might be exposed in a laboratory setting.

During the SARS episode, as no virus-specific antiviral agent was available, a variety of treatments were used, including the broad-acting antiviral agents ribavirin and interferon as well as corticosteroids. Because of the severity of the disease, many were used in combination, and it was difficult to say retrospectively whether any individually or in combination had a positive effect [162]. Corticosteroid therapy was associated with both short-term (secondary infections, increased viral load) and long-term (osteoporosis, avascular necrosis) adverse effects [221].

10 Unresolved Problems

The major problem in working with the respiratory coronaviruses has been solved with the development of RT-PCR. Previously, because of the difficulty in growing them in cell culture, epidemiologic and clinical studies had to rely on serology. While less limiting in epidemiologic studies, where regular blood collections can be scheduled, it sharply constrained the ability to identify the role of hCoVs in causing severe respiratory infections. Now we recognize the existence of four different coronaviruses, and there may be more that have not yet been identified. Paradoxically, the situation has now been reversed; there are many reports on the involvement of these agents in hospitalized cases, but epidemiologic studies involving all four hCoVs in different populations over time have been relatively scarce. It was previously thought that the viruses cycle in their appearance over a period of years, but recent evidence is lacking, especially pertaining to the newly identified viruses, NL63 and HKU1; however, there are still data suggesting that, in the temperate zones, the viruses are most active in late winter–spring. Ironically, with the PCR technique, it has become common to identify more than one virus from the same individual. This is not limited to the coronaviruses but includes many other respiratory viruses as well. There is a need to determine whether these are true coinfections or whether there may be asymptomatic or prolonged carriage involved. If they are real coinfections, there may be consequences of having more than one agent present during an illness.

The SARS-CoV emerged from a zoonotic reservoir and spread worldwide in a short period of time. We still do not know how and why this happened, and therefore we must be concerned that such an event could occur again. We do not have either vaccines or antivirals for the SARS-CoV; the need is probably greater for antivirals, given the severity of the illness and the question of how a vaccine would be used in the current situation. The recent identification of a novel coronavirus gives increased urgency to this need; it is likely that an anticoronavirus drug would be of use whatever the particular type involved. Overall, the epidemiologic lesson to be learned from SARS is the need for good surveillance at the animal–human interface. The virus was probably transmitting locally from human to human for months before it escaped to the rest of the world. If this had been recognized, there could have been earlier efforts to contain spread, which was effectively accomplished later, but only after much damage had been done.

The emergence of a novel MERS coronavirus with potential to cause severe human disease, though so far originating in the Middle East and manifesting limited human-to-human transmission including transmission within health-care facilities, is reminiscent of the emergence of SARS and is a concern for global public health [120].

The numbers of laboratory-confirmed patients with MERS continues to increase with 837 laboratory confirmed cases and 291 deaths being reported to WHO as of 23 July 2014. The median age of all cases is 52 years, but primary human cases (those who have no exposure to other confirmed cases) are older (median age 58 years) compared to secondary cases (median age 45 years). The majority of confirmed cases have underlying health conditions. All cases so far have a link to the Middle East with primary human infections reported from Jordan, Kuwait, Oman, Qatar, Saudi Arabia and the United Arab Emirates. Cases reported from outside the Middle East have either a history of travel to the Middle East or exposure to a patient who acquired infection from that region. Clusters of human cases and evidence of limited human-to-human transmission have been reported. To date, more than half of the secondary cases have been associated with health care settings, including health care workers. Health care workers appear to have less severe disease in general, although deaths have occasionally been reported [222].

MERS coronavirus (MERS-CoV) has been detected in nasal swabs of apparently healthy dromedary camels, and adult animals from the Middle East and Africa have high rates of sero-positivity [223, 224]. In some cases, infection of dromedary camel herds has preceded disease in humans in close contact with such animals [225]. However, in a large number of human cases, there appears to be no record of a history of contact with camels. The dromedary MERS-CoV virus appears genetically identical to those infecting humans, but abattoir workers with repeated exposure to potentially infected animals have little serological evidence of infection [223]. The geographic distribution of MERS-CoV infection in camels (including North East Africa) is wider than that reported in primary human cases reported so far. It remains to be seen whether this represents under-recognition of human cases in a wider geographic area. MERS-CoV antibodies have been detected in archived dromedary sera collected over two decades ago [226], and this may indicate that MERS is a recently recognised, rather than a newly emerging, disease. However, the possibility of a recent virus mutation that increased the risk of transmission to humans cannot be ruled out.

No specific validated therapeutic options or vaccines are available so far.

Enteroviruses and Parechoviruses: Echoviruses, Coxsackieviruses, and Others

11

M. Steven Oberste and Susan I. Gerber

1 Introduction

The enteroviruses (genus *Enterovirus*, family *Picornaviridae*) are among the most common viruses infecting humans. In addition to the human enteroviruses (polioviruses, coxsackieviruses, echoviruses, and numbered enteroviruses), the genus *Enterovirus* also contains viruses that infect nonhuman primates and livestock, as well as the human rhinoviruses, a recent addition to the genus [117, 201] (Table 11.1). These viruses share a number of clinical, epidemiologic, and ecological characteristics as well as physical and biochemical properties. Originally, the enteroviruses were classified into the subgroups of polioviruses (PV), coxsackie A viruses (CVA) and coxsackie B viruses (CVB), and echoviruses, based on the empirical observations of their association with certain clinical syndromes or disease, tissue tropism, nature of disease in suckling mice, growth in certain specific cell cultures, and in some cases antigenic similarities [46–48, 203] (Table 11.2). The viruses now known as "parechoviruses" share a number of physical and biological properties with the enteroviruses and were originally classified in the genus *Enterovirus*. However, biological differences were apparent even 50 years ago, and, once molecular diagnostics and genome sequences became available, it was obvious that the parechoviruses were distinct from the enteroviruses and they have been reclassified into a separate genus, *Parechovirus* [45, 102]. Nevertheless, the enteroviruses and parechoviruses are very similar clinically, cause the same spectrum of illnesses, and can be detected in the same clinical specimens, so they are considered together here. The rhinoviruses are described in detail in Chap. 29.

The rate at which new enteroviruses and parechoviruses have been discovered has accelerated following the introduction of molecular typing methods [182, 184] and the ready availability of genome sequences for every known enterovirus type. In addition to the enteroviruses of humans, numerous enteroviruses of other animals are known, including those of nonhuman primates and of livestock, primarily cattle, swine, and sheep. In some cases, human enteroviruses and human parechoviruses have also been detected in nonhuman primates (Table 11.1) [89, 190].

Enteroviruses can cause a wide variety of illnesses in humans, ranging from minor undifferentiated febrile illness to severe and permanent paralysis. For all members of the group, however, subclinical infection is far more common than clinically manifest disease. Although certain enteroviruses have been more frequently responsible for epidemics involving a specific syndrome, the same serotypes may at other times and in other places be associated with infections having different clinical manifestations or producing no symptoms. On the other hand, different viruses may produce the same syndrome. For these reasons, clinical disease is not a satisfactory basis for classification or, as a rule, for diagnosis.

Poliomyelitis is an acute infectious disease that in its serious form affects the CNS. The destruction of motor neurons in the spinal cord results in flaccid paralysis. Because polioviruses can cause the most severe disease of any for which enteroviruses are responsible, these agents have received the most comprehensive study and have served as models in studies of other enteroviruses. The polioviruses are described in detail in Chap. 13.

The disease manifestations caused by the coxsackieviruses, echoviruses, and numbered enteroviruses largely overlap. The

Table 11.1 Picornavirus genera, species[a], and (sero)types

Genera and species		# Types	Comments
Genus *Enterovirus*		**269**	
	Human enterovirus A[b]	22	Five have been found only in nonhuman primates
	Human enterovirus B[b]	60	Two have been found only in nonhuman primates
	Human enterovirus C[b]	21	
	Human enterovirus D[b]	4	
	Human rhinovirus A[b, c]	77	
	Human rhinovirus B[b, c]	25	
	Human rhinovirus C[b, c]	49	
	Simian enterovirus A	1	
	Bovine enterovirus	2	Possible 3rd type detected in sheep
	Porcine enterovirus B	3	
	Unclassified	5	Detected in nonhuman primates
Genus *Parechovirus*[d]		**20**	
	Human parechovirus[b]	16	Types 1 and 2 formerly classified in genus *Enterovirus*
	Ljungan virus	4	
Genus *Hepatovirus*[b, e]		**1**	
Genus *Cardiovirus*		**12**	
	Encephalomyocarditis virus[b]	1	
	Theilovirus[b]	11	
Genus *Kobuvirus*		**3**	
	Aichi virus[b]	1	
	Bovine kobuvirus	1	Also found in sheep and pigs
	Porcine kobuvirus	1	
	Unclassified	2	One virus detected in rodents and one in dogs
Genus *Teschovirus*		**11**	
Genus *Erbovirus*		**3**	
Genus *Aphthovirus*		**11**	
	Foot-and-mouth disease virus	7	
	Bovine rhinitis A virus	1	
Bovine rhinitis B virus		2	
	Equine rhinitis A virus	1	
Genus *Sapelovirus*		**8**	
	Simian sapelovirus	3	
	Porcine sapelovirus	1	Formerly porcine enterovirus A in genus *Enterovirus*
	Avian sapelovirus	1	
	Unclassified	3	One virus detected in rodents and two in sea lions
Genus *Senecavirus*		**1**	
Genus *Tremovirus*		**1**	
Genus *Avihepatovirus*		**3**	
Proposed genus *Aquamavirus*		**1**	
Proposed genus *Cosavirus*[b]		**4**	
Proposed genus *Megrivirus*		**1**	
Proposed genus *Salivirus*[b]		**1**	
Unclassified picornaviruses		**18**	Viruses detected in bats, cats, rodents, sheep, birds, fish, and reptiles

[a]The classification scheme shown is from the Picornavirus Study Group of the International Committee on the Taxonomy of Viruses [117, 118]. The types that comprise the human enterovirus species are listed in Tables 11.3, 11.4, 11.5, and 11.6
[b]At least one virus in the genus or species has been detected in humans
[c]See Chap. 30
[d]The human parechovirus types are listed in Table 11.7
[e]See Chap. 18

Table 11.2 Classification of human enteroviruses

Traditional taxonomy	Current taxonomy
Polioviruses	[*Human*] *enterovirus A* (*HEV-A*)
PV1–3	CAV2–8, 10, 12, 14, 16; EV71, EV76 EV89, EV90, EV91, EV114, EV119 (EV92, SV19, SV43, SV46, and BA13 are classified in HEV-A, but they have been detected only in nonhuman primates)
Coxsackie A viruses	[*Human*] *enterovirus B* (*HEV-B*)
CVA1–22, 24	CAV9; CBV1–6; E1–7, 9, 11–21, 24–27, 29–33; EV69, EV73–75, EV77–88, EV100–101, EV106–107 (EV110 and SA5 are classified in HEV-B, but they have been detected only in nonhuman primates)
Coxsackie B viruses	[*Human*] *enterovirus C* (*HEV-C*)
CVB1–6	PV1–3, CAV1, 11, 13, 17, 19–22, 24, EV95–96, EV99, EV102, EV104–105, EV109, EV113, EV116–118
Echoviruses	[*Human*] *enterovirus D* (*HEV-D*)
E1–7, 9, 11–21, 24–27, 29–33	EV68, 70, EV94, EV111 (EV120 is classified in HEV-D, but it has been detected only in nonhuman primates)
Numbered enteroviruses	*Unassigned*
EV68–71	EV122–123

In the new taxonomy, "Human" is in brackets because there is a pending taxonomy proposal to drop host species from picornavirus species names [117]. The gaps in numbering result from changes in classification. Since the time of their discovery and initial classification, some serotypes have been found to be identical to another enterovirus (i.e., coxsackievirus A15 is the same as coxsackievirus A11, coxsackievirus A18 is the same as coxsackievirus A13, coxsackievirus A23 is the same as echovirus 9, echovirus 8 is the same as echovirus 1, and echovirus 34 is a variant of CVA24). In addition, some serotypes have been reclassified as members of other picornavirus genera or other virus families. Echovirus 10 is reovirus 1 (genus *Orthoreovirus*, family *Reoviridae*), echovirus 28 is human rhinovirus 1A (genus *Enterovirus*, family *Picornaviridae*), enterovirus 72 is human hepatitis A virus (genus *Hepatovirus*, family *Picornaviridae*), and echoviruses 22 and 23 are now considered human parechoviruses 1 and 2, respectively (genus *Parechovirus*, family *Picornaviridae*). Additional types (SV6, EV103, EV108, EV112, EV115, and EV121) have been detected only in nonhuman primates and are classified in the proposed species, *Enterovirus J*. Modified from Khetsuriani et al. (2006)

coxsackieviruses produce a variety of illnesses, including aseptic meningitis, herpangina, epidemic myalgia (pleurodynia, Bornholm disease), hand, foot, and mouth disease, myocarditis, pericarditis, pneumonia, rashes, and common colds, with some differences between the group A and group B coxsackieviruses. They may also have a role in some congenital malformations and in the development of type 1 diabetes. Aseptic meningitis, febrile illnesses with or without rash, and common colds are among the diseases caused by echoviruses. Among the newer enterovirus (EV) types, EV68 has caused lower respiratory illness, EV70 is the agent of widespread epidemics of acute hemorrhagic conjunctivitis (as is a variant of CVA24), and EV71 has caused aseptic meningitis, brainstem encephalitis, and hand, foot, and mouth disease in a number of countries. EV71 is described in detail in Chap. 12. Most of the numbered enteroviruses are also associated with the same illnesses as the coxsackieviruses and echoviruses. (Further details of clinical manifestations of enterovirus infections are given in Sect. 8.)

2 Historical Background

Enteroviruses have been studied in detail for over a century. As a result, a great deal of information is available in earlier reviews and textbooks [55, 65, 149, 150, 157, 166, 200–202, 225, 238, 251]. Consequently, only a few key highlights will be addressed here (see also Chap. 14).

The history of the enteroviruses begins with the history of poliovirus. Paralytic poliomyelitis appears in records of early antiquity, but it was first recognized as a clinical entity only in the late eighteenth and early nineteenth centuries. Poliomyelitis became the subject of intense study after large epidemics began to appear in Europe and North America. In 1908, Landsteiner and Popper successfully transmitted the disease to nonhuman primates, marking identification of the first human "filterable agent" (virus) [123]. During the first half of the twentieth century, many details of poliovirus biology and pathogenesis were elucidated, primarily by using nonhuman primates as a model system, though some strains could be adapted to growth in laboratory rodents, allowing for studies that were not feasible in larger animals. Despite the primary pathology occurring in the anterior horn of the spinal cord, the virus was shown to be excreted in stools of patients, suggesting a role for fecal-oral transmission and enteric replication. Certain nonhuman primates could be infected by the alimentary route, further aiding in the understanding of pathogenesis and transmission. Significant antigenic differences among poliovirus strains were documented, and neutralization studies identified three antigenic types [24]. One of the key innovations—and, indeed, a key enabling technology for all of animal virology—was the discovery that polioviruses could be isolated and propagated in vitro, in cell cultures derived from primate nonneural tissues [67].

The first of the viruses in coxsackievirus group A was isolated by inoculation of infant mice with fecal material from two paralyzed children during an epidemic of poliomyelitis in 1948 in Coxsackie, New York [54]. Additional coxsackie A viruses, as well as the first coxsackieviruses of

group B [144], were discovered shortly thereafter by similar methods. Group B coxsackieviruses were associated with aseptic meningitis and with epidemic myalgia and pleurodynia [52]. Group A and B coxsackieviruses were distinguished by their differing pathological effects in baby mice as well as their antigenic properties (see Sect. 4).

Once human and monkey cell cultures were implemented in a number of virology laboratories, largely for poliovirus isolation from stool specimens of patients with acute flaccid paralysis [67], additional enteric viruses were discovered. While these new viruses readily produced cytopathology in cultured cells, they were not pathogenic for laboratory animals, unlike the polioviruses and coxsackieviruses [146, 219]. These viruses could be isolated from healthy children [84, 96, 146, 216] as well as from patients with aseptic meningitis [146, 147], and multiple serotypes were identified [147, 216]. Because they failed to produce illness in laboratory animals and were not yet clearly associated with human disease, they were called "orphan" viruses or human enteric viruses; later they became known as ECHO (enteric cytopathogenic human orphan) viruses [47], a name subsequently simplified to "echoviruses." "Orphan" viruses causing cytopathology in culture were also identified in nonhuman primates and livestock.

In addition to their characteristic mouse pathogenicity, certain of the coxsackieviruses were found to grow readily in tissue cultures; other strains, serologically identical with the mouse-pathogenic prototype, failed to produce disease in baby mice. Conversely, certain strains of echoviruses were found to be pathogenic for mice. As instances of such overlapping properties accumulated, blurring the initial distinction made between coxsackieviruses and echoviruses, it was recommended that subsequently, as new enterovirus types were discovered, they would simply be assigned sequential numbers, as enterovirus 68, enterovirus 69, and so on [222]. The currently accepted enterovirus types are listed in Tables 11.3, 11.4, 11.5, and 11.6, and the parechovirus types are listed in Table 11.7.

3 Methods for Epidemiologic Analysis

3.1 Sources of Mortality Data

In the United States, enterovirus infections are not generally notifiable in that they are not required to be reported to local, state, and national public health authorities. In addition, encephalitis and aseptic meningitis are not uniformly reportable, although some jurisdictions within the United States may collect information on these illnesses. Often, enteroviral infections may go unrecognized unless clinicians order appropriate testing, and because there are no recommended antivirals, virologic diagnosis does not lead to a specific antiviral therapy.

The most recent enterovirus mortality data for the United States is described in the Morbidity and Mortality Weekly Report published by the Centers for Disease Control and Prevention [113], with periodic updates [36]. The National Enterovirus Surveillance System (NESS) is a voluntary passive reporting system that monitors trends in circulating enteroviruses since 1961. The data in NESS are contributed by state and local public health laboratories and a few large clinical reference laboratories. Outcome was reported for 3,392 (15.9 %) of 24,654 cases during 1983–1998. During this period, 131 (3.3 %) fatal outcomes were reported. Of the 115 deaths with known age, 77 (67 %) occurred among children <1 year. In 1998, the NESS reporting form was simplified to encourage broader reporting by public health laboratories, and outcome data are no longer collected.

3.2 Sources of Morbidity Data

Sources of population morbidity data for enteroviruses are often not representative due to variable diagnostic capabilities, lack of uniform reporting, and lack of necessary correlation between enteroviral excretion and association with disease. Most morbidity data are obtained from outbreak investigations and case reports, with consequent extrapolations to the surrounding community.

Historically, the Virus Watch Program in the 1960s in the United States provided prospective longitudinal data from a defined population [83, 241]. Families were observed for acute illnesses for a period of years and periodically sampled for viruses. Although an expensive study design, data collected about illness incidence with accompanying virologic sampling yielded important information about the association of enterovirus identification with disease [49, 66, 83].

Trends in enterovirus types and human parechovirus (HPeV) types are reported through NESS in the United States [113]. Although only laboratory data is reported through NESS, descriptions of diseases associated with common serotypes may be apparent amidst outbreak reports where detailed clinical information is collected. For example, in 2007 and 2008 CVB1 was the predominant serotype reported, and in 2007 CVB1 was the cause of an outbreak of severe neonatal infections in the United States [34]. In addition to NESS, the Infectious Agents Surveillance Report from Japan's National Institute of Infectious Diseases describes viral detections associated with specific diseases such as herpangina and hand, foot, and mouth disease.

3.3 Serological and Clinical Surveys

Since there are many enterovirus and HPeV types, few serological surveys exist that fully characterize seroprevalence in vulnerable populations. However, understanding

susceptibility to EV71 infection has received more attention because of the potential for large outbreaks of hand, foot, and mouth disease (HFMD) including a subset of children with severe neurologic complications, particularly in Asia. In Shanghai, after a large outbreak of HFMD in 2010, a serosurvey revealed that loss of maternal antibodies later in infancy and lack of acquired anti-EV71 immunity were likely responsible for a large number of severe HFMD cases in the 1–2-year age group in 2011 [285]. Likewise in Singapore, high EV71 neutralizing antibody titers were identified in a group of children aged one to six years compared to older children, indicating that infections were acquired in early childhood [7].

The predominantly circulating enteroviral serotypes may change over time and may be associated with large outbreaks of clinically recognizable syndromes. Enterovirus surveillance systems vary greatly worldwide, but all contribute information regarding circulating serotypes over geography and time [201]. Molecular typing and phylogenetic surveys yield important information for detection of new viral strains and outbreaks of clinical disease [169, 270].

Although enteroviruses are commonly identified among children, especially in summer and autumn months, targeted epidemiologic surveillance may provide a snapshot of circulating seasonal serotypes. Recently, specimens obtained clinically from children were collected along with environmental samples in the Republic of Georgia from 2002 to 2005 [114]. A wide range of enteroviruses were identified, with notable genetic diversity, including some that have been rarely identified in the United States. The information obtained from environmental and clinical specimens created a better understanding of circulating serotypes, which is important in preparing for large-scale outbreaks associated with the emergence of new enterovirus strains. Another survey of clinical specimens obtained from hospitalized children in Cyprus from 2003 to 2007 demonstrated changes in predominant serotypes over time; these changes were consistent with those in other European countries [254]. In the United States, NESS has provided seasonal information on circulating serotypes (Fig. 11.1). Correlations between serotype detection and certain specimen types may reflect clinical presentations observed in the community [36, 113]. For example, echovirus 9 and echovirus 30, which are commonly associated with aseptic meningitis,

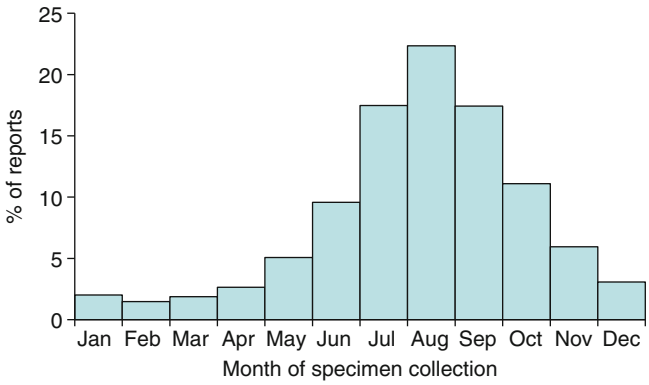

Fig. 11.1 Percentage of enterovirus reports by month, United States, by month of specimen collection, 1983–2005 (From Khetsuriani et al. [114], in the public domain)

Echovirus types 1 and 8 share antigens, type 1 having the broader spectrum. Type 10 was soon excluded from this group: it turned out to be a larger RNA virus and was reclassified as a prototypic reovirus. Type 28 was reclassified as rhinovirus type 1. Types 22 and 23 have been reclassified as members of the genus parechovirus and are named parechovirus 1 and 2. Type 34, DN-19, is now considered a prime strain of CVA24, rather than a distinct echovirus. Additional newer serotypes (EV73 and higher) are proposed new types defined on the basis of genetic sequence information

were mostly detected from cerebrospinal fluid specimens. Epidemiologic assessments of enteroviral serotypes and clinical disease worldwide are important for understanding outbreaks of disease caused by emergent strains in new geographic areas. This type of surveillance is also important to identify modified clinical presentations of common diseases such as HFMD caused by coxsackievirus A6 during 2010–2012 [22, 37, 76, 267, 277]. Knowledge of circulating enteroviral serotypes in time and place may allow for better recognition of large-scale outbreaks and consequent approaches to control viral transmission.

3.4 Detection of Viruses in the Environment

Enteroviruses excreted in feces will end up in sewage in developed countries and in surface waters and waterways in developing countries that lack a closed sewage collection system. As a result, virus isolation from sewage, whether in a closed or open system, provides an opportunity for a relatively unbiased sampling of enteroviruses circulating in the population. Typical sewage treatment systems may not fully remove or inactivate viruses, including enteroviruses [72]. The primary disadvantage of sewage testing is the extra effort required to remove solids and other potential inhibitors of cell culture isolation or molecular detection methods. However, a number of methods have been developed to overcome this problem, including simple filtration, adsorption to charged filters, and concentration by phase separation [228]. In some cases, concentration systems can be deployed in the field, to reduce the amount of sample that must be transported to the laboratory [155, 158, 159, 161, 261]. A second disadvantage is that sewage can often be expected to contain a mixture of enteric viruses, especially in areas with high population density and poor sanitation. Separation of the virus mixtures may require passage on multiple cell lines, cloning by limiting dilution, or plaque purification, steps which may impact the feasibility of routine environmental surveillance.

Environmental sampling has been used to supplement patient-based virus surveillance [20, 23, 43, 81, 110, 122, 135, 148], but it has also been applied to outbreak investigations, to demonstrate the source of infection. For example, isolation of coxsackievirus B5 from an open lake swimming area identified the lake as a source of an epidemic at a summer camp [91].

3.5 Laboratory Methods

Detailed descriptions of the principles and procedures for diagnosis of enterovirus infections have been published [166, 187, 202, 224].

Understanding the epidemiology of enterovirus infections and disease depends largely on the ability of the laboratory

to identify the specific virus involved and to integrate that information in the context of other studies of the same serotype or the same disease. Traditionally, enterovirus identification was based on virus isolation in culture and typing by serotype-specific antisera, either individually or in specific intersecting pools, a system which depends on shared, standardized reagents [47, 154]. While this system was sufficient for most purposes, and was the standard for more than four decades, it became increasingly complicated as more enterovirus serotypes were discovered. It was recognized as early as 1962 that "the rate of making new [enterovirus] discoveries has slowed, probably only because the labors involved in establishing 'new' serotypes are now so very great." [269] Since the late 1990s, molecular typing methods have become the standard for identifying enterovirus serotype (often now referred to as simply "type"), and the methods are equally adept at identifying new enteroviruses, more than 50 of which have been discovered since 2000.

3.5.1 Virus Isolation and Identification

The specimens that most frequently yield enterovirus or parechovirus in culture are stools, rectal swabs, throat swabs, and naso- or oropharyngeal swabs [156, 202]. In addition, cerebrospinal fluid (CSF) may yield virus in cases of neurologic illness, such as aseptic meningitis. In children, even after development of symptoms has led to hospitalization, a variety of non-polio enteroviruses may be detected in the blood, either free in the serum or in mononuclear leukocytes [212]. Virus may also be isolated from vesicle fluids (e.g., from HFMD cases), urine, conjunctival swabs (EV70 and CVA24 variant), and nasal secretions. In general, virus may be recovered from throat swabs up to about 2 weeks after onset of symptoms and from stool for up to 8 weeks [6]. In fatal cases of suspected enteroviral etiology, virus may be detected in the organ system affected as well as in colon contents. Of course, other viruses may also be isolated from feces or respiratory secretions, including rotaviruses, reoviruses, adenoviruses, rhinoviruses, and the viruses of measles, mumps, rubella, and herpes simplex. Many of these agents produce distinctive cytopathic effects (CPE), which at once differentiate them from enteroviruses.

Traditionally, experienced laboratory personnel could make a presumptive diagnosis of enteroviral infection on the basis of the nature of the associated illness (if any), the time of year when the specimen was obtained, the culture (or mouse) system in which the virus isolate grew, and the characteristic CPE observed in the cultures or the characteristic pathology induced in the mice. There was some value in reporting a presumptive identification without waiting for specific typing as early recognition of probable enteroviral infection could provide information for the management of a patient or of a community outbreak and serve to contraindicate administration of unnecessary or undesirable antibiotic therapy.

The enteroviruses can generally be propagated in either cell culture or suckling mice [156, 201, 202], but some of the newer enterovirus and parechovirus types have been identified only by direct detection in stool specimens. Most types can be grown in at least one human or primate continuous cell culture [119, 125, 180, 196, 205, 206, 211, 229, 234]; however, no single cell line can be used to isolate or propagate all cultivable enteroviruses. Despite many years of work, a few types (e.g., CVA19) have been propagated only in suckling mice. The typical host range of human enterovirus in cell cultures or animals is not clearly associated with a given virus species.

Infection of target cells depends on virus binding to specific receptors on the cell surface. Collectively, the enteroviruses use at least eight different receptors, including two different integrins ($\alpha_v\beta_3$ and $\alpha_2\beta_1$), decay-accelerating factor (DAF; CD55), the coxsackievirus-adenovirus receptor (CAR), intracellular adhesion molecule 1 (ICAM-1), scavenger receptor B2 (SCARB2), P-selectin glycoprotein ligand-1 (PSGL-1), and the poliovirus receptor (CD155) [174, 223, 236, 279]. Some enteroviruses may use more than one receptor (e.g., EV71 uses both SCARB2 and PSGL-1; some group B coxsackieviruses can use both CAR and DAF), and other, unidentified receptors may also exist. The parechoviruses use two different integrins, $\alpha_v\beta_3$ and $\alpha_v\beta_1$, as well as at least one additional, unknown receptor. The procedure for virus isolation involves inoculation of appropriate specimens onto susceptible cultured cells. In clinical laboratories, it is common to simultaneously inoculate several types of human and primate cells to increase the spectrum of viruses that can be detected [156, 240]. The coxsackieviruses, including those that do not grow in cell culture, can be isolated and propagated by intracerebral inoculation of suckling mice [234].

It is usually not clinically necessary to identify the specific serotype for every enterovirus isolate; simply knowing an enterovirus has been detected is usually sufficient. However, knowing the type can be important in outbreak investigations, to determine whether a case is part of the outbreak or part of the sporadic enterovirus background. Knowing the type can also be of interest in cases that are particularly severe or that have an unusual presentation.

Many clinical laboratories no longer perform cell culture isolation for suspected enterovirus cases in routine diagnostic testing. When isolates are obtained, they may be confirmed as a specific enterovirus type by neutralization with type-specific antisera. The most widely used reagent antisera were prepared in horses and can be obtained from the World Health Organization (WHO) [85, 86, 151–153]; however, supplies are now quite limited. Type-specific monoclonal antibodies may also be used for typing, usually in indirect immunofluorescence assays to identify viruses isolated in culture [130, 218]. Commercially available monoclonal antibodies can be used to detect relatively common serotypes, including PV1 to 3, CVA9, CVA24, CVB1 to 6, E4, E6, E9, E11, E30, EV70, and EV71. Additional monoclonal

antibodies have recently been developed for CVA2, CVA4 to 5, and CVA10 [130]. Indirect immunofluorescence is faster and easier to perform than neutralization, and the reagents can be produced in large quantity as needed, but the method still suffers from the same limitations as other antigenic typing methods, namely, the requirement for a virus isolate in culture prior to typing and the need for a large number of reagents to identify all serotypes. Despite these limitations, the method has been adopted as the standard typing method in a large number of clinical and reference laboratories.

3.5.2 Molecular Detection and Identification

Because of distinct advantages in speed, molecular detection techniques have already supplanted traditional methods of detection and characterization as the gold standard. Specifically, molecular procedures are now the methods of choice for enterovirus detection in CSF and are widely used for diagnosis of patients with a clinical presentation of meningitis. Several of these are licensed for clinical use in the United States or Europe.

By far the most common use of reverse transcription (RT) PCR for enterovirus diagnosis is the direct detection of virus in clinical specimens [189, 220, 231]. The individual details of the procedures may vary, but all methods that can generically detect enterovirus are similar in their key features. The most important property of these tests is that the primers target conserved sequences in the 5′ non-translated region (NTR) of the virus genome. Many different primers targeting this region have been published, recognizing different sequence motifs and slightly different sequences within those sites [187, 226]. Many of these assays, however, have not been completely evaluated on a large number of clinical isolates to confirm reactivity with all enterovirus types and/or with multiple strains within a given type. Therefore, they have not been validated sufficiently for diagnostic use [187]. The major advantage of these pan-enterovirus RT-PCR assays is that rapid detection is possible, even with very small amounts of clinical specimens such as CSF. Such assays also facilitate detection of enteroviruses that do not readily grow in cell culture. As with all RT-PCR, the sensitivity of amplification of RNA from biological specimens is highly variable, depending on the nature of the specimen. Many assays can be shown to give a positive result even from only a few copies of viral RNA in a "clean" specimen such as CSF, but it is not uncommon for the sensitivity to be many orders of magnitude lower in other specimen types (e.g., stool). The introduction of "real-time" PCR methods has greatly improved sensitivity, as the fluorescence detection systems generally increase the sensitivity significantly.

A common goal in virus identification is knowledge of the sequence of the viral genome. Encoded within this sequence are determinants for all the biological properties that are attributable to a given virus. In theory, therefore, the nucleic acid sequence of a virus represents its ultimate characterization. All important information about a virus could potentially be obtained directly by PCR in conjunction with nucleic acid sequencing if all the molecular correlates of viral phenotypic determinants were understood. The genetic correlates for many enterovirus properties remain uncertain, but it is possible to use sequence information to assign a sequence to a particular type [30, 31, 175, 179, 182, 183, 187]. The most common molecular typing system is based on RT-PCR and nucleotide sequencing of a portion of the genomic region encoding VP1 [175, 182, 184]. The type is inferred by comparison of the partial VP1 sequence with a database containing VP1 sequences for the prototype and variant strains of all human enterovirus types [187]. Using this approach, strains of homologous types can be easily discriminated from heterologous types, and new types can be identified. This method can greatly reduce the time required to type an enterovirus and can be used to type samples that are difficult or impossible to type using standard immunologic reagents or that fail to grow in culture [175, 184]. The technique is also useful to rapidly determine whether viruses isolated during an outbreak are epidemiologically related.

3.5.3 Tests for Antibody

Testing for the presence of type-specific antibody against enteroviruses is appropriate only when (i) a known enterovirus isolate from the patient is available and confirmation of the infecting serotype is necessary or (ii) a seroepidemiologic survey is being conducted to determine the community or study-group history of experience with a particular serotype or group (e.g., polioviruses). For routine diagnosis in a single patient or a locality, virus detection by RT-PCR is far simpler and faster and is the recommended approach, with virus isolation and/or molecular typing as options depending on the individual circumstances. For any purpose except a serological survey, paired serum specimens are required; the first sample must be taken as early as possible in the course of the illness or infection, the second 3–4 weeks later.

The neutralization test [156, 160] is accurate and type specific; complement fixation and agglutination (or agglutination inhibition) tests are no longer commonly used and are not recommended. Acute and convalescent sera are usually tested simultaneously, using various dilutions of serum against a constant amount (usually 100 $CCID_{50}$) of the specific virus [266]. A fourfold or greater rise in type-specific neutralizing antibody titer is considered diagnostic of recent infection. Antibody, however, may already be present at the time the original specimen is obtained because of the extended incubation period and prodromal period of many enteroviral illnesses, which complicates interpretation of results. If neutralizing antibody titers are found to be equally high in both acute and convalescent specimens, the infection might have taken place either recently or many years

before, since neutralizing antibody to any of the enteroviruses persists for years if not for life. In addition to the homologous antibody, antibodies against other enterovirus types may appear transiently and at low levels.

For diagnosis and study of acute hemorrhagic conjunctivitis caused by enterovirus type 70, isolation of the virus has been difficult, and most of the recent outbreaks have been identified solely by serological means, though RT-PCR can also be used to detect and identify virus directly in conjunctival swab samples.

Many serological studies rely on the detection of IgM antibody as evidence for recent enterovirus infection, and this is sometimes used as an alternative to the neutralization test, especially in epidemiologic studies. Several groups have developed an enzyme-linked immunosorbent assay (ELISA) for enterovirus-specific IgM [14, 61, 78, 94, 248]. These tests have been found positive for nearly 90 % of culture-confirmed group B coxsackievirus infections and can be performed rapidly. The ELISA has been successfully applied for epidemiologic investigations of outbreaks [79] as well as for specific diagnostic use [57, 264]. Depending on the configuration and sensitivity of the test, from 10 % to nearly 70 % of serum samples show a heterotypic response caused by other enterovirus infections. This heterotypic response has been exploited to measure broadly reactive antibody, and the assay has been used to detect enterovirus infection generically [26, 245]. It is clear that the human immune response to enterovirus infection includes antibodies that react with both serotype-specific epitopes and shared epitopes [74]. Despite this problem, there is a reasonably high concordance of results between assays of different configurations [94]. The IgM assays that are used in epidemiologic studies have very good sensitivity and appear to be very specific for enterovirus infection; however, these assays detect heterotypic antibodies resulting from other EV infections and, therefore, cannot be considered strictly serotype specific. A positive result with either the neutralization test or IgM ELISA indicates a recent viral infection; however, the infecting serotype found with the IgM assay may not be the same one determined by the neutralization test, and because the duration of IgM is relatively long and variable among individuals, the presence of enteroviral IgM is not a definitive test for current infection. Therefore, IgM data must be interpreted with some caution.

3.5.4 Parechovirus Diagnostics

Despite their original classification, sequencing and PCR studies demonstrated that echoviruses 22 and 23 are distinct from the enteroviruses, resulting in their reclassification as members of a new picornavirus genus, *Parechovirus* [45, 102, 117, 242]. Since then, 14 additional human parechovirus types have been identified (Oberste MS, unpublished data, 2008) [3, 11, 17, 18, 62, 105, 126, 265]. Like the enteroviruses, human parechoviruses were traditionally detected and identified by virus isolation and antigenic typing [127]. By these methods, HPeV1 (formerly echovirus 22) consistently accounted for 2–4 % of "enteroviruses" reported to the CDC from 1975 to 2005 [113]. RT-PCR began to supplant virus culture as the method of choice for enterovirus detection in clinical diagnostic laboratories in the mid-1990s. Since that time, the number of HPeV1 reports has declined to under 1 %, probably because HPeV-containing specimens are usually reported as enterovirus PCR-negative and not further characterized.

More recently, a number of investigators have developed real-time RT-PCR assays to detect HPeVs [11, 16, 17, 51, 60, 108, 176, 178]. These methods target conserved sites in the parechovirus 5′ NTR that are analogous to those targeted by enterovirus-specific RT-PCR assays. Like the enterovirus assays, the HPeV RT-PCR assays vary in level of validation; in particular, several have not been shown to detect the more recently identified types. Despite this possible limitation, a number of recent studies have applied molecular methods to the detection of human parechoviruses in patients with enteritis, respiratory illness, and neonatal sepsis-like syndrome [3, 11, 19, 105, 257, 265]. As these methods are increasingly integrated into the diagnostic routine of clinical and reference laboratories, a better estimate will emerge of the burden of disease attributable to this group of picornaviruses.

4 Biological Characteristics

4.1 General Properties

Enteroviruses share the basic properties of picornaviruses, including a ~7,500 nt genome of single-stranded, positive-sense RNA, small size (diameter 22–30 nm), lack of an envelope (i.e., a "naked" nucleocapsid), and insensitivity to ether and other lipid solvents, indicating lack of essential lipids (Fig. 11.2) [117, 201]. The genome encodes a single long open reading frame, flanked by non-translated regions at the 5′ and 3′ ends. The virus replicates in the cytoplasm of infected cells.

The enterovirus infectious particle is an icosahedral virion consisting of 60 copies of each of four capsid proteins (VP1–4) and a molecule of single-stranded genomic RNA. The molecular biology of enterovirus replication is typical for that of other plus-strand RNA viruses: uptake into the host cell through attachment to a specific cellular receptor, release of genomic RNA, protein synthesis, genome replication, and encapsidation. The molecular mechanisms underlying each of these steps are under intensive investigation. Because genomic RNA is of positive polarity, infectious virus can be recovered by transfection of naked RNA into appropriate cell cultures. Full-length cDNA clones have been generated for

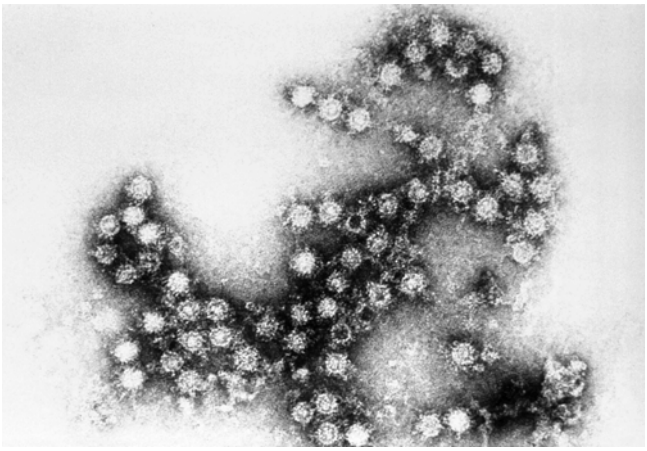

Fig. 11.2 Transmission electron micrograph of coxsackievirus B4 particles (From the Public Health Image Library, Centers for Disease Control and Prevention, 1981, in the public domain)

many enteroviruses, facilitating a reverse genetics approach to understanding the function of individual viral proteins and RNA elements.

Although much is known about the enteroviruses, still unresolved is the biochemical basis of virus stability associated with its portal of entry through the enteric tract, the determinants of virus spread in the host, and knowledge of how the virus penetrates its target tissue, thereby causing disease [167]. The key to the early events of infection is determined by unique cell surface receptors. The receptor plays a key role in the binding, penetration, and uncoating of the virus [223].

The human enteroviruses use at least eight different receptors to bind and gain entry into the host cell (CD155, DAF [CD55], CAR, ICAM-1, SCARB2, PSGL-1, and two different integrins) [174, 223, 236, 279]; however, the receptors for many enteroviruses remain unknown. The receptors for the polioviruses and rhinoviruses are members of a large group of normal cellular proteins known as the immunoglobulin gene superfamily [87, 177, 217, 223]. The receptors for echovirus 1 receptor and CVA9 are integrins [21, 252], proteins known to play a role in the interactions between cells and the extracellular matrix.

4.2 Reactions to Chemical and Physical Treatment

Enteroviruses are resistant to most laboratory disinfectants and to lipid solvents (e.g., ether), but they are rapidly inactivated by treatment with 0.3 % formaldehyde, 0.1 N HCl, or free residual chlorine at a level of 0.3–0.5 ppm. However, the presence of organic matter (e.g., in stool or sewage) is protective, so caution should be exercised when attempting to extrapolate from laboratory sensitivity data, often generated using purified virus, to real-world situations. The viruses lose infectivity rapidly when heated to 50 °C, but 1 M magnesium chloride can make the virions resistant to treatment at 50 °C for 1 h [259]. Enteroviruses are stable at freezing temperatures for decades, at 4 °C for weeks, and at room temperature for days. Virus in stool is stable at room temperature for at least 4 weeks and is also resistant to multiple freeze-thaw cycles. Desiccation quickly renders enteroviruses noninfectious. They are also inactivated by treatment with ultraviolet light, and vital dyes, such as neutral red, acridine orange, proflavine, can be incorporated into the structure of the viruses, making them susceptible to visible light [232, 260].

4.3 Antigenic Properties

The enterovirus serotypes were originally defined by neutralization assays, either in cell culture or in susceptible animal models [46–48, 203]. Antigenicity by neutralization in vitro correlates well with human immunity. Initially, enteroviruses were identified by neutralization with a standard set of antisera that recognized the "known" serotypes. When a virus was not neutralized by the standard panel, an antiserum was raised against the new virus and used in neutralization tests with standard reference strains. Strains which exhibited no cross-neutralization were considered putative new types. However, most of the newer types have been defined strictly on the basis of capsid sequences [185]; hence, their antigenic relationships to one another and to the older types is unknown. The extensive use of the neutralization assay in the 1950s and 1960s also revealed a number of minor cross-reactions and other antigenic relationships, both within and between the established types.

The neutralizing epitopes are located primarily at the edges of the "canyon" on the capsid surface, an area of virus-receptor interaction. These epitopes tend to be "conformational," i.e., they are not contiguous amino acids but, rather, are composed of residues on adjacent loops of one or more of the capsid proteins, VP1–3 (the VP4 protein is internal to the capsid and does not contribute to antigenicity). In the polioviruses, where the neutralization sites have been studied most extensively, sites on VP1 appear to be a major component of the key epitopes, with additional contributions by VP2 and VP3. Enterovirus capsids also contain a number of non-neutralizing epitopes, some of which are shared widely among the different types [74]. These can be readily detected by ELISA.

Despite the high error rate inherent in the enterovirus RNA-dependent RNA polymerases [1], the antigenic identity of enteroviruses is relatively stable (e.g., unlike influenza virus). Indeed, polio vaccines, developed using strains isolated over 50 years ago, are still effective against strains circulating today, even with considerable amino acid variation in the capsid (up to about 12 % difference in VP1).

4.4 Host Range

Almost by definition, humans are the natural host for the human enteroviruses. There is no evidence for zoonotic transmission, though at least some human enteroviruses can naturally infect certain nonhuman primate species [190]. In areas where humans and nonhuman primates are in frequent and close contact, such as in South Asia, infected primates presumably may participate in transmission, forming a single human and primate reservoir. Swine vesicular disease virus, an important livestock pathogen primarily because it is part of the differential diagnosis for foot-and-mouth disease virus, is genetically and antigenically related to coxsackievirus B5, presumably through infection of swine with the human virus at some time in the recent past [115, 287].

Many enteroviruses can infect or be adapted to infect common laboratory animal species, including rodents and monkeys, though blind passages may be needed in some cases. Indeed, the polioviruses and coxsackieviruses were first discovered by inoculation of laboratory animals. In newborn mice, the group A coxsackieviruses induce flaccid paralysis and extensive degeneration of skeletal muscle, with no involvement of the tongue, heart, and CNS; the animals usually succumb to infection within a week. By contrast, infection with group B coxsackieviruses proceeds more slowly and is characterized by spastic paralysis and tremors associated with encephalomyelitis, focal myositis, necrosis of brown fat pads, myocarditis, hepatitis, and acinar cell pancreatitis. With few exceptions, the echoviruses do not generally cause disease in mice. Most enteroviruses can be isolated and propagated in a wide range of cell cultures, usually of human or monkey origin, including cells derived from kidney, lung, and other tissues. However, some enteroviruses have been grown in only one or a few cell lines (e.g., some of the coxsackie A viruses have been propagated only in human rhabdomyosarcoma cells) [234]. The range of cells that can be infected is probably related to receptor usage, though differentially expressed intracellular factors necessary for virus replication could also play a role.

4.5 Replication of Enteroviruses

Most of the details of enterovirus replication have been elucidated through the use of poliovirus as a model [214]. When a virus particle binds to its cellular receptor, a conformational change is induced in the virion, resulting in extrusion of the genomic RNA into the cell cytoplasm [27, 95]. The viral RNA is translated through a cap-independent mechanism facilitated by direct interaction of the viral internal ribosome entry site ("IRES") in the 5′ NTR with cellular ribosomes [10]. Picornaviruses encode a single polyprotein, which is subsequently processed by viral proteinases to yield the mature viral proteins. A number of viral proteins interact with cellular proteins and structures to effectively inhibit cellular transcription and translation, shifting the cellular machinery to produce virus [53]. Once sufficient viral proteins are produced, viral synthesis shifts from an emphasis on translation to RNA replication, catalyzed by the virally encoded RNA-dependent RNA polymerase and using intracellular membranes derived from the rough endoplasmic reticulum and Golgi as a scaffold for the replication complexes [15, 170]. RNA synthesis is primed by the genome-linked viral protein ("VPg") which remains covalently linked to the genomic RNA [243]. Unlike cellular organisms and most DNA viruses, viral RNA-dependent RNA polymerases do not have proofreading and error-editing functions capable of correcting viral polymerase errors, and a large number of faulty nucleotide incorporations accumulate during RNA replication [272]. Mature virions are assembled in the cytoplasm through a mechanism that is not yet fully understood.

The time required from initiation of infection to completion of virus assembly ranges from 5 to 10 h, depending on pH, temperature, host cell, and number of particles to which the cell is exposed. Yields may be up to 100,000 particles per cell, but only 0.1–1 % of particles may be infectious.

Complete genome sequences have been determined for at least one strain of every enterovirus serotype, except for the absolute newest—even those can be expected soon, given the ease with which viral sequences can be generated [116]. Full-length cDNA clones are available for many serotypes, often downstream of a bacterial promoter than can be used to synthesize infectious RNA. Such clones have been invaluable in elucidating the function of individual viral proteins, as well as RNA structures that regulate viral translation and replication [192].

5 Descriptive Epidemiology

5.1 Key Features of Epidemiology of Enteroviruses

Over 100 enterovirus types have been identified, and many cause overlapping spectra of illness presentations, from subclinical or asymptomatic infections to central nervous system manifestations and sepsis. In particular, neonates and very young children are susceptible to more severe illness due to antigenic inexperience, and most children are exposed to enteroviruses early in life. However, some enterovirus infections may preferentially infect older age groups, and prognoses may vary. Parechoviruses are known to cause more severe disease in neonates and young children.

Enteroviruses are common and are primarily transmitted via the fecal-oral route. They may also be spread via respiratory droplets and from mother to infant prenatally and during the peripartum period. Enteroviruses may survive on surfaces

long enough that fomites may play a role in transmission. In addition, vesicle fluid may be another important route of transmission for children who have HFMD or other exanthems.

Outbreaks of enterovirus infections may be identified in communities and group settings. Families may spread enteroviruses among each other, and outbreaks often occur in day-care and school settings. Hygiene practices play an important role in transmission so viruses are often spread from child to child. Fecal shedding of enteroviruses may persist for several weeks, thus allowing children to potentially remain infectious for long periods.

In temperate climates, enteroviral infections are more often identified during summer and fall months, usually June–October (Fig. 11.1). However, in tropical climates, where sanitation may be poor and population density high, children may become infected with multiple enterovirus types and strains simultaneously and year-round. Because of the opportunity for increased transmission of enteroviruses in this setting, most neonates are born with maternal antibodies to a broader range of enterovirus types and are thus protected from illness. However, these children will acquire multiple enteroviral infections when maternal antibodies wane, usually in infancy and preschool ages.

5.2 General Epidemiology of Enteroviruses

5.2.1 Incidence and Prevalence

Seasonality of enteroviruses may be an indicator of disease incidence for common disease presentations such as HFMD. In summer and fall months, the percentage of specimens testing positive for enterovirus by NESS is elevated as compared to other seasons [36, 113]. Occurrences of clinical syndromes associated with specific enteroviral serotypes may serve as a marker of incidence of a particular enterovirus type in the community. Because surveillance is passive and dependent on case finding, the true incidence and prevalence of enteroviruses is unknown, and estimates of circulating enteroviruses are often obtained from outbreak investigations. For example, an epidemic of encephalitis in Uttar Pradesh, India, in 2008 was found to be associated with echovirus 19 and coxsackievirus B5 [121]. In 2007 in the United States, coxsackievirus B1 was the predominant type at the same time an outbreak of serious neonatal infections was reported [36, 270]. Outbreak investigations of clinical syndromes and associated enterovirus types will often correlate with predominant strains circulating in the community. Understanding trends of circulating serotypes may help predict increases in incidence and prevalence.

5.2.2 Epidemic and Endemic Behavior

Outbreaks of enterovirus infection/illness occur throughout the world. One set of types may be predominant for a time in a given geographic area, only to be succeeded by other types in subsequent years. There are two general patterns of circulation that describe enteroviruses in a population, endemic and epidemic activity. Endemic circulation within a population is best described as sporadic activity each year over a long period of time such that children acquire infection early in life. Most individuals have acquired antibodies within the first few years of life. Because of constant sporadic activity, a large population of nonimmune children will not occur; thus, it is unlikely a wide epidemic will follow. For example, in the United States between 1970 and 2005, coxsackieviruses A9, B2, B4, and enterovirus 71 were identified consistently at low levels of circulation with few distinct peaks during this time period [113]. The epidemic pattern is best described as large waves of circulation with longer periods of time between waves such that a nonimmune and therefore susceptible population accumulates, potentiating an outbreak when the virus is later introduced. Epidemic patterns of circulation in the United States from 1970 to 2005 were best exemplified by echoviruses 9, 13, and 30 and CVB5. Each of these viruses peaked and was among the most prevalent enteroviruses reported in a given year [113]. Interestingly, enteroviruses associated with endemic and epidemic patterns of circulation in one geographic area or country may exhibit a different pattern of circulation in another part of the world. Thus, enterovirus circulation patterns and surveillance priorities are unique to different areas in the world, and trends in enterovirus activity and identification of outbreaks should be an important priority such that information can be shared with other countries where a specific type may not yet be circulating.

Outbreaks of infections caused by enteroviruses and parechoviruses have occurred frequently in a wide variety of geographic regions at different times. Enterovirus 71, first isolated in California in 1969 from stools from an infant with encephalitis, is known to cause large outbreaks of HFMD, most frequently affecting young children. Over the next 3 years, 19 patients were identified with EV71 [5]. Notably, EV71 activity has been identified to some degree in many countries of the world, but the largest outbreaks have occurred more recently in the Asia-Pacific region. Large outbreaks of EV71 were identified in this region in the late 1990s, with the first report from Malaysia in 1997, followed by several outbreaks in other countries, including Singapore, Taiwan, and China [38, 141, 263, 288]. Although most affected children will have mild illnesses consistent with HFMD, a subset of children will have more serious clinical presentations with neurologic manifestations, including aseptic meningitis, acute flaccid paralysis, and brainstem encephalitis. The World Health Organization has drafted guidelines for clinical management and public health response to HFMD [275]. In Hong Kong, enterovirus 71 infection has been a notifiable disease since March 2009 [136]. These large outbreaks with associated severe neurologic disease appear to be restricted to the

Asia-Pacific region, while in other parts of the world EV71 is generally associated with uncomplicated HFMD with few serious cases. The reasons for this geographic disparity are unclear but could include genetic differences or cultural differences in treatment. Enterovirus 71 is discussed in more detail in Chap. 13.

Enteroviruses that cause acute hemorrhagic conjunctivitis (AHC) may cause large epidemics in specific regions of the world. AHC, primarily caused by EV70 and CVA24 variant, is a rapidly progressive and highly contagious disease. AHC was first recognized in 1969 in Ghana [40] and, at the time, was sometimes termed "Apollo eye disease" as its emergence coincided with the first moon landing. During a 4-month period, 13,664 cases were seen at one clinic, and all had subconjunctival hemorrhages associated with conjunctival inflammation. A subsequent pandemic occurred from 1969 to 1971, when hundreds of millions of people were estimated to have developed AHC. Since then, epidemics have been periodically identified, mostly in tropical regions of the world. Outbreaks of AHC caused by CVA24v have occurred in Singapore, Brazil, Uganda, Southern Sudan, China, and Cuba [35, 70, 246, 280, 284].

5.2.3 Geographic Distribution and Climate

Enteroviruses are most often identified during the summer to fall months in temperate climates. In the United States, 77.9 % of enterovirus cases were reported from June to October [113]. Likewise, NESS reported the majority of enterovirus detections during July–October in 2008 [36] (Fig. 11.1). However, seasonality is less pronounced in tropical climates, with the peak incidence generally occurring during the rainy season. Prevalence tends to be highest in the tropics and lowest in cold regions. Children who live in tropical climates and who may be exposed to poor hygienic circumstances may transmit enteroviruses year-round.

5.2.4 Age and Sex

Enteroviruses may cause disease in any age group, although young children are the primary reservoir for these infections. In the United States during 1970–2005, among reports where age was known, 44.2 % of cases were aged <1 year [113]. Similarly, from 2006 to 2008 from reports where age was known, 47 % of laboratory detections of enteroviruses and parechoviruses were from children aged ≤1 year [36]. In a recent study performed in Spain, 76.8 % of all meningitis cases where a pathogen was isolated were positive for enteroviruses and 65 % of the meningitis cases identified were in children ≤15 years [58].

Children may be most susceptible to enteroviral infections, but epidemiologic and clinical features of disease can vary across age groups. EV71 causes more severe neurologic manifestations in young children, particularly in Asia-Pacific countries. For example, in 2008 in Taiwan, a younger age was associated with severe central nervous system complications [263]. During an investigation of enterovirus-associated acute respiratory infections in older children and adults in China from 2006 to 2010, the two most frequently detected types were identified in two distinct age groups. The median age of patients with CVA21 was 22 (15–67) years, while the median age for EV68 detection was 34 (18–67) years [278].

Male preponderance has been documented among surveillance data and descriptions of outbreaks of enteroviral illnesses. In the United States from 1970 to 2005, males predominated in the <20-year age group, but no gender preponderance was seen in the ≥20-year age group (male/female ratios, 1.4 and 0.9, respectively) [113]. Surveillance data for echovirus 6 and echovirus 9 infections in Taiwan from 2000 to 2008 revealed a male preponderance for both types; 57 and 69 % of echovirus 6 and echovirus 9 cases, respectively, were male [124]. Among pediatric HFMD cases in Shanghai from 2009 to 2010, 61 % were male [286].

5.2.5 Occurrence in Families and Closed Ecological Units

Transmission of enteroviruses is a frequent event in families and contained group settings. The New York Virus Watch Program in the 1960s demonstrated that spread of coxsackieviruses within families was relatively high, 76 %, as compared to spread of echoviruses at 43 % [118]. The reason for this discordance is unknown. Outbreaks of enteroviruses may occur in day-care settings, preschools, and summer camps; in particular, clusters of illnesses will be more likely identified in group settings of younger children. Outbreaks have been described at summer camps [91, 140], where children were involved with multiple group activities and lived in cabins or crowded dwellings. Enterovirus outbreaks characterized by HFMD or aseptic meningitis have occurred in schools for younger children [2, 276]. Huang et al. reported an outbreak of EV71 infection among infants in a newborn nursery [99]. Seven of 19 infants were documented with clinical illnesses that included fever, poor activity, and drowsiness. Another nosocomial outbreak involved transmission of echovirus 30 from an index patient to five babies within a neonatal nursery [9]. In addition, a nosocomial outbreak of HPeV1 was described in a neonatal postintensive care unit in Croatia [132]. Seven patients, six of whom were born prematurely, were documented to have had HPeV1. Transmission of enteroviruses among older children and adolescents in a defined group has also been documented, including an outbreak of CVB2 infection identified among members of a high school football team [4].

5.2.6 Socioeconomic Setting

Low socioeconomic status has been associated with increased transmission of enteroviruses, most probably due to poor hygiene and high population density. Low socioeconomic

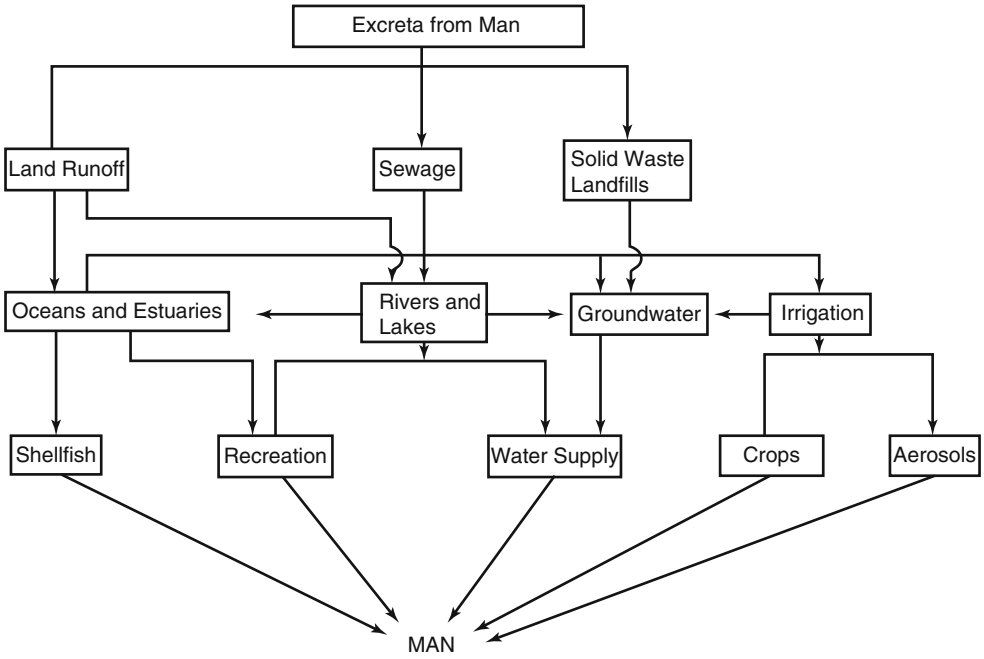

Fig. 11.3 Routes of enteric virus transmission (From Melnick et al. [156], used with permission)

settings have played a role in increased acquisition of enteroviruses in both temperate and tropical climates. Neonatal acquisition of enteroviruses was found to be associated with lower socioeconomic status in an urban area in the United States [107]. In tropical climates, where enteroviruses are transmitted continuously throughout the year, poor sanitation has been shown to be a factor in frequency of virus infection among infants [195].

6 Mechanisms and Routes of Transmission

Enteroviruses are primarily spread by the fecal-oral and respiratory routes (Fig. 11.3). Lack of hygiene will facilitate spread of virus person to person especially in areas of poor sanitation. Because individuals may shed virus in the stool for several weeks, fecal contamination of fingers and hands may lead to efficient spread particularly in young children. Droplets or aerosols may play a role in transmission and will also contribute toward contamination of the hands of young children. Under optimal conditions, which include temperature and pH, enteroviruses may survive for weeks in the environment, so fomites may play a role in viral spread as well.

Select enterovirus types may be spread from person to person by other specific routes. EV70 and CVA24 variant are causes of acute hemorrhagic conjunctivitis. Transmission of these viruses from person to person is most likely through eye secretions, as virus has been isolated from conjunctival swabs in outbreak settings [280]. In addition, enteroviruses that cause rashes may be transmitted from person to person via vesicular fluid which contains infectious virus.

Transmission from mothers to babies may occur prenatally, during the peripartum period, and possibly through breastfeeding. Mothers who have symptomatic or subclinical infections may transmit virus to neonates which can result in aseptic meningitis or sepsis-like disease. A study performed in Taiwan among pregnant women who had herpangina demonstrated an increased risk of infection in low birth weight and small for gestational age babies, as well as preterm delivery [41]. Enteroviruses have been detected in breast milk, though the role of breastfeeding in transmission from mothers to babies is unclear [139].

Shedding of enteric viruses, such as enteroviruses, in the stool raises the possibility of contamination of recreational waters. Enteroviruses have been identified in clams or oysters, and in recreational hot spring waters, but the role of shellfish and water in direct transmission to humans remains unclear [42, 98, 134]. Outbreaks of viral meningitis have been associated with swimming in ponds and pools [33, 109]. In 2001 in Germany, an outbreak of echoviruses 13 and 30 was found to be associated with swimming in a pond [90]. An investigation of an echovirus 30 outbreak among children in Italy in 1997 showed the risk of meningitis-like illness to be higher among children attending a common school, among children who swam at any public pool, and those who swam at a specific pool [68]. In Mexico in 2004, an outbreak of echovirus 30 and coxsackievirus A1 infections among travelers was associated with swimming in sewage-contaminated seawater [12]. Enteroviruses have the potential to contaminate recreational waters and may pose a health risk to swimmers.

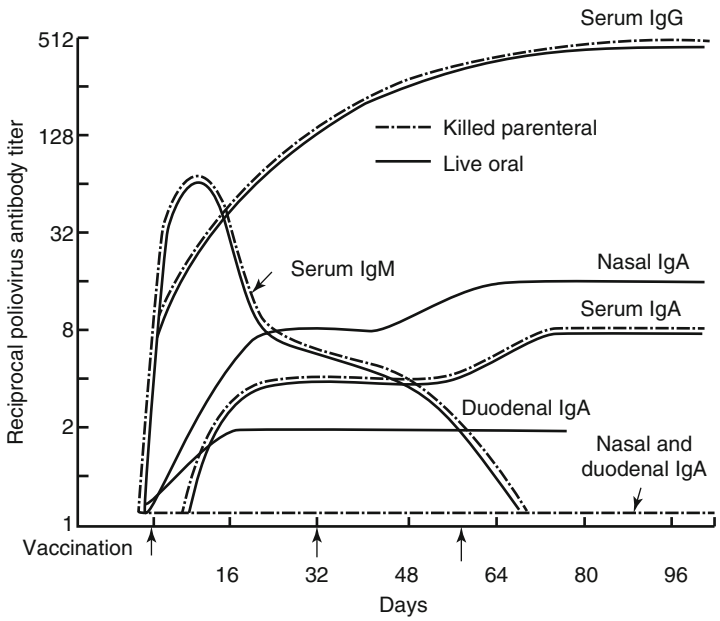

Fig. 11.4 Serum and secretory antibody response to oral administration of live attenuated polio vaccine and to intramuscular inoculation of killed polio vaccine (From Ogram et al. [192], used with permission)

7 Pathogenesis and Immunity

7.1 Pathogenesis

The enteroviruses and parechoviruses are transmitted primarily by the fecal-oral route, with entry through the alimentary tract, though respiratory transmission may also occur. The incubation period is generally 7–14 days, but it can range from as few as two to as long as 35 days. Initial replication occurs in the pharynx and gut, probably in lymphoid tissues such as Peyer's patches. In some cases, a brief viremia may be followed by replication at secondary sites in specific target organs such as the spinal cord and brain, meninges, myocardium, muscle, or skin, with some variability by strain or type. Virus is excreted in stool for 4–8 weeks postinfection and in respiratory secretions for 1–2 weeks [6]. Mixed infections and detection of multiple enteroviruses in a single stool sample are not uncommon, especially in areas with poor sanitation and high population density [188, 190, 204].

EV70 and certain strains of CVA24 are unique in that they can cause explosive outbreaks of acute hemorrhagic conjunctivitis, sometimes of pandemic proportions. These viruses are rarely detected in stool or respiratory specimens, but they can be readily detected in conjunctival swabs [199].

7.2 Immunity

Enterovirus infection elicits a strong humoral immune response. In young children, the response tends to be type specific, whereas older children and adults tend to mount a more heterotypic response, probably due to previous exposures to other enterovirus types and the presence of shared, cross-reactive epitopes [61, 208]. Enterovirus immunity in humans has been most easily studied using polio vaccine as a model system (Fig. 11.4) [191]. Antibody plays the major role in protection from disease. A type-specific poliovirus serum neutralization titer of 1:8 protects from paralytic disease; however, even very high titers do not protect from reinfection by the homologous virus. Maternal antibody passively transferred to the infant gradually wanes during the first 6 months of life, with a half-life of approximately 28 days. Type-specific immunity is also transferred from mother to infant via milk [145]. Upon exposure to virus, neutralizing antibody appears within a few days, often before the onset of symptoms; antibody may persist for life [209]. The tonsils and adenoids appear to play a role in development of immunity, as surgical removal decreases secretory antibody levels in the nasopharynx and resistance to poliovirus infection is also decreased.

Persons with primary immunodeficiency disorders, especially those with profound antibody deficits, are at increased risk for enterovirus disease, as they lack the ability to clear the infection [93, 142, 173, 181, 213, 235, 271, 290]. Such persons may become chronically infected and excrete virus over an extended period [93, 142]. There has been some suggestion that treatment with intravenous immune globulin is helpful in some cases, but, overall, results have been mixed. Patients treated for B-cell lymphoma with monoclonal antibody drugs such as rituximab appear to be at increased risk for persistent enteroviral infection and disease [8, 198], probably through depression of B-cell function [255].

8 Patterns of Host Response

8.1 Clinical Syndromes

Enteroviruses may cause a wide spectrum of clinical syndromes, with severity ranging from asymptomatic presentations to acute flaccid paralysis, encephalitis, and myocarditis. Specific enterovirus types may be associated with a particular clinical syndrome or multiple clinical presentations. In addition, a particular clinical syndrome may be caused by multiple enterovirus types. The ability of individual enterovirus and parechovirus types to cause overlapping clinical syndromes emphasizes the notion that typing in the laboratory is necessary for diagnosing a potential cause of an enterovirus illness.

8.1.1 Asymptomatic Infections

The vast majority of enterovirus infections are asymptomatic or result in only very minor symptoms such as lethargy and general malaise, transient low-grade fever, or minor upper respiratory tract illness [77, 171, 201, 225]. Despite the lack of discernible illness, persons with asymptomatic infections may excrete virus for long periods and participate in transmission.

8.1.2 Meningitis, Encephalitis, and Acute Flaccid Paralysis

Neurologic manifestations caused by non-polio enteroviruses and parechoviruses include aseptic meningitis, encephalitis, and acute flaccid paralysis. Aseptic meningitis is characterized by fever, myalgia, nuchal rigidity, nausea, and vomiting [227]. In small children <2 years of age, fever and irritability are the predominant symptoms [221]. In a prospective study of viral infections of the central nervous system in Spain from March 1, 2008 to February 28, 2009, the most common cause of meningitis was an enterovirus [58]. Aseptic meningitis may be caused by many enterovirus types including echoviruses 4, 6, 9, 11, 14, 16, 25, 30, 31, and 33 and coxsackieviruses B1–B6, A7, and A9. EV71 has frequently been associated with aseptic meningitis [193]. Ultimately, virtually all enteroviruses are capable of causing aseptic meningitis at some frequency.

Meningoencephalitis, aseptic meningitis with inflammation involving the brain parenchyma, and encephalitis without aseptic meningitis may also be caused by enteroviruses. Although an etiology is not associated with most cases of encephalitis, enteroviruses are consistently identified. From 1998 to 2005, the California Encephalitis Project reported nearly 1,600 encephalitis cases, of which 4.6 % were either confirmed as enterovirus etiology by detection in CNS samples or of possible enterovirus etiology, by detection in other specimen types [71]. Enterovirus encephalitis cases tended to be younger and had less severe symptoms than those with other identified etiologies. Similarly, the New York State Department of Health identified 21 cases of encephalitis due to enteroviruses from June 2004 to September 2007 [63].

EV71 is known to cause brainstem encephalitis and acute flaccid paralysis, particularly in young children in Asia-Pacific countries. Brainstem encephalitis is often associated with cardiorespiratory symptoms which may include neurogenic pulmonary edema. Severe cases of EV71 disease may also include acute flaccid paralysis as the presenting feature and anterior horn cell destruction may be identified as well [193].

8.1.3 Pleurodynia (Epidemic Myalgia, Bornholm Disease)

Pleurodynia is described as fever with accompanying chest and upper abdominal pain. It is characterized by abrupt onset of fever and lower chest pain, sometimes preceded by malaise, headache, and anorexia [13, 97, 268]. The chest pain may be located on either side or substernally, is intensified by movement, and may last from 2 days to 2 weeks. Abdominal pain resulting from involvement of the diaphragm occurs in approximately half the cases; in children, this often takes the place of chest pain and may be the chief complaint. The syndrome was first described after an outbreak on the island of Bornholm in Denmark. Epidemic pleurodynia or Bornholm syndrome is usually caused by group B coxsackieviruses. Less commonly, this syndrome may be caused by echoviruses and group A coxsackieviruses. A recent outbreak of epidemic pleurodynia caused by coxsackievirus B3 included clinical descriptions of pain with deep inspirations [100]. These findings may indicate inflammation of the pleura as part of this syndrome. The illness is self-limited, and recovery is complete with no long-term sequelae.

8.1.4 Herpangina

Herpangina is caused by a wide variety of different group A coxsackievirus types [82]. The illness is characterized by an abrupt onset of fever and sore throat. There may be anorexia, dysphagia, vomiting, and abdominal pain. The pharynx is usually hyperemic, and a few (not more than 10–12) characteristic tiny discrete vesicles with a red areola occur on the anterior pillars of the fauces, the posterior pharynx, the palate, the uvula, the tonsils, or the tongue. The illness is self-limited and occurs most frequently in small children.

8.1.5 Hand, Foot, and Mouth Disease

Hand, foot, and mouth disease (HFMD) is a common illness in young children. HFMD is characterized by almost universal occurrence of enanthem, usually on the buccal mucosa, generally followed by exanthem on the palms of the hands and soles of the feet. The oral lesions are ulcerative, while lesions on the hands and feet are usually vesicular. CVA16 and EV71 are the most common causes, though other group A coxsackieviruses are also frequently associated with HFMD, especially CVA6 and CVA10. The disease is usually mild and self-limiting, but more severe illness has accompanied large HFMD outbreaks due to EV71, primarily in Asia.

In 2010–2012, there were large outbreaks of hand, foot, and mouth disease due to coxsackievirus A6 in Asia, Europe, and North America [37, 69, 76, 80, 133, 162, 194]. These outbreaks were somewhat unusual in that illness was often more severe, with a more pronounced, often pustular-appearing rash that involved the face and trunk as well as hands and feet; in addition to young children, adults were also affected, often in the context of day-care centers or other exposures to very young children [37]. HFMD may sometimes be accompanied by onychomadesis (shedding of nails) sometime after resolution of initial symptoms [56, 194, 267]; however, the nails usually regrow without complication.

8.1.6 Respiratory Illness

Many different enteroviruses, from each of the traditional taxonomic groups and each of the current viral species, have been associated with mild upper respiratory tract illness [55, 165]. CVA21 has caused outbreaks of pharyngitis in military recruits and has induced respiratory tract disease in normal adult volunteers. For the most part, severe disease is rare, but EV68 was initially isolated from children with bronchiolitis and pneumonia [233]. More recently, EV68 has been associated with sporadic cases and outbreaks of bronchitis, bronchiolitis, and pneumonia [103, 104, 106, 143, 186, 215].

8.1.7 Eye Disease

Infection with a number of different enteroviruses has been occasionally accompanied by conjunctivitis. However, in 1970, an explosive epidemic of acute conjunctivitis occurred in Singapore, with some 60,000 cases reported. The causative agent was identified as an antigenic variant of CVA24 [128, 163]. Additional large outbreaks occurred elsewhere in Asia in subsequent years [39, 129, 282, 283], and CVA24 variant conjunctivitis has been reported globally since then [28, 29, 32, 64, 70, 111, 253]. Conjunctivitis associated with CVA24 variant is generally mild, with complete recovery in 1–2 weeks. The only potentially serious sequelae are due to secondary bacterial infections.

Beginning in 1969 and extending to 1971, a somewhat different form of conjunctivitis emerged in Africa, India, Southeast Asia, and Japan, reaching pandemic proportions, with tens of millions of cases. This pandemic of acute hemorrhagic conjunctivitis (AHC) was due to a new enterovirus, EV70 [120, 163, 281]. About 10 years later, AHC reappeared, causing outbreaks in several of the countries initially affected and spreading to the Caribbean and tropical Latin America, with a few cases reported in the continental United States [207], as well as several Pacific islands. AHC is characterized by severe eye pain, photophobia, and blurred vision, accompanied by subconjunctival hemorrhage which can vary in extent from discrete petechiae to large blotches. The incubation period is about 24 h, onset is sudden, and recovery is usually complete within less than 10 days.

For both forms of enteroviral conjunctivitis, virus can be readily detected in conjunctival swab and throat swab specimens by PCR. While CVA24 is excreted in feces, EV70 is only rarely detected in stool [163].

8.1.8 Cardiac Diseases

Acute Cardiac Disease

Group B coxsackieviruses are known to be associated with myocarditis. CVB3 is the most common cause of human viral myocarditis, although group A coxsackieviruses and echoviruses have been identified in association with cardiac disease [274]. Most cases of group B coxsackievirus myocarditis occur in young adults, though severe coxsackievirus B myocarditis can also occur among neonates. Although a number of serological studies have attempted to correlate myocarditis with enterovirus seropositivity or antibody titer, there has not been a clear association between viral antibody and causality of myocarditis. Endomyocardial biopsy is the diagnostic test of choice to determine etiology of viral myocarditis [137].

Chronic Cardiovascular Disease

The pathogenesis of chronic heart disease due to enterovirus-associated dilated cardiomyopathy has been thought to begin with acute myocarditis and progress over time. Although enteroviruses have not been isolated directly from these chronic cardiac disease patients, the presence of enteroviral RNA has been detected [138].

8.1.9 Neonatal Disease

Acquisition of enteroviruses is common during the first month of life [164]. In one study, 12.8 % of neonates were found to have enterovirus infections, although most of these infections were asymptomatic [107]. Of over 26,000 enterovirus detections reported to NESS during 1983–2003, 11.4 % of those with known age were from neonates (age $\leq$ 1 month) [112]. The 10 enterovirus types most frequently reported were echoviruses 11, 9, 6, and 30 as well as coxsackieviruses B1–B5 and CVA9. The risk of a fatal outcome was higher for neonates as compared to reports where age was noted to be $\geq$1 month. Infection with CVB1–4 and echoviruses 11 or 25 was significantly associated with increased risk for fatal outcome, with odds ratios of 1.4–2.3. Similarly, neonates comprised 9.5 % of patients from whom enterovirus was isolated during a 2-year study in the Netherlands [256].

Severe illnesses caused by enteroviruses in this age group include sepsis, meningoencephalitis, hepatitis, and myocarditis [247]. A study of neonatal enterovirus infections in a Taiwan children's hospital revealed 43 cases of nonspecific febrile illness, 61 cases of aseptic meningitis, and 42 cases of hepatic necrosis with coagulopathy [131]. Of these 42 cases, 10 were fatal; eight of the 10 fatalities were associated with group B coxsackievirus infections (four CVB1, three CVB3,

and 1 CVB2), with the remaining two cases due to echovirus 4 and an untypable enterovirus. In the United States, from 2007 to 2008, CDC received reports of six neonatal deaths associated with CVB1 infection, all of which were due to multisystem organ involvement [270]. During the outbreak, a cluster of eight neonates with severe myocarditis due to closely related strains of CVB1 was also described [258]. An additional two infants, one with a diagnosis of CVB1, were identified. Of these ten neonates, one patient died and one patient required cardiac transplantation. In the Netherlands, Freund et al. reported a case series of seven patients with severe neonatal myocarditis, of which two died and the remaining five infants had cardiac sequelae [73].

Human parechoviruses have been associated with severe disease in young infants [19, 25, 88, 257, 273]. In Spain, eight (3 %) of 264 CSF samples collected from children <2 months from January 2006 to September 2009 were positive for human parechoviruses [210]. Human parechovirus was identified in 7.4 % of CSF samples tested in 2006–2008 in a regional children's hospital in the Midwestern United States [237]. Associated clinical syndromes were mostly associated with sepsis and meningitis. Notably, CSF pleocytosis was rarely documented. Likewise, another case series identified ten children, aged 6–59 days, with parechovirus type 3 associated with workups for sepsis and meningitis [262]. HPeV3 was identified in 51 (13 %) of 388 CSF samples from children aged <6 months from a children's hospital in Kansas City in 2009 [239]. CSF pleocytosis is often absent [239, 257]. HPeV3 has been specifically associated with more severe disease in neonates, compared with HPeV1 [19].

8.1.10 Gastrointestinal Diseases

Group B coxsackieviruses have been associated with inflammation of the pancreas. Coxsackievirus-associated pancreatitis has been described in case reports [50, 197]. Mouse models of pancreatitis induced by group B coxsackieviruses have demonstrated pancreatic damage that may be similar to human disease [101].

8.1.11 Diabetes

While the connection is not yet conclusive, a number of studies have demonstrated an association between enterovirus infection and development of prediabetic autoimmunity or onset of type 1 diabetes in individuals at genetic risk for diabetes [44, 92, 168, 230]. Several ongoing longitudinal studies have also been designed to address the association between a variety of potential environmental triggers with diabetes onset, including enterovirus or other infections, foods, and other factors [reviewed in reference 244].

Helfand et al. tested sera from 128 children with new onset insulin-dependent diabetes mellitus and 120 matched controls [92]. The sera were tested for enterovirus-specific IgM using 14 different serotypes as antigen. Case children were significantly more likely than controls to have IgM to one or more of the enteroviruses tested, with the strongest association in the age group 13–18 years. A second study used RT-PCR to assess the presence of enterovirus RNA in three groups of children: 47 with newly diagnosed type 1 diabetes, 50 positive for at least one common islet autoantibody, and 50 negative for islet autoantibodies [168]. Enteroviral RNA was detected in 36 % of those with newly diagnosed diabetes, 20 % of the autoantibody-positive group, and only 4 % of the autoantibody-negative group, again suggesting an association between enterovirus infection and islet autoimmunity or diabetes. Similarly, another RT-PCR study detected enteroviral RNA in serum of 26 % of children with newly diagnosed type 1 diabetes versus 3 % of matched controls [230]. The latter study is significant in that it was conducted in Cuba, a country with high enterovirus prevalence and low rate of type 1 diabetes, a situation in which one might expect it to be difficult to demonstrate the association.

8.1.12 Summer Minor Illnesses with or Without Exanthems

Enteroviruses are often isolated from patients with undifferentiated acute febrile illnesses of short duration occurring during the summer or fall. In young children, the illness may be accompanied by a rubelliform, maculopapular rash on the face, neck, and chest. The incidence of rash tends to be higher in young children and decreases with age. Conjunctivitis may also be present. Echovirus 16 has been associated with outbreaks of "Boston exanthem disease," characterized by fever and maculopapular rash [171, 172].

9 Control and Prevention

There are currently no licensed antiviral therapies available to treat enterovirus or parechovirus infections or illness, but it is an area of active research and a number of compounds are in preclinical development [59, 249, 250]. Similarly, there are no vaccines available to prevent disease due to non-polio enteroviruses or parechoviruses. However, there is interest in developing a vaccine for EV71, particularly in Asia, where large outbreaks have occurred over the last 15 years, with a considerable burden of severe disease and hundreds of fatalities. One EV71 vaccine candidate has recently completed a phase II immunogenicity trial, with favorable results [289]. There has been apparent success with the use of immunoglobulin for prophylaxis and control of an outbreak of enterovirus infection in a nursery [75].

Prevention and control generally depend on stressing good personal hygiene, including hand washing and thorough cleaning of potentially contaminated items such as toys, etc., especially in settings such as day cares where very young children may be together. In a hospital setting, enteric

precautions are important, as nosocomial infections can be particularly serious in newborns and immunocompromised patients. Cohorting of patients and staff can also be useful to control transmission during an outbreak. In some cases, further virus spread has been limited by closing newborn nurseries to new admissions during an outbreak among newborns.

10 Unresolved Problems

Despite decades of clinical and basic research, there remain a number of key gaps in our knowledge of enterovirus and parechovirus disease, pathogenesis, and epidemiology. For example, "neonatal enteroviral sepsis" is well known as a potential outcome of perinatal infection, yet the burden of disease has not been described. One could imagine that having a reasonable estimate of the incidence of this life-threatening illness in such a highly vulnerable population might stimulate efforts to develop effective antiviral therapies. Enterovirus infection is generally within the differential diagnosis in cases of febrile or sepsis-like presentation in neonates; enterovirus RT-PCR is part of the standard of care, but the capacity to type, as well as detect, enteroviruses may be important to monitor trends in severe illness.

Similarly, we are just beginning to appreciate the role of human parechoviruses and their contribution to the overall burden of disease in young children. While enterovirus testing may be standard in most medium and large clinical centers, parechovirus RT-PCR is available in very few clinical laboratories. Several studies have detected enteroviruses and parechoviruses at similar rates in CSF in young children with aseptic meningitis. Given that enteroviruses are considered the major cause of aseptic meningitis in the United States and Europe, these data suggest that parechoviruses are a significant contributor to illness in this age group; if one considers antivirals against enteroviruses a worthwhile proposition, then one could also make a strong argument for antivirals targeting parechoviruses. It will be important to introduce parechovirus testing into the routine for diagnostic testing in cases of suspected enterovirus illness.

Enterovirus 71 remains an enigma—how can a virus that circulates more or less benignly in Europe and North America, causing HFMD and the occasional aseptic meningitis or encephalitis case with very few fatalities, become such a menace in Asia, with infections in the millions and deaths in the hundreds? Clearly there is a great deal to be learned about the epidemiology of EV71 in this setting. Is there a genetic component or some other Asia-specific factor that predisposes to severe disease? Development of an EV71 vaccine, probably based on the model of inactivated polio vaccine, is a high priority in the countries most affected by the large-scale EV71 outbreaks.

Acknowledgments We are indebted to the late Dr. Joseph Melnick, enterovirus pioneer and author of the previous edition of this chapter. His outstanding text has helped guide the development of the current edition.

Enteroviruses: Enterovirus 71

12

Mong How Ooi and Tom Solomon

1 Introduction and Historical Background

The global polio eradication campaign has eliminated this devastating enteroviral disease from Europe, the Americas, and most of Africa and Asia. However, in the past 15 years, a related virus, human enterovirus 71 (EV71), has emerged across Asia, where it threatens to become the "new polio" [120]. EV71 first appeared in California in the 1960s and subsequently caused sporadic cases or small outbreaks of hand-foot-and-mouth disease (HFMD) [120], neurological disease, or both. In 1997, the virus caused an unexpectedly large and severe outbreak with many fatalities in Sarawak, Malaysia. Since then, countries of the Asia-Pacific region have been hit by regular epidemics of EV71, including an epidemic in Taiwan in 1998, in which millions of people were thought to have been infected, and an outbreak of HFMD in China in 2009, during which nearly 500,000 cases were reported [13, 16, 33, 55, 56, 76, 98, 112, 146, 171, 177]. Although the virus circulates worldwide, the largest outbreaks of disease have so far been largely confined to the Asia-Pacific region, for reasons that are incompletely understood [12, 13, 16, 17, 33, 56, 70, 76, 98, 136, 146, 176, 178]. The neurological manifestations range from aseptic meningitis to acute flaccid paralysis and brainstem encephalitis. They are often accompanied by systemic complications such as severe pulmonary edema and shock, which are thought to be neurogenic in origin [22, 63].

2 Descriptive Epidemiology

2.1 Initial Epidemiological Observations

Although EV71 was first isolated from the stool of a 9-month-old infant with encephalitis in California in 1969, a retrospective analysis of samples from the Netherlands showed that EV71 was circulating as early as 1963 [128, 147]. Before long small outbreaks of neurological infection including encephalitis and aseptic meningitis attributed to the newly identified neurotrophic virus were reported in New York, Melbourne, and Sweden in the early 1970s [9, 43, 74]. The dermotropic properties of EV71 were first recognized during epidemics of HFMD in Japan in 1973 [54, 67]. In the 1970s, two large and severe EV71 epidemics occurred in Europe. The first was in Bulgaria in 1975, initially attributed to polioviruses because its epidemiological, clinical, and pathological characteristics mimicked those of poliomyelitis [40, 137]. In fact, at the height of the epidemic, nationwide administration of live-attenuated poliovirus vaccine was instituted. Isolation of EV71 later confirmed this virus as the etiological agent in 347 (77 %) of 451 children who presented with nonspecific febrile illness or neurological disease, of whom 44 died. The second major European epidemic occurred in Hungary in 1978, with 1,550 cases (826 aseptic meningitis and 724 encephalitis) and 47 deaths. Unlike the Bulgarian epidemic, the Hungarian one included a small number of patients with HFMD [103].

2.2 EV71 Activity in the Asia-Pacific Region

After the Australian and Japanese EV71 epidemics of the 1970s, further small epidemics and sporadic clusters occurred in Hong Kong (1985) and Australia (1986) [51, 126]. Then in 1997, a large outbreak in Sarawak, Malaysia, heralded the beginning of a series of large outbreaks across the Asia-Pacific region. These continuing epidemics have established EV71 as a major public health threat across the region (Table 12.1) [11, 12, 27, 39, 64, 66, 71, 79, 82, 97, 136, 146, 177, 178].

Subgenogroups underlined are those which caused large outbreaks
[a]Subgenogrous that were isolated in a smaller number
None: No HEV71 was detected despite active surveillance
– No data

Table 12.2 Clusters and outbreaks of EV71 infection occurring outside the Asia-Pacific region, 1988–2010

Country	Year	Ages	*N*	Clinical features and comments	Reference
Brazil	1988–1990	Children	90	IgM to EV71 in 20 blood samples of patients with flaccid paralysis	[42]
Finland	1994–2010	Children <11 years	928	Neutralizing antibodies in 1.6 % of serial serum samples	[58]
	1996–2008	Children <6 years	359	PCR positive in 0.3 % of serial stool samples	
Central African Republic	1997–2006	Children	93	EV71 in stool samples of patients with flaccid paralysis	[7]
Canada	1998	Children	20 EV71	Aseptic meningitis; respiratory symptoms	[100]
Brazil	1998–2001	Children ≤15 years	389	Neutralizing antibodies in 222 serum samples	[14]
Kenya	1999–2000	Children	–	–	[15]
France	2000–2009	Mostly children	81 EV71	Neurological disease, HFMD, fever rash, gastrointestinal symptoms, respiratory symptoms, and gingivostomatitis; 2 fatal: cardiorespiratory failure and encephalitis	[141]
Austria	2001–2004	Children	181 with aseptic meningitis	16 with EV71 in stool	[113]
United Kingdom	2001–2006	–	32 EV71	Most with neurological disease or HFMD	[8]
Norway	2002–2003	Children	19 EV71	Asymptomatic	[161]
Denver, USA	2003, 2005	Children: 4 weeks to 9 years	15 EV71	1 fatal	[116]
Denmark	2005–2008	Mostly infants	29 EV71	Aseptic meningitis, gastroenteritis, HFMD	[130]
Netherlands	2007	–	58 EV71	Fever, gastrointestinal, and neurological symptoms	[147]
Greece	2009–2010	Children	6 EV71	Fever, rash, or HFMD	[138]

During the Sarawak outbreak, between May and July 1997, a total of 2,618 HFMD cases and 34 deaths were recorded. EV71 also caused four deaths in peninsular Malaysia and a number of cases of severe neurological disease in Japan [13, 76, 92]. Another large epidemic occurred in Taiwan in 1998 when 405 children were hospitalized for serious neurological complications and 78 died. Epidemiological studies estimated that almost 1.5 million people were infected with the virus [56]. The largest epidemic to date occurred in China in 2008; approximately 490,000 children including 126 deaths were reported nationwide. At the epicenter in Anhui Province, more than 6,000 HFMD cases and 22 deaths were reported [178]. Surveillance improved following designation of HFMD as a notifiable disease in China in May 2008, and regular massive epidemics with alarming number of deaths were recorded. There were 1.1 million cases (353 deaths), 1.8 million cases (905 deaths), 1.6 million cases (509 deaths), and 2.2 million cases (567 deaths) reported in 2009, 2010, 2011, and 2012, respectively (http://www.chinacdc.cn/tjsj/fdcrbbg/index_1.html, accessed 15/7/2013). In addition to these very large outbreaks, many countries, including Sarawak, Taiwan, Singapore, Vietnam, and Japan, have experienced cyclical epidemics at 2- to 3-year intervals [59, 101, 119]. The most recent EV71 epidemic occurred in Cambodia in 2012. The outbreak, first labeled as a mysterious illness by local media, was associated with more than 50 sudden deaths within 24 h of hospitalization in children who were 3 years of age and below [129].

The clinico-epidemiological features of the EV71 epidemics in Asia in recent years differ considerably from earlier epidemics in that in addition to HFMD, aseptic meningitis, and flaccid paralysis, brainstem encephalitis associated with cardiopulmonary dysfunction also occurs, which has been the principal cause of death in most fatal cases in Asia [13, 63, 120, 146, 178]. The affected children have typically presented with a short febrile illness accompanied by subtle neurological signs, following which they develop signs of tachycardia, poor perfusion, and tachypnea, which rapidly develops into acute intractable cardiac impairment and fulminant, often fatal, pulmonary edema or hemorrhage [111]. Diagnostic imaging and autopsy examination indicate that this is associated with encephalitis in the brainstem, especially the medulla, and neurogenic pulmonary edema is thought to be the primary pathogenic process [22, 63, 91, 92]. Such rapidly fatal HFMD was not observed in epidemics caused by EV71 in the 1970s and 1980s, where aseptic meningitis was the predominant clinical manifestation [9, 74].

2.3 EV71 Circulation Outside the Asia-Pacific Region

Outside the Asia-Pacific region, EV71 has continued to circulate at low levels of activity in America, Europe, and Africa, producing sporadic cases or small outbreaks. The outbreaks involve mainly young children who develop aseptic meningitis, hand-foot-and-mouth disease, and other complications (Table 12.2).

Clearly, EV71 has spread across the world. Why the huge epidemics have been confined to the Asia-Pacific region, and whether they might be seen elsewhere in the future is not fully understood, though recent molecular epidemiological work on of the evolution of the different genotypes of virus has offered some key insights into this important question.

3 Molecular Epidemiology

3.1 Virus Genogroup, Evolution, and Geographical Distribution

Before 1999, data about the molecular epidemiology of EV71 were sparse. However, systematic laboratory surveillance established in several Asian countries following the first epidemics in the late 1990s has provided invaluable information on the geographical distribution, spread, and evolution of the virus.

The first complete phylogenetic analysis of EV71 based on the structural VP1 gene identified three independent lineages of EV71 and designated them as genogroups A, B, and C [11]. A sequence diversity of at least 15 % in the VP1 gene was used to distinguish genogroups. Genogroup A consists of a single member, the prototype BrCr strain, which was first identified in California in 1970 and until very recently had never been reported outside the USA (see below). The genogroup B viruses, subdivided into subgenogroups B1 and B2 with divergence of 12 % at the nucleotide level, were the predominant circulating strains in the 1970s and 1980s. The genogroup C viruses, also similarly subdivided into C1 and C2, were only identified later in the mid-1980s (Fig. 12.1). A recent phylogenetic analysis suggests that EV71 may have emerged from the genetically closely related coxsackie virus (CV) A16 as recently as 1940 [144].

A number of new subgenogroups within genogroups B and C have emerged in the Asia-Pacific region in recent years. Subgenogroup B3 and B4 viruses are thought to have co-circulated in the region since 1997 [12, 97, 136]. Subgenogroup B5 was first isolated in Sarawak and Japan in 2003 and was responsible for epidemics in Sarawak, Taiwan, and Brunei in 2006 [1, 66, 101, 119]. Except for the major community outbreak in Sydney in 1986, subgenogroup C1 viruses have mostly been isolated from sporadic cases since the mid-1980s, suggesting a low level of endemic circulation across the globe [11, 127]. Subgenogroup C2 viruses were responsible for the large EV71 epidemic in Taiwan in 1998 and the Perth outbreak in 1999 [12, 82, 96, 98]. Subgenogroup C3 was isolated in Japan in 1994 and Korea in 2000 [12, 68, 70]. Since 2000, subgenogroup C4 has been the predominant circulating genogroup in mainland China, through the most recent epidemic in 2008, and has occurred in Japan, Vietnam, and Taiwan [82, 136, 146, 178]. Subgenogroup C5 has been reported from Southern Vietnam and Taiwan [66, 146]. A genetically distinct EV71 strain (R13223, GenBank accession no. AY179600 to AY179602), with no genetic relationship to other strains recently isolated in the Asia-Pacific region, was isolated from a child with acute flaccid paralysis in India in 2001; it has been assigned as the only member of genogroup D [44]. In short, two major EV71 genogroups (B and C) have co-circulated and coevolved into subgenogroups in the Asia-Pacific region over the past 15 years. In Malaysia and Singapore, the genogroup B viruses have dominated, whereas in East Asia, particularly in mainland China and Vietnam, genogroup C viruses have dominated.

Interestingly, EV71 isolates of genogroup A were reported from 5 of 22 children presenting with HFMD in Anhui province of Central China during the 2008 outbreak that was the first ever reported detection of genogroup A viruses since the original prototype was isolated in America [174]. The nucleotide sequence of the complete VP1 gene of the isolates clusters very closely with that of the prototype genogroup A virus, with minimal divergence. This highly unexpected occurrence could indicate that the genogroup A virus has been circulating undetected in central China with very little evolutionary change for four decades or it could raise doubts about the source of the virus templates that were sequenced. Surveillance from the same outbreak by the Chinese Center for Disease Control does not appear to have identified any genogroup A viruses [178]. Hence, it is important to await confirmation by other laboratories before concluding that genogroup A viruses have reemerged. Another genetically distinct EV71 strain (NMA-03-008, GenBank accession no. JN255590) belonged to a previously unknown novel genogroup has been reported in Central African Republic; this indicates the existence of an additional African genogroup, which may have restricted geographical distribution so far [7]. Clearly, good surveillance programs are required in many different geographical regions in order to gather accurate and relevant information about EV71 transmission and evolution.

3.2 Transmission and Epidemic Potential of Genogroups

Following the initial outbreaks in Sarawak and Taiwan in the late 1990s, surveillance systems for EV71 were established in a number of countries in the Asia-Pacific region; while primarily aimed at monitoring transmission and spread, they have also provided invaluable insights into how the virus evolves in the community during outbreaks. For example, a virological surveillance system in Sarawak, Malaysia, has shown that increased EV71 circulation occurred every 3 years (1997, 2000, 2003, 2006, and 2008/09), closely paralleling increased reports of HFMD in the community [119]. The phenomenon of regular cyclical epidemics has also been observed in Fukushima Prefecture, Japan [59]. Such cyclical activity is presumed to relate to the availability of new birth cohorts of

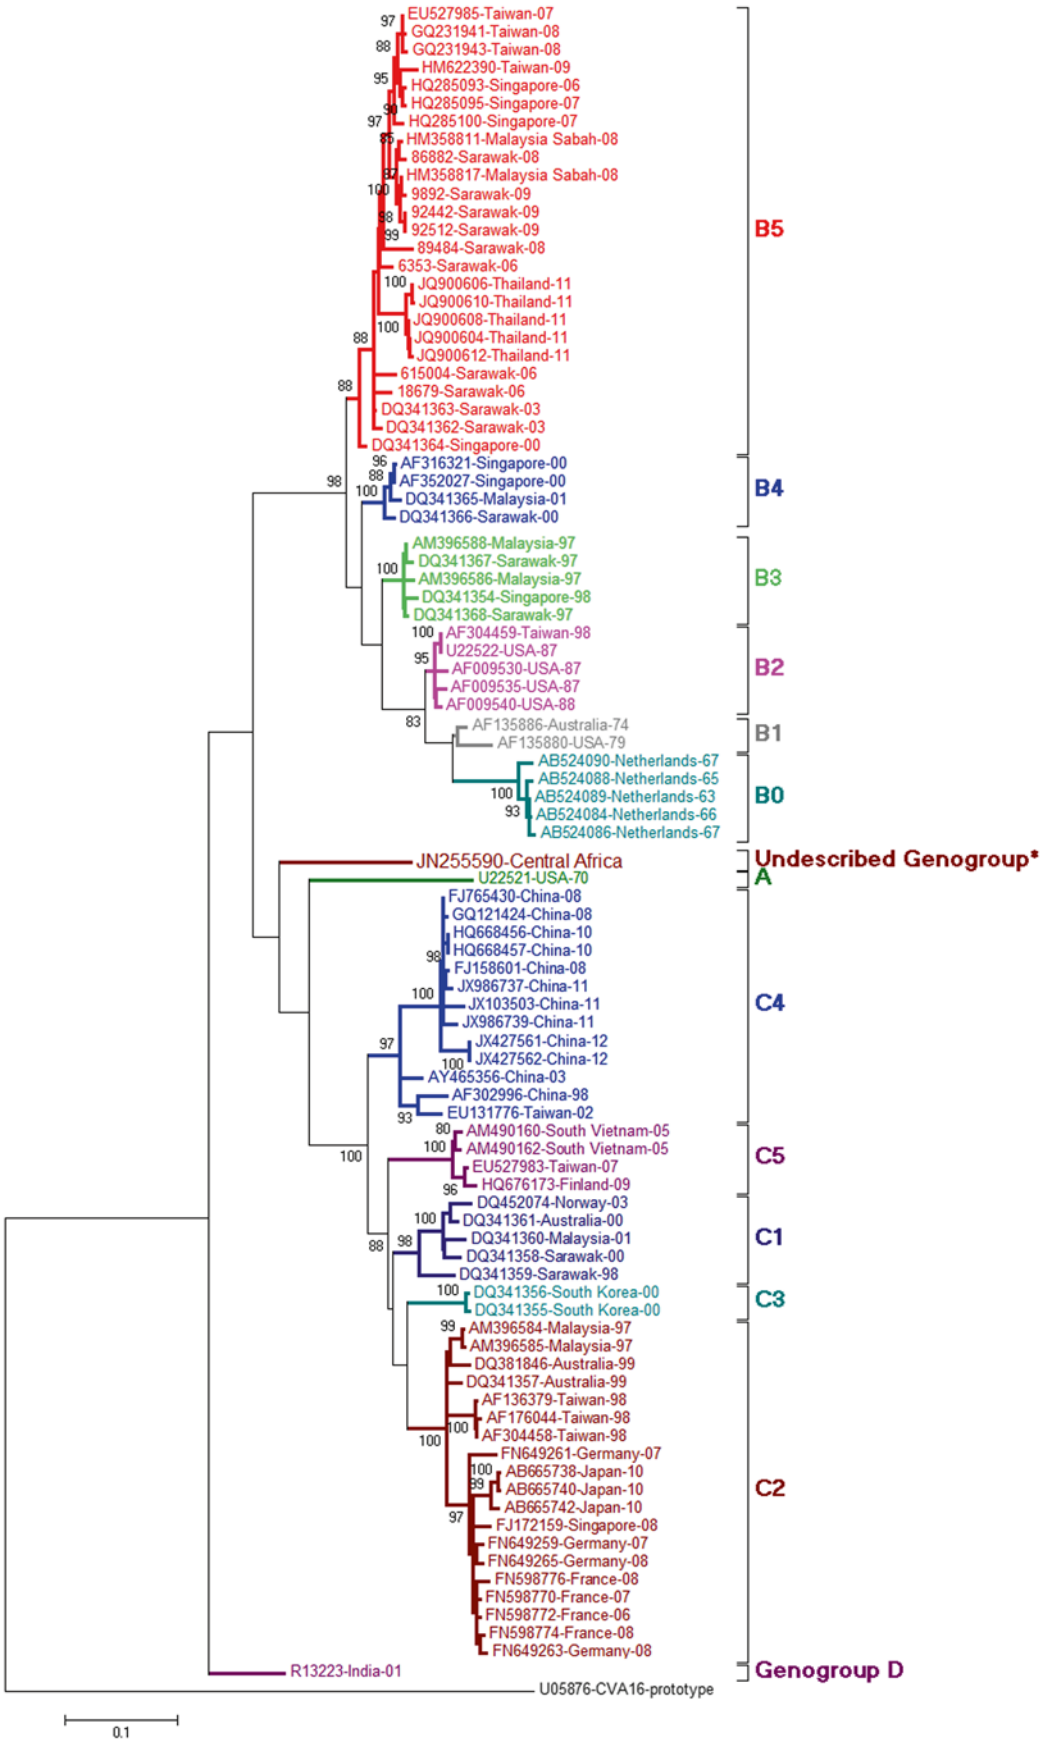

Fig. 12.1 Phylogenetic analysis of EV71 VP1 gene sequences. A neighbor-joining tree constructed using the Kimura-2 parameter as a model for nucleotide substitution. The robustness of the tree was determined by bootstrapping using 1,000 pseudoreplicates. Sequences are labeled according to the following convention: "GenBank accession number" – "Country of origin" – "Year of isolation." The scale bar represents nucleotide changes per site per year

susceptible children who have not been exposed to the virus during the earlier epidemics [23, 89]. Trying to make predictions about the epidemic potential of specific subgenogroups has proved difficult, beyond the observation that some subgenogroups, such as C1, appear to be less virulent and cause endemic disease rather than large epidemics, whereas other subgenogroups, particularly those that appear to have emerged in Asia in recent years, are associated with large epidemics.

More than one subgenogroup may co-circulate, and a shift from one dominant genogroup to another was described during outbreaks in Sarawak and Vietnam [12, 119, 146]. In Japan and Taiwan, subgenogroup B and C viruses have caused epidemics at different times (Table 12.1) [66, 82, 149]. On the contrary in the Netherlands, a permanent shift appears to have occurred, from genogroup B viruses prior to 1986 to genogroup C viruses since 1987; cross-neutralization among the genogroup B viruses, but not with genogroup C viruses, is postulated as one explanation for this, although other experimental cross-neutralization data did not support it [77, 102, 147, 148]. While the older subgenogroups of virus have been circulating and causing low levels of disease for many years, some of the more recently evolved subgenogroups such as genogroup B5, which possess distinctive antigenicity from other viruses may have the potential to cause massive epidemics [64, 148]. Although these have been confined to the Asia-Pacific region so far, the fact that humans are the natural reservoir for the virus and that international air travel is increasing means that every region is at risk of EV71 epidemic.

4 Biological Characteristics

EV71 is a small, non-enveloped virus with a positive-stranded RNA genome about 7.4 kb in size [169]. The genome has a single open reading frame encoding a polyprotein that is cleaved into 11 proteins: the four capsid proteins (P1 – VP1, VP2, VP3, VP4) and seven nonstructural proteins (P2 – 2A, 2B, 2C; P3 – 3A, 3B, 3C, 3D) [99]. The VP1 open reading frame has considerable genetic variability, which confers antigenic variability and enables investigators to differentiate EV71 strains [53, 100]. VP1 is also important for attachment to cellular receptors and for viral virulence [169]. Other details regarding the biological characteristics of EV71 were provided earlier in the molecular epidemiology section; additional general information regarding the characteristics of enteroviruses can be found in Chap. 11.

5 Clinical Features

EV71 infection may present with a wide spectrum of clinical features, although central nervous system (CNS) infection and HFMD are the two most commonly recognized disease manifestations [114].

Fig. 12.2 Mucocutaneous lesions in hand-foot-and-mouth disease. This Malaysian child has ulcers that are seen inside the upper lip (*top*) and has vesicular and macular lesions on the wrists (*middle*) and soles (*bottom*) (Photos from T. Solomon) (Reproduced from Ooi et al. [111])

5.1 Mucocutaneous Manifestations

HFMD is a common childhood exanthema characterized by a short, usually mild, febrile illness with papulovesicular rashes over the palms and soles and multiple mouth ulcers (Fig. 12.2).

Table 12.3 Neurological syndromes associated with EV71 infection

Purely neurological manifestations	
Encephalitis, especially brainstem	Common
Acute flaccid paralysis (anterior myelitis)	Common
Encephalomyelitis	Common
Aseptic meningitis	Very common
Cerebellar ataxia	Uncommon
Transverse myelitis	Rare
Neurological plus systemic manifestations	
Brainstem encephalitis with cardiorespiratory failure	Common
Manifestations indicative of immune-mediated (para-infectious) mechanisms	
Guillain-Barré syndrome	Uncommon
Acute disseminated encephalomyelitis	Rare
Opsoclonus-myoclonus syndrome	Rare
Benign intracranial hypertension	Rare

Modified from McMinn [96]

Herpangina, a closely related childhood enanthema, is characterized by a febrile illness associated with multiple mouth ulcers at the anterior pharyngeal folds, uvula, tonsils, and soft palate. Although the classical HFMD picture is typically seen in older children with EV71, widespread and atypical rashes may occur in children aged 2 years and below. Besides EV71, another picornavirus, CVA16, is also a principal causative agent of HFMD in both sporadic and epidemic forms. The virus is not normally associated with neurological complication [114], but the rash it causes is indistinguishable from that caused by EV71. There may be other clues that HFMD is due to EV71 rather than CVA16; for example, studies from Sarawak and Taiwan show that children with EV71 are more likely to have a longer duration of fever (≥3 days), a higher peak temperature (≥38.5 °C), lethargy, and myoclonus [108, 152]. A household contact study in Taiwan during the 2001–2002 epidemic showed that, in addition to HFMD and herpangina, there is a broad range of mild clinical manifestations, including upper respiratory tract infection, gastroenteritis, and nonspecific rashes [24]. Other respiratory manifestations in young children include acute exacerbation of bronchial asthma, bronchiolitis, and pneumonia [100]. More than 20 % of adult contacts during one Taiwanese outbreak had symptoms of an upper respiratory tract infection, while asymptomatic infection occurred in more than 50 %, indicating that adults may be important source of infection for younger children [24].

5.2 Neurological, Respiratory, and Systemic Manifestations

Similar to other enteroviruses, EV71 can cause aseptic meningitis, acute flaccid paralysis, encephalitis, and other rarer manifestations (Table 12.3) [96].

Encephalitis typically affects the brainstem, and unlike most other enteroviruses, it is often accompanied by marked cardiorespiratory dysfunction. This feature is also seen in poliomyelitis and has been attributed to neurogenic pulmonary edema [6], although the mechanism of disease remains controversial.

During a 7-year prospective clinical study of HFMD in Sarawak that covered several epidemics, 10–30 % of hospitalized children with HFMD due to EV71 had CNS complications [108, 112]. Brainstem encephalitis was the most common presentation, accounting for about 60 % of neurological syndromes, followed by aseptic meningitis (36 %) and brainstem encephalitis with cardiorespiratory dysfunction (4 %). Most children with CNS disease will also have features of HFMD; however, a small proportion may present with neurological disease only. Myoclonic jerks are seen more often with EV71 than with other enterovirus infections. This sign may be an early indicator of neurological involvement, particularly in the brainstem [90]. However, it is not pathognomonic for enterovirus infection; myoclonus has also been reported in other virus infections of the CNS including Japanese B encephalitis, subacute sclerosing panencephalitis, and Nipah virus, herpes simplex virus, varicella-zoster virus, and HIV infection. Myoclonic jerks are also often seen in otherwise healthy young infants, particularly when they are asleep and may occur spontaneously or be provoked by a loud noise.

Seizures, if they occur at all in EV71 infection, tend to be seen in younger children and are short-lived with rapid recovery of consciousness, suggesting that they are febrile convulsions, rather than due to CNS infection itself. Unlike those seen in other viral encephalitides, recurrent and prolonged seizures are very rare with EV71 infection, a distinction probably reflecting predominantly brainstem rather than cortical involvement.

Brainstem encephalitis with associated pulmonary edema has been the hallmark of EV71 CNS infection in Asia since the late 1990s. This distinctive clinical syndrome has a stereotypic clinical course characterized by a

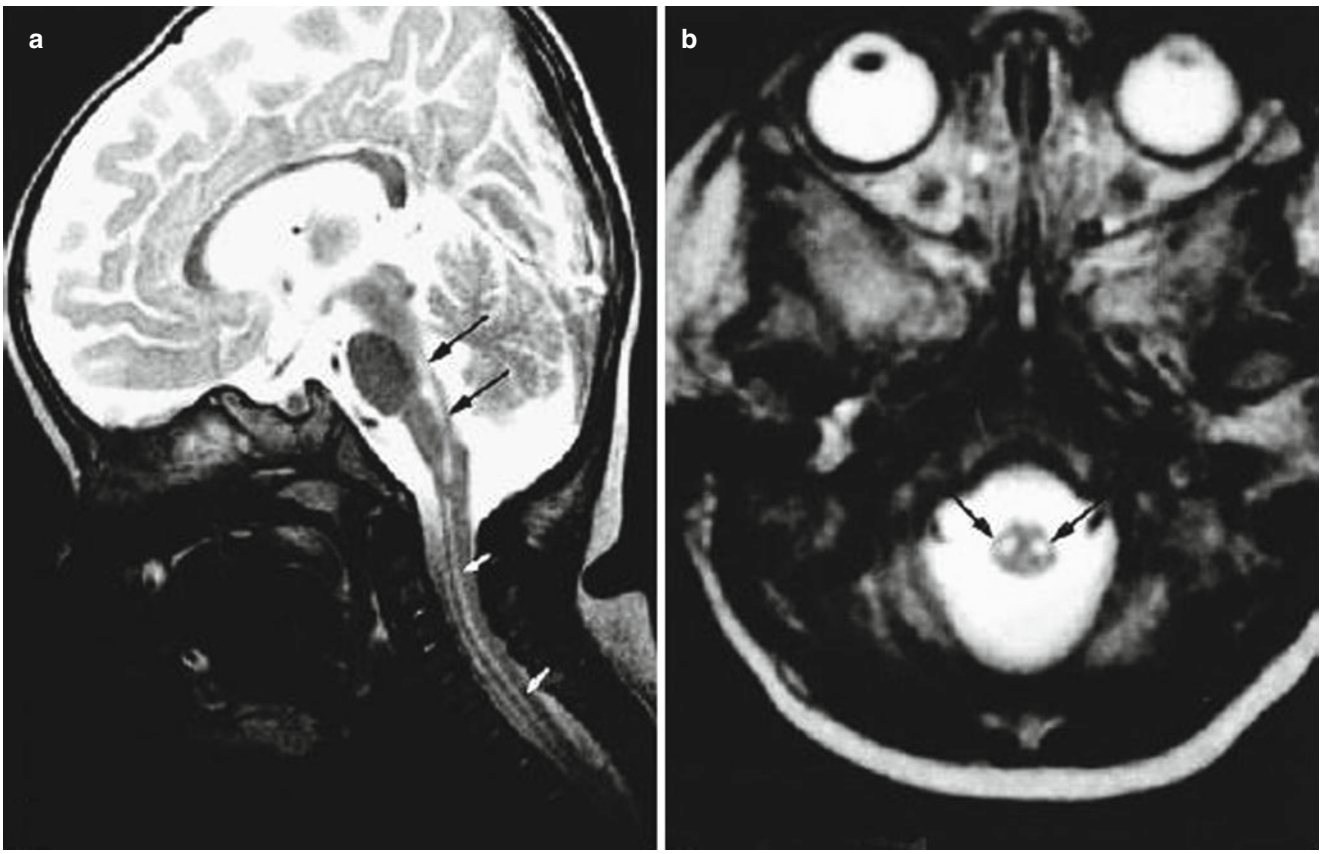

Fig. 12.3 MRI changes in EV71 encephalomyelitis (Modified from Shen et al. [131]). T2-weighted images of a 10-month-old female who presented 3 months earlier with somnolence tachycardia, tachypnea, and coma and who recovered consciousness but remained ventilator dependent. (**b**) Axial section showing the high signal intensity in the two anterior horns of the cervical cords (*black arrows*)

prodromal illness of HFMD followed by a sudden deterioration that typically occurs after 3–5 days of fever. Children then develop acute rapidly progressing cardiorespiratory failure presenting as shock and pulmonary edema or hemorrhages. Without critical care support, most of these children die within 24 h of hospital admission and in some even before arriving at the hospital. A system of clinical staging (stage 1 through stage 4) has been used to help monitor the progress of the affected children during the clinical course of EV71 infection and to guide management, from uncomplicated febrile illness to CNS involvement to cardiorespiratory failure and development of neurological sequelae [20, 85, 86]. Such staging systems have not been adopted widely, possibly because they are not always easy to remember and they imply sequential progression through stages that do not always occur. In 2010, a WHO Informal Consultation on Hand Foot and Mouth Disease proposed the use of a simple clinical description of disease manifestation to assess the disease severity. It included uncomplicated HFMD/herpangina, HFMD with CNS involvement, HFMD with autonomic system dysregulation, and HFMD with cardiopulmonary failure [160].

Findings on magnetic resonance imaging (MRI) of children with brainstem encephalitis correlated well with those of autopsy examination; both procedures demonstrate frequent involvement of the medulla oblongata, reticular formation, pons, and midbrain in several studies (Fig. 12.3) [29, 131, 162].

Acute flaccid paralysis is the primary presenting feature of a number of neurological syndromes caused by EV71 including poliomyelitis-like paralysis, Guillain-Barré syndrome, and transverse myelitis. Poliomyelitis-like paralysis is probably the most common of these, though it may be less severe than that caused by polioviruses, with a higher recovery rate [96]. Other respiratory manifestations in young children include acute exacerbation of bronchial asthma, bronchiolitis, and pneumonia [100]. More than 20 % of adult contacts during one Taiwanese outbreak had symptoms of an upper respiratory tract infection, while asymptomatic infection occurred in more than 50 %, indicating that adults may be important source of infection for younger children [24].

6 Clinical Management

During outbreaks of EV71, tens of thousands of children develop symptoms, and while most of them have mild self-limiting illness, in a small proportion of apparently well children, the condition can rapidly deteriorate to severe and fatal neurological and systemic complications over days or even hours. Whereas in the past children with mild HFMD tended to be managed at home, with increasing parental awareness about the risk of fatal complications, many are now brought directly to hospital, and health services can easily become overwhelmed. The challenges faced by primary care clinicians are recognizing which patients are likely to deteriorate, knowing which investigations yield the best diagnostic information, and deciding which treatments might be appropriate, without the benefit of guidance from controlled clinical trials.

6.1 Laboratory Tests

In mild disease, the blood count is usually normal, but in severe disease, the white blood cell count is often high with a neutrophilia [25]. Blood urea and electrolytes are typically unaffected, but there may be hyperglycemia in severe disease [25]. Creatine kinase is sometimes elevated in patients with cardiac involvement [46] and elevated cardiac troponin I has been reported as a predictor of imminent cardiopulmonary failure in children with brainstem encephalitis [65]. Chest X-ray characteristically shows a normal heart size, even in the presence of marked pulmonary congestion, indicating that neither acute viral myocarditis nor congenital heart disease is causing the illness. There are often nonspecific ECG changes [46], and continuous monitoring may show abnormal beat-to-beat variability, which may predict imminent cardiovascular collapse [83]. Echocardiography shows generalized left ventricular hypokinesia, occasionally accompanied by mitral regurgitation, in children who are hemodynamically unstable with tachycardia, hypotension, or pulmonary edema [46]. Pericardial effusion is rare.

Lumbar puncture is essential in children who are unwell with suspected CNS involvement. In some patients, the clinical features, such as meningismus or myoclonic jerks, may clearly point to CNS involvement. However in other children particularly those younger than 2 years of age, there may just be high fever, vomiting or lethargy, but a lumbar puncture reveals CNS disease. There is typically a mild CSF lymphocytic pleocytosis of 10–100 cells per mm^3, but not always [116]. The CSF-to-plasma glucose ratio is usually normal but it can be low.

6.2 Virological Diagnosis

Laboratory diagnosis of EV71 is established primarily through virus isolation or molecular detection of the virus nucleic acid in appropriate clinical specimens.

6.2.1 Choice of Sample

A wide range of samples may be available, depending on the disease manifestations; these include throat and rectal swabs, serum, urine, and, when taken, cerebrospinal fluid (CSF), as well as fluid from vesicles and swabs from ulcers, if they are present. The sensitivity, specificity, and usefulness vary according to the sample [109]. In particular, virus detection in sterile sites such as vesicular fluid, CSF, serum, urine, serum, or autopsy material more reliably indicates a causative organism than does detection from non-sterile sites such as throat or rectum, which may indicate coincidental carriage. However, many of the sterile sites only occasionally yield virus. For example, virus is isolated from only 0–5 % of the CSF of patients with neurological disease [25, 40, 51, 67, 74, 103, 108, 112], because, as for poliomyelitis, the viral load in the CSF is very low [48]. The yield for serum is similarly low [112, 159]. Vesicular fluid, when present, is more useful. Although throat and rectal swabs are more likely to have an enterovirus detected, one study from Malaysia found that this was not always the same enterovirus as that isolated from a sterile site: using the isolate from vesicle swabs as a reference, 10 % of positive throat swabs gave a different isolate, and for rectal swabs the figure was 20 % [109]. Presumably, the isolate from the non-sterile site represented coincidental carriage, whereas that from the vesicles was actually pathogenic.

Prolonged viral shedding from the gastrointestinal tract (throat, rectum, or stool) may occur after complete resolution of EV71 infection, as it does for other enteroviruses; a study in Taiwan showed that EV71 may be detected in the throat up to 2 weeks after recovery from HFMD or herpangina; in the stool, it can be detected up to 11 weeks later [41]. During an outbreak, so many samples could potentially be positive that laboratories can soon become overwhelmed. In one study, the most efficient approach was to examine throat swabs for all patients plus swabs either from at least two vesicles when present or from the rectum when vesicles are absent [109].

6.2.2 Virus Isolation, Serotyping, and Nucleic Acid Detection

The gold standard for diagnosis of enterovirus infection is virus isolation. Several human and nonhuman primate cell lines may be used: rhabdomyosarcoma (RD), which is most efficient; human lung fibroblast cells (MRC5); and African green monkey kidney cells (Vero) [114]. In RD cells, a characteristic cytopathic effect is typically observed 7–10 days

after inoculation. However, to improve the yield, blind passage may be necessary before cytopathic effects become apparent. Once a cytopathic effect is observed, the virus is identified by neutralization tests using intersecting pools of type-specific antisera, by EV71-specific antisera, or by an indirect immunofluorescence assay using EV71-specific monoclonal antibodies [114]. More recently, a molecular "serotyping" approach has been devised. It involves amplifying part of the VP1 gene of the cultured virus, using polymerase chain reaction (PCR) and pan-enterovirus EV71-specific primers, and then sequencing the product [104]. To this end, several sets of primers directed at different regions of the VP1 gene of human enterovirus have been developed [10, 104, 115].

EV71-specific primers are now also being used to perform PCR directly on clinical samples. The advantage of this approach over virus culture is that it can provide rapid diagnosis in the midst of explosive EV71 outbreaks where urgent public health intervention is needed. Several sets of real-time RT-PCR protocols directed to detect EV71 and CVA16 in primary clinical samples have been published recently; however, their disadvantage is that the technique detects only the suspected virus for which primers are available, but they will miss any agents that are unexpected or for which no primers have been generated [34, 115, 142, 167]. DNA microarray technology is a powerful, though expensive, new tool designed to detect multiple pathogen targets by hybridization of pathogen-specific probes. Two groups have recently reported using such an approach to distinguish EV71 and CVA16 infection in primary clinical specimens [34, 134].

6.3 Serology

Serological diagnosis of an acute virus infection is classically established by demonstrating a fourfold rise in specific neutralizing antibody between the acute and convalescent samples [114]. However, in the case of EV71, very high levels of neutralizing antibodies are often detectable within the first few days of illness, and thus a fourfold rise cannot be demonstrated [40, 103]. Furthermore, although homologous antibody is produced when young children encounter their first enterovirus infection, heterologous cross-reacting IgG and IgM antibodies are produced by older children and adults following repeated infection with different enterovirus serotypes; this reduces their diagnostic usefulness [87]. Several rapid IgM ELISA tests for EV71 have recently been developed to try to overcome some of these limitations [153]; however, cross-reactivity remains an issue [168], and the duration of detectable EV71-specific IgM following an infection is also uncertain.

6.4 Diagnostic Imaging

Computer tomography scans are almost always normal in EV71 encephalitis, where the pathology is mostly in the brainstem. Conventional MRI may be normal in the early phase of EV71 encephalitis. Conversely, it may show characteristic high signal intensities on T2-weighted and fluid-attenuation inversion recovery (FLAIR) images in the dorsal pons and medulla, most of the midbrain, and the dentate nuclei of the cerebellum. Similar high-signal lesions may also be found in the anterior horn cells of cervical spinal cord (Fig. 12.3) [63, 131, 175]. Gadolinium-enhanced MRI examination improves the results [175]. Diffuse-weighted imaging (DWI), a sensitive tool for detecting of early changes in brain cellular function, seems to be better at detecting EV71 encephalitis than conventional MRI [81]. However, the value of MRI screening has yet to be demonstrated. In children with acute flaccid paralysis, MRI typically shows unilateral high-signal lesions in the anterior horn cells of spinal cord on T2-wieghted images and contrast-enhancing ventral root on T1-weighted images [28, 63, 132].

6.5 Predictors of Severe Disease

Several clinical features and laboratory abnormalities have been associated with neurological and fatal EV71 disease, but few have been prospectively validated as prognostic indicators [25, 60, 65]. Younger age is associated with increased risk of severe disease [21]. A prospective clinical study of nearly 1,500 children presenting to one hospital in three EV71 outbreaks in Sarawak over 7 years suggested that peak temperature of 38.5 °C or higher, duration of fever for 3 or more days, and a history of lethargy were useful clinical predictors for neurological involvement. The presence of at least two of those three factors was strongly associated with the subsequent development of neurological disease [108]. The study corroborated the findings from early retrospective studies. However, it did not confirm other findings from earlier studies, such as the association between the absence of mouth ulcers and development of complicated or fatal disease [38, 112]. Hyperglycemia and leukocytosis have also been associated with fatal EV71 disease in a retrospective evaluation [25], and although these findings were confirmed in the prospective study, because they were late changes occurring about the same time as the fulminant disease, they were not helpful clinically in identifying children at high risk of complications and death [108].

Not all children with CNS involvement in EV71 infection will progress to cardiorespiratory collapse. A recent study in Southern Vietnam revealed that, in general, about 6 % of children with CNS involvement would develop autonomic

system dysregulation. Children with frequent myoclonus observed by doctors and healthcare workers, with or without other focal neurological signs, were at higher risk of disease progression compared with those children with no history of myoclonus (22.2 % vs 4.4 %). A small study involving 46 patients showed that children developed abnormal heart rate variability, an index of autonomic nervous system disease, about 7 h before the clinical onset of cardiorespiratory instability [83]. The authors proposed that screening children with CNS involvement for abnormalities in heart rate variability may provide early warning of imminent cardiorespiratory failure and allow timely institution of appropriate interventions. Cardiac troponin I is a cardiac-specific biomarker for myocardial damage, used for early diagnosis of acute coronary syndrome in adults. Elevated cardiac troponin I has been observed in children with brainstem encephalitis and cardiopulmonary failure [65]; in some cases, it was elevated prior to the development of cardiopulmonary failure, suggesting that serial measurement of troponin may be helpful in identifying children at risk of left ventricular failure. However, neither the evaluation of heart rate variability nor the measurement of troponin I level has become routine clinical practice in the management of EV71 infection, probably because the former requires relatively sophisticated equipment not widely available and the latter is relatively expensive in developing countries. Overall simple clinical parameters such as length of illness, height of fever, and lethargy are probably more useful indicators of potentially severe disease.

6.6 Outcome

Follow-up for as long as 7 years after infection shows that children who present with aseptic meningitis generally have a favorable outcome, although a recent report documented the incidence of attention-deficit/hyperactivity disorder-related symptoms, as reported by parents and teachers, is higher (20 %) in children who had recovered from CNS infection compared with the matched controls (3 %) [49]. Approximately one-fifth of those with more severe neurological disease, including encephalitis, poliomyelitis-like paralysis, and encephalomyelitis, have sequelae, particularly focal limb weakness and atrophy [21, 110, 145]. Cerebellar dysfunction is observed in about 10 % of patients who had moderately severe brainstem encephalitis, including cranial neuropathies, myoclonus, tremor, and ataxia. However, only a quarter of those with more severe brainstem encephalitis associated with fulminant cardiorespiratory failure make a full neurological recovery. Common sequelae include focal limb weakness and atrophy, swallowing difficulties requiring nasogastric feeding, central hypoventilation, facial nerve palsies, seizures, and psychomotor retardation.

7 Pathogenesis

7.1 Viral Determinants of Virulence

The factors that determine whether EV71 infection will be asymptomatic or result in HFMD or severe neurological disease remain unknown. For poliovirus, the 5'UTR and VP1 genes are known to contain virulence determinants [72]. Several studies have therefore examined the nucleotide sequence of these genes, or the whole genome, comparing EV71 isolates from fatal and nonfatal cases, but for the most part the isolates have been nearly or entirely identical, and significant changes have not been found [135, 139]. The incidence of CNS disease and other severe complications of EV71 infection seems to have varied among the recent outbreaks in Asia, leading to the postulation that differences in the virulence of the various genotypes may have a role. However, comparisons between outbreaks have been hampered by the retrospective nature of many of the studies as well as differences in inclusion criteria, definitions of disease severity, and viral diagnostic approaches and capabilities. Perhaps the strongest data supporting the hypothesis that strain virulence determinants play an important role in the pathogenesis of severe neurological disease come from studies in Perth and Sarawak. During the Perth epidemic in 1999, two subgenogroups, B3 and C2, co-circulated, thus providing a unique opportunity to examine the role of virulence determinants in a single epidemic setting [96, 97]. In this outbreak, subgenogroup C2 viruses linked to the Taiwan epidemic of 1998 were almost exclusively isolated from children with severe neurological disease, and only a single isolate came from a case of uncomplicated HFMD. Conversely, subgenogroup B3 viruses, similar to those from the Sarawak 1997 epidemic, were isolated mainly from children with uncomplicated HFMD, aseptic meningitis, or post-infectious neurological disease, none of whom died [98]. A detailed prospective clinical study of EV71 disease in Sarawak, which included 277 children with EV71-associated HFMD, provided further clinical and epidemiological evidence for different biological behavior of EV71 subgenogroups, with regard to risk of CNS disease and transmissibility within families [112]. Two discrete EV71 epidemics, caused predominantly by subgenogroup B3 and B4, respectively, but with small numbers of cases caused by subgenogroup C1, occurred [112]. Children infected with subgenogroup B4 viruses were less likely to present with CNS infection than those infected with C1 or B5 viruses, and they were also less likely to be part of a family cluster. On the other hand, children infected with B5 were more likely to be part of a family cluster, and there was a trend toward a greater incidence of CNS disease in these patients. These results suggest that subgenogroups do indeed vary in their propensity to cause neurological disease.

7.2 Dual Infection

During the first of the Asian EV71 epidemics in Sarawak in 1997, which was due to subgenogroup B3, an adenovirus type 21 was also implicated in the fatal cases as well as in some cases with acute flaccid paralysis [13, 110]. The adenovirus was isolated from sterile sites such as CSF, brain, and heart in fatal cases and indeed was more frequently detected than EV71 itself; this led to the suggestion that the fatalities were due to dual infection, rather than EV71 alone [13]. However, subsequent detailed studies, including longitudinal studies from Sarawak, have not found evidence of adenovirus 21 infection in other HFMD or neurological cases, though dual infection of EV71 with other viruses, including dengue and Japanese B encephalitis, has been found [112]. Furthermore, adenovirus 21 has never been isolated in Sarawak since 1997.

7.3 Host Susceptibility

A range of host factors may affect pathogenesis, particularly partial cross-protective immunity from prior outbreaks. Lack of cross protection may partially explain why young age is a risk factor for severe disease [23, 24, 89]. The potential for host genetic variants to explain differential susceptibility, clinical severity, and outcome of EV71 has also been studied. One study in Taiwan reported that HLA-A33 is associated with increased susceptibility to EV71, although the role of the major histocompatibility complex in the virus infection is still unknown [19]. HLA-A33 is more frequently found in the populations of Asian ancestry than in those of European ancestry, and a causal association of this allele could help explain the higher frequency of EV71 epidemics in Asia. In the same study HLA-A2 was linked to the risk of cardiopulmonary failure often observed in fatal cases [19]. HLA-G, an important immunotolerant molecule, is involved in the suppression of T lymphocytes, NK cells, and antigen-presenting cells and in the induction of regulatory T cells and tolerant dendritic cells. Increased levels of cell surface bound HLA-G and plasma sHLA-G were found in EV71-infected children and in children with pulmonary edema [179]. Cytotoxic T lymphocyte antigen-4 (CTLA-4) is an important regulator of T cell cytotoxicity and is involved in the regulation of immune response. Studies of polymorphisms in the gene encoding CTLA-4 in children with meningoencephalitis have yielded conflicting results [19, 173]. Th17 cells are effector cells in human immune response, and its related cytokines, IL-17 and IL-23, are important mediators in pro-inflammatory response. Chinese children with the IL-17 F 7488C allele, which has been associated with a blunted pro-inflammatory response, were more likely to have milder EV71 infection, and patients who were homozygous for the T allele had significantly higher level of C-reactive protein, leukocytosis, and neutrophil counts when compared with patients with CC+CT genotypes [93]. Another Chinese study showed increased frequency of Th17 cells, as well as elevated serum IL-17 and IL-23, in peripheral blood of children infected with EV71 when compared to the healthy controls [32]. Interferon gamma, a Th1 antiviral cytokine, and IL-10, a potent anti-inflammatory cytokine that suppresses innate host defense, including interferon gamma production, have been implicated in the pathogenesis of severe EV71 infection. Susceptibility to EV71 encephalitis has been reported in children with the IFN-gamma+874 T/A genotype, previously associated with reduced IFN-gamma production, and in children with the IL-10-1082G/A genotype, previously associated with reduced IL-10 production [172]. All of these associations require replication.

7.4 Viral Entry and Spread

EV71 is transmitted predominantly via the feco-oral route, with respiratory spread also implicated [114]. As for other enteroviruses, initial viral replication is presumed to occur in the lymphoid tissues of the oropharyngeal cavity (tonsils) and small bowel (Peyer's patches), with further multiplication in the regional lymph nodes (deep cervical nodes, mesenteric nodes), giving rise to a mild viremia. The majority of infections are controlled at this point and remain asymptomatic. However, in vivo studies show that if enteroviruses disseminate further, they reach target organs, particularly the reticuloendothelial system (liver, spleen, bone marrow, and lymph nodes), heart, lung, pancreas, skin, mucous membranes, and central nervous system, coinciding with the onset of clinical features.

The mechanism by which enteroviruses enter the CNS is not completely understood. A number of epidemiological and experimental animal studies on polioviruses indicate that the virus can invade the CNS system by permeation through a disrupted blood-brain barrier or by retrograde axonal spread along cranial or peripheral nerves. For EV71, this latter route has been implicated both in mouse models and by examining the distribution of virus and inflammation in fatal human cases [31, 107, 163].

7.5 Pathological Findings

The topographical distribution of CNS inflammation has been stereotypic and is observed predominantly in the neuronal areas of spinal cord, the entire medulla oblongata except the pyramidal areas, the tegmentum and floor of fourth ventricles in the pons but not the anterior pons, and the whole midbrain sparing the cerebral peduncles. In addition, the hypothalamus, subthalamic and dentate nuclei, and to a lesser degree motor cortex of the cerebrum and meninges are involved (Fig. 12.4) [62, 63, 91, 92, 131, 133, 163].

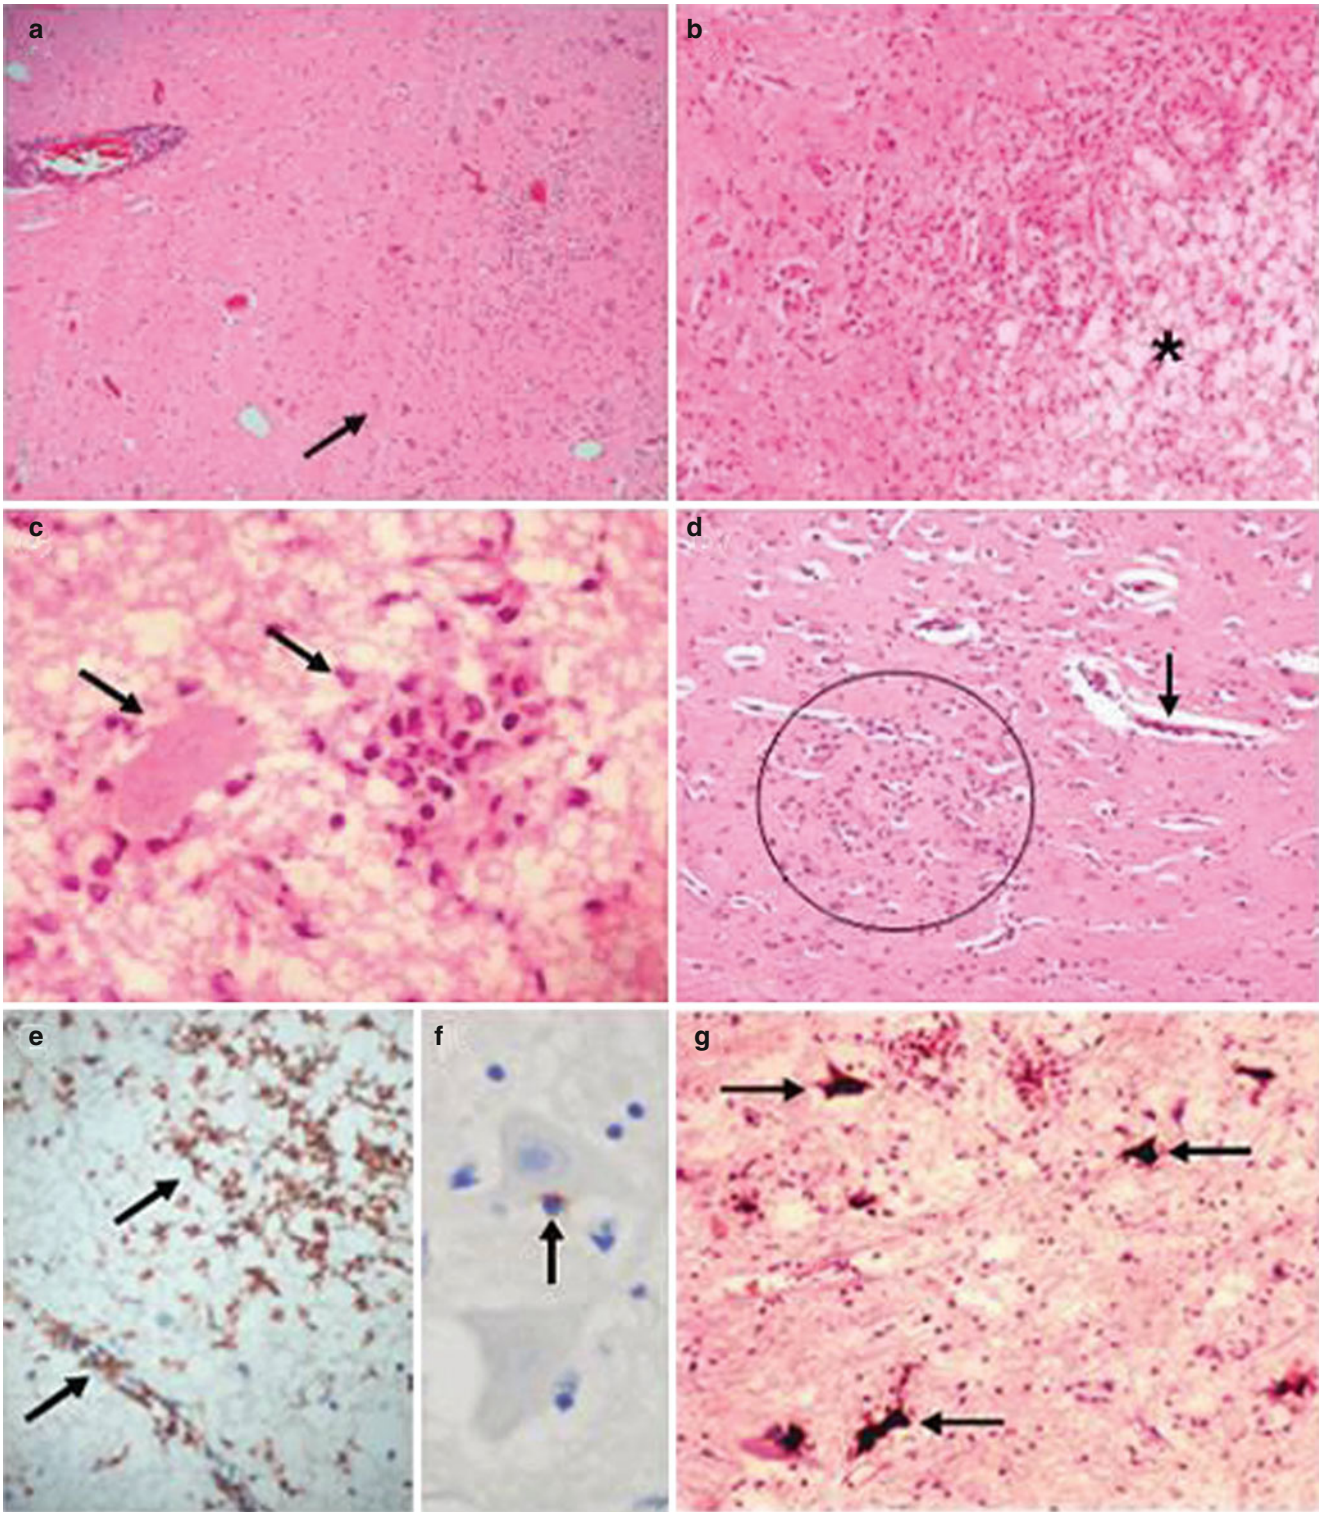

Fig. 12.4 Pathological findings in enterovirus 71 encephalitis (Modified from [163]). Parenchymal inflammation (*arrows*) and perivascular cuffing in the medulla (**a**); more severely inflamed areas (**b**), with edema (*) and neuronophagia (**c**, *arrows*). More subtle inflammation in the motor cortex with mild perivascular cuffing (*arrow*) and parenchymal inflammatory cells (*circle*) (**d**). Numerous CD68-positive macrophages/microglial (**e**), CD8-positive lymphocyte adjacent to a neuron (**f**). Viral RNA in the anterior horn cells of the spinal cord (**g**). (**a**–**d**: hematoxylin and eosin stains; **e**, **f**: immunohistochemistry/peroxidase/DAB; **g**: ISH/nitroblue tetrazolium/5-bromo-4-chloro-3-indolyl phosphate stains. Original magnification: (**a**) 4×; (**b**, **d**) 10×; (**c**, **f**) 40×; (**g**) 20×

Inflammatory changes were absent in the cerebellar cortex, thalamus, basal ganglia, mammillary body, hippocampus, temporal lobe, peripheral nerve, and autonomic ganglia. The histopathological changes, characterized by perivascular cuffing of macrophages, lymphocytes, neutrophils and plasma cells, variable edema and necrosis, focal neuronophagia, and microglia nodules, are similar to those in encephalitis caused by other viruses [50]. Neither virus inclusion nor vasculitis has been observed, and viral antigens and RNA can only be seen in a small number of neuronal processes and phagocytic cells [163, 164].

7.6 Pathogenesis of Severe Pulmonary Edema and Heart Failure

While it is clear that fulminant pulmonary edema is closely associated with, and preceded by CNS involvement, there is no consensus on its cause, especially the relative contributions of neurogenic pulmonary edema, cardiac dysfunction, increased vascular permeability, and a cytokine storm (Fig. 12.5).

Neurogenic pulmonary edema is classically seen following a head injury, where the associated raised intracranial pressure is thought to be important. Although the pathogenesis is not completely understood, studies from animal models suggest that the hypothalamus, and vasomotor centers of the medulla, and nuclei in the cervical spinal cord are important; lesions to various nuclei in these regions can increase activity along the sympathetic trunk, resulting in profound systemic and pulmonary hypertension and consequent pulmonary edema [57]. Pulmonary edema was also seen in poliomyelitis, and because it was associated with damage to brainstem nuclei, it was thought to be neurogenic in origin [6]. Thus when severe pulmonary edema was first seen in EV71 encephalitis, and brainstem inflammatory changes were observed too, the development of edema was attributed to neurogenic origin. Autopsy examination and magnetic resonance imaging studies of children with EV71 brainstem encephalitis showed that there was extensive inflammation of gray matter of the spinal cord and the whole medulla oblongata, as described above [62, 63, 91, 92, 131, 163]. The observations of hyperglycemia and leukocytosis were also postulated to be due to increased sympathetic discharges [25].

However, detailed hemodynamic observations of children with EV71 and pulmonary edema have not always shown the profound systemic and pulmonary hypertension that would be expected [46, 86, 89, 165] This may be because the changes in vascular pressures in neurogenic pulmonary edema are only transient, as was shown for one child with EV71 [165]. Others have argued that cardiac impairment is a major contributor to the pulmonary edema. Although there is no histological or virological evidence of a viral myocarditis, increased cardiac-specific troponin I level suggests some degree of cardiac injury [22, 46, 65, 91, 92]. A detailed echocardiographic study of 11 children with EV71 brainstem encephalitis shows that their cardiac function was impaired, with significantly reduced left ventricular ejection fraction [46]. Two children whose cardiac output was supported with a left ventricular assist device survived, whereas all the others died [45].

Although there is no myocardial inflammation, histological examination of heart ventricular tissue from six fatal cases and one survivor, obtained though a biopsy, revealed significant coagulative myocytolysis, myofibrillar degeneration, and cardiomyocyte apoptosis which are characteristic of catecholamine cardiotoxicity [46, 47]. Thus it is argued by some that the massive release of catecholamine caused by brainstem encephalitis may have a direct effect on cardiac function, as well as causing pulmonary edema through raised pulmonary pressures.

The other potential contributor to pulmonary edema is increased vascular permeability, which is postulated to have occurred following the systemic inflammatory response. Early studies that examined a narrow range of cytokines and chemokines have shown that interleukin (IL)-6, IL-1B, IL-10, IL-13, tumor necrosis factor (TNF)-α, and interferon (IFN)-γ are all significantly higher in EV71 patients with pulmonary edema than in those with uncomplicated encephalitis, and several of these, including IL-1, IL-6, IL-13, and IFN-γ, are known mediators of increased vascular permeability [84–86, 151]. In addition, increased plasma levels of several chemokines including interferon gamma-induced protein (IP-10), monocyte chemoattractant protein (MCP)-1, monokine induced by interferon gamma (MIG), and IL-8 have been found in children with pulmonary edema when compared to those with uncomplicated brainstem encephalitis [156]. A study of 30 cytokine and chemokine levels in EV71-infected Malaysian children confirmed that cardiorespiratory impairment was associated with a widespread elevation of both pro-inflammatory and anti-inflammatory mediators in the serum and CSF. In addition, the study also showed that serum IL-1Ra and G-CSF levels were significantly elevated in patients who died, with a serum G-CSF/IL-5 ratio of >100 being the most accurate prognostic marker [52]. Children with edema also had depleted lymphocyte population particularly in CD4, CD8, and natural killer cells [151, 173]. Thrombocytosis, neutrophilia, and hyperglycemia are all thought to be indicative of a systemic inflammatory response [84, 151]. Fewer studies have looked at cytokines in the CSF. Elevated CSF IL-1b was found in patients with encephalitis complicated by edema when compared to those with encephalitis alone [84]. It has previously been proposed that the CNS may be the source of the inflammatory cytokines detected in the serum of patients with EV71-associated cardiac dysfunction [156]. A study examining the relative abundance of inflammatory mediators in the serum and CSF samples from

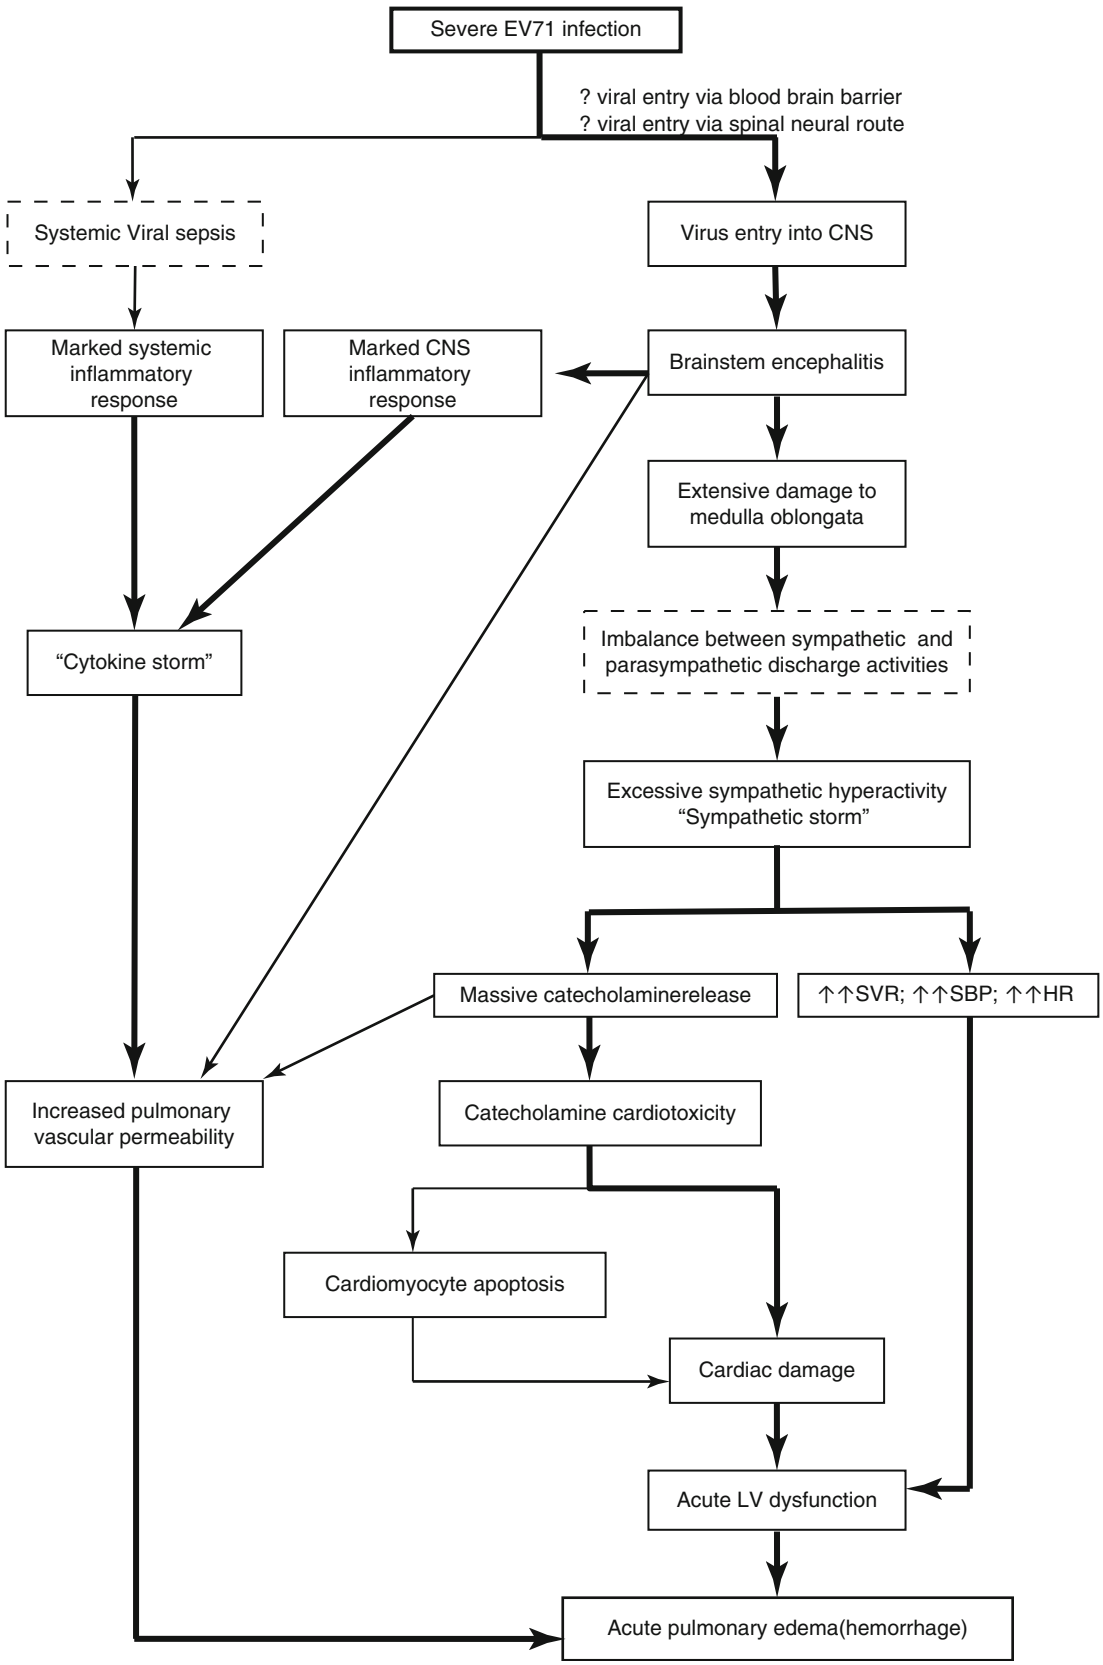

Fig. 12.5 The postulated pathogenesis of enterovirus 71-associated acute pulmonary edema Major postulated pathogenic pathways are shown with thick lines; lesser contributory pathways are shown with thinner lines. The solid boxes indicate strong supporting evidence from human clinical or pathological studies, while the dotted boxes indicate hypothetical but unproven steps or evidence from animal models only. *EV71* human enterovirus 71, *BBB* blood-brain barrier, *CNS* central nervous system, ↑↑ markedly high, *SVR* systemic vascular resistance, *SBP* systemic blood pressure, *HR* heart rate, *LV* left ventricular (Reproduced from Solomon et al. [140])

88 Malaysian children showed two distinctive immune response patterns occurring independently in these two compartments [52]. Because the development of pulmonary edema in patients with EV71 encephalitis appears to be strongly associated with a dysregulated systemic and CNS inflammatory response, this observation has at least partly formed the basis for treatment with intravenous immunoglobulin, which appears to be effective [20, 85, 86, 108, 112, 154].

In summary, although still ill-defined, brainstem inflammation appears to be an important neurogenic mechanism for pulmonary edema in EV71 encephalitis. However, similar pathological changes are also observed in other encephalitides without pulmonary edema as a prominent feature. Cardiac compromise and the effects of the systemic inflammatory response on the vascular endothelium may also make an important contribution. In vivo mouse and nonhuman primate models have replicated some of the features of severe EV71 disease, such as neuroinvasiveness with marked inflammatory changes; however, no model has yet reproduced the severe systemic features such as pulmonary edema [5, 31, 36, 107, 158, 163].

8 Control and Prevention

8.1 Treatment

8.1.1 Antiviral Agents

There are no established antiviral treatments for EV71. Pleconaril is an antiviral drug that inhibits entry into cells for a number of enteroviruses by blocking viral attachment and uncoating. It has been used in clinical trials of aseptic meningitis [122–124]; however, it is not active against EV71 [35]. Several other newer capsid-function inhibitors have been investigated, and some have demonstrated promising anti-EV71 activities in preclinical studies [35]. Two human transmembrane proteins, P-selectin glycoprotein ligand-1 (PSGL-1) and scavenger receptor class B member 2 (SCARB2), have recently been identified to be functional receptors of EV71 [106, 170]. Analysis of the much-awaited crystal structure of EV71 revealed important structural differences from other enteroviruses. The mature virion of EV71 has a shallower canyon (believed to be the receptor binding site) on the viral surface and a relatively exposed "pocket factor" (which stabilizes the virus) compared to other enteroviruses [118, 157]. These discoveries are major steps forward and will guide rational design of antivirals against EV71.

8.1.2 Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) was used during the initial epidemics of EV71 in Sarawak and Taiwan in the late 1990s on the basis that its anti-EV71 neutralizing antibodies and nonspecific anti-inflammatory properties might be therapeutic [112, 152]. Retrospective comparisons of patients who received IVIG with those who did not suggested possible benefit from IVIG if given early [20, 108]; for example, in Sarawak over 3 seasons, 204 (95 %) of 215 children who survived despite severe CNS complications had timely IVIG treatment, typically once severe disease occurred, whereas only one (11 %) of nine fatal cases received this treatment (OR 148.36, 95 % CI 16.34–6609.04, $p<0.0001$) [108]. Proinflammatory cytokines measured before and after IVIG treatment were significantly lower in EV71 patients with autonomic dysfunction than patients with less severe disease [84–86, 151, 154]. IVIG has since become routine treatment for severe EV71 disease, and it has been recommended in the national treatment guidelines in Taiwan and Vietnam [20, 75, 85, 86, 108, 112, 150]. While remaining uncertainty over the efficacy of this treatment warrants randomized placebo-controlled trials, they would be logistically and ethically challenging to conduct in the face of the wide acceptance of IVIG as the current standard of care and the beliefs in their value strongly held by some. Carefully designed phase II trials would need surrogate end points for disease progression (e.g., failure of resolution of tachycardia).

8.1.3 Milrinone

Milrinone is a cyclic nucleotide phosphodiesterase (PDE) inhibitor currently used in the treatment of congestive heart failure. Inhibition of PDE subtype III by milrinone results in an increase in intracellular cyclic adenosine monophosphate (cAMP), which in turn leads to increased cardiac output and decreased peripheral vascular resistance. In a small nonrandomized retrospective comparison involving 24 children with EV71-induced pulmonary edema, those treated with milrinone had reduced tachycardia and lower mortality [150, 155]. Intriguingly, the peripheral white blood cell count, platelet count, and plasma IL-13 were also lower [155], suggesting an immunomodulatory as well as a cardiovascular effect of the drug. More recently a prospective, open-label, randomized controlled trial conducted by the same authors, involving 41 Vietnamese children 5 years of age and below, showed that milrinone significantly reduced the 1-week mortality from EV71-induced cardiovascular collapse without adverse effect. This encouraging finding has tentatively raised hope that earlier milrinone treatment might be useful in halting disease progression of cases with severe brainstem encephalitis [37].

8.1.4 Fluid Balance and Ionotrope Support

Hypovolemia and dehydration are the commonest causes of shock in children and are treated with rapid fluid resuscitation with good results. However, similar approaches used in the early EV71 epidemics in Asia precipitated massive pulmonary edema. Judicious use of intravenous fluid and early

institution of inotrope support are critical in children with severe EV71 infection. Where fluid management could be guided by central venous pressure monitoring, in Taiwan, management algorithms based on this approach appear to have improved outcome [20].

8.1.5 Novel Treatment Approaches

Although better recognition of early signs of CNS involvement and the disease progression has helped improve the clinical outcome, many children continue to succumb to severe EV71 infection because of late presentation or disease progression despite intervention. A left ventricular assist device with extracorporeal membrane oxygenation was associated with a higher survival rate in a small number of recent cases than in historical controls, but with significant neurological sequelae [69]. Hemofiltration has been employed to treat children with cardiovascular collapse in Vietnam [117].

8.2 Prospects for Prevention

8.2.1 Surveillance

The only measures available currently for disease control at the population level are public health approaches. Countries in Asia (Singapore, Taiwan, Japan, and Vietnam) have implemented heightened surveillance for EV71 [2, 3, 33, 101, 119]. HFMD has now become a notifiable disease in many places, including Malaysia, Singapore, Thailand, Taiwan, Vietnam, and China [3, 4]. However, HFMD may be caused by a number of enteroviruses including CVA8, 10, and 16, and concurrent virological surveillance is necessary. Virological surveillance also provides invaluable molecular epidemiological data about the circulating EV71 genotype and may thus help to track the spread of the virus across the region.

Because humans are the only known natural hosts of human enteroviruses, outbreak control measures are targeted primarily at interrupting person-to-person virus transmission via contact with throat and nose secretions, saliva, stool, and vesicular fluid but also at minimizing contact with contaminated surfaces, toys, or fomites. Because of the lack of a lipid envelope, EV71 has considerable stability in the environment. It can remain viable at room temperature for several days and has been recovered from surface and ground water and hot spas [30, 61]. Hence, health education focuses on personal hygiene and good sanitation including frequent hand washing, proper disposal of soiled diapers, and disinfection of soiled surfaces with sodium hypochlorite [73]. Like other enteroviruses, EV71 is resistant to alcohol. Consequently, use of the widely available alcohol-based (70 % ethanol or isopropanol) disinfectants alone for hand hygiene is ineffective in preventing EV71 transmission [26]. A recent study showed that EV71 can be destroyed by virucidal disinfectants such as Virkon [18].

Transmission of enteroviruses including EV71 is most efficient in overcrowded settings, and most countries in the region including Malaysia, Singapore, Taiwan, Hong Kong, and China have adopted "social distancing" measures during epidemics. These measures include closures of childcare facilities and schools and cancelation of public functions involving children [2, 3]. Although there has been little systematic research to examine the effectiveness of public health interventions, a few studies of school closure or other approaches from Singapore and Hong Kong appeared to show some benefit [2, 95]. It nevertheless remains uncertain whether social distancing measures are effective or what the optimal timing for instituting them may be—at the onset of an HFMD outbreak or at the time of laboratory confirmation of an EV71 etiology. Although this widely adopted empirical measure has considerable socioeconomic impact, the cost of the disease and its control measures have not yet been studied. If experience with other directly transmissible viruses applies to EV71, then such measures as school closure could decrease the peak incidence but prolong the outbreak, with no reduction in the overall number of cases (Fig. 12.6) [140].

Further epidemiological work to elucidate the transmission dynamics of the virus will guide the formulation of evidence-based interventions to control the spread of EV71. Critical pieces of information such as precise estimates of the incubation period, ratio of asymptomatic to symptomatic cases, and time and duration of infectiousness are needed. The reproduction number (R_0) for EV71 has been estimated to be higher than that of CVA16 (median 5.48, IQR 4.20–6.51 compared with 2.50 [1.96–3.67], respectively; $p = 0.002$) [94].

8.2.2 Vaccine Development

The success story of the control of poliomyelitis indicates that vaccines would be the best approach for future disease control, and the target population should be younger children, especially those less than 3 years of age, because they are at highest risk of severe disease. In fact, an inactivated EV71 whole virus vaccine was developed in Russia in 1976 after the Bulgaria epidemic. But it received no further evaluation because no further outbreaks of EV71 occurred [78]. More recent candidates for an EV71 vaccine include inactivated whole virus, live-attenuated, recombinant viral protein, virus-like particle, and DNA vaccines. These are at different stages of the development in China, Taiwan, and Singapore [78, 176]. Among these, inactivated whole virus vaccine candidates, the development of which modeled that of inactivated polio vaccine, are at the final stages of the clinical evaluation. A phase 3 randomized double-blinded, placebo-controlled trial of inactivated alum-adjuvant EV71 vaccine (Beijing Vigoo Biological, EV71 strain FY7VP5/AH/CHN/2008, genogroup C4) involving 10,245 Chinese children between the

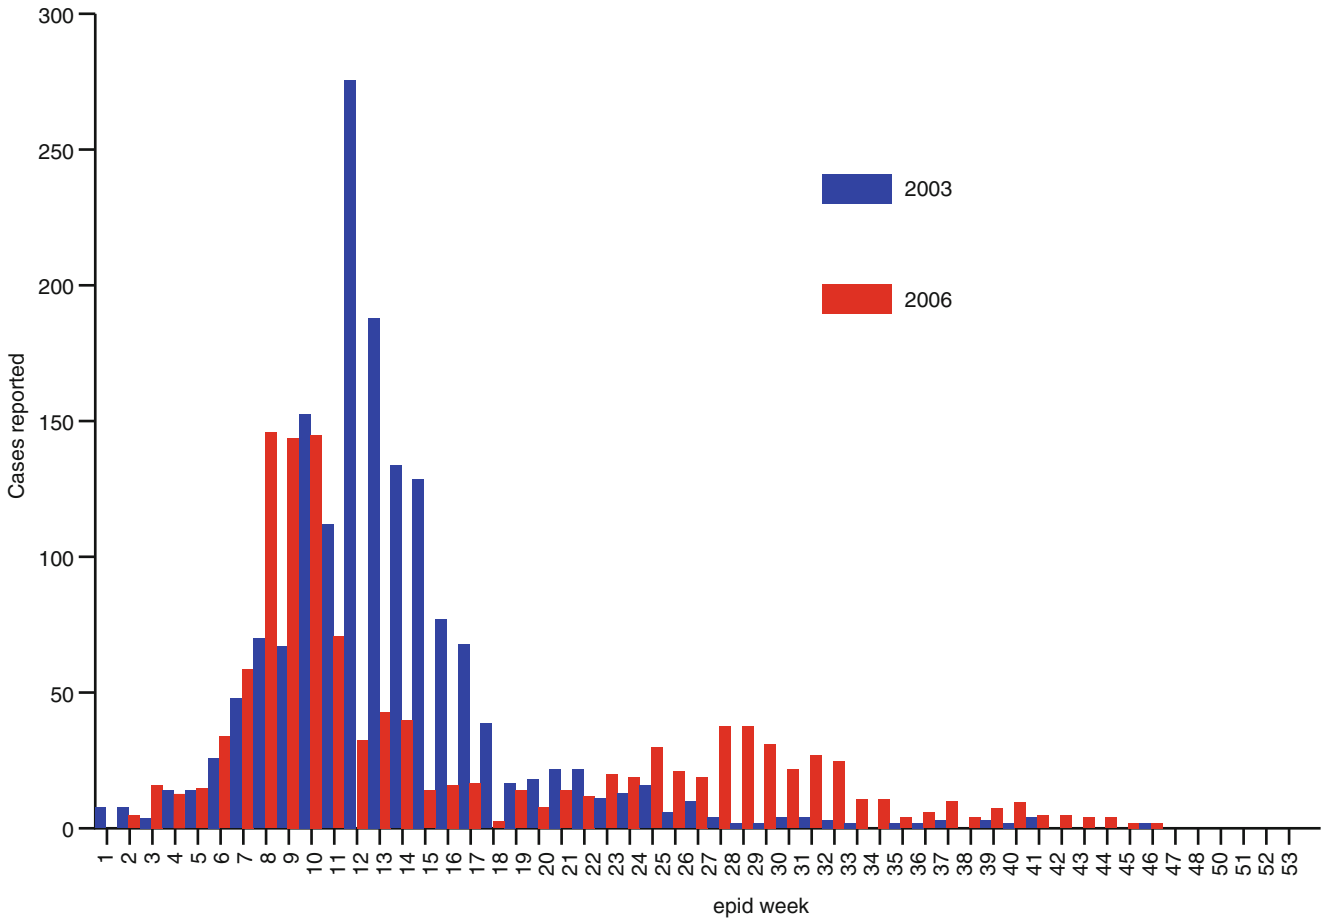

Fig. 12.6 The effect of public health interventions on hand-foot-and-mouth disease outbreaks, comparing sentinel surveillance data from the 2003 outbreak in Sarawak, Malaysia, when the public health response was limited, and the 2006 outbreak, when more rigorous social distancing measures were encouraged. (Reproduced from Solomon et al. [140])

ages of 6 and 35 months has shown encouraging vaccine efficacy, immunogenicity, and safety [180]. Another alum-adjuvant inactivated whole virus candidate (EV71 strain H07, genogroup C4) produced by Sinovac Biotech Co., LTD) was reported to be well tolerated and highly immunogenic in a phase 1 trial in infant populations in China [80]. While an eagerly awaited vaccine will likely be available for routine use in the near future, it remains uncertain whether the vaccine developed from a specific genogroup would provide adequate cross protection against all genogroups. This concern is critical because genogroup B and C virus so far appear to have different geographical distributions in Asia, and the data to date on cross protection between genogroups are conflicting. Another important issue pertaining to manufacturing processes of inactivated whole virus vaccine is that no international reference standards for potency assays and quantification of EV71 vaccine antigens exist [78]. Establishment of such standards is urgent in Asia, where the vaccine will likely be used soonest and most extensively.

9 Concluding Remarks and Unsolved Problems

The emergence of EV71 in the Asia-Pacific region over the last 15 years has had a major public health impact. Molecular epidemiological studies suggest that some subgenogroups appear to have massive potential for explosive epidemics, while others circulate in a more indolent pattern. However, the biological determinants of these differences are poorly understood. The epidemiological differences observed between EV71 in the Asia-Pacific region and the strains found in Europe and USA also represent an unsolved puzzle. There are no reliable and easy-to-use clinical tools to predict who will develop neurological complications and which patients with CNS involvement are at risk of disease progression. The virological and host determinants of the wide-ranging clinical phenotypes in those infected remain unclear. There are relatively good animal models of neurological disease caused by EV71, but there is an urgent need for an animal model of cardiorespiratory dysfunction to advance

understanding of its pathogenesis. Despite lack of solid evidence for its efficacy, the wide use of IVIG for severe EV71 infection in many Asian countries will make efficacy trials difficult. There is still no specific antiviral drug available for EV71 infection although the determination of its crystal structure and identification of several EV71 receptors should accelerate drug discovery. An inactivated whole virus vaccine is nearing clinical availability, but important steps must be taken to ensure that it ultimately reaches the populations in greatest need. Public health intervention and control measures of EV71 epidemics so far have been empirical and generic, not stringently evidence based. Because they have significant socioeconomic impact, further research is needed on the transmission dynamics of the virus and which of these public health intervention strategies most effectively limit the havoc wreaked by future EV71 outbreaks.

Acknowledgment The authors are grateful to Associate Prof. David Perera, Institute of Health and Community Medicine, Universiti Malaysia Sarawak (UNIMAS), for his help in generating the phylogenetic tree of EV71 VP1 gene sequences (Fig. 12.1).

Enteroviruses: Polio

13

Olen M. Kew

1 Introduction

Six decades ago, every child faced the threats of lifelong paralysis or death from poliomyelitis. Poliomyelitis, an infectious disease dating back to antiquity (Fig. 13.1), suddenly appeared in epidemic form in the late nineteenth century in northern Europe and the United States and emerged as one of the great epidemic diseases of the twentieth century [1–3]. The threat of poliomyelitis quickly receded in developed countries following the introduction of the inactivated poliovirus vaccine (IPV) in 1955 [4, 5] and the oral poliovirus vaccine (OPV) in 1961 [6, 7] and had all but disappeared in high-income countries by the early 1970s [8, 9]. In sharp contrast, poliomyelitis remained largely uncontrolled in the developing countries of Latin America, Asia, and Africa and continued to threaten the majority of the world's children with crippling disease [8, 9].

Today, poliomyelitis is on the verge of eradication, and its etiologic agents, the three poliovirus serotypes, are on the brink of extinction from the natural environment (Figs. 13.2 and 13.3) [12]. Circulation of indigenous wild type 2 poliovirus ceased in 1999 [13], and wild type 3 poliovirus may be nearing eradication [12]. Wild type 1 poliovirus circulation is localized to a small and decreasing number of districts in parts of three countries (for updates see http://www.polioeradication.org/) [12].

This brightening picture is the direct result of the initiatives launched in 1985 by the Pan American Health Organization (PAHO; the Regional WHO Office for the Americas) to eradicate poliomyelitis in the Americas by 1990 [14], and subsequently by the World Health Organization (WHO) to eradicate poliomyelitis worldwide by the year 2000 [15]. The Global Polio Eradication Initiative (GPEI), established by a landmark 1988 resolution of the World Health Assembly (the governing body of the WHO) [15], has grown to become the largest public health program in history [16], engaging key segments of both the public and private sectors [17]. The launch of the GPEI was made in light of dramatic progress by PAHO toward achieving its regional eradication goal, attained in 1991 [18]. Like the PAHO initiative, the GPEI achieved early rapid progress, reducing poliomyelitis incidence worldwide by >99 %, from an estimated 350,000 cases in 125 countries in 1988 to a low of 493 cases reported in 10 countries in 2001, raising the long-held hope that a polio-free world would soon be realized [19]. Optimism was fueled by the eradication of wild poliovirus type 2 and reinforced by the cessation of wild poliovirus transmission in many highly challenging settings. However, progress stalled between the years 2000 and 2010 as the global incidence poliomyelitis stabilized at ~500–2,000 cases per year (Fig. 13.2a) [10, 19, 20]. With intensified efforts, the GPEI steadily reduced the number of endemic reservoirs, such that by the end of 2012 the global poliomyelitis case count again fell to a new all-time low of 223, and only three countries (Nigeria, Pakistan, and Afghanistan) had never stopped wild poliovirus transmission (Figs. 13.2 and 13.3) [12, 21]. Despite setbacks, the GPEI achieved many landmark successes: coordinating the vaccination of 2.5 billion children, many of them among the most vulnerable living in the most under-resourced communities in the world, and saving more than ten million people (mostly children <2 years of age) from lifelong paralysis and sparing the lives of more than 250,000 others [22]. The WHO GPEI is now developing a detailed endgame strategic plan to secure forever the many gains achieved by polio eradication (http://www.polioeradication.org/portals/0/document/resources/strategywork/endgamestratplan_20130414_eng.pdf) [22].

Polioviruses are members of the *Enterovirus* genus of the family *Picornaviridae* (*pico*, L., small; *rna*, RNA genome) (Chap. 11) [23]. The *Enterovirus* genus, comprising >100 serotypes, is divided into 12 species (enterovirus species A to J and rhinovirus species A to C); poliovirus, along with >20 other serotypes are members of human enterovirus species-C (for updates see: http://www.ictvonline.org/) [24, 25]. Enteroviruses inhabit the intestinal tracts and/or the nasopharyngeal tissues of humans and other mammals. Polioviruses, for which humans are the only natural reservoir host, occasionally invade the central nervous system (CNS) and cause destruction of motor neurons in the spinal cord, resulting in acute flaccid paralysis (AFP). However, poliovirus invasion of the CNS occurs in less than 1 % of infections and represents a dead end for transmission, which occurs by the fecal–oral or respiratory routes [23, 26]. The abrupt appearance of large poliomyelitis outbreaks generated intense interest in the disease and prompted intensive studies of poliovirus epidemiology, pathology, immunology, and virology, leading to the development and worldwide deployment of effective poliovirus vaccines and many groundbreaking contributions to public health, medical science, and basic research [3, 19, 23, 27].

2 Historical Background

The rich history of research on poliomyelitis and polioviruses has been chronicled in numerous excellent books, chapters, and reviews and in an extensive scientific literature

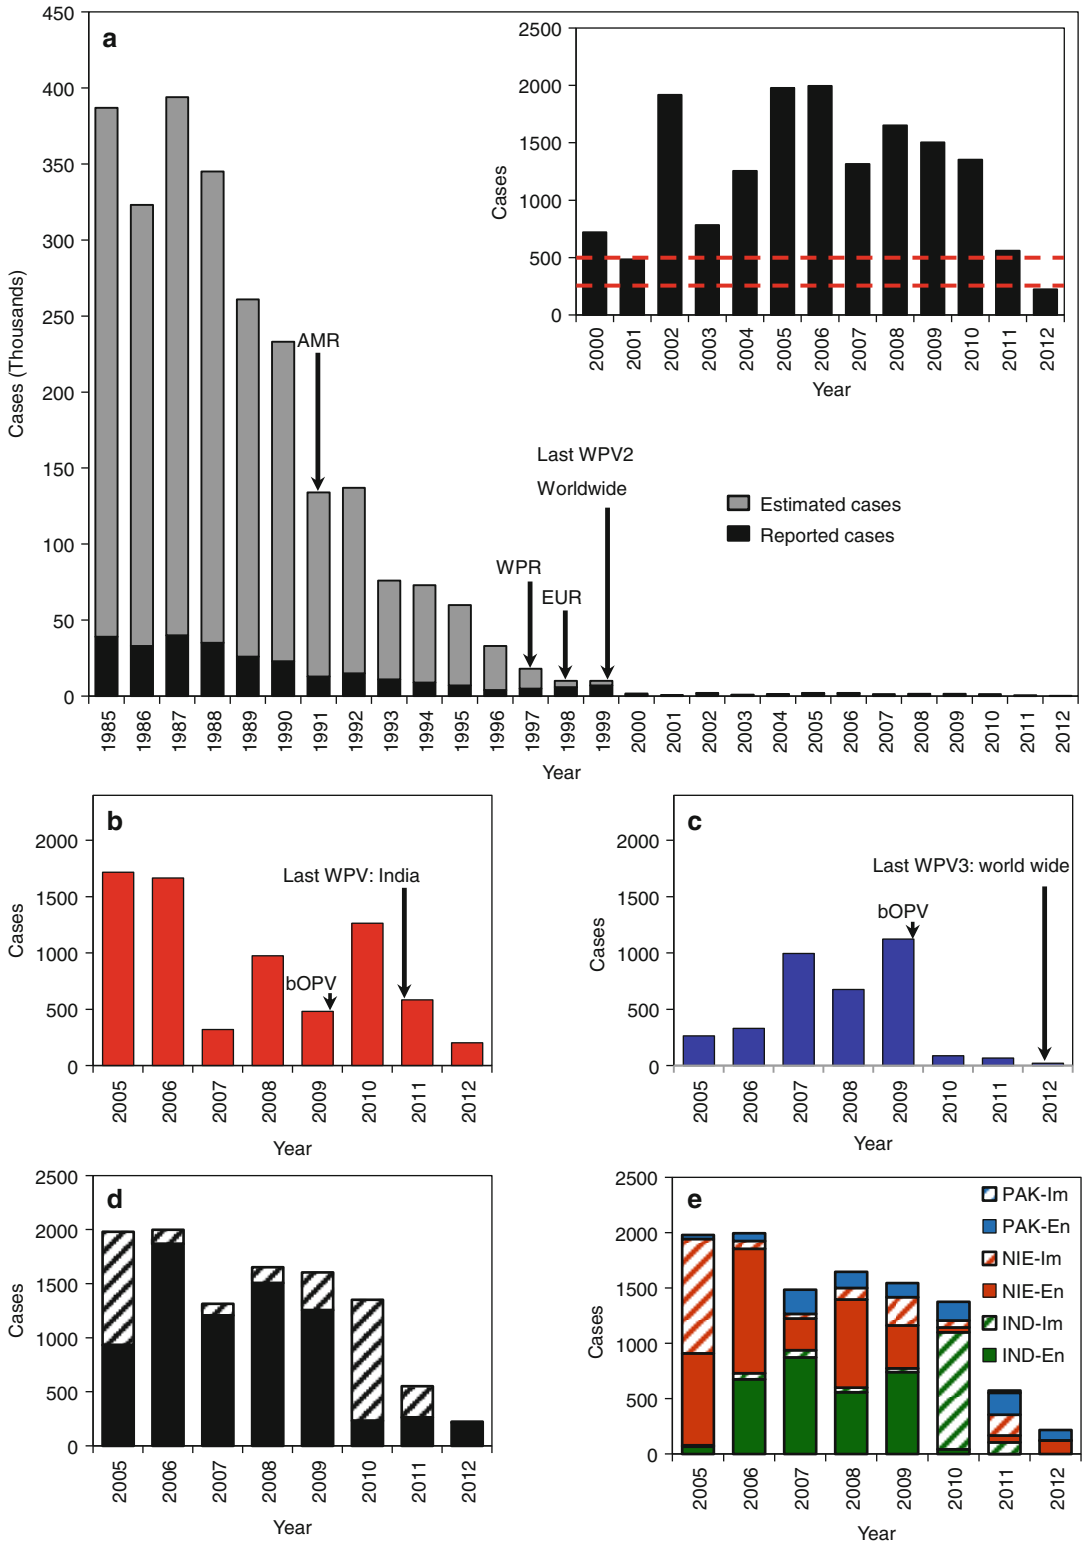

Fig. 13.2 (**a**) Incidence of paralytic poliomyelitis cases associated with wild poliovirus (*WPV*) infections worldwide, 1985–2012 (source http://www.polioeradication.org/). Estimated cases are shown as gray bars; reported, clinically confirmed, and virologically confirmed cases are shown as *black bars*. Starting in 2001, all WPV case counts were based on virologic confirmation by the GPLN. *Arrows* below three-letter codes for WHO regions (*AMR* Americas, *EUR* Europe, *WPR* Western Pacific) indicate year of last detection of indigenous WPV. *Red dashed lines* in inset indicate estimated number (250–500) of cases of VAPP per year worldwide. (**b**) Wild poliovirus type 1 (*WPV1*) poliomyelitis cases, 2007–2012. Introduction of bivalent OPV (bOPV; types 1 + 3) in late 2009 is indicated by the arrow. (**c**) Wild poliovirus type 3 (*WPV3*) poliomyelitis cases, 2007–2012. (**d**) Poliomyelitis cases from endemic (*solid bars*) and imported (*hatched bars*) WPV, 2007–2012. (**e**) Poliomyelitis cases associated with endemic (En) and imported (Im) WPV, 2007–2012 (*PAK* Pakistan [and Afghanistan], *NIE* Nigeria, *IND* India). dating back over a century [1–3, 7, 23, 28–35]. The disease probably emerged at the dawn of civilization, when population centers grew in size and density sufficient to support continuous endemic circulation. The earliest evidence for endemic poliomyelitis comes from Egypt, recorded on a small funerary stele from the Eighteenth Dynasty (c.1550 to c.1292 BCE), depicting a crippled young man, standing with the aid of a staff, with an atrophied right leg and flaccid foot drop characteristic of the long-term sequelae of paralytic poliomyelitis (Fig. 13.1) [1]. Three millennia later, in 1789, Underwood in England wrote the first clear clinical description of poliomyelitis as a "debility of the lower extremities" [36]. In 1840, the German orthopedist, von Heine, described "Spinale Kinderlähmung" (infantile spinal paralysis) and postulated that the disease could be contagious [37]. In Sweden, Medin conducted the first investigations of the epidemiology of poliomyelitis during the outbreak in Stockholm in 1887 [38]. Sporadic small outbreaks of paralytic disease had been described in the United States since 1841 [33, 39], but the first large outbreak (132 cases) occurred in Rutland, Vermont, in 1894 [40]. In northern Europe, major epidemics (>500 reported cases) erupted in Norway and Sweden (1905), Austria (1908–1909), Germany (1909), and England and Wales (1911) [34, 39]. During this period, Wickman in Sweden firmly established that poliomyelitis was transmitted by person-to-person contact, that the disease spread along the major lines of transportation, and that it gave differing clinical presentations. Wickman hypothesized that all infections, both severe and mild, contributed to spread, and that the incubation time was 3–4 days [41]. In Vienna in 1908, Landsteiner and Popper demonstrated that monkeys became paralyzed after intraperitoneal injection of a filtered homogenate from the spinal cord of a 9-year-old boy (who died within 3 days of onset of paralysis), and that they developed neural lesions similar to those observed in paralyzed humans [42]. Landsteiner and Popper were unable to passage the virus, but several groups, including Flexner and Lewis in 1909, achieved serial passage of poliovirus by nasal inoculation of monkeys [43]. With continued passage in monkeys, they selected a strictly neurotropic type 2 variant, MV, leading them to postulate that poliovirus grew only in neural tissues. However, in 1912, Kling, Wernstedt, and Pettersson isolated poliovirus not only from neural tissues but also from the oropharynx and small intestine, as well as from intestinal contents and throat swabs [44], but the views of Flexner and colleagues prevailed, and the critical findings from human pathology were overlooked for nearly three decades [1, 2].

After 1906, large epidemics appeared in the northeastern and north central states of the United States, culminating in the epidemic of 1916 centered around New York City, far larger at 23,000 reported cases than any previous outbreak [34, 45]. Nationwide poliomyelitis surveillance had begun in the United States in 1910, when all states were requested to forward monthly poliomyelitis case counts to the Surgeon General's Office [46]. The Drinker respirator, commonly known as the "iron lung," was introduced in 1929 as a device to save the lives of patients with respiratory paralysis (many of whom would subsequently recover unassisted respiratory function) [47]. In 1931, reinfection experiments in monkeys by Burnet and Macnamara provided the first evidence of more than one poliovirus serotype [48]. Seven years later, President Franklin D. Roosevelt, who had been paralyzed in both legs by poliomyelitis in 1921, cofounded with Basil O'Connor the National Foundation for Infantile Paralysis and the March of Dimes campaigns, providing a critical source of support for poliovirus vaccine research [1, 3]. Adaptation of the type 2 Lansing strain to cotton rats and mice by Armstrong in 1939 opened the way for much broader and more quantitative virologic and serologic studies on a scale previously unattainable with titrations in monkeys [49]. By the early 1940s, Trask and Paul [50, 51] and Sabin and Ward [52] recognized that poliovirus replicated in the tissues of the intestinal tract as well as the CNS, confirming the earlier observations of Kling. In 1949, Enders, Weller, and Robbins cultivated the type 2 Lansing strain of poliovirus in nonneural cells from human embryonic tissue—including skin, muscle, and intestine—yielding large quantities of virus, thereby accelerating the pace of poliovirus research and opening the way for expanded vaccine development and large-scale vaccine production [53]. That same year, Bodian and colleagues established that there were only three poliovirus serotypes [54, 55]. In 1953, following the peak year for poliomyelitis cases reported in the United States (57,628) [56], Hammon et al. demonstrated that administration of immune gamma globulin was protective against paralytic disease [57], and the following year Horstmann et al. showed that viremia preceded paralysis in humans [58]. With these strong experimental underpinnings, the stage was set in 1954 for Francis to conduct a field trial enrolling 1,800,000 children in the United States [59], demonstrating the safety and efficacy of the IPV developed by Salk and colleagues [4]. The new IPV was promptly licensed and distributed following announcement of the field trial findings in April 1955 [1, 3, 35]. In 1959, large field trials of the OPV of Albert Sabin were conducted in the Soviet Union, Poland, and Czechoslovakia [60], leading to the licensure and distribution of monovalent OPV types 1 and 2 in 1961 and type 3 in 1962 [6].

3 Methodology Involved in Epidemiologic Analysis

3.1 Sources of Data

Poliomyelitis has been a notifiable disease in the United States since 1910 [46], when case reports from state and territorial boards of health and health departments were summarized

monthly (1910–1926) and then weekly (1927–1951) in *Public Health Reports* [61]. Starting in 1952 [62], reports were regularly published in the CDC (Communicable Disease Center, later Centers for Disease Control and Prevention) *Morbidity and Mortality Weekly Report* (*MMWR*) [63]. Special annual poliomyelitis surveillance summaries were also published by CDC through 1974 [64]. In addition to the United States, many European countries and Canada established systems early in the last century for reporting cases of poliomyelitis, allowing epidemiologists to monitor rising disease incidence up to mid-century [65, 66] and the sharp decline after the introduction of poliovirus vaccines [8, 9]. In contrast, data on poliomyelitis incidence in developing countries was very incomplete, with only a small fraction of cases reported and with many populous countries not reporting any cases at all [8, 9]. In 1969, the World Health Assembly adopted a resolution that placed poliomyelitis "under international surveillance" [67]. However, systematic and sensitive surveillance for poliomyelitis in developing countries only followed the launch of polio eradication efforts in the Americas [14, 18] in 1985 and the GPEI in 1988 [15] and the establishment of field surveillance for cases of acute flaccid paralysis (AFP) [68] closely integrated with virologic testing of clinical specimens [69]. The quality of the integrated surveillance data improved gradually, usually in step with improvements in OPV coverage, and the findings were published regularly in reports by PAHO [70], WHO [71], and CDC [72]. Current weekly and monthly reports are posted on the WHO website (http://www.polioeradication.org/Dataandmonitoring/Poliothisweek/.aspx), and lists of wild polioviruses by country and year are posted on http://www.polioeradication.org/Dataandmonitoring/Poliothisweek/Wildpolioviruslist.aspx.

Over the past century, the large majority of case counts were based on clinical diagnoses, and it was soon recognized that the most accurate counts were obtained in outbreak settings [73]. Cases not associated with large outbreaks were more likely to be underreported. In the PAHO and WHO eradication initiatives, AFP cases were systematically reported and investigated, and as national and regional laboratory networks developed, all specimens from AFP cases were tested for the presence of poliovirus [69, 74, 75]. Countries and regions shifted from a clinical case definition to a virologic case definition once field surveillance for cases of AFP was tightly integrated with laboratory investigations for poliovirus. By 2001 global poliomyelitis case counts were based on virologic findings.

Data on case/fatality (CFR) ratios are not routinely available as ratios vary with the age distribution of population susceptibility and by setting [9, 23]. CFRs increase with age and are generally on the order of 2–5 % in children <5 years of age and 10–30 % in adults [23, 76, 77]. The epidemics early in the twentieth century were associated with high CFRs (27 % in the 1916 New York epidemic) [45], and more recent outbreaks from importation of wild poliovirus into previously polio-free countries have also been characterized by high CFRs in older age groups: Albania, 1996 (18 % for ages 19–24 years) [78]; Cape Verde Islands, 2000 (57 % for ages >15 years) [79]; Namibia, 2006 (31 %; most paralytic cases were among adults) [80]; the Republic of Congo, 2010–2011 (43 %; most paralytic cases were among adults) [81]; and Xinjiang, China, 2011 (10 %) [82]. During the outbreak year of 2006 in India, highly sensitive surveillance documented a CFR of 7.1 % among children <2 years [77].

3.2 Serologic Surveys

Serologic studies of infectious diseases were initially applied to the diagnosis of individual cases [83]. The first applications of serology to epidemiology were the studies by Aycock and Kramer in 1930, who used the newly developed neutralization test to show that antibodies to poliovirus appeared at younger ages in urban compared with rural populations [84]. Despite the methodological limitations (neutralization tests were performed in monkeys and predated recognition of more than one poliovirus serotype), these early studies heralded a powerful new tool to address fundamental questions about the epidemiology of poliomyelitis. In the pre-vaccine era, serologic surveys played an indispensable role in defining the prevalence of poliovirus infection, the intensity of transmission of each poliovirus serotype, the age profiles of exposure in different settings, the years and the associated serotypes of past outbreaks in isolated populations, the duration of type-specific immunity, the identification of susceptible populations, and key aspects of the pathogenesis of paralytic disease—including estimates of age-specific case/infection ratios [23, 28, 85, 86]. In the post-vaccine era, seroepidemiology has been used to detect immunity gaps in underserved populations [87, 88], to estimate the extent of wild poliovirus circulation in populations [89], to determine the efficacy of different OPV formulations in inducing neutralizing antibodies [90], and to provide evidence for eradication of indigenous wild polioviruses [91]. In the GPEI (and in the earlier PAHO initiative), serology was found not to be useful in the diagnosis of individual cases, because the response to detection of an AFP case was prompt administration of trivalent OPV (tOPV) to the patient and to the community ("mop-ups"; Sect. 10.4), such that many initially seronegative children had seroconverted to all three poliovirus serotypes by the time of the second blood sample [18]. However, seroprevalence studies continue to be important in measuring the immunogenicities of different OPV formulations [92], in detecting otherwise inapparent spread of OPV-derived viruses in unimmunized populations [93, 94], and in providing objective data on population immunity [95, 96],

including in polio-free countries where OPV coverage rates have fallen and the rising risks of outbreaks might not otherwise be recognized [22]. In recent outbreaks, primarily associated with poliovirus type 1 (Sect. 10.6), determination of the prevalence of neutralizing antibodies to poliovirus type 2 is a surrogate for vaccine-induced population immunity when the initial immunization response is deployment of type 1 monovalent OPV (mOPV1).

3.3 Lameness Surveys

Severe underreporting of poliomyelitis cases in many developing countries led to the misperception that the disease was not a source of serious morbidity in the tropics [8, 66]. Lameness surveys conducted in the 1970s and 1980s in Africa, Asia, and the Middle East confirmed the high prevalence of paralytic disease in developing countries and prompted many countries to begin polio vaccination programs [97, 98]. For example, in India in 1981–1982, estimates of the incidence of poliomyelitis from lameness surveys were as high as 200,000 cases per year, more than tenfold higher than officially reported case counts, with 83 % of cases occurring before 3 years of age [99]. Methods to improve the comparability of lameness surveys in different settings, including the use of standardized case definitions, has been reviewed [97].

3.4 Acute Flaccid Paralysis (AFP) Surveillance

AFP is the most serious clinical manifestation of wild poliovirus infection (Sect. 8.1) [100]. Poliomyelitis outbreaks are readily recognized, but low-level circulation in interepidemic periods may be missed in the absence of a sensitive surveillance system. This is especially true for endemic circulation of poliovirus types 2 and 3, which have much lower paralytic case/infection ratios than type 1 (estimated case/infection ratios [assuming an overall case/infection ratio of 1/150]: type 1, ~1/190; type 2, ~1/1,900; type 3, ~1/1,150) [34, 101]. Recent importation of wild poliovirus or emergence of circulating vaccine-derived polioviruses (cVDPVs; Sect. 10.8) may also be missed by the AFP surveillance system unless high sensitivity is maintained. Starting in 1985, PAHO built an AFP surveillance system to support the regional Polio Eradication Initiative [18]. Performance indicators for reporting of AFP cases were established assuming a background rate of nonpolio AFP of at least 1 case per 100,000 population <15 years. In addition, surveillance sites were required to report weekly, including "zero reporting" when no AFP cases were identified during the previous week [75]. AFP surveillance was closely integrated with virologic surveillance whereby stool samples from at least 80 % of patients with AFP were tested for the presence of poliovirus (Sect. 3.6) [69]. The successful PAHO strategy was adopted by the GPEI and implemented in all polio-endemic countries [68, 74, 102]. The benchmark AFP rate was raised to at least 2 cases per 100,000 population <15 years in endemic areas, and the global rate has been >4 since 2007 (http://apps.who.int/immunization_monitoring/en/diseases/poliomyelitis/afpextract.cfm). In the last stages of polio eradication in India, AFP surveillance sensitivity reached the extraordinarily high levels of >25 AFP cases per 100,000 population <15 years in the remaining polio-endemic states of Uttar Pradesh and Bihar (http://www.npspindia.org/bulletin.pdf) [91]. Only a small fraction of the AFP case-patients had wild poliovirus infections, and the integrated AFP and poliovirus surveillance system was approximating a community stool sampling survey of a population of ~300 million. It was critical to integrate AFP surveillance with laboratory-based poliovirus surveillance because AFP has multiple etiologies (including Guillain–Barré syndrome, transverse myelitis, infections by other neurotropic viruses, and traumatic neuritis; Sect. 8.1) [7], and the large majority of wild poliovirus infections are inapparent.

3.5 Environmental Surveillance

Sewage sampling was used as early as the 1940s to monitor the seasonal variation of poliovirus circulation in urban communities [51, 103]. Because most poliovirus infections are inapparent (Sect. 3.4 and 8.1), sewage sampling can greatly increase the overall sensitivity of poliovirus surveillance. For example, during the pre-vaccine era in the United States, poliovirus could be detected in sewage shortly before and after the seasonal appearance of paralytic cases, and the combined clinical data and environmental poliovirus isolation rates permitted estimation of the ratio between inapparent infections and paralytic cases [103]. Sewage sampling is widely implemented in Europe (conducted by 20 countries, including Israel [104–108]) and Japan [109] as a component of enterovirus (and poliovirus) surveillance. During the 1984 poliovirus outbreak in Finland, environmental surveillance demonstrated widespread circulation of the wild type 3 outbreak virus and provided a basis for the estimate of the occurrence of at least 100,000 inapparent infections despite the appearance of only nine paralytic cases [104, 110]. Wild poliovirus type 3 was found to be present in the environment 3 weeks before the appearance of the first paralytic case during the 1992–1993 outbreak in the Netherlands, and circulation of the outbreak virus was found to be localized to communities that refused immunization [106]. Environmental surveillance coupled with sequencing of wild poliovirus isolates was introduced on a limited basis in the PAHO program [111, 112]. Sampling of wastewater in a high-risk community

in Cartagena, Colombia, revealed close sequence relationships between sewage isolates, stool survey isolates, and paralytic case isolates obtained from the community over the same period, but also detected circulation of lineages not found by AFP surveillance [111]. Sewage sampling in Israel and adjoining Palestinian territories detected outbreaks of wild poliovirus infections in Gaza, Ashdod, and the West Bank in 1990 (type 3), 1991 (type 1), 1994–1995 (type 1), and 1996 (type 1) [107]. The outbreaks were described as "silent" because no poliovirus-associated paralytic cases had been detected by the AFP surveillance systems. All of the wild poliovirus sewage isolates were found to be related to viruses circulating in Egypt. The continued detection in Gaza of wild polioviruses of Egyptian origin at times when none were reported by the AFP surveillance system in the source reservoir communities prompted the implementation of environmental surveillance in Egypt in September 2000, which by 2004 sampled 33 sites in 18 governorates [113–115]. This approach, combined with strengthened AFP surveillance, improved the overall sensitivity of the poliovirus surveillance system, and wild polioviruses disappeared from the environment soon after their disappearance in specimens collected from patients with AFP [113, 115]. Implementation of sewage sampling in the open canals in the large slum communities of Mumbai, India [116], coupled with sequencing (section "Nucleotide sequencing of poliovirus isolates"), confirmed the disappearance of the local wild polioviruses and the repeated importation of wild polioviruses from known reservoirs in the northern Indian states of Uttar Pradesh and Bihar [91]. Because no suitable sampling sites were available in the highest-risk rural reservoir communities, additional sites were established in Delhi and Patna, Bihar, which receive migrants from the endemic rural areas [91]. As in Egypt, the findings from the environmental and AFP surveillance systems were in agreement: the last environmental wild poliovirus isolate (a type 1) was found in Mumbai sewage in November 2010, and the last wild poliovirus isolate (a type 1) from an AFP case-patient was in West Bengal in January 2011 (http://www.npspindia.org/bulletin.pdf) [91]. The GPEI and the Global Polio Laboratory Network (Sect. 3.6.1) have extended environmental surveillance to six cities in Pakistan and three cities in Nigeria and are planning further expansions in countries at high risk of reestablishment of poliovirus circulation either by importation or by the emergence of cVDPVs (see below and Sect. 10.8) [22].

VDPVs closely resembling those excreted by individuals with primary immunodeficiencies (Sect. 10.8.2) have been detected in sewage in Israel [117], Estonia [118], Slovakia [119], and Finland [120]. Despite efforts in each country to identify the source of the excreted virus, no poliomyelitis cases or chronically infected individuals have so far been identified.

Environmental surveillance has also helped inform the endgame strategy for the GPEI (Sect. 11.2). A key question is the persistence of vaccine-related viruses in the population and environment following cessation of OPV use. In Cuba, where OPV is delivered only in mass campaigns in the form of two rounds of National Immunization Days (NIDs), vaccine-related viruses were detected in stool surveys for up to 8 weeks and in the environment for up to 15 weeks after the second NID round [121]. New Zealand shifted from OPV to IPV in February 2002, and vaccine-related viruses were regularly detected in sewage samples until May 2002. Sporadic vaccine-related isolates detected subsequently showed very limited sequence divergence from the parental OPV strains, indicating that they were recent imports from OPV-using countries rather than persistence of vaccine-related viruses in the community [122].

An important difference between environmental sampling and AFP surveillance is that environmental sampling is most sensitive in locations with developed sewage systems or open sewage canals in large slums and therefore is usually established in more urbanized settings. Sewage sampling sites in urban centers are selected to include communities of migrant populations from rural areas. Environmental surveillance is necessarily localized, targeted, and intermittent, in contrast to a well-functioning AFP surveillance system that monitors the entire population on a continuous basis. Consequently, poliovirus isolates obtained by the two surveillance approaches may yield different kinds of public health information. For example, a wild poliovirus isolate from an AFP case is directly linked to a specific patient from a specific locale and usually signals many other inapparent infections in the community. In contrast, the high sensitivity of environmental sampling can result in multiple poliovirus isolations from a single infected person but does not yield further information about the specific source of infection. However, some information about the extent of poliovirus circulation can be obtained from the extent of genetic diversity of polioviruses obtained at a sampling site [111, 115].

3.6 Laboratory Methods

3.6.1 The Global Polio Laboratory Network (GPLN)

The GPLN was established by the WHO to support the GPEI [123]. Currently the GPLN consists of 145 laboratories, initially organized in three tiers: (1) National and Subnational Laboratories ($n=122$), (2) Regional Reference Laboratories ($n=16$), and (3) Global Specialized Reference Laboratories ($n=7$) (Fig. 13.4). As the GPLN developed, activities once assigned to Regional Reference Laboratories are frequently performed by many National and Subnational Laboratories, and Regional Reference Laboratories currently perform

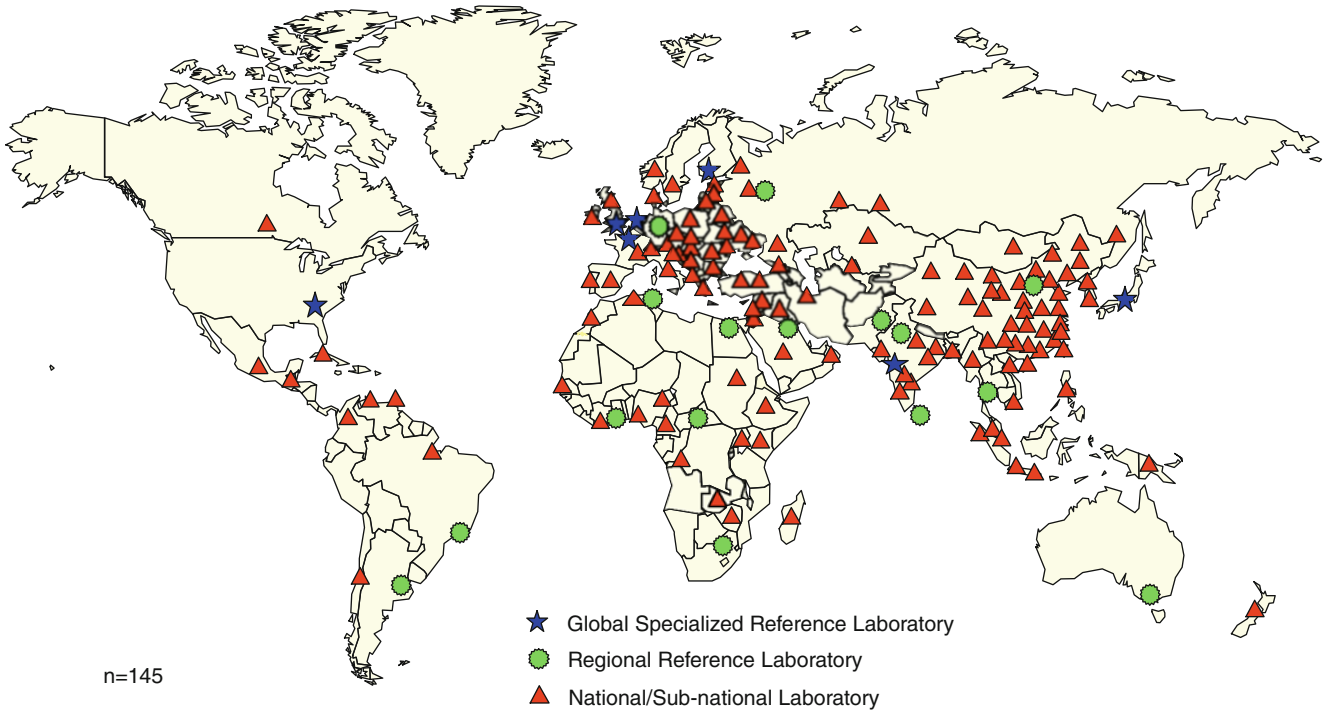

Fig. 13.4 Distribution of laboratories of the Global Polio Laboratory Network (GPLN). *Triangles* National and Subnational Laboratories, *circles* Regional Reference Laboratories, *stars* Global Specialized Reference Laboratories

many functions (such as genomic sequencing) originally assigned to Global Specialized Reference Laboratories. These trends have strengthened the GPLN, permitted continuous technical innovation, and moved many of the diagnostic activities closer to the endemic areas of highest priority. The GPLN was patterned after the PAHO Regional Laboratory Network established in parallel with development of AFP surveillance [69]. Close integration of AFP and poliovirus surveillance was facilitated by the use of standardized case ("EPId") numbers accessible to surveillance officers, virologists, and program managers [100, 124].

Methods for poliovirus isolation, identification, and serology have been described in detail previously [23, 125, 126]. Laboratory manuals were developed by the GPLN to standardize methods for detecting and characterizing polioviruses in clinical specimens and environmental samples [124], and a GPLN Quarterly Update was published by the WHO to keep GPLN virologists and others abreast of new developments and innovations [127]. Because the overriding emphasis of the GPLN is to monitor poliovirus circulation, less attention has been given to the routine typing and characterization of nonpolio enterovirus isolates, and readers are referred to Chap. 11 for details on those methods. The WHO Polio Laboratory Manual [124] is regularly updated as new methods are developed and tested for suitability for use by GPLN laboratories. New methods, designed to increase sensitivity, specificity, and work efficiency, are developed in concert with the rising technical capabilities of the GPLN and in anticipation of (or in response to) increasingly focused surveillance questions posed by the GPEI [22]. All GPLN laboratories participate in a formal accreditation process which includes review of performance in standardized proficiency tests as well as routine diagnostic work as confirmed by GPLN reference laboratories [128]. Well-characterized cells, reference OPV virus stocks, serologic reagents, and molecular reagents are distributed by GPLN reference laboratories to ensure a high degree of standardization, and internal quality control procedures are regularly implemented by all GPLN laboratories to ensure high routine performance [128]. GPLN laboratories participate in annual regional and global meetings to review performance, discuss effective implementation of new methods, develop approaches to improve coordination, and plan research and other future activities (http://www.polioeradication.org/Dataandmonitoring/Surveillance/GlobalPolioLaboratoryNetwork.aspx) [128]. The GPLN is interdependent, applying common approaches to problem solving, parallel testing as needed, training, and other kinds of technical support. The GPLN is guided by expert WHO virologists who serve as global and regional laboratory coordinators. The GPLN, with its close integration with program, has served as the model for newer regional and global networks supporting laboratory-based surveillance for other viral and bacterial vaccine-preventable diseases [129–131]. Many of the methods and reagents used by the GPLN have also been shared with state laboratories in the United States [132].

3.6.2 Virus Isolation and Identification

Categories of Poliovirus Isolates

The primary purpose of infectious disease surveillance is to identify agents that present potential public health risks. Poliovirus isolates of each serotype are grouped into three categories, correlating with the risk of transmission and spread, and based on the extent of divergence of the VP1 nucleotide region compared to the corresponding OPV strain: (1) wild polioviruses (no genetic evidence of derivation from any vaccine strain and demonstrated capability of continuous person-to-person transmission); (2) vaccine-derived polioviruses (VDPVs) (vaccine-related polioviruses that are >1 % divergent [types 1 and 3] or >0.6 % divergent [type 2] from the corresponding OPV strain and potentially capable of causing paralytic disease and establishing person-to-person transmission) (Sect. 10.8); and (3) "OPV-like" polioviruses (vaccine-related polioviruses that are ≤1 % divergent [types 1 and 3] or ≤0.6 % divergent [type 2] from the corresponding OPV strain) that are ubiquitous wherever OPV is used [133]. VDPVs are further categorized as (1) circulating VDPVs (cVDPVs), when there is evidence of person-to-person transmission in the community; (2) immunodeficiency-associated VDPVs (iVDPVs), which are isolated from persons with primary immunodeficiencies who have prolonged VDPV infections; and (3) ambiguous VDPVs (aVDPVs), which are either clinical isolates from persons with no known immunodeficiency or sewage isolates whose ultimate source is unknown [133].

Clinical Specimens

The specimens of choice for AFP and poliovirus surveillance are stool samples collected as soon after onset of paralysis as possible. The GPEI has defined "adequate" stool specimens as "two stool specimens of sufficient quantity (~8 g) for laboratory analysis, collected at least 24 h apart, within 14 days after the onset of paralysis, and arriving in the laboratory in good condition and with proper documentation" (http://www.polioeradication.org/Dataandmonitoring/Surveillance.aspx). Two samples are collected because poliovirus shedding is often intermittent [134]. The GPEI has established clear performance guidelines and training procedures for proper specimen transport to the laboratory via a "reverse cold chain" similar to the forward cold chain used for deployment of OPV [100, 124]. Such importance has been assigned to specimen collection from AFP cases that runners with specimens in insulated backpacks were allowed safe passage through combat lines in war zones where use of motorized transport was very hazardous.

Poliovirus may be isolated at lower frequencies from rectal swabs [135] and throat swabs (if taken within the first few days of infection) and only rarely from cerebrospinal fluid (CSF); however, none of these specimens are recommended by the GPEI and the GPLN [100, 124].

Virus Isolation in Cell Culture

The most critical and basic procedure is virus isolation in cell culture. Polioviruses can be grown in a wide range of human cells (RD, HeLa, HEp-2, WI-38, MRC-5, HEK293) and simian cells (from rhesus macaques and African green monkeys; primary monkey kidney cells, Vero, LLC-MK2, BGM) (http://www.atcc.org/) [23], but two cell lines are routinely used in combination by the GPLN for virus isolation [124]: (1) RD cells (a continuous line from human rhabdomyosarcoma [136]) which are highly sensitive to poliovirus infection and yield virus at high titers [23] and (2) L20B cells (a derivative of the mouse L cell line engineered to express the human poliovirus receptor, CD155) which are highly selective for growth of poliovirus [124, 137]. Viruses that grow in L20B are usually polioviruses (although some Coxsackie A viruses can grow in L20B cells [124, 138]) and are further characterized by molecular identification methods.

Molecular Characterization and Intratypic Differentiation of Isolates

The original methods for identification of polioviruses and other enteroviruses were based on antigenic properties. Virus isolates were typed by testing for growth in the presence of pools of antisera containing different combinations of high-titer neutralizing antibodies [23]. Typing of individual poliovirus (or enterovirus) isolates was then confirmed by use of type-specific antisera. Heterotypic poliovirus mixtures were resolved by growth in the presence of different pairs of type-specific neutralizing antisera.

Intratypic differentiation (ITD; distinguishing wild polioviruses from vaccine-related isolates) was originally based on antigenic or phenotypic properties [139]. Before the development of molecular methods, the most reliable of these were the antigenic methods, and isolates were described as "vaccine-like," "non-vaccine-like," or "intermediate." Most assignments based on antigenic methods were confirmed by the more precise molecular methods. It is remarkable that the antigenic methods worked so well in view of the fact that the Sabin OPV strains undergo frequent antigenic evolution toward "non-vaccine-like" antigenicity during replication in the human intestine [139–141], and that the wild polioviruses themselves are antigenically diverse [139, 142]. Although the Sabin type 1 OPV strain (Sabin 1) has multiple non-consensus antigenic changes in its neutralizing antigenic sites [139, 143, 144], Sabin 2 and Sabin 3 are usually less antigenically divergent from the corresponding wild polioviruses [139]. ITD based on antigenic properties was improved by use of highly specific cross-absorbed monotypic sera which contained antibodies that reacted specifically with "vaccine-like" or "non-vaccine-like" antigens [143]. ITD using cross-absorbed antisera was adapted to an ELISA format [145] and widely used by the GPLN, especially in recent years for the characterization of VDPVs

Table 13.1 Poliovirus identification by real-time RT-PCR

RT-PCR primer–probe set	Poliovirus/enterovirus isolate category[a]								
	NPEV	WPV1[b]	WPV3[b]	S1	S2	S3	WPV1/WPV3	VDPV1	VDPV2

VDPV1	–	–	–	–	–	–	–	+	–
VDPV2	–	–	–	–	–	–	–	–	+
VDPV3	–	–	–	–	–	–	–	–	–

Based on data from references [151, 153, 157–159]. Reagents for identification of VDPV3 isolates have also been prepared. All suspected wild poliovirus and VDPV isolates are routinely further characterized by VP1 sequencing. Special sequencing primer sets have been developed to resolve both heterotypic and homotypic mixtures. The combinations shown, along with others (especially different combinations of Sabin vaccine-related isolates), have been observed in clinical isolates

[a]*Abbreviations*: *NPEV* nonpolio enterovirus, *WPV1* wild poliovirus type 1, *WPV3* wild poliovirus type 3, *S1* Sabin type 1 vaccine-related, *S2* Sabin type 2 vaccine-related, *S3* Sabin type 3 vaccine-related, *VDPV1* vaccine-derived poliovirus type 1, *VDPV2* vaccine-derived poliovirus type 2

[b]As previously described for other wild poliovirus genotypes [152], wild genotype-specific real-time RT-PCR primers and probe sets have been prepared for the Nigeria wild type 1, Nigeria wild type 3, Pakistan–Afghanistan wild type 1, and Pakistan–Afghanistan wild type 3 genotypes (D. Kilpatrick, manuscript in preparation)

[133]. Other ITD methods based on antigenic properties used panels of neutralizing monoclonal antibodies [140, 142, 145, 146]. However, none of the antigenic ITD methods could overcome the basic biological limitations arising from the antigenic evolution of the OPV strains [140, 141, 145], and antigenic methods have been replaced by methods based on the nucleotide sequence properties of poliovirus isolates.

The earliest molecular method for routine ITD was oligonucleotide fingerprinting [147, 148]. This approach had the high reliability required for poliovirus surveillance in support of eradication, but it was also laborious, expensive, and difficult to scale up and required the use of radioisotopes. Therefore, oligonucleotide fingerprinting was not appropriate for developing country laboratories. Consequently, oligonucleotide fingerprinting was replaced by nucleic acid probe hybridization [149, 150], and the transfer of this ITD method to the PAHO Polio Laboratory Network commenced in the late 1980s. The reverse transcriptase-polymerase chain reaction (RT-PCR) offered specificities and sensitivities unattainable with probe hybridization, and it became the method of choice within the GPLN [151, 152], although full deployment awaited adaptation to a real-time format, which greatly reduced the risks of contamination by PCR products [153]. RT-PCR coupled to restriction fragment length polymorphism analysis was also widely used, because this routine test provided insights into the origins of wild poliovirus isolates [154]. An elegant approach based on microarrays was also developed [155, 156], but it was less readily transferrable to developing country laboratories at the front lines of global poliovirus surveillance.

Currently the GPLN uses real-time RT-PCR for ITD [124]. A series of primer pairs and specific fluorescent probes have been developed that identify isolates hierarchically: (1) as enteroviruses (panEV), (2) as polioviruses (panPV), (3) by poliovirus serotype (Sero1, Sero2, Sero3), and (4) whether vaccine-related (Sab1, Sab2, Sab3) (Table 13.1) [153, 157, 158]. The sets of real-time RT-PCR reagents are deployed as kits for routine use by the GPLN [160] and can be supplemented with additional real-time RT-PCR reagents that further identify wild polioviruses by genotype (Sects. 3.6.3 and 10.7) and can facilitate screening for genetically divergent VDPVs (VDPV1, VDPV2, VDPV3) [133, 161]. The rapid evolution and high genetic diversity within and across poliovirus serotypes presented special challenges to development of the panPV and serotype-specific primer and probe sets (Table 13.1), as it was necessary to use degenerate and inosine-containing oligonucleotides to base pair with the appropriate specificities at positions of codon degeneracy [157, 158]. Although the nondegenerate Sabin vaccine strain-specific RT-PCR reagents can be used in a multiplex format, the complexity of the degenerate reagents limits the number of reactions that can be combined in multiplex.

Nucleotide Sequencing of Poliovirus Isolates

ITD screens for wild polioviruses and VDPVs and screens out OPV-like polioviruses that are unlikely to be of current epidemiologic importance. Since 2001, all wild poliovirus and VDPV isolates are sequenced by GPLN laboratories following standardized procedures and using standardized sequencing primer sets. The ~900-nucleotide interval

(representing ~12 % of the total genome) encoding the major capsid protein, VP1, is routinely sequenced. VP1 sequences are used for routine comparisons because they encode several serotype-specific antigenic sites [162] and evolve primarily by successive fixation of nucleotide substitutions rather than by recombination [163, 164]. Wider genomic intervals, up to the complete genome, may be sequenced to obtain higher epidemiologic resolution or to address specific virologic questions [165–168]. Serotype- and genotype-specific sequencing primers have been developed to specifically amplify components of heterotypic and homotypic poliovirus mixtures, bypassing selective cultivation in the presence of neutralizing antibody or incubation at supraoptimal temperatures [169]. Sequence relationships among poliovirus isolates are summarized in phylogenetic trees and genotypic maps that are distributed monthly by GPLN laboratories to Ministries of Health, WHO country and regional offices, WHO-Geneva, and other GPLN laboratories.

3.6.3 Molecular Epidemiology of Polioviruses

The application of genomic sequencing of poliovirus isolates has added a new dimension and resolving power to the understanding of the epidemiology of poliomyelitis [170]. Because poliovirus genomes evolve rapidly (typically just over 1 % nucleotide substitutions per site per year at all sites, equivalent to one to two nucleotide substitutions per week) [164, 165, 168, 171–174], links between poliomyelitis cases can be determined with precision, and the sources and timing of importations from the remaining poliovirus reservoirs can be established [11, 163, 164, 168, 175–178]. Sequence analyses offer an additional tool to monitor the progress of the GPEI and has shown that poliovirus genotypes (viruses within a genotype differ by <15 % in their nucleotide sequences) and genetic clusters within genotypes (viruses within a cluster differ by <5 % in their nucleotide sequences) disappear sequentially through intensive immunization efforts (Sect. 10.7) [11]. Experience in the Americas has found that in settings of sensitive surveillance, a genotype that is not detected for more than a year has probably become extinct [11, 170]. Molecular epidemiology has established the existence of numerous poliovirus genotypes endemic to different regions of the world (Sect. 10.5.3) [11, 170], demonstrated that poliovirus type 2 is usually the first serotype to be eliminated [13], that poliovirus type 3 appears to circulate more locally than type 1 [10], and that poliovirus type 1 appears to be most commonly associated with importations from neighboring countries and with intercontinental or global spread of the virus (Sect. 10.6) [10, 11, 163, 175, 176, 179–181]. In some settings, different genotypes of poliovirus type 1 have been found to have co-circulated in a geographically limited area [163, 179, 182, 183].

Molecular epidemiologic methods are routinely used to help identify reservoir communities with low population immunity and where demographic and environmental conditions favor poliovirus circulation. During the peak months of poliovirus circulation, virus spreads from the reservoir communities to adjacent non-reservoir indicator communities (where the density of nonimmune susceptible children can support some poliovirus circulation during the peak transmission season). This has led to a refinement in the concept of virus importation, which in previous usage referred to virus transmission across national boundaries. Although many importations over long distances have been documented [10, 180], reservoir communities and their associated indicator communities frequently overlap international borders [10, 184], underscoring the importance of regional synchronization of NIDs and Subnational Immunization Days (SNIDs). Equally important are the patterns of importation from reservoir communities to indicator communities within a country [168, 184, 185]. High vaccine coverage in the reservoir communities, especially in mass campaigns conducted during the low transmission season, prevents the subsequent spread to indicator communities.

Sequence analysis led to the recognition of highly divergent iVDPVs [165, 186] and cVDPVs [166, 187, 188] (Sect. 10.8), and it has been used to resolve at high-resolution chains of cVDPV transmission [132, 188–190] and separate iVDPV lineages in individual immunodeficient patients with prolonged infections [165, 173, 186, 191, 192].

Molecular epidemiologic methods have also opened a new avenue for detecting gaps in polio surveillance. In areas with good surveillance, poliovirus isolates representing frequent sampling of a single chain of transmission are typically closely related (usually >99.5 % VP1 sequence identity among the closest relatives). These closely related viruses are routinely visualized as sequences connected by short branches on phylogenetic trees [193]. Long-branch connections between isolate sequences indicate missing information. If the virus is imported, the missing information may be recovered from the sequence relationships to viruses from the source reservoir [11]. However, in many other circumstances, no closely related viruses can be found, and the recent virologic history of the isolate lineage is indeterminate. For example, gaps in AFP surveillance in southern Egypt were inferred from the sequence data, because indigenous type 3 isolates in 1999 appeared as “orphan lineages” at the tips of long branches on phylogenetic trees, and the closest relatives were isolated nearly 3 years earlier [194], observations that highlighted the importance of environmental surveillance to improve sensitivity. Orphan lineages have been repeatedly found in areas with insensitive surveillance. The GPLN regularly monitors for the appearance of poliovirus orphan lineages as a means to assess surveillance sensitivity.

A serious challenge to the integrity of poliovirus surveillance data is the occurrence of poliovirus contamination of

cultures. High workloads in many GPLN laboratories potentially increase the risk of contamination. Fortunately, sequence analysis can distinguish contaminants from true clinical isolates. Contaminants are easily recognized when they are standard wild reference strains, such as Mahoney, MEF-1, or Saukett (OPV-like contaminants are usually of little current programmatic importance), but are more difficult to recognize when they are the wild polioviruses indigenous to a country or community. However, when wild polioviruses isolated at different times and locations have identical VP1 sequences, contamination is suspected, because such sequence identities are inconsistent with the rapid rate of evolution of the poliovirus genomes. Contamination can be definitively confirmed (or ruled out) by complete genomic sequencing. At the advanced stages of polio eradication, laboratory contamination could have severe programmatic consequences if unrecognized, prompting the diversion of resources into unnecessary immunization campaigns mobilizing large populations and costing many millions of dollars.

3.6.4 Tests for Antibody

Because precise and detailed epidemiologic information is routinely obtained from characterization of poliovirus isolates, virologic methods are the mainstay for global poliovirus surveillance [195]. However, antibody tests, especially those measuring population immunity or vaccine efficacy, have assumed greater prominence in recent years [92, 95, 196–200]. The "gold standard" is the neutralization test, as the presence of neutralizing antibody is regarded as the key indicator of protective immunity to poliovirus [7]. Current automation methods permit tests for neutralizing antibody to be performed at scales previously unattainable.

4 Biological Characteristics of Poliovirus

4.1 General Properties

Polioviruses, as members of species-C of the *Enterovirus* genus, share most properties with other members of that species and genus (Chap. 11) [201, 202]. Polioviruses are small (~30 nm in diameter [203]), non-enveloped viruses with capsids of icosahedral symmetry enclosing a single-stranded, positive-sense RNA genome. The genome is ~7,500 nucleotides long, has a small (22-amino acid) basic protein, VPg, covalently linked to the 5′-end, and is polyadenylated at the 3′-end (Fig. 13.5). The single open reading frame (ORF) is flanked by a long (~740 nucleotides) 5′-untranslated region (5′-UTR) and a short (~70 nucleotides) 3′-UTR. Complete genomic sequences have been determined for numerous representatives of each of the three serotypes, including those of the three Sabin OPV strains [204]. Only the sequences encoding the capsid proteins are unique to polioviruses, as the flanking sequences are frequently exchanged by recombination with the closely related species-C enteroviruses during circulation (Sect. 4.6.2) [24, 166, 188, 205, 206]. The poliovirion consists of 60 copies each of 4 capsid proteins (VP1–4) that form a highly structured capsid shell [203]. The three major proteins (VP1, VP2, VP3) share a similar basic architecture and were probably derived from a common ancestral protein [203]. The smallest protein, VP4, internalized in the native virion, is formed by the cleavage of the precursor VP0 (VP4 + VP2) during final maturation of the virion. The external surface of the poliovirion is decorated by peptide loops extending from VP1, VP2, and VP3, which form the neutralizing antigenic sites (Fig. 13.5) [162, 207]. Polioviruses attach to and enter cells via the specific poliovirus receptor (PVR) on the cytoplasmic membrane; the PVR was later identified as CD155, a glycoprotein of the immunoglobulin superfamily [208–210]. The key distinguishing properties of poliovirus capsids are their antigenic surfaces and their abilities to specifically bind to CD155, as the sequences and structures of the internal capsid domains are largely conserved among species-C enteroviruses.

4.2 Physical Properties

Poliovirus capsids contain no essential lipids, and infectivity is insensitive to inactivation by detergents and lipid solvents such as ether, chloroform, or alcohol [23]. The viruses are stable at pH 3–5 for 1–3 h and can therefore pass through the stomach without inactivation. Exposure to 0.3 % formaldehyde, pH <1, pH >9, or free residual chlorine at 0.3–0.5 ppm causes rapid inactivation. Infectivity is stable indefinitely at –20 °C or lower, and stable for weeks at 4 °C, but is rapidly inactivated at temperatures above 50 °C [211]. Molar concentrations of $MgCl_2$ significantly increase the thermal stability of poliovirions [212], both at elevated and ambient temperatures, and $MgCl_2$ is added to many OPV preparations to preserve potency [7, 213]. High intensity ultraviolet light or desiccation inactivate infectivity by causing an irreversible conformational transition from D-antigenicity to C-antigenicity (Sect. 4.3) [211, 214]. The three-dimensional crystal structures of representatives of all three serotypes have been determined [203, 215, 216]. Poliovirions have a buoyant density of 1.34 g/ml and a sedimentation coefficient of 160S, properties that can be exploited to obtain highly purified virus preparations [217].

4.3 Antigenic Properties

There are three poliovirus serotypes [54, 55]. Three (or four) neutralizing antigenic sites have been identified by patterns

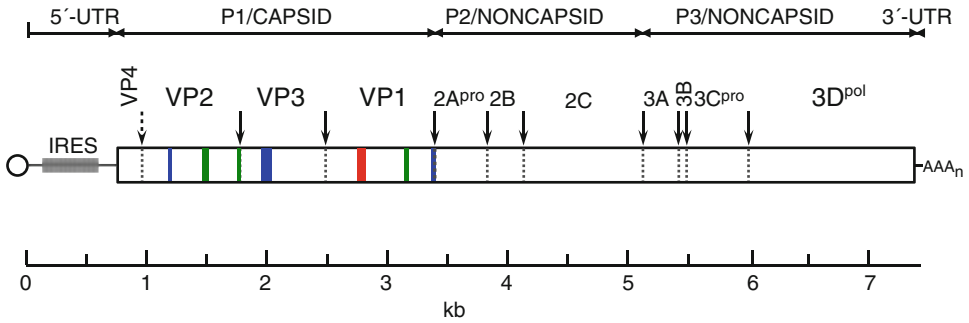

Fig. 13.5 Schematic of the poliovirus genome. The single open reading frame (ORF) is indicated by a rectangle, flanked by the 5′- and 3′-untranslated regions (*UTRs*); the small protein VPg (encoded by the 3B sequence interval) is covalently attached to the 5′-UTR and is represented by a circle at the 5′ end. The internal ribosome entry site (*IRES*; nucleotide positions 130–600) in the 5′-UTR is shown as a shaded rectangle. A single polyprotein is translated from the ORF, which is cotranslationally processed by virus-encoded proteases $2A^{pro}$ (catalyzes cleavage between VP1 and $2A^{pro}$; the cleavage site is indicated by a *dashed arrow*) and $3C^{pro}$ (catalyzes all other cleavages except the VP4/VP2 maturation cleavage; the cleavage sites are indicated by the *solid arrows*). Mature cleavage products are bounded by *dashed lines*. Protein $3D^{pol}$ is an RNA-dependent RNA polymerase (RdRP). *Colored bars* symbolize virion surface loops forming neutralizing antigenic sites 1 (*red*), 2 (*green*), and 3 (*blue*) (Redrawn from reference Kew et al. [94])

of reactivity with neutralizing murine monoclonal antibodies (Fig. 13.5) [162], and the assignments have been confirmed by high-resolution x-ray crystallography [216, 218, 219]. Neutralizing antigenic site 1 is continuous and formed by a loop in VP1; sites 2 and 3 are discontinuous and formed from loops contributed by different capsid proteins. The major type-specific differences in the capsid polypeptides primarily reside on the most surface-accessible peptide loops, which represent less than 4 % of the total capsid protein [204]. Although the neutralizing antigenic sites vary within each serotype [139, 142, 164, 165, 174, 220–223], the range of variability is constrained, possibly because of steric requirements for interaction with CD155 [224, 225], such that all polioviruses within a serotype can be neutralized by type-specific antisera, and poliovirus vaccines (both IPV and OPV) can induce protective immunity to all known antigenic variants. Poliovirus antigenic evolution differs importantly from that of influenza virus in that there is no cumulative antigenic divergence from ancestral viruses during person-to-person transmission, and genetically unrelated viruses may have similar antigenic properties and shared epitopes.

Limited cross-neutralization has been observed for all three poliovirus serotypes [226], and a shared epitope between types 1 and 2 has been identified by mapping escape mutants to cross-reactive neutralizing monoclonal antibody [227]. Recently, chimeric chimpanzee–human monoclonal antibodies have been produced showing patterns of strong cross-neutralization [228]. Epitope mapping with these primate monoclonal antibodies have identified shared determinants not previously recognized by studies using murine monoclonal antibodies [228], suggesting that the poliovirus antigenic surface may be more complex than previously thought.

Within each serotype there are two basic antigenic conformations: D-antigen ("dense"; sometimes also called N or "native" antigen) and C-antigen ("coreless"; corresponding to H or "heated" antigen) [211, 229]. The D-antigen corresponds to that of the intact native virion, and IPV potency is measured in D-antigen units [5]. The C-antigen contains no RNA and is not cross-reactive with the D-antigen [211]. Transitions between the D and C conformations are rapid in empty capsids, but D-antigen is stabilized by RNA packaging [214].

Poliovirus antigenic properties have been reviewed by Minor [162].

4.4 Host Range In Vivo and In Vitro

Humans are the only reservoir host for poliovirus [230]. Chimpanzees, gorillas, and orangutans have been infected while in captivity [231, 232], and chimpanzees can be experimentally infected by the oral route [233]. Poliomyelitis cases appeared in a natural chimpanzee colony following an outbreak in an upstream African village [234]. Old World monkeys are susceptible to experimental poliovirus infection upon intraspinal or intracerebral injection, and macaques (cynomolgus, rhesus, and bonnet) can be infected by the oral route, but high virus titers are required for infection [235–238]. New World monkeys are not susceptible to poliovirus infection by any route of administration because of substitutions in the variable domain of their CD155 orthologs [239, 240]. Paralytic attack rates in humans differ by poliovirus serotype in the order type 1>type3>type 2 (Sect. 3.4) [8, 9, 34, 241]. Susceptibility to oral infection is in the order of humans>chimpanzees>macaques, whereas neural susceptibility is in the order macaques>chimpanzees>humans [242–244].

Poliovirus variants of all three serotypes have been selected for growth in mice [245–247] and a type 2 variant has also been selected for growth in chick embryos [248]. Polioviruses normally cannot directly infect cultured mouse or chick cells, but can replicate efficiently when viral RNA is introduced by transfection, an observation that led to the concept of a specific viral receptor [249]. The CD155 PVR is a transmembrane glycoprotein with three extracellular immunoglobulin-like domains, encoded by a gene mapped to human chromosome 19 [250]. The normal function of CD155 is as a receptor for establishment of intercellular junctions between epithelial cells, a function that is "misused" by poliovirus to gain entry into human cells [251].

4.5 Poliovirus Replication Cycle

An overview of the poliovirus replication cycle is shown in Fig. 13.6. Virus attaches to cells through specific interactions between the amino-terminal variable domain 1 of CD155 and a "canyon" that surrounds the fivefold axis of the virion [225, 253–257]. After endocytosis, viral RNA is uncoated and released into the cytoplasm [257], VPg is cleaved from 5′-end of the RNA, and the RNA is translated. Translation is under the control of the internal ribosome entry site (*IRES*; Fig. 13.5), an element (nucleotides ~130–600) within the 5′-UTR that has a highly conserved stem-loop structure [258, 259]. The translation product is a single polypeptide, the

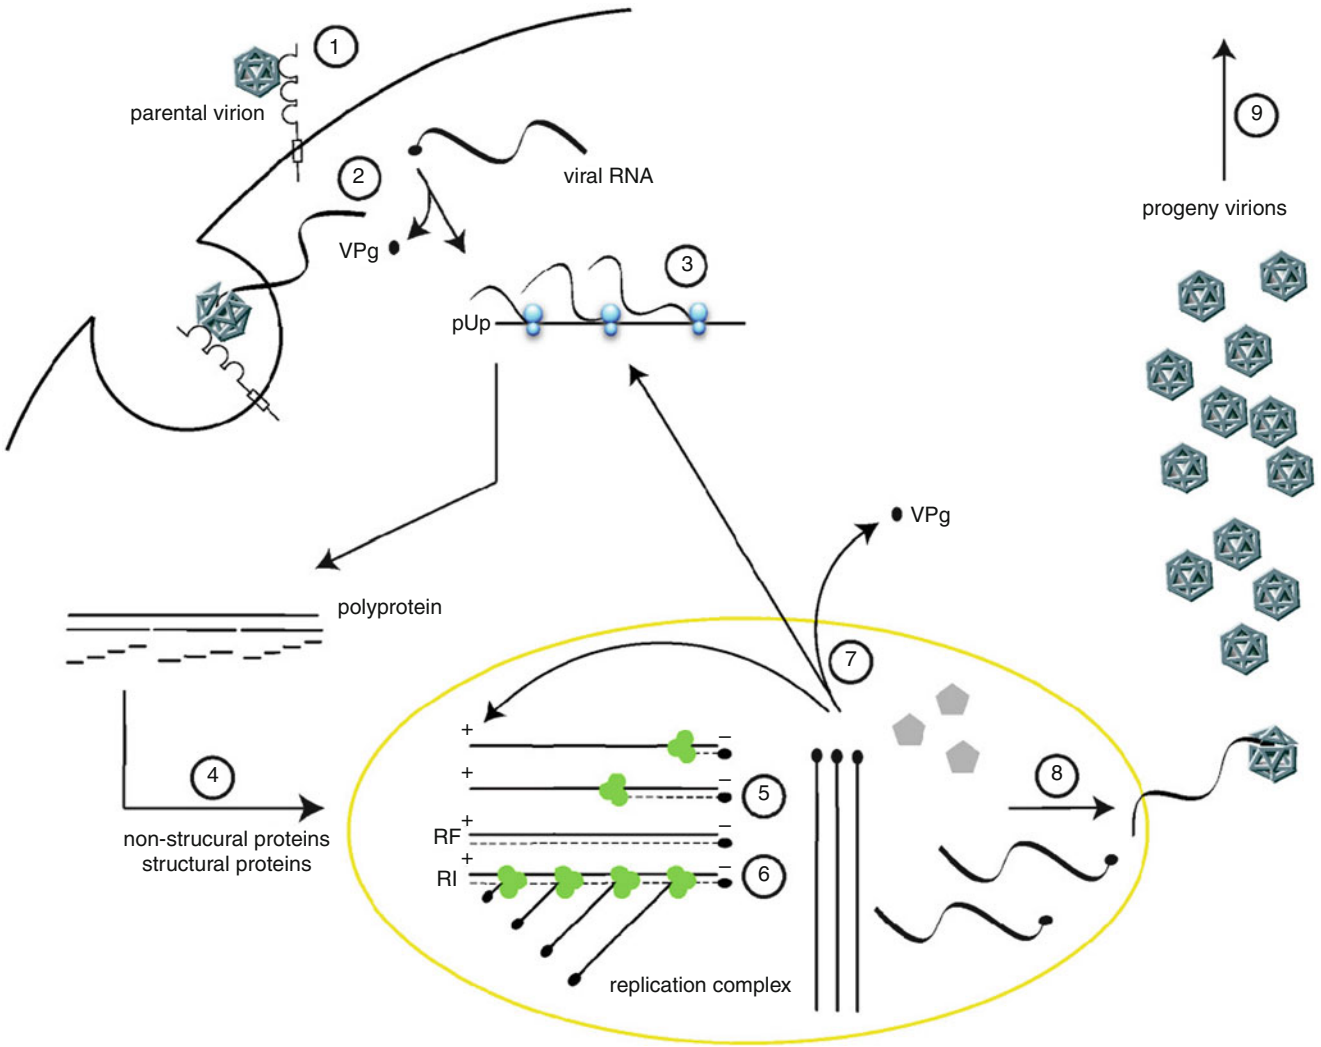

Fig. 13.6 Overview of the poliovirus replication cycle: *1* attachment of polio virion to poliovirus receptor (PVR; CD155) on cytoplasmic membrane, *2* endocytosis and uncoating of RNA, release into cytoplasm, and cleavage of VPg from 5′-end of RNA, *3* translation of viral proteins from viral RNA serving as mRNA, *4* proteolytic processing viral proteins, *5* replication of negative (–) strands of viral RNA by poliovirus RNA-dependent RNA polymerase (RdRP), *6* replication of positive (+) strands of viral RNA by RdRP in replication intermediates (RI), *7* cleavage of VPg from some + RNA strands for programming as mRNA, *8* encapsidation of other + RNA strands into virions, and *9* release from cytoplasm of infected cell. In cell culture, the entire infectious cycle is complete within ~6 h with release of up to 10,000 infectious virions per cell (Reproduced from reference De Jesus [252] with permission from BioMed Central)

polyprotein, which is cleaved by virus-encoded proteinases, $2A^{pro}$ and (primarily) $3C^{pro}$, into mature viral proteins [260]. Host protein synthesis is rapidly inhibited by the cleavage by $2A^{pro}$ of the translation initiation factor eIF4G, required for initiation of translation of capped host messenger RNA but not for the internal initiation of translation from the poliovirus IRES [259, 261]. One cleavage product is $3D^{pol}$, an RNA-dependent RNA polymerase (RdRP), that catalyzes the synthesis of negative-polarity (–) RNA strands from the genomic and mRNA-polarity (+) strands forming a duplex called the replicative form (RF) [262, 263]. Multiple copies of positive RNA strands are produced from negative-strand templates in replicative intermediates (RI) arrayed in intracellular membrane complexes [262, 263]. VPg is cleaved from some newly synthesized positive RNA strands for programming as mRNA and further translation [260]. Other positive strands are encapsidated during the maturation step in which the VP0 precursor to VP4 and VP2 is cleaved followed by release of infectious virions from the infected cell. The entire replication cycle takes place within the cytoplasm, and poliovirus can replicate in anucleate cells. Infected cells show cytopathic effects within 6 h and can release up to 10,000 infectious virus particles upon cell lysis and death. This rapid rate of cellular destruction accounts for the rapid progression of paralysis when poliovirus infects motor neurons [264].

Poliovirus (and picornavirus) replication has recently been reviewed in depth [27, 202, 259].

4.6 Poliovirus Genetics

4.6.1 Rapid Evolution of Poliovirus Genomes

Poliovirus is one of the most rapidly evolving viruses known [147, 164, 171, 172, 265]. Most of the nucleotide substitutions generate synonymous codons [164], and the basic biological properties of wild polioviruses remain unchanged, although the Sabin OPV strains can undergo important phenotypic changes (Sects. 9.1.4 and 10.8). Estimates of the rates of total nucleotide substitution into poliovirus capsid regions average ~10^{-2} substitutions per site per year [164–166, 171–173, 188, 191]. The rates appear to be similar across the three poliovirus serotypes and for both circulating polioviruses and polioviruses associated with chronic infections, and constitute a robust poliovirus molecular clock. Underlying the rapid pace of poliovirus genomic evolution are the high rates of base misincorporation (in the range of 10^{-5} to 10^{-3} per base per replication) by the poliovirus RdRP [266–271]. These high mutation rates are attributable to the absence of $3' \rightarrow 5'$ exonuclease proofreading mechanisms for the viral RNA polymerases [267], although other mechanisms may also be involved [272]. This exceptionally rapid rate of genomic evolution has facilitated high-resolution molecular epidemiologic studies (Sects. 3.6.3 and 10.7), even as deeper evolutionary relationships among poliovirus genotypes are obscured by saturation of variable nucleotide sites [164].

Poliovirus populations in cell culture and in humans [173] are a spectrum of mutational variants termed "quasispecies" [273, 274]. On average, each genome in a virus population contains one nucleotide substitution difference from the consensus "master sequence" of the quasispecies population. Two important consequences are that the virus populations in the live, attenuated OPV contain preexisting variants of higher potential neurovirulence [275], and that antigenic variants can be rapidly selected in cell culture [218, 276] and in humans [141, 220–223].

4.6.2 Recombination

Recombination occurs continuously during poliovirus infection of cultured cells [271, 277, 278] and individuals [173, 279]. Wild polioviruses undergo frequent recombination with the closely related human species-C enteroviruses during circulation [24, 167, 205, 206]. Indeed, the 5′-UTR and P2/P3 noncapsid sequences (Fig. 13.5) of wild polioviruses are drawn from a potentially large and constantly exchanging genetic pool that includes the locally circulating human species-C enteroviruses [167, 206, 280]. Crossovers usually map outside the capsid region when the exchange partners are different poliovirus or enterovirus serotypes, but crossovers may occur within the capsid region when the partners are of the same poliovirus serotype [173, 271, 277]. The biological role of recombination in poliovirus is unclear. Recombination may facilitate maintenance of replicative fitness by countering the accumulation of deleterious mutations [281]. However, natural selection apparently maintains wild poliovirus near its fitness optimum, and multiple recombinational variants can co-circulate locally [168]. Children fed tOPV regularly excrete vaccine/vaccine recombinants [279] and most circulating VDPVs (Sect. 10.8) are vaccine/non-vaccine recombinants [133, 166–168].

The genetics of poliovirus and other RNA viruses has been comprehensively reviewed [268, 273, 274, 277, 282, 283].

5 Descriptive Epidemiology

The epidemiology of poliomyelitis remained obscure until inapparent infections and mild cases were recognized [40, 41]. Unlike smallpox, where every infection of a susceptible person is associated with overt and characteristic clinical signs [284], the first poliomyelitis outbreaks erupted with no evident source [1, 34]. Five phases in the natural history of poliomyelitis can be recognized: (1) the endemic phase, (2) the epidemic phase, (3) the vaccine era, (4) the eradication era, and (5) the post-eradication era [22, 23]. Most developed countries eradicated their indigenous wild polioviruses four

to five decades ago [8, 9, 33, 34]. Similar progress has now been achieved by all but three developing countries (Fig. 13.3), parts of which remain in the endemic and epidemic phases because the vaccine era has not yet been fully implemented [12].

5.1 Endemic, Epidemic, Vaccine Era, and Eradication Phases

During the endemic phase, virtually all children were exposed to wild polioviruses at an early age. Large outbreaks were rare because large cohorts of nonimmune susceptible children rarely accumulated. Frequent exposure to wild polioviruses maintained population immunity and had the potentially important additional beneficial effect of boosting the immunity of women of childbearing age. Outbreaks were more likely to occur in smaller, more isolated populations than in large populations that could support continuous poliovirus circulation. The endemic phase was inevitably followed by an epidemic phase [1, 8, 9, 23, 28, 29, 33, 34, 66]. In the United States and Europe, outbreaks of increasing size and severity occurred for six decades until the mid-1950s and were halted only by the introduction of IPV [8, 9, 23, 29, 34]. Unfortunately, the vaccine era arrived unequally in the world, starting first with the most developed countries of Europe, North America, Australia, and New Zealand and progressing to Japan, the Soviet Union and Eastern Europe, and the countries of temperate South America [8, 9]. As the vaccine phase progressed in more developed countries, periodic epidemics appeared in less developed countries [8, 9]. Incomplete vaccine coverage in some developing countries had the perverse effect of reducing, but not eliminating, poliovirus circulation, potentially increasing the risk of explosive epidemics following the buildup of nonimmune susceptible persons in the population. The eradication phase has been permanent in most countries, but continued wild poliovirus circulation in a few areas carries ongoing global risks, and some countries have allowed immunity gaps to widen after eradication of indigenous wild polioviruses and suffered outbreaks from imported wild polioviruses [10, 12] (Sect. 10.6) or from the emergence and spread of cVDPVs (Sect. 10.8) [133]. The global post-eradication phase (Sect. 11.2) is far more complex than originally envisioned and is a key element of the current WHO strategic plan [22].

5.2 Geographic Distribution

Before the vaccine era, all three poliovirus serotypes had virtually a worldwide distribution. Virus circulated continuously in populous tropical areas, and the intensity of wild poliovirus circulation ("force of infection") was high, especially in areas with high population densities [180]. For example, up to the 1990s in Mumbai, India, all three serotypes of wild poliovirus could be found in the community, and children in high-risk urban slums were occasionally found to be concurrently infected with all three wild poliovirus serotypes [285, 286]. In recent years, some children in low-coverage endemic communities were coinfected with wild poliovirus types 1 and 3.

As with other enteroviruses, poliovirus circulation had a distinct seasonality in temperate zones. Paralytic cases peaked during summer and early autumn and could disappear altogether in winter. Sewage sampling could detect the presence of virus before and after the appearance of cases, but generally not throughout the year in smaller communities in cooler climates [103]. In both temperate zones and tropical areas, different serotypes predominated in different years. Poliovirus circulation would stop completely in small, rural populations, which would then be subject to outbreaks once poliovirus was reintroduced into the community [28].

Very isolated communities had no poliovirus infections for years. For example, age-stratified seroprevalence data have shown that Eskimo communities in Canada and the United States experienced sharp outbreaks covering a broad age distribution preceded and followed by many years with no serologic evidence of poliovirus circulation [85, 287]. A similar pattern of infrequent outbreaks also occurred in isolated tropical communities. Following introduction of poliovirus from the mainland, a large outbreak in the Andaman and Nicobar Islands in the Bay of Bengal in 1947–1948 affected a broad age distribution, with an overall paralytic attack rate of 10 % and a CFR of 14 % [288].

In the vaccine era, poliovirus type 1 had the widest geographic distribution, and poliovirus type 2 the most restricted [180]. It is difficult to separate out the effects of immunization, even at low rates of coverage, from the intrinsic biological properties of wild polioviruses. For example, type 1 is most frequently associated with large outbreaks and appears to be able to spread over wider geographic areas than type 3 [180] and (especially) type 2. Wild poliovirus type 2 was the first to be eradicated globally (Fig. 13.3) [13] but was also the first to disappear regionally. In the United States, for example, wild poliovirus type 2 disappeared long before type 3 and finally type 1. By the mid-1980s, no wild type 2 polioviruses could be found in several large countries, including Brazil and China, where the other two serotypes were still endemic [170]. Only wild poliovirus type 1 was found in the Caribbean during the 1970s and 1980s, whereas both types 1 and 3 could be found in the larger island populations of the Philippines and Indonesia until the mid-1990s [289, 290].

With the introduction of OPV, OPV-like viruses of all three serotypes became ubiquitous in areas of high coverage. Unlike wild polioviruses, vaccine-related strains usually do

not persist. For example, in Cuba, where OPV was administered only twice a year in campaigns, vaccine-related viruses disappeared from the environment within 4 months of the second campaign round [291].

5.3 Seasonality

In temperate zones, circulation of polioviruses, like that of all enteroviruses, is seasonal [23]. The summer-fall seasonality of poliomyelitis outbreaks was clearly described in the early reports of epidemics in Europe and the United States [41, 45]. Seasonality was most pronounced in temperate zones and gradually decreased toward the equator, where intense poliovirus circulation could occur throughout the year [9, 34, 56]. In the tropics, the residual poliomyelitis seasonality was variable and circulation tended to increase during the rainy season. The typical summer-autumn wild poliovirus seasonality peak was offset by 6 months between the northern and southern temperate zones [9, 292]. Poliomyelitis outbreaks have occurred on rare occasions during the winter months [110].

Poliovirus seasonality is a reflection of the fluctuation in the number of transmission chains during the year [168, 193]. However, the underlying mechanisms for poliovirus seasonality are unknown. Seasonal patterns of human association do not appear to be major factors because the peaks of the poliovirus and rotavirus (another non-enveloped enteric virus) seasons are offset by 6 months in the United States [34]. One hypothesis for poliovirus seasonality is based on the observation that poliovirus is more stable when relative humidity is above 40 % [293]. In temperate zones, indoor relative humidity is highest in the summer, and in the tropics humidity is high during the rainy season and throughout the year in coastal areas, a pattern closely correlated with the observed patterns of poliovirus seasonality. However, seasonal patterns of human migration can also facilitate poliovirus dissemination. For example, the spread of wild poliovirus from the tropics to more temperate zones was correlated with the seasonal migration of underimmunized farm worker families moving with the harvest season. Reaching underimmunized children in migrant populations remains a key eradication strategy in developing countries [22].

Seasonality has been an important facilitating factor for the eradication of wild polioviruses in developing countries. Mass immunization campaigns in the cooler months, when the transmission chains of poliovirus (and potentially competing enteroviruses) are at their seasonal low [193], have been a mainstay of eradication efforts [294–296]. In the northern Andean region, polio circulation ceased in cities in the temperate highlands years before it ceased in cities of the tropical coastlands [164]. In temperate Bolivia, OPV coverage rates of only 50 % were sufficient to eradicate polio [70]. Sequence data showed that wild poliovirus was imported into the Bolivian highlands from tropical coastal Peru [170]. In Brazil, polio was rapidly controlled in the south, but the reservoirs persisted in the northeast, with its more tropical climate as well as poor sanitation [70]. Polio had already been eradicated from the temperate Southern Cone (Argentina, Chile, Paraguay, Uruguay) before the launch of the PAHO Polio Eradication Initiative [18]. In China, polio persisted in the provinces of the southeast but not in the coastal northeast [172, 297, 298]. One caveat is that the level of immunization (and OPV efficacy) is usually higher in temperate zones than in tropical zones.

5.4 Age and Sex

In endemic areas, children are chiefly responsible for maintaining poliovirus circulation. The primary ages of first infection (as indicated by appearance of cases) was 2 years or younger in the pre-vaccine era [9, 23, 28, 29, 66]. Older individuals may have added to poliovirus transmission, but their contributions were likely to have been relatively small because most would have had prior exposure to poliovirus and the effect of reexposure would have been to boost mucosal immunity and thus limit poliovirus excretion. In both developing and developed countries, the hygiene of children <2 years of age favors enteric virus dissemination, but in the pre-vaccine era the likelihood of exposure to wild poliovirus was much higher in settings with poor sanitation [29].

The age distribution of poliomyelitis cases has shifted dramatically to older age groups over the past century [9, 23, 28, 29, 66]. During the 1916 epidemic in New York, 80 % of cases were among children <5 years of age. By the mid-1950s, peak cases were in children 5–9 years of age and two-thirds of deaths were in patients >15 years of age [23]. In developing countries, poliomyelitis remained a disease of younger children, with >75 % of cases <2 years of age and >95 % of cases <5 years of age [299, 300].

In the endemic phase, which represented all countries before the late nineteenth century, many children would be infected by the then-prevalent wild polioviruses while still protected by maternal antibody, and thus could become immune without risk of paralytic disease. As sanitation improved, the first exposures to poliovirus were delayed to later in life, when the risk of severe disease is increased, and after protective maternal antibodies had waned. Delayed infection also resulted in expansion of the pool of nonimmune susceptible individuals, increasing the potential for explosive outbreaks once wild poliovirus was reintroduced into the population. Paul had first proposed this process to explain the sudden appearance of epidemic poliomyelitis, first in the most developed parts of Europe and North America and then elsewhere [1]. Paul's hypothesis has been repeatedly confirmed [23, 34], and it predicted an irreversible shift from the endemic to the epidemic phase. This had been the pattern in all countries until poliomyelitis was finally brought under control through immunization.

It has been known for decades that males are more susceptible than females to paralytic poliomyelitis and to more severe forms of the disease [9, 23, 66, 301]. The reasons for this are unknown, although it has been suggested that greater physical exertion by boys might be a factor [23]. A majority of the paralytic cases occurred in males in recent outbreaks in Namibia (89 %) [80], Republic of Congo (68 %) [302], and Tajikistan (66 %) [178].

5.5 Occurrence in Families and Contact Groups

Polioviruses, like other enteroviruses, are highly communicable [23]. In the pre-vaccine era, virus was spread efficiently by young children to other family members, many of whom had prior exposure and were not susceptible to disease. In the vaccine era, most cases of contact vaccine-associated paralytic poliomyelitis (VAPP; Sect. 9.1.4) were within the family unit [303, 304]. More recently, concerns have focused on extended family units in developing countries, especially among groups that refuse immunization and who could represent an interconnected, socially defined reservoir of poliovirus transmission within an otherwise adequately immunized population. Attention is also being given to nomads and other mobile populations who could facilitate dissemination of poliovirus originating from fixed reservoir communities [22].

5.6 Epidemiologic Patterns of Poliomyelitis

5.6.1 Epidemiologic Patterns in Developed Countries in Temperate Zones

The shift from endemic to epidemic phase was first observed in countries with the highest standards of community sanitation and personal hygiene [23, 28, 29, 33, 34]. As outlined above, the epidemic phase appears to have been the consequence of delaying poliovirus exposure to later age groups who are prone to more severe paralytic disease and to the accumulation of nonimmune susceptible populations poised for large outbreaks. As sanitation conditions continued to improve, the poliomyelitis outbreaks steadily shifted in size and severity and peaked in increasingly older age groups. In some settings the shift was gradual; in others it was abrupt [23].

The mechanism proposed by Paul [1] for the shift from endemicity to epidemicity received further support by the observation that families with the highest socioeconomic advantages were at highest risk for severe poliomyelitis, whereas less advantaged families living in communities with poor sanitation were at reduced risk [23]. Indeed, the last outbreaks in the United States in the epidemic pre-vaccine era included parents in more advantaged families whose children carried wild poliovirus into the home [305].

5.6.2 Poliomyelitis in the Vaccine Era

The high-income countries of North America, Western Europe, and the southwest Pacific were quick to adopt widespread immunization with IPV. The impact was rapid and dramatic. In the United States, for example, the incidence of paralytic poliomyelitis fell from 13,850 in 1955 to 829 in 1961 (Fig. 13.7) [308]. With the availability of OPV in 1961, more countries adopted immunization against poliomyelitis, and the downward trend continued. In the United States, Canada, Australia, and New Zealand, combined cases fell >700-fold from 44,378 in 1951–1955 to 62 in 1968 [8], and in Europe cases fell >50-fold from 28,359 in 1951–1955 to 529 in 1968 [8]. Dramatic progress was also made in the Soviet Union as some republics reported no cases by 1968 [8]. Poliomyelitis cases in Japan, which did not use IPV and introduced OPV in 1961 [309], fell >120-fold from 2414 in 1951–1955 to 20 in 1968 [8]. Apart from Singapore, the picture for the rest of Asia was not encouraging. Several countries in Latin America (Costa Rica, Uruguay, Chile, and Argentina) reduced cases by 4- to 50-fold [8], and Cuba eradicated indigenous polioviruses in 1962 [8, 310], as did Jamaica in 1968 [8]. However, many other countries in Latin America and the Caribbean made little progress [8]. Only Israel in the Middle East made evident progress (>35-fold reduction by 1968), and poliomyelitis in Africa remained virtually uncontrolled [8].

The downward trends continued in the United States and other higher-income countries through the 1970s (Fig. 13.7) [9]. Circulation of wild polioviruses indigenous to the United States apparently ceased after the 1970 outbreak along the Texas-Mexico border [163, 311]. Subsequent sporadic poliomyelitis cases (and a small outbreak in 1972) were usually associated with wild type 1 polioviruses imported from Mexico [163]. An outbreak associated with type 1 virus originating in Turkey spread to underimmunized religious communities in the Netherlands and Canada, and to the Amish community in the United States in 1978–1979 [147], was followed in August 1979 by one last sporadic case associated with wild type 1 poliovirus imported from Mexico [163]. A similar picture emerged in Europe. Outbreaks associated with imported wild polioviruses occurred in the Netherlands in 1971 (type 1) [312, 313], 1978 (type 1) [163, 312, 313] and 1992 (type 3) [314, 315]; in Sweden in 1977 (type 2) [105]; in Spain in 1983 (type 3) [180]; in Finland in 1984 (type 3) [110, 316]; and repeatedly in the Balkans and the southern Republics of the Soviet Union (types 1 and 3) [180, 317]. Also, a large outbreak in Taiwan in 1982 (1,031 cases) from wild type 1 poliovirus (probably imported from Indonesia) highlighted the risk to poliomyelitis-free countries in Asia of reinfection by importation from neighboring countries [318].

In many developed countries using OPV, the only cases of poliomyelitis each year were from VAPP (Sect. 9.1.4) [24, 319–323]. However, the risks of importation of wild polioviruses

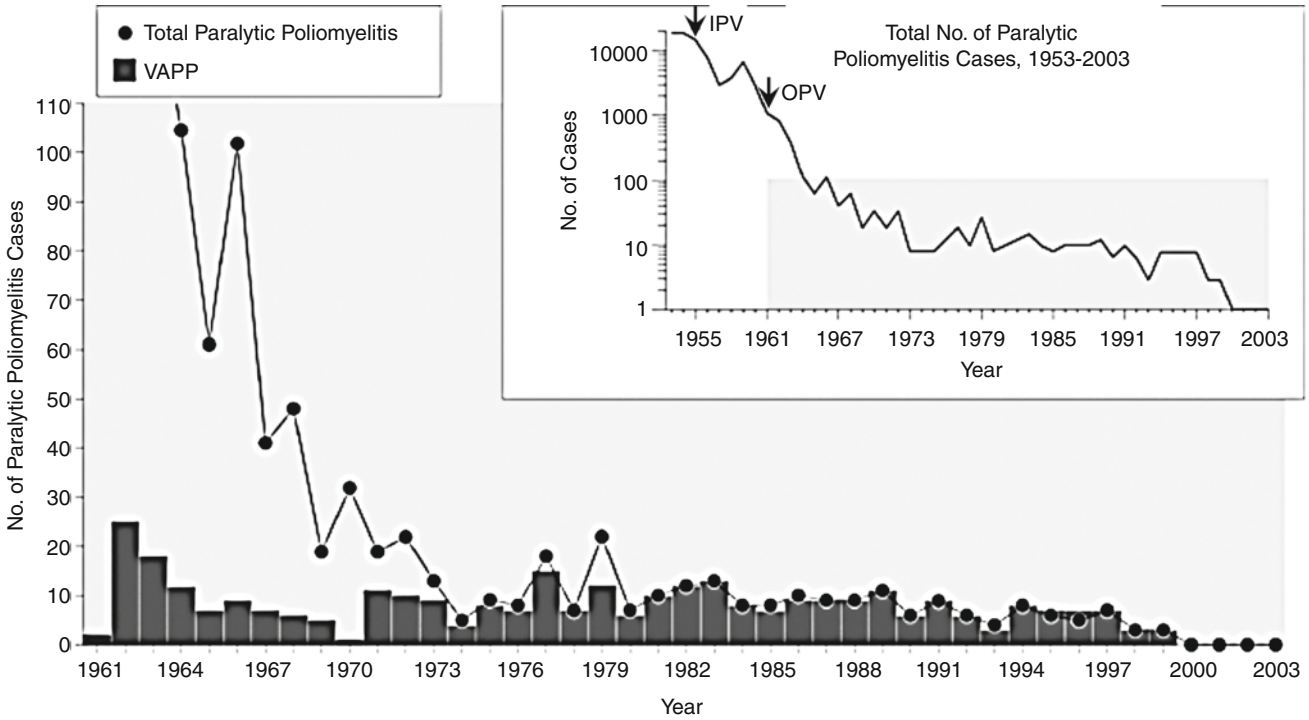

Fig. 13.7 Reported cases of poliomyelitis, United States, 1953–2003. Arrows indicate years of introduction of inactivated poliovirus vaccine (IPV; 1955) and oral poliovirus vaccine (OPV; 1961–62). The last wild poliovirus (type 1) case occurred in August 1979 [163, 306]. Bars indicate cases of vaccine-associated paralytic poliomyelitis (VAPP). New VAPP cases stopped after the shift to IPV in 2000 [307], but vaccine-derived poliovirus (VDPV) infections occurred in Minnesota in 2005 (type 1) [132] and a separate immunodeficiency-associated VDPV (iVDPV) case occurred in Minnesota in 2008 (type 2) [223]. Note that abscissa of inset is a logarithmic scale and abscissa of main graph is a linear scale (Source: Centers for Disease Control and Prevention (CDC). Reproduced from reference Alexander [307])

remained, and the sharp divergence between the poliomyelitis-free and poliomyelitis-endemic worlds was unsustainable.

5.6.3 Poliomyelitis in Developing Countries

By 1980, many developing countries had made little progress in controlling poliomyelitis in the nearly two decades since the widespread availability of OPV [9, 324]. With their growing populations, the problem of epidemic poliomyelitis in developing countries, well recognized by the mid-1950s [292], was increasing [98, 324]. In addition, lameness surveys revealed that the incidence of poliomyelitis in Africa and other developing countries was far higher than originally believed [97, 98, 319, 325]. Poliomyelitis cases in much of Africa and Asia had been grossly underreported [324], with the actual global incidence being tenfold greater than the officially reported counts. For example, lameness surveys in 1981–1982 suggested that India had half of the estimated world total of 400,000 poliomyelitis cases per year [326, 327]. Throughout the 1980s, the city of Mumbai alone reported ~1,000 cases per year [285, 286], more than 100 times the rate (from VAPP) for the United States over the same time period (Fig. 13.7) [303, 304]. Moreover, large outbreaks, some recurring, occurred in many developing countries as they steadily shifted to the epidemic phase [180]. Clearly, remedial action was urgently needed.

6 Mechanisms and Routes of Transmission

As with other enteroviruses, poliovirus is spread by person-to-person contact via two routes of transmission, fecal–oral and respiratory [23, 29]. The relative importance of these two routes varies by setting. Fecal–oral is the more efficient route because fecal shedding continues for up to 6 weeks, and the quantities of virus shed in stool may be as high as 300 million infectious particles per day [328]. Under experimental conditions, vaccine virus was shown to spread to contacts even when administered in gelatin capsules, thereby bypassing throat infection and respiratory transmission [329]. In areas of poor sanitation and hygiene, fecal–oral transmission (via contaminated fingers, food or water, utensils, or toys) is most likely the dominant route, as young children are continually exposed to unsanitary conditions and live in close proximity to contaminated soil and open sewers. Respiratory transmission probably played a more important role in developed countries with high standards of hygiene and sanitation, and where in the pre-vaccine era exposure to poliovirus in higher socioeconomic communities was typically delayed by several years. The effectiveness of IPV, which blocks oropharyngeal but not intestinal infection [330], to stop wild poliovirus transmission is evidence of the

importance of respiratory transmission in settings where fecal–oral transmission is less prominent.

There is no evidence for an extrahuman reservoir for poliovirus, apart from virus stored in laboratory freezers [331]. Sequence analyses show close genetic relatedness among the polioviruses obtained in the same locales from clinical cases, stool surveys, and sewage sampling [111, 113]. Virus imported over short or long distances can consistently be linked by molecular epidemiologic methods to infections recently occurring in the source communities [10, 11, 163, 193, 332].

On very rare occasions, poliomyelitis infections and outbreaks have started by mechanisms other than direct person-to-person transmission. In the spring of 1955, 204 vaccine-associated cases occurred in the United States following injection of children with IPV preparations which contained residual infectious wild poliovirus (the Cutter incident) [333, 334]. The majority of case isolates were derived from the neurovirulent type 1 Mahoney strain used in IPV production [1, 333, 334]. A small number of cases in Uttar Pradesh, India, in 2000 and again in 2002–2003 were found to be associated with the type 2 reference strain, MEF-1, found in contaminated lots of OPV [335, 336].

7 Pathogenesis and Immunity

7.1 Pathogenesis

Studies on the pathogenesis of poliomyelitis in humans date to the nineteenth century [1]. The availability of a primate model for pathogenesis in 1909 accelerated the pace of pathogenesis research up to the mid-1950s [1, 242, 243]. Interest in the pathogenesis of poliomyelitis waned with the availability of poliovirus vaccines and the increased focus on molecular virology, even though pathology studies continued to address key unanswered questions [337, 338]. Two major models of pathogenesis, one by Bodian [242] (Fig. 13.8) and the other by Sabin [243], were proposed in 1955 and 1956. The principal difference between the two models is whether the major primary sites of poliovirus replication are in lymphatic tissues (Bodian) or mucosal tissues (Sabin) [244]. According to Bodian's model, orally ingested poliovirus first replicates locally in lymphatic tissues at the sites of initial virus implantation (tonsils, intestinal microfold epithelial [M] cells of the Peyer's patches in the ileum). Within 1–2 days virus spreads via lymphatic pathways from the small intestine to the mesenteric lymph nodes and from the tonsils and adenoids to deep cervical lymph nodes.

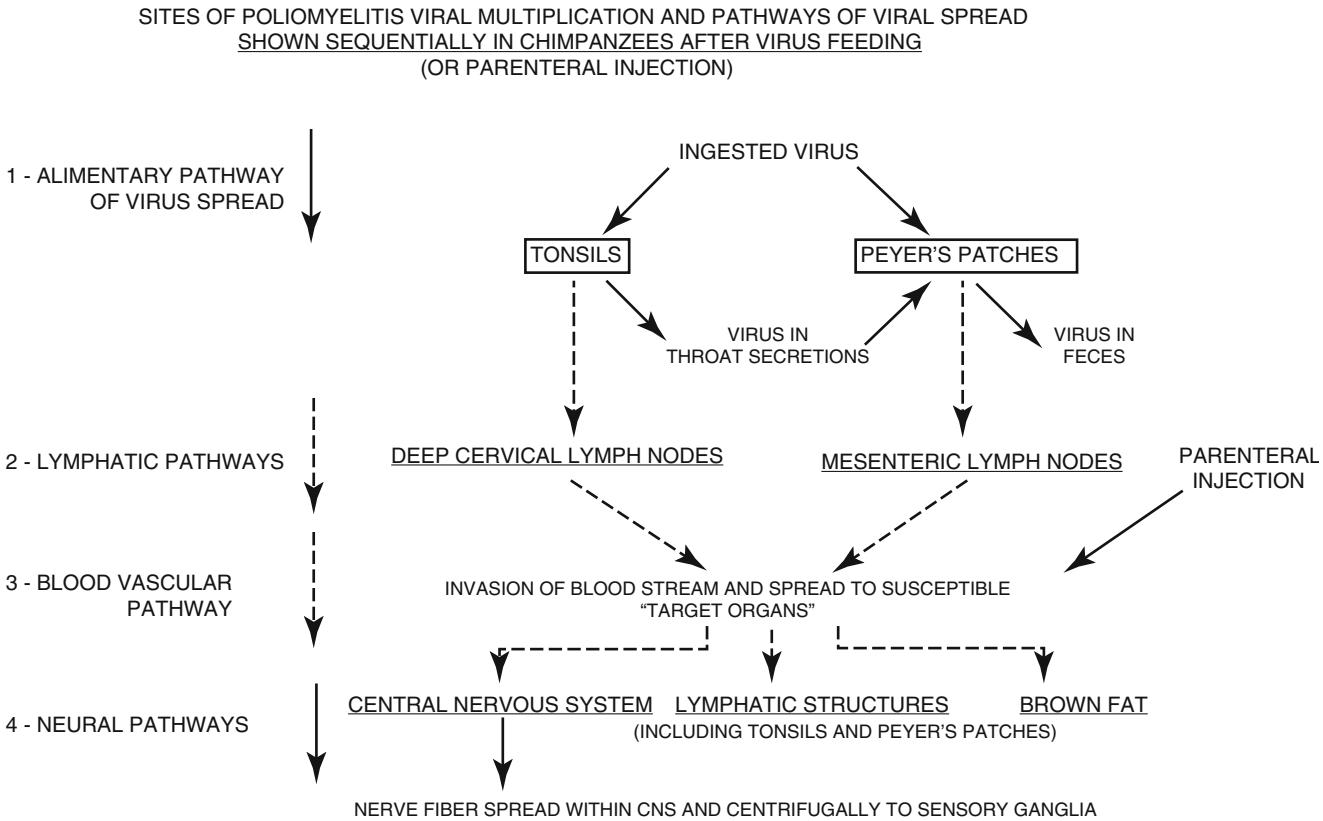

Fig. 13.8 David Bodian's scheme of the pathogenesis of poliovirus infection based on studies in monkeys, chimpanzees, and humans. Reproduced with permission from the original article by Bodian [241]. (Copyright 1955, American Association for the Advancement of Science (http://www.sciencemag.org).) *CNS* central nervous system

By days 1–3, virus appears in the feces and throat. In the next viremic phase, virus invades the bloodstream and infects other susceptible "target organs," including further spread to systemic lymph nodes, brown fat, and occasionally motor neurons of the CNS. The first 1–2 days of infection are asymptomatic. During viremia, all tissues are exposed to virus, and about 10 % of infected persons experience "minor illness" at days 3–4, with malaise and fever accompanying systemic viral infection. Clinical signs subside after day 4. Viremia ends with the appearance of antibody by day 6, and virus bound to antibody can be detected for a few days longer [320]. Incubation periods (time from exposure to disease onset) vary in different individuals, but they are usually from 7 to 17 days but range from 2 to 35 days [23]. Virus replicates in the oropharynx for 1–2 weeks and is shed in the stool for 3–6 weeks [23, 321].

Progression to "major illness," including nonparalytic poliomyelitis (aseptic meningitis) and paralytic poliomyelitis, occurs within 8–30 days of exposure [28]. The biphasic nature of the disease, with minor illness followed by major illness, has been termed the "Dromedary" form [322] to imply two humps (even though the dromedary is a one-humped camel) [1]. Invasion of the CNS may occur by either penetration of the blood–brain barrier or by retrograde axonal transport. Paralytic illness follows directly from the lytic infection of motor neurons, constituting the gray matter of the spinal cord. In fatal cases, virus replication in motor neurons rises sharply the day preceding paralysis, peaks to high titers at day 3, and disappears by day 7 [29]. In spinal poliomyelitis, motor neurons in the anterior horn of the spinal cord are rapidly destroyed, with the severity of paralysis correlated with the extent of neuronal destruction [29]. In bulbar poliomyelitis, motor neurons in the medulla in the brainstem are primarily affected. Lesions may also occur in the reticular formation in the brainstem and in the thalamus and hypothalamus just above the brainstem. Lesions in the brain occur in the roof nuclei of the cerebellum and in the precentral gyrus of the motor cortex [23, 29]. Other regions of the cortex are usually resistant to infection [264]. Some motor neurons may lose function because of edema, but the damage is temporary and motor function is restored once the inflammation subsides [23]. Local secretory IgA immunity can block poliovirus replication in tonsils and the intestinal tract, and neutralizing IgG and IgM antibodies can prevent virus spread to motor neurons of the CNS.

Poliovirus pathogenesis has enjoyed a renaissance [26, 232, 244, 323, 338] after cloning and identification of the PVR, CD155 [208], and the development of transgenic mice expressing CD155 [340–342]. The transgenic mice are susceptible to poliovirus infection upon intraspinal, intracerebral, intravenous, intranasal, intraperitoneal, or intramuscular inoculation and exhibit clinical signs and neural lesions typical of human poliomyelitis [232]. However, the transgenic mice are usually resistant to infection by the oral route [232, 340, 343]. It has been found in both humans and transgenic mice that CD155 RNA and protein are expressed in a wide variety of tissues, including tissues that do not support poliovirus replication [323]. Therefore, CD155 expression is necessary but not sufficient for poliovirus replication in vivo, and a stage in the replication cycle after initiation of translation determines tissue tropism [323]. One potential mechanism for the observed patterns of tissue tropism is that a barrier of innate immunity in extraneural tissues blocks poliovirus replication [232]. In support of this view, it was found that in PVR-transgenic mice deficient in the interferon-α/β receptor, poliovirus replication occurred not only in the CNS but also in extraneural tissues such as the liver, pancreas, and small intestine [343, 344].

The mechanism of axonal retrograde transport has been reexamined in transgenic mice [345]. At the molecular level, the cytoplasmic domain of CD155 was found to specifically bind to Tctex-1, a light chain of the dynein motor complex (a driver for retrograde transport), and that the rate of Tctex-1 transport is similar to the rate of poliovirus ascent along nerve fibers [232, 346].

New developments in the pathogenesis of poliomyelitis have been the subject of several recent reviews [26, 232, 244, 323, 338].

7.2 Immunity

Neutralizing antibody protects against paralytic disease [57]. Type-specific immunity from natural infection is lifelong [85], and immunity also appears to be permanent for individuals who have produced neutralizing antibodies after receipt of OPV or IPV. Infants are protected against disease during the first few months of life by maternal antibody, which has a half-life of approximately 28 days and falls to undetectable levels after 6 months [347]. In the endemic period, children <6 months of age rarely contracted paralytic disease, but could induce protective immunity when infected with wild poliovirus [28]. It has long been known that even low levels of circulating antibodies are protective [57], because virus titers during viremia are low [58].

Neutralizing IgM and IgG antibodies appear within a few days of exposure to virus. IgM titers decline after 10 days, but IgG titers continue to rise for at least 2 months [348]. Mucosal immunity in the gastrointestinal tract and oropharynx, in the form of secretory IgA, rises more slowly and persists for at least several months, but the duration of mucosal immunity to poliovirus has not been intensively studied [7, 349]. Children who have had tonsillectomy are more susceptible to poliomyelitis than children with intact oropharyngeal lymphoid tissue, a finding that points to the importance of oropharyngeal mucosal immunity in protection from disease [350–352]. OPV induces both serum antibody and intestinal immunity, whereas intestinal immunity from IPV is low (Sect. 9.1.5) [7, 348].

Additional evidence for the critical importance of neutralizing antibody to immunity is that individuals with primary

(B-cell) immunodeficiencies are at a 3,000-fold higher risk than immunocompetent individuals of contracting VAPP when exposed to OPV (Sect. 9.1.4) [353], and some may develop prolonged poliovirus infections [354]. Patients with primary immunodeficiencies are treated with intravenous immunoglobulin (IVIG), and preparations used in the United States must meet minimum neutralization titers to poliovirus [7]. However, IVIG neutralizing titers become undetectable after 3–5 weeks [23], and several immunodeficient individuals with chronic poliovirus infections have contracted poliomyelitis despite IVIG treatment, presumably after titers of neutralizing antibodies fell below protective levels (see Sect. 10.8.2) [186, 223]. Newly developed chimpanzee–human neutralizing monoclonal antibodies may hold promise for the availability of high-titer preparations for immunotherapy of immunodeficient patients with prolonged poliovirus infections [228].

8 Patterns of Host Response and Diagnosis

8.1 Clinical Features

The patterns of host response were described in Sect. 7.1 in the context of the pathogenesis of poliomyelitis. Paul recognized four categories of response to poliovirus infection in susceptible individuals: (1) inapparent (asymptomatic) infections, (2) abortive poliomyelitis, (3) nonparalytic poliomyelitis (aseptic meningitis), and (4) paralytic poliomyelitis [28]. Abortive poliomyelitis is described as minor illness, and nonparalytic and paralytic poliomyelitis constitute major illness. The proportion of each category of host response depends on the patient age, the poliovirus serotype, and other physiologic factors such as tonsillectomy, pregnancy, recent injections, trauma, or recent strenuous physical exertion [29].

8.1.1 Inapparent (Asymptomatic) Infections

Most (up to 95 %) wild poliovirus infections of nonimmune susceptible individuals are without fever or other symptoms. Infected individuals produce protective neutralizing antibodies and have permanent resistance to paralysis upon reinfection by the same poliovirus serotype. Infections that occur under the cover of maternal antibody are asymptomatic. Individuals with inapparent infections shed virus in their stool and can participate in the spread of infection.

8.1.2 Minor Illness: Abortive Poliomyelitis

Abortive poliomyelitis is the most frequent disease manifestation, occurring in about 8 % of poliovirus infections [23, 28]. Symptoms are indistinguishable from those of many other infections and include fever, malaise, drowsiness, headache, vomiting, and sore throat. Abortive poliomyelitis occurs during the viremic phase a few days after infection. Complete recovery occurs within a few days, although virus shedding may continue for up to 6 weeks postexposure.

8.1.3 Major Illness: Nonparalytic Poliomyelitis (Aseptic Meningitis)

Aseptic meningitis occurs in 1–2 % of infections. It may be preceded by minor illness and is characterized by signs of inflammation of the meninges, including severe headache, and stiffness and pain in the back and neck. Aseptic meningitis lasts 2–10 days and is usually followed by complete recovery. In rare instances, the disease progresses to paralytic poliomyelitis. Other viral infections, including those of many nonpolio enteroviruses (Chap. 11), may cause aseptic meningitis [23].

8.1.4 Major Illness: Paralytic Poliomyelitis

Paralytic poliomyelitis occurs in <1 % of wild poliovirus infections (Sect. 3.4) and is characterized by acute flaccid paralysis (AFP) usually accompanied by fever. It may be preceded by minor illness with apparent recovery followed a few days later by rapid onset of paralysis. Minor illness preceding paralysis may be absent in adolescents and adults, but pain in the affected extremities during onset of paralysis may be severe. Paralysis progresses rapidly and is descending (i.e., moving proximally to distally), with loss of deep reflexes but no sensory loss. Paralysis is usually asymmetric and affects the legs more frequently than the arms, especially in young children. Residual paralysis persists beyond 60 days. The affected muscles and severity of paralysis depends on the location and concentration of neuronal lesions [29]. Paralytic poliomyelitis is further divided into three categories based on the CNS lesions and the corresponding affected muscle groups.

Spinal Poliomyelitis

Spinal poliomyelitis (~79 % of paralytic poliomyelitis cases) occurs when lesions are localized to the spinal cord and cause weakness in the legs, arms, back, or abdominal muscles. Spinal poliomyelitis may also paralyze the diaphragm and intercostal muscles, causing respiratory failure.

Bulbar Poliomyelitis

Bulbar poliomyelitis (~2 % of paralytic poliomyelitis cases) occurs when lesions form in the cranial nerve or medulla and results in paralysis of the pharynx, vocal cords, and facial nerves. Bulbar poliomyelitis may rapidly progress to respiratory failure when the respiratory centers of the medulla are attacked.

Bulbospinal Poliomyelitis

Bulbospinal poliomyelitis (~19 % of paralytic poliomyelitis cases) is a combination of the above two forms and is most frequently seen in adults [29].

8.1.5 Post-Polio Syndrome

Post-polio syndrome is a recrudescence of weakness, pain, fatigue, and atrophy in the muscles originally affected by acute paralytic poliomyelitis [355]. Symptoms progress over a period of years and first appear on average 30–35 years after recovery from the initial acute attack [356]. It is estimated that

25–50 % of patients with acute paralytic poliomyelitis will develop some signs of post-polio syndrome, the risk being highest among survivors with more severe paralysis from the original attack. In the United States, over 440,000 survivors of paralytic poliomyelitis were recognized in 1994–1995, but no updated counts have been obtained. Post-polio syndrome is a neurologic condition whose underlying mechanisms are unknown. Current evidence indicates that the syndrome results from the denervation of the peripheral neuromuscular junctions that expanded during recovery to compensate for neuronal damage from the original infection [355]. It is thought that the neurologic dysfunction progresses subclinically for many years until a critical threshold is reached beyond which the remaining motor neurons cannot maintain the extended number of neuromuscular junctions [355]. Post-polio syndrome does not appear to result from persistence of the original poliovirus infection [357]. Polio eradication is the most effective way to prevent post-polio syndrome.

8.2 Diagnosis

Most clinicians trained since the late 1960s in the United States and other developed countries have never seen a case of poliomyelitis. Similarly, clinicians in most developing countries no longer see poliomyelitis, apart from rare sporadic cases of VAPP (Sect. 9.1.4). Nonetheless, the risk of importation of wild poliovirus (or cVDPVs; Sect. 10.8.1) and the potential for outbreaks remain as long as poliovirus circulation continues anywhere in the world [10, 12, 80–82, 132, 175–178, 181]. Diagnosis of paralytic poliomyelitis is primarily based on three criteria: (1) clinical signs and course, (2) virologic testing, and (3) residual neurologic deficit at 60 days after onset of paralysis [7].

8.2.1 Clinical Signs and Course

The most obvious sign of poliomyelitis is the appearance of AFP. However, AFP has multiple etiologies, including Guillain–Barré syndrome, transverse myelitis, enterovirus infections (especially EV71; Chap. 11), other viral infections, traumatic neuritis, Bell's palsy, hypokalemia, and toxin exposure [7]. Studies in the Americas comparing clinical findings with the isolation of wild poliovirus from stool specimens reported a sensitivity of 75 % and specificity of 73 % for poliomyelitis when the diagnostic criteria for AFP cases were age <6 years and fever at onset of paralysis [68]. Inclusion of progression to complete paralysis in <4 days increased sensitivity [68], whereas inclusion of specific patterns of paralysis (descending, asymmetric, absence of paralysis in all limbs) increased specificity but reduced sensitivity [7]. In India, which achieved AFP rates >25 per 100,000 children <15 years of age, residual paralysis at 60 days was most strongly correlated with wild poliovirus infection [358].

8.2.2 Virologic Testing

Virologic testing has high sensitivity provided that adequate specimens are collected soon after onset of paralysis and received by the laboratory in good condition (section "Clinical specimens"). Because wild polioviruses can be accurately identified by molecular methods, and contaminants ruled out by sequence analysis, specificities approach 100 %. Classification of cases of VAPP requires the inclusion of clinical, epidemiologic, and laboratory findings [303, 304, 307, 359]. In countries using OPV, most isolations of OPV-like virus from patients with AFP are independent events and do not signal the occurrence of VAPP. Laboratory detection of genetically divergent vaccine-derived polioviruses (VDPVs; Sect. 10.8) indicate either prolonged replication in an immunodeficient individual or community circulation of VDPVs [133]. The distinguishing genetic properties of the more divergent VDPVs, coupled with information about the rates of poliovirus vaccine coverage in the source community, are strong predictors of the VDPV category [133].

8.2.3 Residual Neurologic Deficit

The clinical case definition for paralytic poliomyelitis includes residual paralysis at 60 days after onset of paralysis [100, 133]. In less severe cases of paralytic poliomyelitis, residual paralysis may be difficult to discern because of functional compensation by intact muscles [7].

9 Control and Prevention of Poliomyelitis

9.1 Poliovirus Vaccines

Attempts to inactivate poliovirus infectivity through formalin treatment date to 1911, but when the results from leading investigators were consistently disappointing, interest in immunization against poliomyelitis waned [1]. Interest was briefly rekindled during the field trials of 1935, conducted by two groups who took different approaches to experimental poliovirus vaccines, one applying formalin inactivation [360] and the other using live virus that was claimed to be "attenuated" through treatment with detergent [361]. However, the appearance of poliomyelitis cases—including fatalities—linked to the field trials [362] cast a long shadow on further attempts to develop a poliovirus vaccine. The experimental poliovirus vaccines of 1935 were developed before the advent of cell culture, before the identification of three distinct poliovirus serotypes, before the outlines of poliovirus pathogenesis were firmly established, and, in the case of one investigator, a failure to distinguish between chemical inactivation and attenuation of neurovirulence through genetic selection [361]. Prospects for a poliovirus vaccine again brightened in 1948 with the successful immunization of

monkeys with formalin-inactivated poliovirus [363]. Moreover, the rising incidence of paralytic polio in developed countries in the postwar years greatly increased the urgency of developing and deploying effective poliovirus vaccines.

9.1.1 Inactivated Poliovirus Vaccine (IPV)

The IPV of Salk and colleagues was the first poliovirus vaccine to be licensed [4, 5]. Its development followed several key advances in virology, pathology, and immunology [5]: (1) the cultivation of poliovirus in nonneural cells [53], (2) the identification of three poliovirus serotypes [54, 55], (3) the finding that viremia precedes paralysis [58], and (4) the demonstration that administration of immune globulin protected against paralytic poliomyelitis [57]. IPV is prepared by formalin inactivation of three wild, virulent reference strains: Mahoney (type 1), MEF-1 (type 2), and Saukett (type 3). A less virulent type 1 strain, Brunenders [364], is used in IPV production in Sweden and Denmark. Although antigenic sites 1 (Fig. 13.5) of types 2 and 3 are modified by formalin inactivation [365], immunization with IPV can induce high titers of neutralizing antibodies protective against all poliovirus strains. After exposure of some IPV recipients with live wild poliovirus contained in production lots of incompletely inactivated vaccine (the Cutter incident) [333, 334], conditions for IPV manufacture were modified, resulting in a reduction in the immunogenicity of IPV preparations [23]. However, improvements in cell culture technology in the 1970s led to development of an enhanced-potency IPV (eIPV), similar in immunogenicity to the original product [5, 35, 366], which has replaced the second-generation IPV.

IPV was licensed for use in the United States, Canada, and Western Europe in 1955 and was the only poliovirus vaccine available until licensure of OPV in 1961–1962. IPV use in the United States declined after the introduction of OPV, but it has been used continuously by some countries in Western Europe (Finland, Iceland, Sweden, and the Netherlands) and some provinces of Canada [5, 35]. In 1997, in response to the eradication of wild polioviruses in the Americas and the continuing occurrence of cases of VAPP (Sect. 9.1.4), the United States shifted from an all-OPV immunization schedule to a sequential IPV/OPV schedule in 1997, which was replaced in 2000 by an all-IPV schedule [5, 307].

9.1.2 Oral Poliovirus Vaccine (OPV)

Early attempts to produce live-virus vaccines date to the work of Jenner, who "vaccinated" with cowpox virus to protect against smallpox in the 1790s, and Pasteur, who developed an "attenuated" rabies vaccine in the 1880s [35]. Experimental live poliovirus vaccines were tested in monkeys as early as 1910 [29]. In the 1930s, Theiler demonstrated that an effective attenuated yellow fever vaccine could be produced by serial passage of virus in chick embryo tissues [367]. Theiler applied this basic approach to develop an experimental attenuated variant of the poliovirus type 2 Lansing strain in 1946 [368]. In 1952, Enders, Weller, and Robbins developed the attenuated poliovirus type 1 Brunenders strain by serial passage in cultured cells [364]. Two years later, Li and Schaeffer developed a highly attenuated derivative of the neurovirulent type 1 Mahoney strain, LS-c, by passage at 35 °C in cultured rhesus or cynomolgus monkey kidney cells and in monkey skin [369]. The LS-c strain was further treated by three consecutive single-plaque passages by Albert Sabin to produce the LS-c, 2ab strain, generally known as Sabin type 1 (Sabin 1) [370]. Sabin also developed attenuated strains for serotypes 2 and 3. The Sabin 2 OPV strain (P712, Ch, 2ab) was derived from virus (P712) that was isolated from a healthy child and shown to have low neurovirulence [370]. In contrast, the attenuated Sabin 3 strain (Leon 12 a_1b) was produced by rapid passage in monkey kidney cell culture of a highly neurovirulent strain isolated from the spinal cord of a child who had died of bulbospinal poliomyelitis [370]. In addition to Sabin, two other groups, led by Koprowski [329] and Cox [371], developed attenuated poliovirus vaccine strains for each serotype. All three sets were carefully evaluated for low neuropathogenicity for monkeys, immunogenicity, genetic stability on human passage, safety (inability to cause paralysis in man), and restricted capacity to spread [372, 373]. The Sabin strains, which had the lowest neuropathogenicity and an excellent safety record from large-scale field trials [6, 60], were approved for worldwide distribution. In the United States, OPV was licensed sequentially (Sabin 1, August, 1961; Sabin 2, October, 1961; Sabin 3, March, 1962). Licensure of Sabin 3 was delayed because of concerns about its undesirable genetic instability and relatively low immunogenicity [1]. OPV was initially administered serially in monovalent form, frequently in mass immunization campaigns (SOS; "Sabin on Sunday"), but successful tOPV field trials in Canada led to licensure of a trivalent formulation in 1963 [7]. OPV and its application to poliomyelitis eradication has been recently reviewed [7].

OPV was developed in the 1950s using the well-established empirical approach of rapid passage of virus at suboptimal temperatures in cells and tissues of nonhuman origin. It would be another two decades after licensure of OPV that the molecular basis of OPV attenuation became amenable to systematic investigation.

9.1.3 Genetic Determinants of Attenuation of the Sabin OPV Strains

Identification of the genetic determinants of attenuation of the Sabin OPV strains has been comprehensively reviewed [207, 209, 268, 374]. The first reports of the sequences of complete poliovirus genomes in the early 1980s [375, 376] and the development of infectious poliovirus cDNA clones

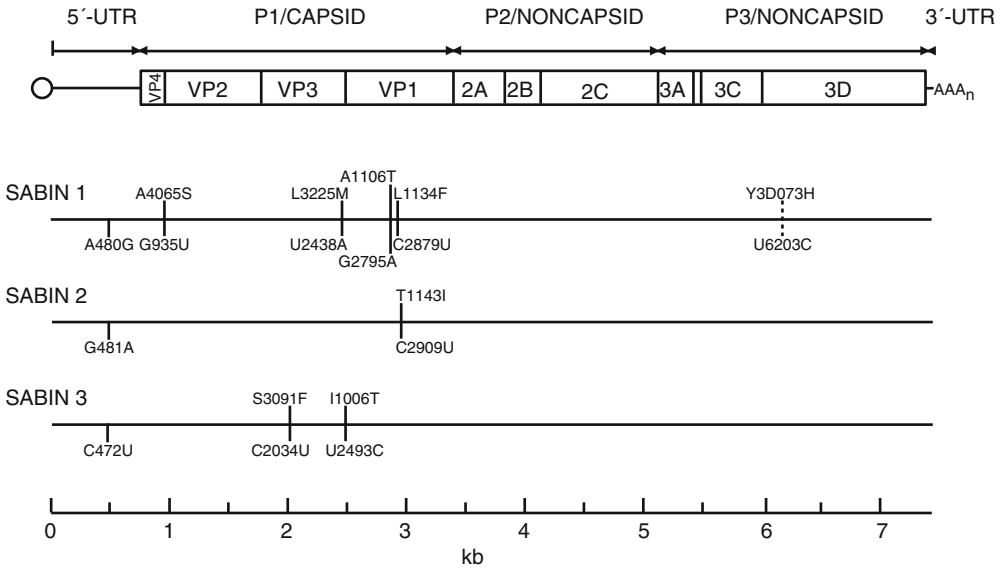

Fig. 13.9 Location of principal attenuating nucleotide (*lower bars*) and amino acid (*upper bars*) substitutions in each of the three Sabin OPV strains. Abbreviations of nucleotide residues: *A* adenine, *C* cytosine, *G* guanine, *U* uracil. Abbreviations of amino acid residues: *A* alanine, *C* cysteine, *F* phenylalanine, *H* histidine, *I* isoleucine, *L* leucine, *M* methionine, *S* serine, *T* threonine, *Y* tyrosine. Substitutions are shown as nonattenuated parent–position–Sabin strain; nucleotide positions are numbered consecutively from residue 1 of the RNA genome; amino acid positions are indicated by the abbreviated name of the viral protein (4, VP4; 2, VP2; 3, VP3; 1, VP1; 3D, 3D-polymerase) and numbered consecutively from residue 1 of each protein. For example, a guanine (Mahoney) → uracil (Sabin 1) substitution at RNA position 935 (G935U) encodes an alanine (Mahoney) → serine (Sabin 1) replacement at residue 65 of VP4 (A4065S). The Y3D073H substitution in Sabin 1 and S3091F substitution in Sabin 3 are important determinants of temperature sensitivity (Figure summarizes findings from references [379–384] (Redrawn from reference Kew et al. [94])

[377] opened the way for systematic investigation of the critical mutations responsible for the attenuated and temperature-sensitive phenotypes of the Sabin OPV strains. A common feature of the Sabin strains is the presence of nucleotide substitutions in the IRES, which in serotypes 1 and 3 have been clearly shown to be critical attenuating mutations. Additional mutations encoding amino acid substitutions in the capsid region contribute to and stabilize the attenuated phenotype.

Sabin 1

The 57 nucleotide substitutions distinguishing the Sabin 1 strain from its neurovirulent parent, Mahoney, are scattered throughout the genome [144]. Six map to the 5′-UTR, 49 map to the coding region (21 of which encode amino acid substitutions), and 2 map to the 3′-UTR. Infectious cDNA constructs containing different combinations of blocks of Sabin 1 and Mahoney sequences were tested for neurovirulence in monkeys or transgenic mice expressing the CD155 receptor, for temperature sensitivity, and for other phenotypic properties distinguishing the two strains [378, 379]. The single most important determinant of the attenuated phenotype of Sabin 1 was the A → G substitution at position 480 (abbreviated A480G) in the IRES [380]. Four other substitutions contributing to the attenuated phenotype mapped to the capsid region (one in VP4, one in VP3, and two in VP1), and a substitution contributing to the temperature-sensitive phenotype (but not to the attenuated phenotype) mapped to the $3D^{pol}$ region encoding the RdRP (Fig. 13.9) [7, 378, 379, 385].

Sabin 2

Only two nucleotide substitutions (G481A in the IRES and C2909U encoding a threonine → isoleucine substitution at position 143 of VP1) appear to be main determinants of the attenuated phenotype of Sabin 2 (Fig. 13.9) [381, 382]. Because P712 has inherently low neurovirulence [370], identification of critical attenuating sites in Sabin 2 involved determination of the effects of introduction of sequences derived from a minimally divergent neurovirulent revertant of Sabin 2 (obtained from a case of VAPP) into infectious cDNA constructs derived from Sabin 2 [381, 382]. The neurovirulence of Sabin 2 is remarkably stable in routine tests of OPV lots in monkeys, because the G481A substitution (not found in the IRES sequences of wild type 2 polioviruses) does not increase neurovirulence in monkeys, as it does in transgenic mice [386].

Sabin 3

Detailed analysis of the attenuated phenotype of Sabin 3 has been possible because the neurovirulent parental strain, Leon, differs from Sabin 3 by only ten nucleotide substitutions

[387]. In addition, numerous neurovirulent revertants of the Sabin 3 strain have been isolated from patients with VAPP [383] and from healthy OPV recipients [388]. Only three substitutions (C472U in the IRES, C2034U encoding a serine → phenylalanine substitution at position 91 of VP3, and U2493C encoding an isoleucine → threonine substitution at position 6 of VP1) appear to be the main determinants of the attenuated phenotype (Fig. 13.9) [207, 383, 388].

In all three Sabin strains, the attenuated phenotype is determined by multiple substitutions. The substitutions in the IRES, which alter stem-loop structures [207, 389–391] and reduce the efficiency of initiation of translation of the poliovirus RNA template [390, 392], contribute most to the attenuated phenotype of the Sabin 1 and Sabin 3 strains. Mutations restoring the original stem-loop structure in the IRES (Sabin 1, G480A [back mutation] or U525C [suppressor]; Sabin 2, A481G; Sabin 3, U472C) are frequently found in vaccine-related isolates from healthy OPV recipients [389, 393] and patients with VAPP [207] as well as from the environment [109]. In Sabin 3, the critical C472U substitution reduces the efficiency of binding of the polypyrimidine tract-binding protein (PTB), required for initiation of translation, to the IRES [394]. The translational deficit for Sabin 3 is moderate in intestinal cells, where PTB levels are high, but severe in neurons, where PTB levels are low. The precise mechanisms by which the capsid mutations contribute to the attenuated phenotype are less clear. Impairment of the efficiency of binding to the CD155 receptor [379] and reductions in the stability of the capsid [215] may play a role.

Sabin and other developers of OPV strains struck a balance between low neuropathogenicity, good immunogenicity, and acceptable levels of genetic stability [373]. The high genetic stability of the Sabin type 1 strain is probably attributable to the greater number of substitutions contributing to the attenuated phenotype. This property is especially important for the Sabin 1 vaccine strain, because wild type 1 polioviruses typically have high paralytic attack rates and can spread over wide geographic areas in explosive outbreaks [10, 170, 175–177, 180, 181]. Sabin 2 may revert more rapidly, but its immunogenicity is very high [7, 373] and the paralytic attack rates of wild type 2 polioviruses are low (Sect. 3.4) [34, 101]. Sabin 3 is associated with the highest rates of VAPP (Sect. 9.1.4), which is probably a consequence of low genetic stability of the critical attenuating substitution [275], relatively low immunogenicity [395], and an intermediate paralytic attack rate for type 3 polioviruses [34, 101]. Nonetheless, all three Sabin strains normally have very low pathogenic potentials, and incidence of VAPP in countries with high rates of OPV coverage [304] are several orders of magnitude lower than the incidence of paralytic poliomyelitis in areas with circulating wild polioviruses.

9.1.4 Vaccine-Associated Paralytic Poliomyelitis (VAPP)

After over 40 years of use and many billions of doses distributed worldwide, OPV has been associated with few adverse events. The most commonly recognized adverse event is VAPP, which is clinically indistinguishable from poliomyelitis caused by wild polioviruses. The first cases of VAPP were recognized within a year of licensure of OPV, and most of the early cases were associated with the Sabin 3 strain [396]. The Sabin 3 association was unambiguous because OPV had been delivered in monovalent form [7, 301, 396]. VAPP rates are very low and similar worldwide [7, 359, 397–400]. In the United States, the risk of VAPP in first-dose OPV recipients is about 1 case per 1.4 million children immunized [7, 301, 303, 304, 307, 401]. In immunologically normal recipients, the risk of VAPP decreases sharply (>tenfold) for subsequent doses. VAPP cases are sporadic and occur in both OPV recipients and their unimmunized household and non-household contacts. A small proportion (~7 %) of VAPP cases in the United States are classified as "community-acquired," indicating no known exposure to OPV. VAPP in OPV recipients and household contacts is most frequently associated with Sabin 3 (71 % of cases), followed by Sabin 2 (26 % of cases) [304]. VAPP in non-household contacts and in community-acquired cases is most frequently associated with Sabin 2 (50 % of cases), followed by Sabin 3 (33 % of cases) [304]. Sabin 1 is rarely associated with VAPP in immunocompetent individuals when administered in tOPV [303, 304, 398].

Poliovirus isolates from immunocompetent VAPP case-patients show only limited genetic divergence from the parental OPV strains, although the key substitutions conferring the attenuated phenotype have frequently reverted [393, 402]. Many isolates from VAPP cases, AFP cases with incidental isolation of vaccine-related virus (much more frequent than VAPP cases), and healthy OPV recipients are vaccine/vaccine recombinants [161, 279, 403, 404]. The biological and genetic properties of viruses isolated from healthy OPV recipients/contacts are often indistinguishable from viruses isolated from patients with VAPP [393, 405].

Persons with primary B-cell immunodeficiencies (Sect. 10.8.3) [406] should not be given OPV because they are at a much higher (~3,000-fold) risk for VAPP [353, 354]. However, some children have received OPV before their immunodeficiency was recognized. Immunodeficiency-associated VAPP (iVAPP) differs markedly from VAPP in immunocompetent individuals, as it is rarely associated with Sabin 3 (14 % of cases), and is more frequently associated with Sabin 2 (72 % of cases) and Sabin 1 (31 % of cases) (some patients were infected with more than one serotype) [354]. On the other hand, persons with T-cell immunodeficiencies, including those infected with HIV, do not appear to be at elevated risk for VAPP [304, 353, 354, 407].

Each case of VAPP is an independent event. It is estimated that 250–500 cases of VAPP occur worldwide, most in countries free of circulating wild poliovirus (Fig. 13.2a) [7]. VAPP is a direct clinical consequence of the genetic instability of the Sabin OPV strains, and the most effective means to prevent VAPP is to stop OPV use after cessation of wild poliovirus circulation [22, 307].

9.1.5 Sequential Use of IPV and OPV

The relative merits of IPV and OPV have been compared for many years [23, 408]. Key advantages of IPV are (1) it efficiently induces serum immunity protective against paralytic disease, (2) it is unaffected by interference by other enteroviruses or among vaccine components, (3) it can be used in combination with other injectable vaccines, and (4) it presents no risk for reversion to virulence. The main disadvantages to IPV are (1) it provides much reduced levels of intestinal immunity; (2) until recently, most preparations had been produced from virulent wild poliovirus strains; and (3) its costs of production and delivery are higher than OPV [24, 409]. Key advantages of OPV are (1) it is easily administered, (2) it confers both serum immunity and intestinal immunity (the latter important to limiting poliovirus transmission), (3) it can be easily used in mass campaigns in developing country settings, (4) it is suitable for use in outbreak control, and (5) it has low costs of production and delivery. Disadvantages to OPV include (1) it presents a continuous, low-level risk of VAPP, (2) it may have low per-dose efficacy rates of seroconversion in some high-risk settings, (3) it is subject to interference by other enteroviruses and among OPV strains (especially by the type 2 strain), (4) it has the potential to establish chronic infections in persons with primary immunodeficiencies, and (5) it has the potential to spread person-to-person and cause poliomyelitis outbreaks when used at low rates of coverage [23, 94, 133, 408, 410]. A sequential IPV/OPV immunization schedule can combine the major advantages of each vaccine and mitigate some disadvantages. A sequential schedule can virtually eliminate VAPP in OPV recipients and reduce it in OPV contacts, because shedding of OPV-related viruses is reduced. This was observed in the United States when it shifted to a sequential IPV/OPV schedule between 1997 and 2000, as no cases of VAPP were observed in persons using the sequential IPV/OPV schedule (Fig. 13.7) [307]. Mucosal immunity induced by an IPV/OPV schedule is much better than with IPV alone [411]. However, global implementation of any schedule using IPV will require much higher rates of routine immunization coverage than currently exist (Sect. 11.2.1) [22, 412].

9.2 Impact of Immunization

As described in Sect. 5.6.2, the high-income countries of North America, Western Europe, and the southwest Pacific were quick to adopt widespread immunization with IPV, with dramatic impact. In the United States, for example, the incidence of paralytic polio fell from 13,850 in 1955 to 829 in 1961 [308]. Although transition to OPV in the United States was not complete until the mid-1960s, the last peak year (>100 cases) for polio was 1966 (Fig. 13.7), and all domestic reservoirs for poliovirus circulation apparently had been eliminated after 1970 [163, 413]. Similar highly favorable results were achieved in other developed countries [8, 9, 309, 414, 415]. IPV was not widely used in developing countries (and some developed countries, such as Japan [309]), partly because of cost and also because of the challenges of administering an injectable vaccine to large populations. Thus, the possibility of widespread immunization against polio had to await the availability of OPV, where its key advantages were decisive. The synchronous induction of intestinal immunity through mass OPV campaigns efficiently blocks person-to-person transmission of wild poliovirus, thereby protecting both individual vaccine recipients and the wider community. Despite its advantages, OPV coverage in most developing countries of Asia, Africa, and the Americas remained low, and by 1970 a widening divide separated high-income countries where wild poliovirus circulation had stopped from most low-income countries where wild poliovirus circulation continued unabated [8, 9]. By 1985, poliomyelitis had all but disappeared in developed countries, while poliomyelitis crippled a child on average every 90 s in developing countries (Figs. 13.2 and 13.3).

10 The Global Polio Eradication Initiative (GPEI)

10.1 Prelude to the GPEI

A compelling case for global poliomyelitis eradication has been advanced for decades [294] and receives continued support from the perspectives of social equity [17, 416], economic benefit [417], and technical feasibility [12, 418]. However, the launch of a vertical program to eradicate poliomyelitis was controversial in the early 1980s [30] and remained so nearly two decades later [419]. Several key factors described below set the stage for the 1988 WHA resolution establishing the GPEI [30].

10.1.1 Poliomyelitis Eradication in Cuba, 1962

Sabin advocated mass OPV campaigns as the most effective means of polio control [294]. Cuba adopted his approach in 1962 and within a year had stopped all wild poliovirus circulation [295, 310], becoming the first country to eradicate poliomyelitis. The experience in Cuba conclusively demonstrated that mass campaigns were effective in a tropical developing country setting.

10.1.2 Smallpox Eradication, 1977

Smallpox was the first infectious disease to be eradicated. Global smallpox eradication was launched in 1966 following a WHA resolution to eradicate the disease by 1976. The last natural case of smallpox was reported in Somalia in 1977,

and global eradication was certified in 1980 [284]. In addition to the complete disappearance of a universally feared viral disease, the successful smallpox program accrued many other public health benefits. The program forged strong international cooperation in public health, trained a generation of international public health professionals who would lead the way to polio eradication, and set an irreversible precedent that infectious diseases could be controlled on a global scale [30]. In light of the smallpox eradication initiative, the Expanded Program on Immunization (EPI) was established by the WHO in 1974 to make immunization against six diseases (diphtheria, pertussis, tetanus, poliomyelitis, measles, and tuberculosis) available to every child in the world by 1990 [420]. The core EPI strategy was high routine immunization coverage, which was to prove insufficient to control poliomyelitis in some developing country settings.

10.1.3 National Immunization Days (NIDs) in Brazil, 1980

Brazil began routine immunization with OPV in the early 1960s [296]. The impact of immunization was initially unclear because poliomyelitis was not a notifiable disease until 1968. Although mass campaigns in 1971–1973 reduced poliomyelitis cases, they were replaced by routine immunization in 1974. Cases sharply increased until 1980, when Brazil reestablished mass campaigns in the form of biannual NIDs, targeting all children <5 years of age (regardless of prior immunizations) for immunization with OPV in a single day. Poliovirus circulation dropped sharply in Brazil after implementation of NIDs and set Brazil on the path to polio eradication [18, 296].

10.1.4 The PAHO Regional Polio Eradication Initiative, 1985

The dramatic success of mass campaigns in Cuba, Brazil, and Mexico led PAHO to resolve in 1985 to eradicate polio from the Americas by 1990 [14]. PAHO modeled their regional initiative on Brazil's successful strategy of NIDs and used poliomyelitis eradication as the vanguard of efforts to revitalize childhood immunization in the Americas. The PAHO approach of coordinated NIDs to supplement improved rates of routine OPV coverage eradicated indigenous wild polioviruses within 6 years [18]. PAHO set the standard for global efforts and built an infrastructure for the subsequent elimination of indigenous measles and rubella viruses from the Americas [421–423].

10.1.5 Rotary PolioPlus, 1985

Rotary International launched their global PolioPlus campaign in 1985, with the goal of helping eradicate poliomyelitis worldwide by 2005, the centennial of Rotary's founding. In their initial drives for support of PolioPlus, Rotarians more than doubled their target goal of $120 million for OPV and have raised more than $1.2 billion since 1985. Rotarians have been active in all phases of polio eradication, including active participation in mass campaigns, training of health workers, communications, regular engagement of national leaders, infrastructure development, support for surveillance and the GPLN, and support for research (http://www.endpolio.org/) [17, 30, 424].

10.2 The 1988 WHA Declaration to Eradicate Polio Worldwide

In view of the rapid progress attained in the Americas, the WHA resolved in 1988 to eradicate polio worldwide by the year 2000 [15], launching the WHO GPEI. At the time of the World Health Assembly resolution, wild polioviruses were circulating unabated in much of the developing world (Figs. 13.2 and 13.3). The Western Pacific Region set a goal of eradication of indigenous wild polioviruses by 1995, a goal reached in 1997 and certified in 2000 [425]. China, after years of outbreaks [426], adopted the strategy of NIDs and Subnational Immunization Days (SNIDs) which, when coupled with strengthened routine immunization, stopped wild poliovirus transmission by early 1994 [297, 427]. Other developing countries soon followed.

10.3 Biological Principles of Poliovirus Eradication

The key biological requirements for poliovirus eradication are the following: (1) the absence of a persistent carrier state, (2) virus is spread by person-to-person transmission, (3) immunization interrupts virus transmission, (4) the absence of any nonhuman reservoir hosts for the virus, and (5) finite virus survival time in the environment [230]. An additional important nonbiological requirement for any disease eradication effort is political will, arising from the perceived benefits of eradication, and expressed internationally through resolutions passed by the WHA. Essential to the success of the GPEI has been the strong alliance among the four "spearheading" partners, WHO (http://www.polioeradication.org/), UNICEF (http://www.unicef.org/health/index.html), Rotary International (http://www.endpolio.org/), and the United States Centers for Disease Control and Prevention (CDC) (http://www.cdc.gov/polio/), as well as strong support from national governments and new partners, including the Gates Foundation (http://www.gatesfoundation.org/What-We-Do/Global-Development/Polio) and the UN Foundation (http://www.unfoundation.org/news-and-media/press-releases/2013/fight-against-polio.html).

10.4 Basic Strategy for Global Polio Eradication

The four pillars of the GPEI strategy are (1) high routine immunization coverage of infants with OPV, (2) supplementary OPV immunization activities in the form of NIDs and

SNIDs, (3) targeted door-to-door "mop-up" OPV immunization in areas of focal transmission, and (4) sensitive surveillance for poliovirus [102]. Very high rates of routine OPV immunization are required to block poliovirus circulation in areas where the risk factors converge, conditions under which routine OPV coverage rates exceeding 90 % may be insufficient to block poliovirus circulation [7, 180, 296, 428]. Such rates are currently unattainable through routine immunization in the least developed countries. Supplementary immunization is the mainstay of polio eradication in developing countries and has been instrumental in raising population immunity rates above the thresholds required to block poliovirus transmission [429]. Supplementary immunization strategies are driven by poliovirus surveillance, which is used to guide the intensified SNIDs and mop-up campaigns to the reservoir communities where the chains of poliovirus transmission continue to survive and propagate.

10.4.1 AFP and Poliovirus Surveillance

Surveillance for circulating polioviruses has two arms: (1) AFP case investigations and (2) virologic studies of polioviruses obtained from clinical specimens or the environment. Even though most wild poliovirus infections are inapparent, over time, all effectively performing AFP surveillance systems can detect endemic poliovirus circulation. In suspected high-risk areas lacking effective AFP surveillance, supplementary surveillance activities, such as sampling community contacts of AFP cases, stool surveys of healthy children, or environmental sampling, have been implemented to increase sensitivity for detecting wild polioviruses [104, 106, 107, 111, 113, 116, 315].

10.5 Increasing Momentum Toward Eradication, 1988–2001

The global incidence of poliomyelitis was on a virtually unbroken downward trend between 1987 and 2001 (Figs. 13.2 and 13.3). Three WHO regions reported their last indigenous cases before 2000: the Americas (last indigenous case: Peru, 1991) [430], the Western Pacific Region (last indigenous case: Cambodia, 1997) [425], and the European Region (last indigenous case: Turkey, 1998) (Fig. 13.3) [431]. Wild poliovirus type 2 was last detected in October 1999 in Uttar Pradesh, India [13]. By 2001, the tide of global polio eradication, although delayed in some places, seemed unstoppable [432].

10.5.1 Polio Eradication in Conflict Countries

The sense of momentum was reinforced by control of poliomyelitis in countries with armed conflict such as Colombia, Peru, the Philippines, Sri Lanka, Cambodia, Angola, the Democratic Republic of the Congo, and Somalia [433, 434]. In many countries, conflict was suspended during "Days of Tranquility" allowing children to be immunized during NIDs and SNIDs. For example, Colombia and Peru were reservoirs for all three wild poliovirus serotypes in the early 1980s. Active cross-border migration of high-risk populations among the northern Andean countries facilitated wide dissemination of wild poliovirus [164, 170] and required close synchronization of NIDs among the affected countries [18]. A guerilla movement in the interior of Peru targeting health clinics and health personnel required active engagement by public health leaders to ensure access to unimmunized children. The final chains of wild poliovirus transmission in the Americas were broken in the interior of Peru in 1991 [18]. In Sri Lanka, major military campaigns in a devastating civil war were suspended during the NIDs, and wild poliovirus circulation stopped after 1993. In the 1990s, Vietnam and Cambodia were still recovering from decades of conflict. Detailed aerial mapping of the migratory at-risk populations in the water courses linking Cambodia and Vietnam (with active cross-border poliovirus transmission) set the stage for house-to-house and boat-to-boat immunization campaigns that stopped wild poliovirus transmission in 1997 [290, 435]. The Democratic Republic of the Congo and Angola have experienced shattering civil conflicts over the past two decades. Nonetheless, both countries eradicated their indigenous wild polioviruses in 2000 and 2002, respectively [11]. Both countries appear to have eradicated polio twice, the second time was a widely disseminated wild type 1 poliovirus imported from India around 2002 [177]. Similarly, Somalia eradicated the indigenous wild polioviruses in 2002 [436], and again eradicated wild poliovirus type 1 imported from Nigeria in 2005 [177, 437].

10.5.2 Polio Eradication in Very High-Risk Settings

Successful control of poliomyelitis in settings of intrinsically high biological risk demonstrated the feasibility of global polio eradication. However, conditions varied widely, and creative local solutions repeatedly had to be found and implemented [434]. The critical test case for the PAHO polio eradication initiative was Brazil, the most populous country in Latin America. Control of wild poliovirus transmission was more difficult in the tropical northeast (with its lower levels of hygiene and sanitation), and migration from the endemic northeast to the rapidly growing megacities of Rio de Janeiro and São Paulo presented the continuous risk of reinfection with wild polioviruses. Nonetheless, steady pressure from NIDs, SNIDs, and mop-up campaigns stopped all wild poliovirus transmission by early 1989 [75]. Success in the Americas did not necessarily presage success elsewhere because the Americas were often seen as having several key advantages: (1) greater resources and infrastructure than many developing countries elsewhere, (2) a tradition of strong public health leadership in many countries, (3) geographic isolation protective against re-importation of wild polioviruses, and (4) a cultural unity conducive to a common approach.

China, comprising 22 % of the world population, presented challenges of scale not encountered in the Americas [426]. Climate varied widely from the temperate north to the tropical south, and levels of infrastructure and sanitation also varied widely in this rapidly developing country. Population size and density across wide areas favored efficient wild poliovirus transmission, and massive economic migration from the countryside into the increasingly prosperous cities presented additional challenges of reaching unimmunized children. However, China had already established good coverage through routine immunization with tOPV, and a series NIDs and SNIDs in 1992–1993 broke the remaining chains of indigenous wild poliovirus transmission by early 1994 [297, 427].

Other successes in high-risk settings in Asia and Africa followed. Indonesia and the Philippines have humid tropical climates and very high population densities in their most populous islands. A combination of strengthened routine immunization and NIDs at high rates of coverage stopped wild poliovirus types 1 and 3 transmission in both countries by 1995 [289, 290]. Bangladesh has one of the highest population densities in the world, and wild poliovirus was deeply entrenched in multiple endemic reservoirs with poor infrastructure. High-quality NIDs built upon a solid national program of routine immunization stopped wild poliovirus transmission in 2000 [425]. Neighboring India has more children <5 years of age than any other country. Despite the biological challenges of high population densities, tropical conditions, and poor infrastructure in many areas, the southern states stopped indigenous wild poliovirus transmission through a combination of high rates of routine immunization coverage and mass campaigns. Progress was much slower in the large and populous states of Uttar Pradesh and Bihar (with a combined monthly birth cohort >500,000), but all wild poliovirus transmission stopped in India in 2011 [12, 91]. Eradication was especially challenging in these two Indian states because the per-dose efficacy of OPV was low, as many children with poliomyelitis had received multiple OPV doses. Mass campaigns (NIDs, SNIDs, and large-scale mop-ups) overcame weaknesses in routine immunization [438]. The most populous parts of Afghanistan (northern provinces) [184], Pakistan (Punjab province) [184], and Nigeria (southern states) [185] stopped wild poliovirus circulation several years ago, only to be subject to reinfection primarily from domestic endemic reservoirs.

10.5.3 Genotypic Indicators of Progress

Progress in polio eradication has been accompanied by a steady reduction in the genetic diversity of circulating wild polioviruses. Of the 20 wild poliovirus type 1 genotypes, 5 wild poliovirus type 2 genotypes, and 17 wild poliovirus type 3 genotypes found in 1988 [439], only 4 (or fewer) wild poliovirus genotypes remain (two type 1 and two type 3) (Figs. 13.10 and 13.11). Diversity within the surviving genotypes continues to decline as genetic clusters steadily disappear (Sect. 10.7), and wild poliovirus type 3 may be very near eradication in both Asia and Africa.

10.6 Resurgence of Wild Polioviruses, 2002–2011

After years of steady decline, poliomyelitis cases increased sharply from 483 cases in 2001 to 1918 cases in 2002 (Fig. 13.2) [436]. This increase was the result of a large epidemic in India (1,600 cases), primarily associated with wild poliovirus type 1, centered in Uttar Pradesh (78 % of total cases) [409], and a rise in reported cases in Nigeria [440]. Global cases fell to 784 in 2003, as the epidemic in India was controlled by large-scale NIDs and SNIDs [441], but wild poliovirus type 1 was beginning to spread from northern Nigeria to neighboring countries [442]. The upsurge in Nigeria followed suspension of NIDs and SNIDs in several northern states in 2003 and 2004 in response to false rumors about OPV safety [443]. By 2006, wild poliovirus type 1 had spread from northern Nigeria to 18 countries, across a wide importation belt in Africa from Guinea in the west to Somalia in the Horn of Africa, and into Asia from Saudi Arabia and Yemen in the west to Indonesia at the southeastern rim, sparking large outbreaks (>100 cases) in Sudan, Somalia, Yemen, and Indonesia [10, 176]. Wild poliovirus type 1 introduced into Angola from Uttar Pradesh caused cases that were first reported in 2005 [176], and Nepal experienced repeated importations from northern India [176]. The majority of cases in 2005 were associated with imported virus, but most of the outbreaks outside of the core endemic reservoirs of Nigeria, India, Pakistan, and Afghanistan were largely controlled by the end of 2005 (Fig. 13.2d, e) [176], except for Kenya and Uganda where virus originating from Nigeria persisted until 2011 [10]. By 2006, most wild type 1 poliovirus cases occurred in the core reservoir countries, but virus of Nigerian origin continued to circulate in Niger, Ethiopia, Yemen, and Kenya [444], and virus of Indian origin spread to Bangladesh and from Angola to Namibia [80] and the Democratic Republic of Congo [444]. Instrumental in rolling back the wave of imported wild poliovirus type 1 was the widespread use in NIDs and SNIDs of monovalent type 1 OPV (mOPV1), which has a higher type-specific per-dose efficacy than tOPV because interference from the robust type 2 component of OPV is eliminated [196, 410]. However, exclusive use of mOPV1 in successive campaigns led to the development of growing immunity gaps to poliovirus types 2 and 3.

In India, as wild poliovirus type 1 cases declined 87 % from 646 in 2006 to 87 in 2007, wild poliovirus type 3 cases surged from 28 in 2006 to 787 in 2007 [445]. Widespread

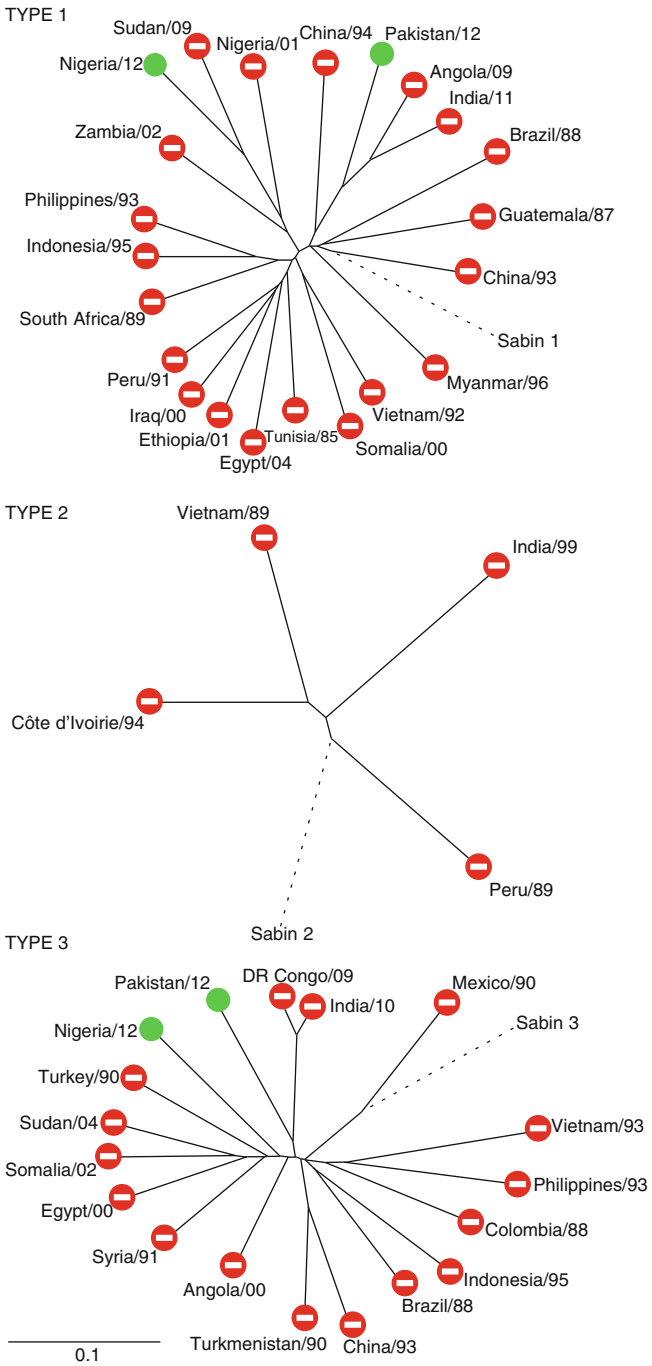

Fig. 13.10 Radial neighbor-joining trees of VP1 sequence relationships of representatives of wild poliovirus genotypes detected since the launch of polio eradication activities in the Americas in 1985. Genotypes believed to be extinct are represented by stop signs at the branch tips. Sequences representing the extinct genotypes usually are from the last known isolate of that genotype (Source: WHO Global Polio Laboratory Network. Modified from reference Chumakov and Kew [439])

circulation of wild poliovirus type 3 continued in Uttar Pradesh and Bihar through 2009 [438]. Wild poliovirus type 3 imported from Uttar Pradesh into Angola caused 24 cases in 2008 and spread to the Democratic Republic of Congo in 2008 and 2009 [10, 177]. During 2007–2011, wild poliovirus type 3 from Nigeria spread east to Chad, Cameroon, and the Central African Republic and north and west to Niger, Mali, Côte d'Ivoire, and Guinea [10, 177].

A second wave of wild poliovirus type 1 from Nigeria began in 2008 and spread to 14 countries, reinfecting many of the same countries that experienced the 2003–2006 outbreaks [177]. Wild poliovirus type 1 imported into Chad from northeastern Nigeria in 2010 caused a large outbreak that continued into 2012, resulting in reestablished transmission in Chad and further export of wild poliovirus type 1 into the Central African Republic [10]. However, effective NIDs and SNIDs in the countries of West Africa again rolled back the imported Nigerian virus [10, 16].

While wild poliovirus type 1 was disappearing from India, virus originating from Uttar Pradesh was associated in 2010 with a large outbreak (458 cases) in Tajikistan [178], with further spread to Turkmenistan, Kazakhstan, the Russian Federation, and probably Uzbekistan [181]. During 2010–2011, wild poliovirus type 1, originally imported several years earlier into Angola from Uttar Pradesh, sparked a large outbreak (~441 cases) in the Republic of the Congo with a very high CFR (Sect. 3.1) [81]. These outbreaks were controlled by aggressive mass immunization campaigns, and all wild polioviruses of Indian origin appear to have been eradicated worldwide.

Wild poliovirus type 1 circulation continued at much reduced levels in Pakistan and Afghanistan [184]. However, in 2011 wild poliovirus type 1 from southern Pakistan was imported into Xinjiang in western China, causing an outbreak of 21 cases [10, 82]. Sensitive surveillance in China detected the outbreak in its early stages, and a series of intensive mass immunization campaigns halted poliovirus circulation. Although China and the Western Pacific Region are again free of wild poliovirus circulation, the risk remains of re-importation from neighboring Pakistan even as poliomyelitis is in decline in that country.

10.7 Wild Poliovirus in Retreat, 2011–2012

A major milestone in global polio eradication was the eradication of indigenous wild poliovirus in India, once the world's most intense wild poliovirus reservoir [326, 327] and the source of repeated dissemination of wild poliovirus into countries in four continents [11, 170, 176, 177, 179, 315, 415, 446]. The last wild poliovirus type 3 in India was isolated in October 2010 and the last wild poliovirus type 1 was isolated in January 2011 (Figs. 13.10 and 13.11) [12, 91]. In neighboring Pakistan and Afghanistan, which constitute a common epidemiologic block, the diversity of wild poliovirus types 1 and 3 has been in steady decline, despite fluctuations in case counts (Fig. 13.12) [12].

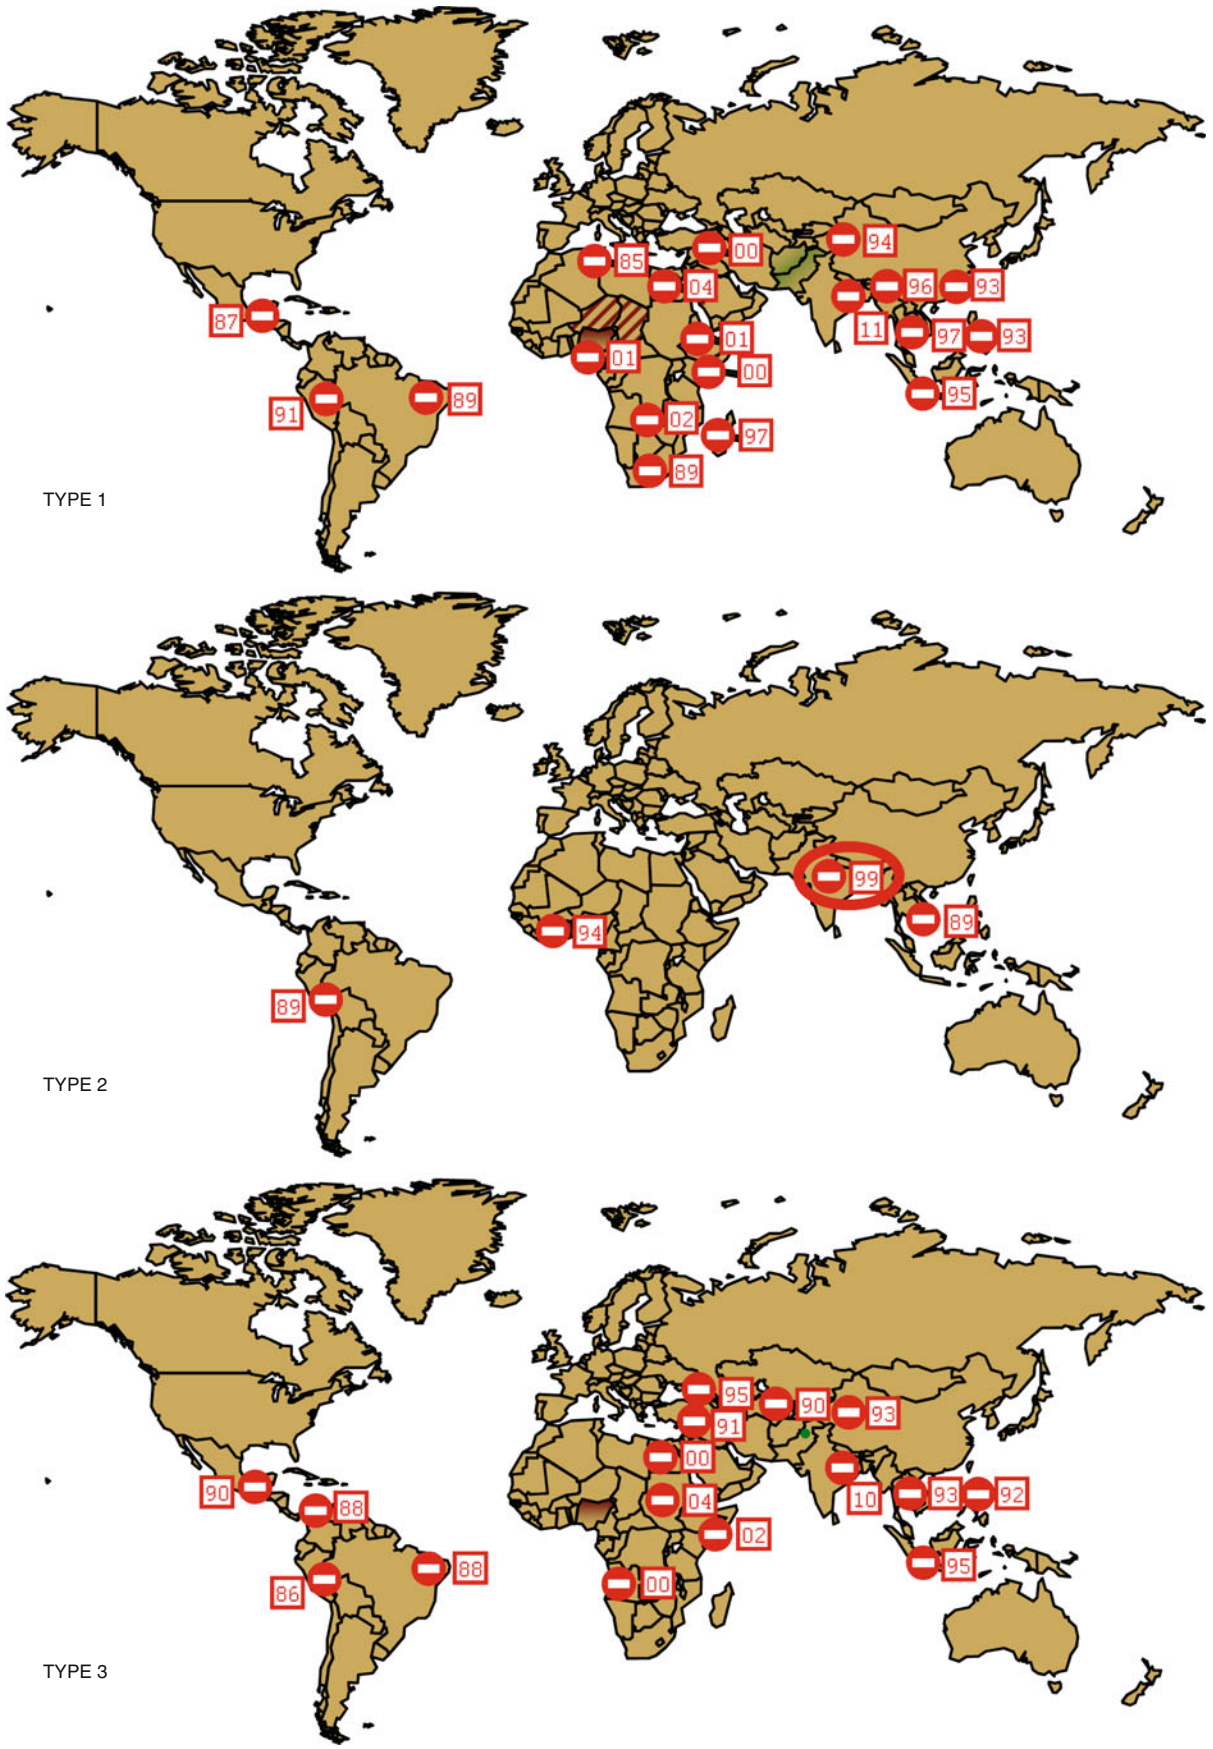

Fig. 13.11 Progressive eradication of wild poliovirus genotypes, 1986 to 2012. Stop signs indicate the year and location where the last isolate was obtained for each extinct genotype. Surviving type 1 and type 3 poliovirus genotypes are color-coded; hatch and shading patterns indicate, respectively, countries with reestablished transmission and sporadic importation of West Africa genotype viruses (Source: WHO Global Polio Laboratory Network. Modified from reference Kew and Pallansch [11])

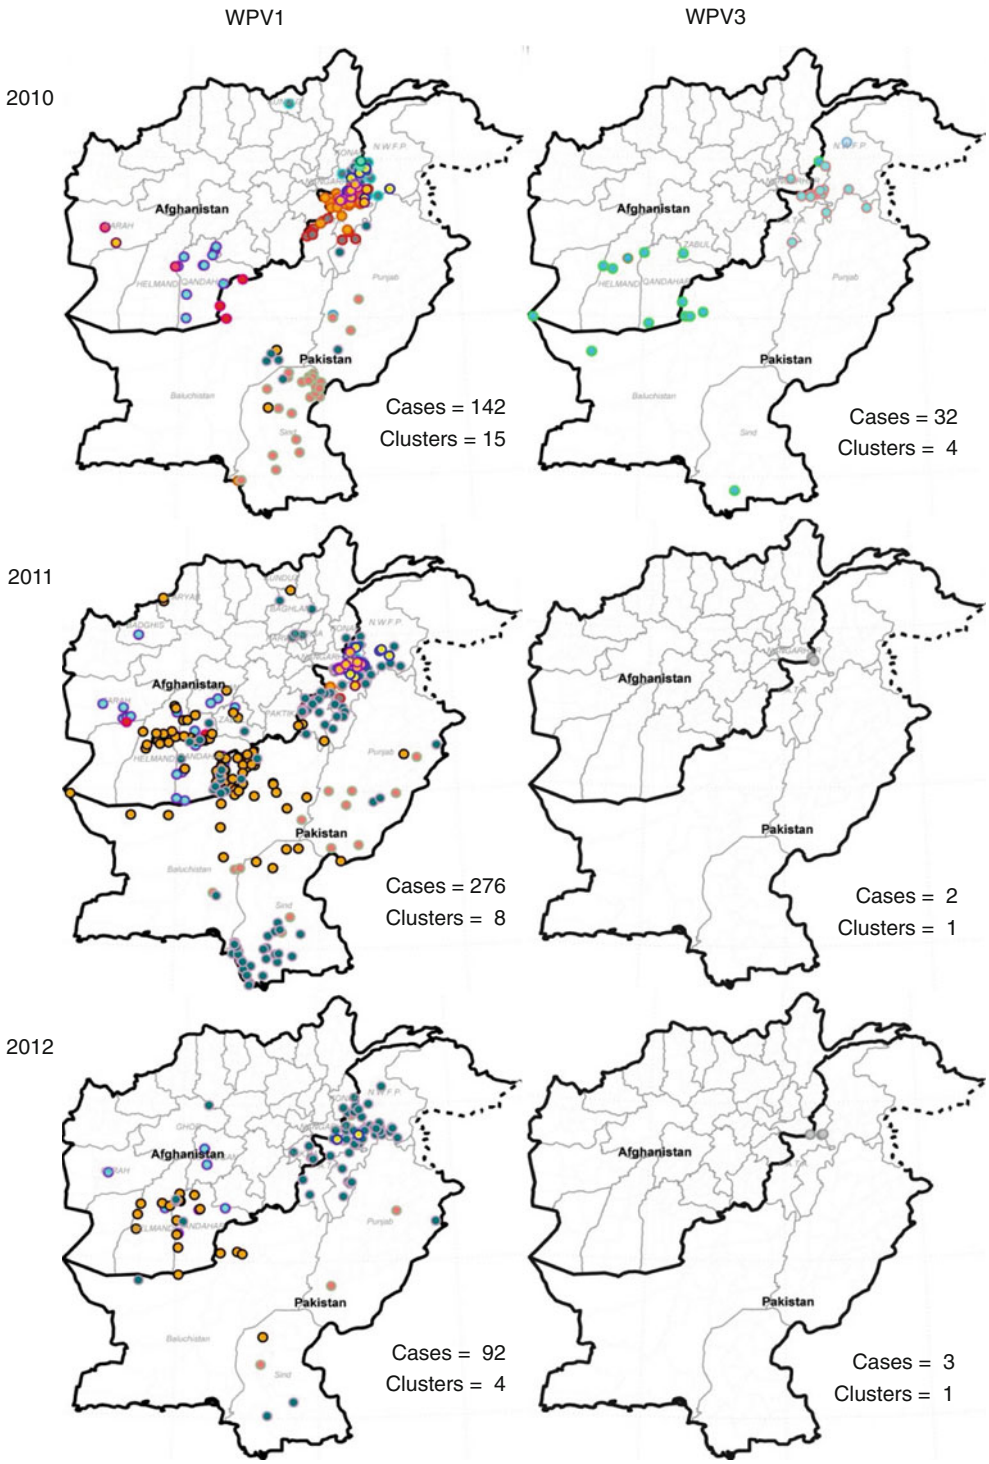

Fig. 13.12 Spot maps of genetic clusters based upon VP1 sequence relationships among isolates of wild poliovirus type 1 (*WPV1* left column) and wild poliovirus type 3 (*WPV3* right column), endemic to Pakistan and Afghanistan, 2010–2012. Isolates within a genetic cluster share ≥95 % VP1 nucleotide sequence identity, and the cluster count provides an indication of the genetic diversity of circulating wild polioviruses. Genetic clusters are color-coded to facilitate visualization of endemic reservoirs, transmission pathways (including cross-border transmission), and decline in genetic diversity. In 2011, poliovirus type 1 from southern Pakistan was imported into Xinjiang, China, and caused an outbreak of 21 cases [82]. (Map prepared by Elizabeth Henderson [CDC] based on sequence data produced by the Regional Polio Reference Laboratory at the National Institute of Health, Islamabad, Pakistan, and by CDC). As of April 2014, the last wild poliovirus type 3 isolate in Asia was from a child in the Federally Administered Tribal Area of Pakistan who had onset of AFP in April 2012

One measure of genetic diversity is the number of genetic "clusters," defined as isolates sharing ≥95 % VP1 nucleotide sequence identity (isolates within a genotype share ≥85 % VP1 nucleotide sequence identity [163]). Distinct clusters originate from different local endemic reservoirs, and in areas of sensitive surveillance, the disappearance of clusters within a genotype is an indication that source reservoirs within geographic area are being cleared of wild polioviruses. Just as the stepwise disappearance of genotypes is a measure of global progress toward eradication (Figs. 13.10 and 13.11), the stepwise disappearance of clusters is a measure of regional and local progress (Figs. 13.12, 13.13, and 13.14). Poliovirus genetic clusters are color-coded and mapped to facilitate visualization of patterns of circulation and to monitor progress toward eradication.

The number of wild poliovirus type 1 clusters in Pakistan and Afghanistan fell from 15 in 2010 to 4 in 2012 (Fig. 13.12).

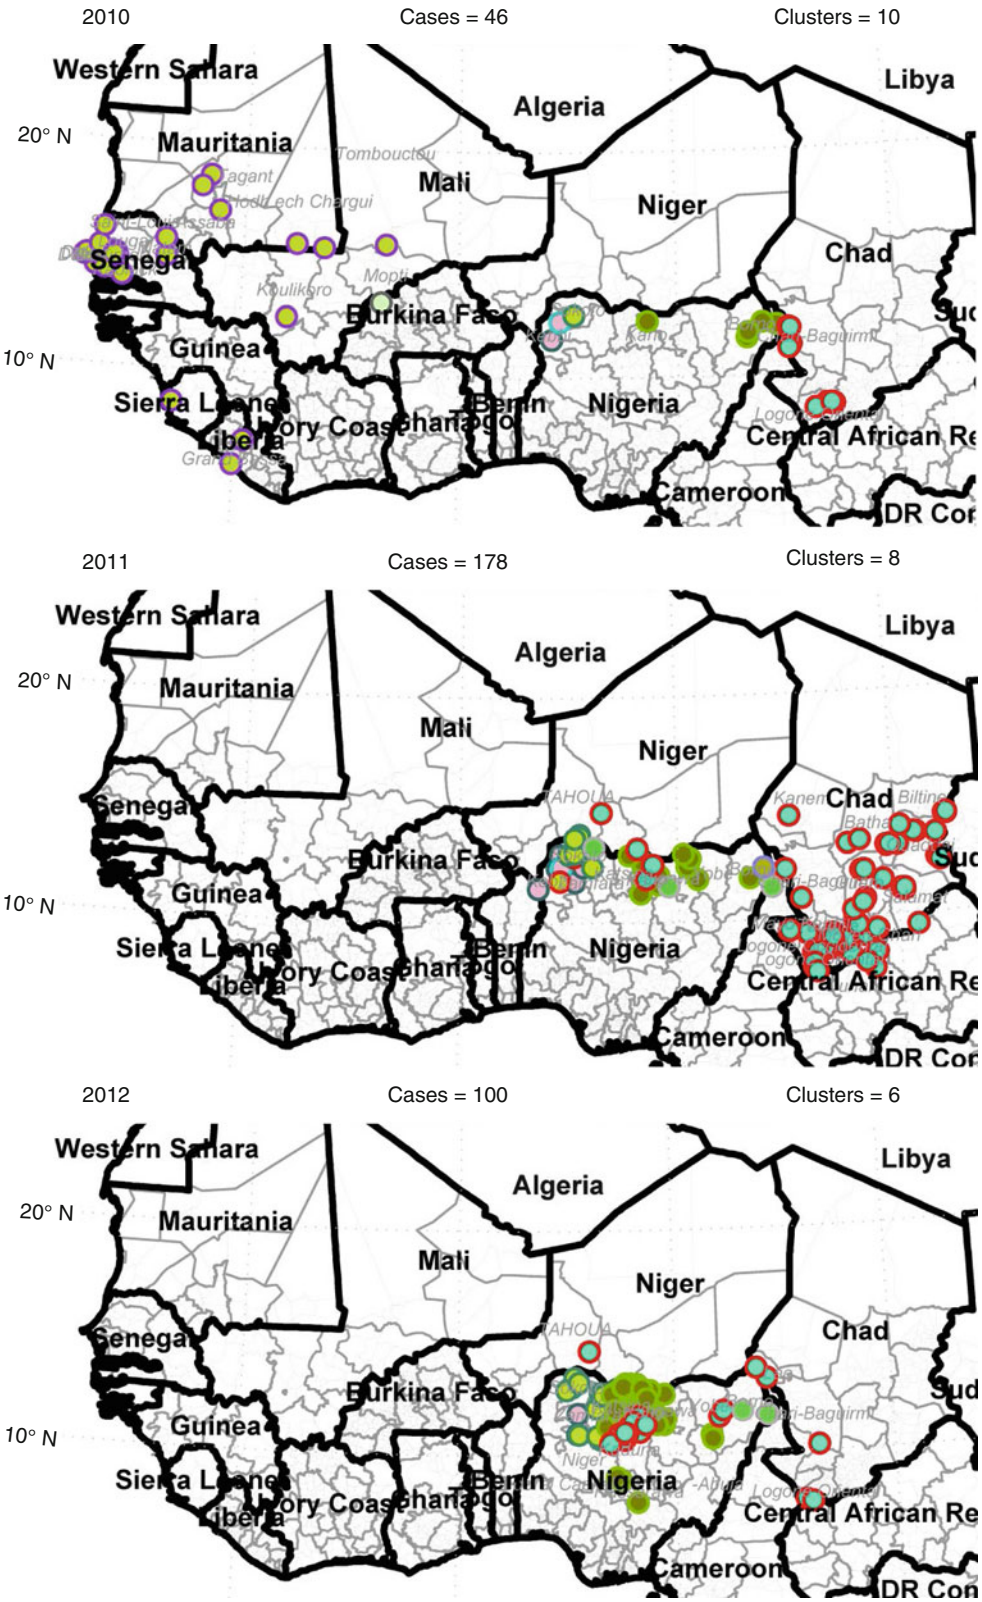

Fig. 13.13 Spot maps showing spread and retreat of genetic clusters of wild poliovirus type 1 from Nigerian reservoirs to neighboring countries in West and Central Africa, 2010–2012 (Map prepared by Elizabeth Henderson (CDC) based on sequence data produced by the Regional Polio Reference Laboratory at the National Institute for Communicable Diseases, Johannesburg, South Africa, and CDC). As of April 2014, the last wild poliovirus type 3 isolate in Asia was from a child in the Federally Administered Tribal Area of Pakistan who had onset of AFP in April 2012

Wild poliovirus type 3 clusters decreased from 4 in 2010 to 1 in 2012 (Fig. 13.12), and the last case associated with wild poliovirus type 3 in Pakistan (and in Asia; Fig. 13.2c) was reported in April 2012 [12]. By the end of 2012, reservoirs within Afghanistan appear to have been cleared of wild polioviruses.

Although progress in Nigeria has been less dramatic than in Pakistan and Afghanistan, wild poliovirus type 1 clusters

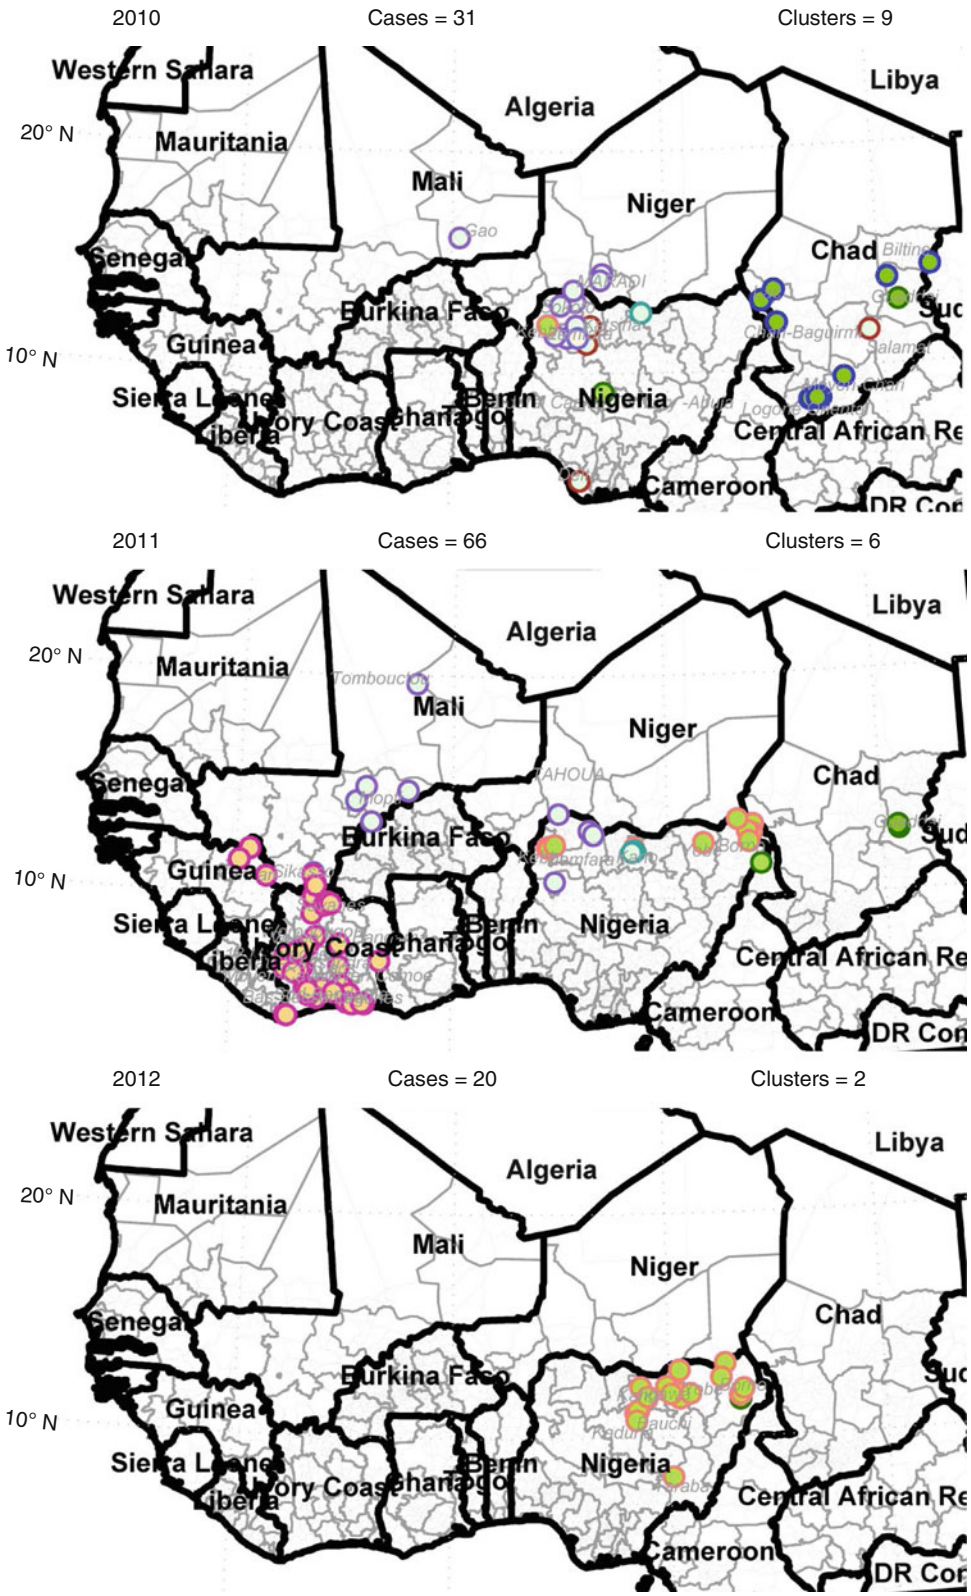

Fig. 13.14 Spot maps showing spread and retreat of genetic clusters of wild poliovirus type 3 from Nigerian reservoirs to neighboring countries in West and Central Africa, 2010–2012 (Map prepared by Elizabeth Henderson based on sequence data produced by the Regional Polio Reference Laboratory at the National Institute for Communicable Diseases, Johannesburg, South Africa, and CDC). As of April 2014, the last wild poliovirus type 3 isolate in the world was from a child in northeastern Nigeria who had onset of AFP in November 2012

[d]Outbreaks in Tajikistan, Turkmenistan, Kazakhstan, and Russian Federation following importation of wild poliovirus type 1 from India [178]

[e]Outbreak in Xinjiang, China, following importation of wild poliovirus type 1 from Pakistan [82]

fell from 10 in 2010 to 6 in 2012 (Fig. 13.13) and wild poliovirus type 3 clusters fell from 9 in 2010 to 2 in 2012 (Fig. 13.14). In addition, the surge of wild polioviruses from Nigeria was again rolled back between 2010 and 2012 (Figs. 13.13 and 13.14). In 2012, only Chad (5 cases in 2012 compared with 132 cases in 2011) and Niger (1 case in 2012 compared with 5 cases in 2011) had residual circulation of the wild poliovirus type 1 imported from Nigeria [12]. Although wild poliovirus transmission in Africa is localized to northern Nigeria, the risk for resurgence remains until immunization activities in key northern states are intensified [12].

Important factors in improving OPV coverage have been intensified community engagement, targeting mobile and migrant populations for immunization, and high-resolution mapping of underserved communities [12, 22]. An additional critical factor for eradication of wild polioviruses has been the widespread use of monovalent OPV type 1 (mOPV1) and mOPV3 in NIDs, SNIDs, and mop-ups. However, in countries where both wild poliovirus types 1 and 3 were co-circulating, balancing the use of mOPV1, mOPV3, and tOPV in NIDs and SNIDs was difficult. Priority was usually given to the use of mOPV1 because of the higher risk of wild poliovirus type 1 spread compared with wild poliovirus type 3 [10, 176, 177, 180, 181] and the greater risk of large outbreaks [181]. Routine OPV immunization exclusively uses tOPV, but coverage rates in the core reservoirs remain low [12], such that immunity gaps to types 2 and 3 could develop with near exclusive use of mOPV1 [447, 448]. The introduction of bivalent OPV (bOPV; types 1 and 3) [92, 449, 450] in late 2009 and early 2010 sharply reduced wild poliovirus type 3 circulation in areas where coverage rates in mass campaigns were high (Figs. 13.2c, 13.12, and 13.14) [12, 16, 82, 451]. However, a remaining challenge is to prevent widening immunity gaps to poliovirus type 2.

In 2012, more than two billion doses of OPV were administered to 448 million people, primarily to children <5 years of age in NIDs and SNIDs in 46 countries [12]. Only 223 cases of poliomyelitis associated with wild poliovirus infection were reported in 2012, an historic low, from a total of 106,937 reported cases of AFP, the most ever investigated (Table 13.2) [12]. The number of wild poliovirus cases in 2012 fell below the estimated number of worldwide VAPP cases (250–500) (Fig. 13.2a). For the first time, the risk of poliomyelitis from the use of OPV exceeded the annual case burden from wild poliovirus infection.

10.8 Emergence of Vaccine-Derived Polioviruses (VDPVs), 2000–2012

In principle, all clinical and environmental vaccine-related poliovirus isolates are VDPVs. However, as described in section "Categories of poliovirus isolates", for the purposes of poliovirus surveillance, vaccine-related isolates have been classified into two broad categories: (1) OPV-like isolates, which have limited divergence from their parental OPV strains and are ubiquitous wherever OPV is used, and (2) VDPV isolates, whose higher level of VP1 sequence divergence from their parental OPV strains (>1 % [types 1 and 3] or >0.6 % [type 2]) indicates prolonged replication (or

transmission) of the vaccine virus. VDPVs are further categorized as (1) circulating VDPVs (cVDPVs), (2) immunodeficiency-associated VDPVs (iVDPVs), and 3) ambiguous VDPVs (aVDPVs) [133].

Although the vast majority of vaccine-related isolates are OPV-like, VDPVs are of particular interest because of their implications for current and future strategies for global polio eradication [22, 94, 133, 428, 450]. VDPVs can cause paralytic polio in humans and have the potential for sustained circulation. The clinical signs and severity of paralysis associated with VDPV and wild poliovirus infections are indistinguishable. VDPVs resemble wild polioviruses phenotypically [133] and differ from the majority of vaccine-related poliovirus isolates by having genetic properties consistent with prolonged replication or transmission. Because poliovirus genomes evolve at a rate of approximately 1 % per year (Sect. 3.6.3), vaccine-related viruses that differ from the corresponding OPV strain by >1 % of VP1 nucleotide positions are estimated to have replicated for at least 1 year in one or more persons after administration of an OPV dose. This is substantially longer than the normal period of 4–6 weeks of vaccine virus replication in an OPV recipient [321]. The demarcation for type 2 VDPVs was lowered to 0.6 % to increase sensitivity for early detection of type 2 cVDPV outbreaks [133, 168, 452].

It seems likely that many OPV-like isolates have recovered the capacity for higher neurovirulence and possibly increased transmissibility. The small number of substitutions controlling neurovirulence (Sect. 9.1.3; Fig. 13.9) was found to have reverted among many OPV-like isolates, especially among isolates of types 2 and 3 [382, 388, 393]. Because the critical attenuating mutations in the 5′-UTRs of the Sabin strains also affect fitness for virus replication in the human intestine [393], it appears possible that revertants at these sites would have a higher fitness for person-to-person spread. However, spread is normally limited by high OPV coverage, and the VDPVs represent viruses whose potentials for prolonged replication or transmission have been clearly actualized, as demonstrated by their genetic prioperties.

The three categories of VDPVs differ in their public health importance. Circulating VDPVs pose the same public health threat as wild polioviruses because they have recovered the biological properties of wild polioviruses, have the potential to circulate for years in settings where poliovirus vaccination coverage to prevent that particular type is low, and require the same control measures. Immunodeficiency-associated VDPVs may be excreted by persons with certain primary immunodeficiencies for many (>10) years with no apparent paralytic signs [223, 453]. Persons infected with iVDPVs without paralysis are at risk of developing paralytic poliomyelitis [186, 223, 454] and may infect others with poliovirus, presenting the potential risk of outbreaks in areas with low poliovirus vaccine coverage [132]. Ambiguous VDPVs are heterogeneous: some represent the initial isolates from cVDPV outbreaks, whereas others, such as highly divergent aVDPVs detected in sewage, are probably iVDPVs from inapparent chronic infections.

10.8.1 Outbreaks of Circulating VDPVs (cVDPVs)

Among the two well-defined categories of VDPVs, cVDPVs are of the greatest current public health concern [22, 450, 455]. Since 2000, cVDPV outbreaks have occurred in 18 countries, with the large majority (86.6 %) of reported cases associated with type 2 (Fig. 13.15; Table 13.3). Type 1 cVDPVs were associated with outbreaks in Hispaniola in 2000–2001 and Indonesia in 2005 [166, 183]. In contrast, type 3 cVDPV outbreaks are rare, accounting for only 1.7 % of known cVDPV cases, an unexpected finding because the type 3 OPV strain is a major contributor to VAPP in OPV recipients [94]. Because the case/infection ratio for poliovirus type 2 infections is low (Sect. 3.4), the number of type 2 cVDPV infections worldwide since 2000 is estimated at nearly one million [168, 461].

During 2005–2012, a polio outbreak of 411 cases associated with cVDPV2 was reported from 11 northern and 3 north central states of Nigeria (Fig. 13.16; Table 13.3) [447, 448, 455]. The outbreak peaked at 153 cases in 2009, but 27 cases were detected in 2010, 35 cases in 2011, and 7 cases in 2012. Genetic analysis resolved the outbreak into >20 independent type 2 VDPV emergences that occurred during 2004–2012, at least 7 of which established circulating lineages [168, 448]. The outbreak occurred in states where routine immunization coverage with tOPV is low and NIDs and SNIDs using tOPV were infrequent [447, 448]. Spread of the type 2 cVDPV from northern Nigeria has been very limited, with only six cases in Niger from multiple importations and one case in Chad from an importation in 2010 (Fig. 13.16; Table 13.3). The limited spread may indicate that surrounding areas have higher levels of population immunity to poliovirus type 2 (because of the high immunogenicity of Sabin 2 and its higher tendency to infect OPV contacts) and that poliovirus type 2 may have an intrinsically lower capacity to spread than types 1 and 3 (Figs. 13.13 and 13.14).

Most of the other recent outbreaks have also been associated with type 2 cVDPVs (Table 13.3), several of which (e.g., Afghanistan, the Democratic Republic of Congo, India, Pakistan, and Yemen) were associated with multiple independent emergences [133]. Other type 2 cVDPVs have emerged successively in the same geographic area [459]. In several settings, this reflects the continued weakness in routine immunization with tOPV and the extensive use of mOPV1 and bOPV in mass campaigns. However, it also reflects the greater tendency of the Sabin 2 OPV strain to revert and spread to contacts [94]. Three separate type 3 cVDPV emergences were detected in Ethiopia in 2009–2010, and a single type 1 cVDPV emergence was detected in Mozambique in 2011 (Table 13.3).

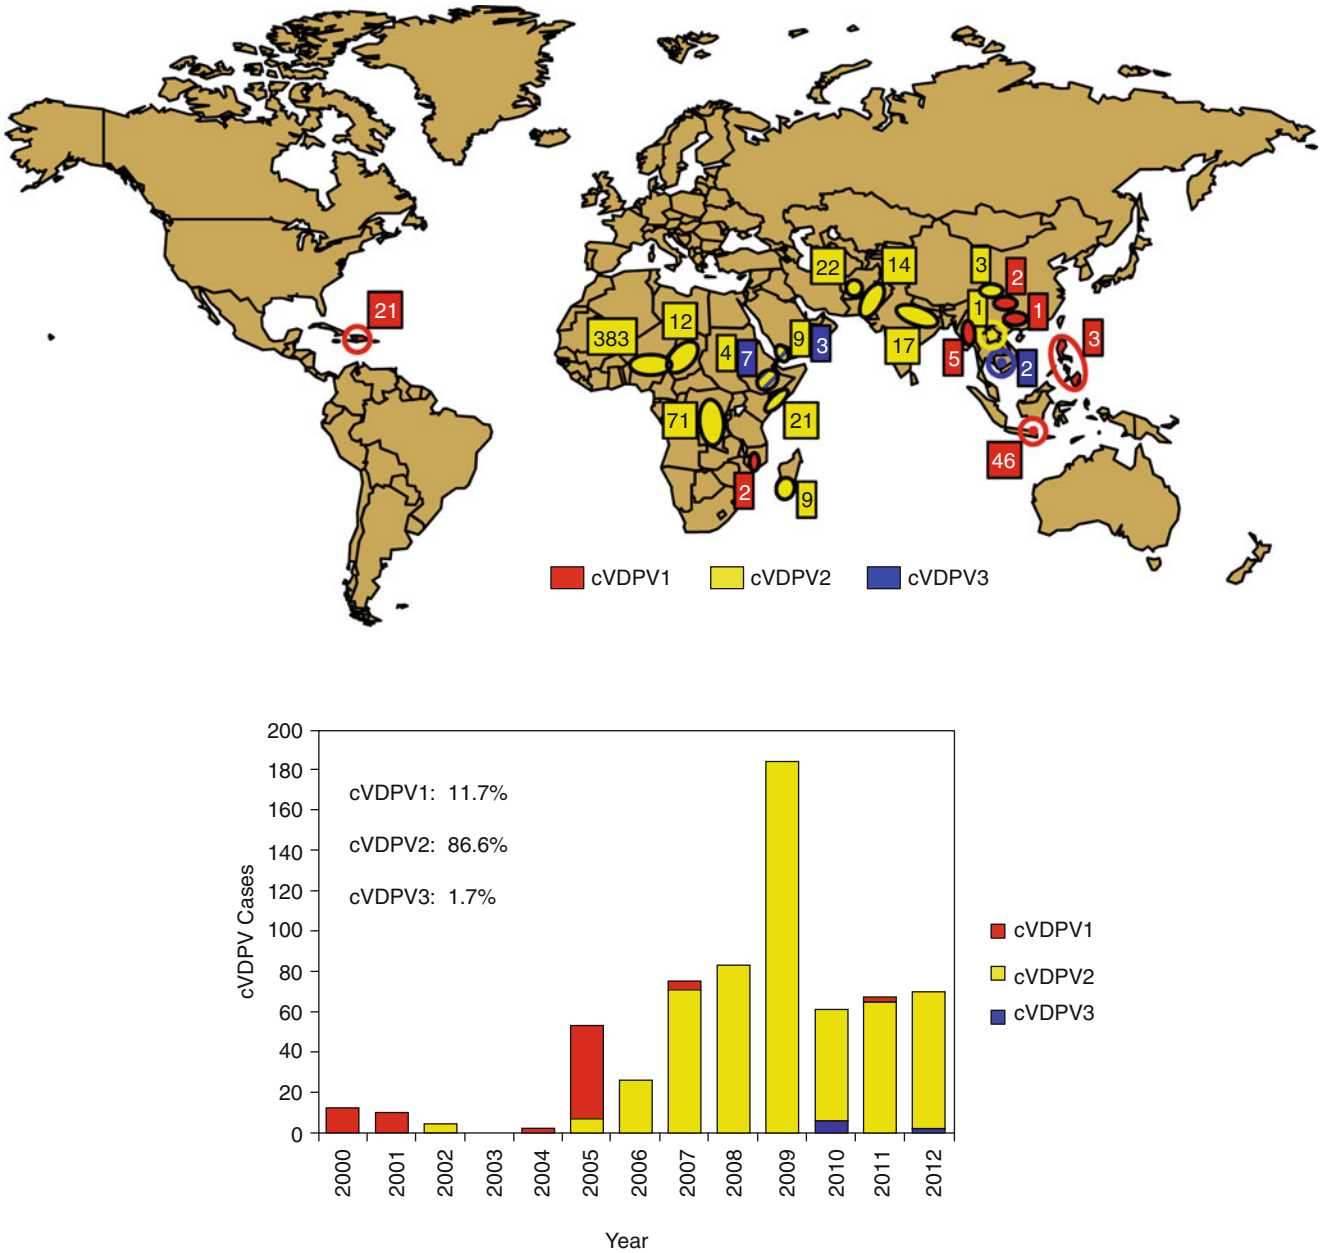

Fig. 13.15 Circulating vaccine-derived poliovirus (cVDPV) outbreaks, 2000–2012. Map: Location of cVDPV outbreaks, color-coded by serotype (*red* cVDPV type 1 [cVDPV1], *yellow* cVDPV2, *blue* cVDPV3). The independent emergences of cVDPV2 and cVDPV3 in Ethiopia and Yemen are indicated by *yellow* and *blue* diagonal patterns. Apart from the 2000–2001 cVDPV1 outbreak on the island of Hispaniola (Haiti and the Dominican Republic) and the limited spread of the cVDPV2 from Nigeria to Niger and Chad, all other outbreaks are independent events. Some countries had successive (e.g., Madagascar) or concurrent (e.g., Nigeria and D. R. Congo) cVDPV2 outbreaks. *Bar chart*: cases associated with cVDPV outbreaks, 2000–2012, color-coded by serotype (Modified from reference Kew [10])

In 2013, cVDPV2 from the outbreak in Chad continued with 4 new cases and spread to Cameroon (4 cases), Niger (1 case), and Nigeria (4 cases). The cVDPV2 outbreak in Pakistan continued with 47 new cases and spread to Afghanistan (4 cases in 2012–2013).

Key risk factors for cVDPV emergence and spread are (1) development of immunity gaps arising from low OPV coverage, (2) prior elimination of the corresponding wild poliovirus serotype, (3) emphasis on use mOPV and bOPV in NIDs and SNIDs [133, 447], and (4) insensitive AFP surveillance. Many of these factors exist in areas of insecurity and where rates of routine tOPV coverage remain low, such as in parts of northern Nigeria, Somalia, and Yemen. In this context, type 2 VDPVs present the greatest threat for emergence [133], and routine immunization should be strengthened and, for the immediate future, whenever possible regular

Table 13.3 Circulating vaccine-derived poliovirus (cVDPV) outbreaks, 2000–2012

Country	Sero-type	Years	Reported cases	% VP1 divergence	Estimated independent emergences	References

Chad	2	2012–	12	0.7–2.1	2	[460]
Pakistan[c]	2	2012–	14	0.7–2.9	2	[460]

[a]cVDPV2 from Nigeria was exported to Niger (2006, 2009–2012; 7 total cases) and Chad (2010 and 2012; 2 cases)
[b]cVDPV2 from Somalia was exported to Kenya (2012; 3 cases)
[c]cVDPV2 from Pakistan was exported to Afghanistan (2012; 3 cases)

immunization campaigns using tOPV should be conducted to close any immunity gaps.

All of the cVDPVs shown in Table 13.3 except those from China have vaccine/non-vaccine recombinant genomes, which are very rare among OPV-like and iVDPV isolates [94]. Recombination with other species-C enteroviruses frequently occurs during wild virus circulation and may be interpreted as an indication of person-to-person transmission. Whether recombination facilitates cVDPV emergence is unclear, because type 1 cVDPVs from China had nonrecombinant genomes [456] and recombination continues after emergence, similar to what is observed with wild polioviruses [94].

10.8.2 Immunodeficiency-Associated VDPVs (iVDPVs)

It has long been recognized that patients with primary B-cell immunodeficiencies (defects in antibody production) could become chronically infected when exposed to OPV [353]. Unambiguous demonstration that vaccine-related poliovirus isolates from immunodeficient patients had unusual sequence properties awaited the application of molecular tools, such as oligonucleotide fingerprinting [186, 462] and genomic sequencing [165, 186, 454], to poliovirus diagnostics. The extent of sequence divergence is correlated with the duration of the prolonged infection [165, 173, 186, 223, 454]. Not all isolates from immunodeficient patients are classified as iVDPVs. Some isolates are from specimens taken early in the prolonged infection and no subsequent specimens were taken. In other situations, either the prolonged infections had resolved spontaneously or the patient died from complications of the immunodeficiency (including fatal poliomyelitis) [354]. Prolonged iVDPV infections are independent events, and the isolates obtained from such infections trace separate pathways of divergence from the original OPV strains.

Since the introduction of OPV in 1961, >70 persons with primary immunodeficiencies have been found worldwide to be excreting iVDPVs; the majority of these immunodeficiencies were detected only after onset of AFP (Table 13.4). The extent of sequence divergence is correlated with the duration of the prolonged infection [165, 173, 186, 223, 454]. Four of the iVDPV isolates are highly divergent (>10 % VP1 sequence divergence from the parental OPV strain),

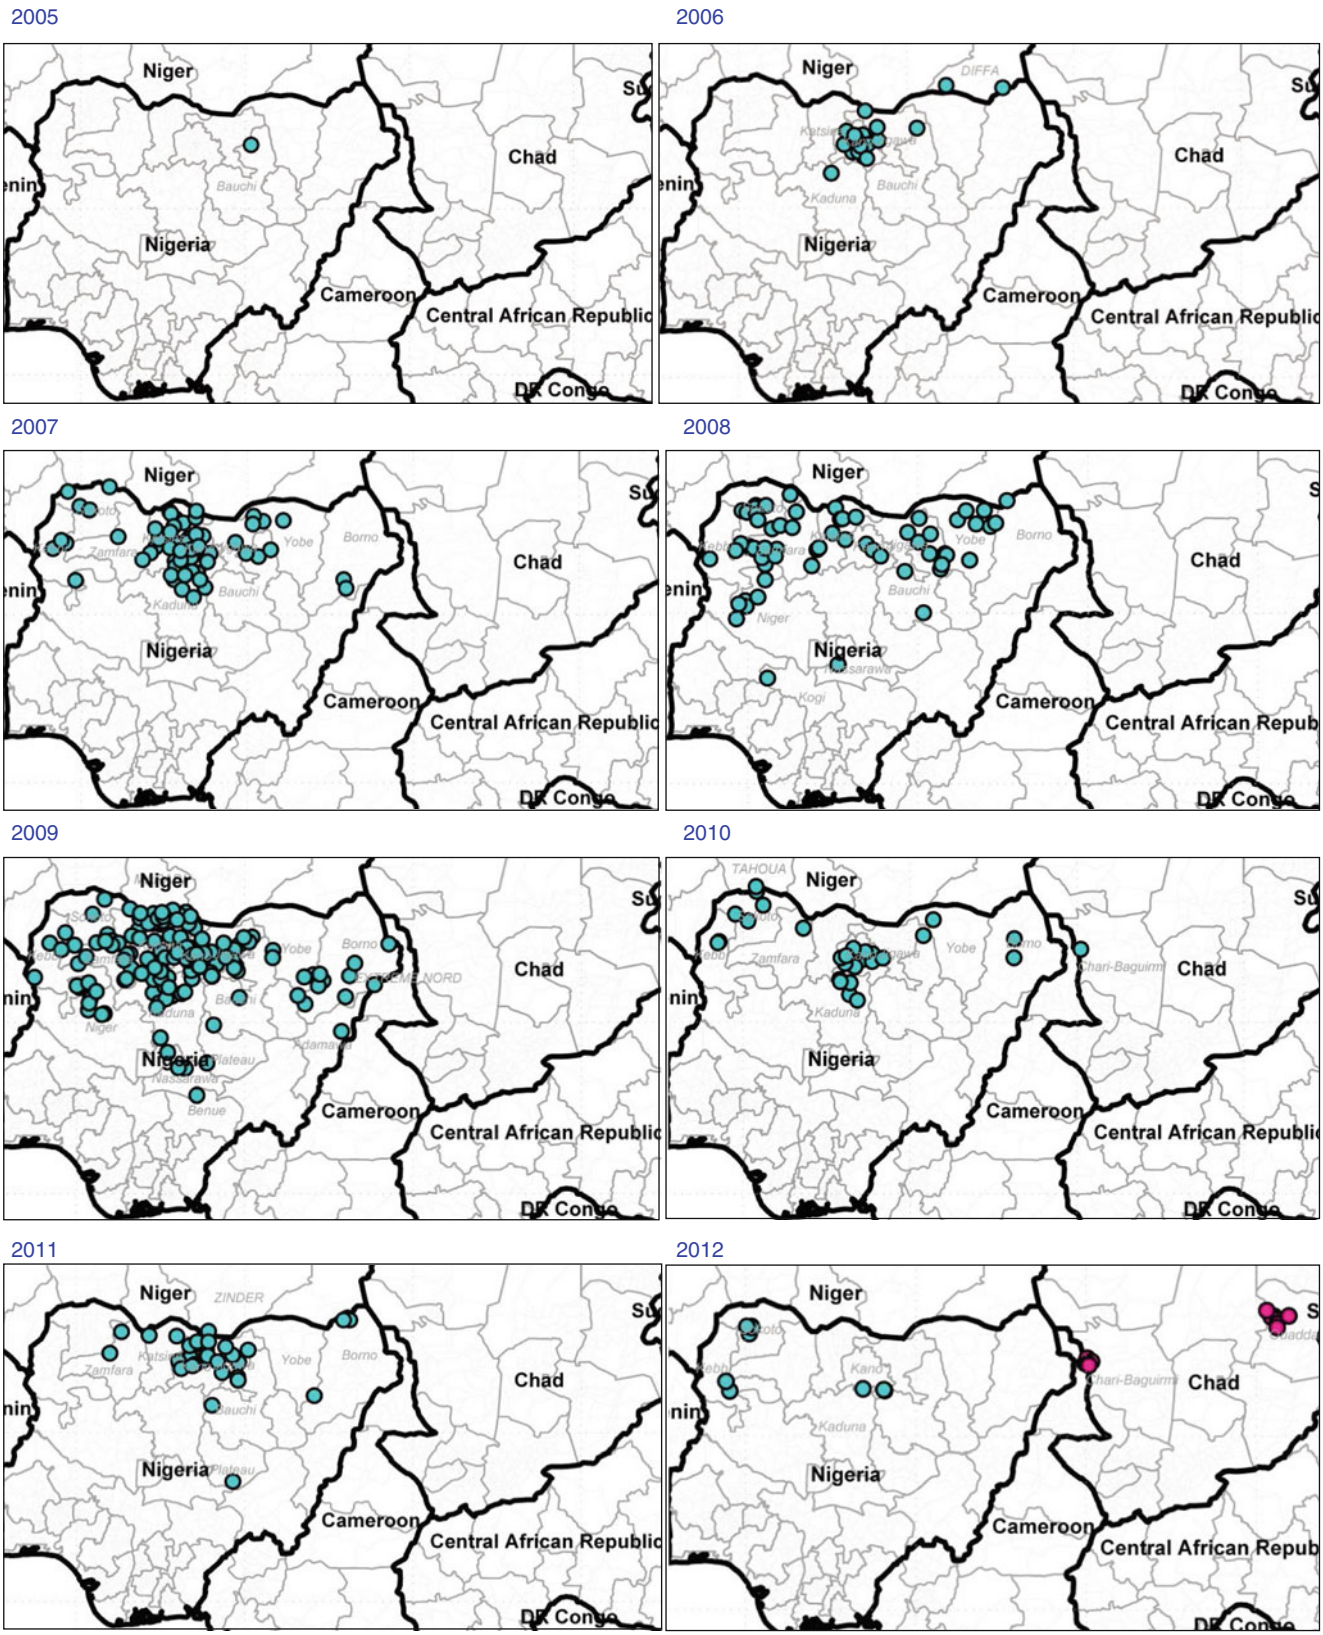

Fig. 13.16 Emergence and spread of type 2 cVDPV in Nigeria, 2005–2012. At least 20 independent emergences of type 2 cVDPVs (*green dots*) occurred in Nigeria between 2005 and 2012. Independent type 2 cVDPV emergences that occurred in Chad in 2012 are represented by *purple dots* (Map prepared by Elizabeth Henderson based on sequence data produced by CDC)

suggesting that the chronic poliovirus infections had persisted for ~10 years (Table 13.4). Patients with the most divergent isolates and the most prolonged (chronic) infections have common variable immunodeficiency (CVID), a group of late-onset immunodeficiencies that have multiple etiologies [476]. CVID is the most prevalent (~1 in 50,000) [476] of the primary immunodeficiencies, but only a small proportion of CVID patients exposed to OPV become chronically infected with iVDPVs.

Unlike cVDPV outbreaks, prolonged iVDPV infections cannot be prevented by high OPV coverage. Persons with prolonged iVDPV infections can transmit poliovirus to others, raising the risk for VDPV circulation in settings of low population immunity to the corresponding poliovirus serotype. So far, all reports of persistent iVDPV infections have been from countries with high to intermediate levels of development, where the rates of vaccine coverage are high and where the survival times of immunodeficient patients may be extended by treatment with intravenous immune globulin. The survival rates for persons with primary immunodeficiencies are probably very low in developing countries at highest risk for poliovirus spread. The population of prolonged iVDPV excretors is declining in developed countries because some patients have died (Table 13.4), some have cleared their infections, and no new iVDPV infections have been found in countries that have shifted to IPV. However, the prevalence of long-term iVDPV excretors might be higher than suggested by existing surveillance of persons with primary immunodeficiencies, and several aVDPVs have properties closely resembling iVDPVs (Sect. 10.8.3). The development of treatment for prolonged iVDPV infections might facilitate detection of and access to those with prolonged infections [133, 477].

Type 2 iVDPVs are the most prevalent (63 %), followed by type 1 (22 %) and type 3 (15 %). Some patients have heterotypic iVDPV infections, with the isolates having similar degrees of divergence from the parental OPV strains, consistent with a common OPV dose initiating the infections (Table 13.4). In addition to the occasional heterotypic infections, iVDPV isolates generally have distinguishing genetic properties, including heterogeneity at sites of nucleotide variability within serotypes (indicative of mixed virus populations), extensive antigenic variability, and either nonrecombinant or vaccine/vaccine recombinant genomes [94, 133].

10.8.3 Ambiguous VDPVs (aVDPVs)

Unlike the well-defined cVDPV and iVDPV categories, aVDPVs are a heterogeneous collection of isolates (Tables 13.5 and 13.6). Some aVDPVs have diverged by just over 1 % from the parental OPV strains, have no detected progeny, and may reflect the extremes of the usual distribution of

Table 13.5 Other vaccine-derived poliovirus (VDPV) with genetic evidence of community circulation, 1965–2012

[a]Group 1 aVDPV2 isolates from Israel are genetically distinct from Group 2 isolates, and are probably derived from two different chronic excretors
[b]Group 2

vaccine-related variants in countries using OPV [133]. Detection of other aVDPVs have foreshadowed subsequent cVDPV outbreaks [133, 478], others indicate limited person-to-person spread of OPV virus in small communities with gaps in OPV coverage [94, 132, 156, 190, 479], whereas others appear to indicate more prolonged circulation (Table 13.5) [133]. Most of these latter aVDPVs have vaccine/non-vaccine recombinant genomes typical of cVDPVs.

Many of the aVDPVs are isolated from the environment, and some have genetic properties (mixed VDPV populations, extensive antigenic changes, and nonrecombinant or vaccine/vaccine recombinant genomes) typical of iVDPVs. Highly divergent aVDPVs have been detected in Israel [117], Estonia [455], Slovakia [119], and Finland [120], countries with high rates of polio vaccination coverage that are unlikely to have extensive VDPV transmission (Table 13.6). The sequence divergence of some of these isolates is consistent with more than 15 years of replication from the original initiating OPV dose. It is likely that the sources of these viruses are immunodeficient persons with asymptomatic VDPV infections, although the infected persons remain to be identified.

10.9 Certification of Polio Eradication

The WHO GPEI has established a formal process for the certification of polio eradication to ensure that future immunization policy decisions are based on the best available evidence [481]. The certification process for polio is modeled on the International Smallpox Certification Commission, which certified in December 1979 that smallpox had been eradicated [482]. However, polio certification differs in important ways from the smallpox model. PAHO established its Regional Certification Commission (RCC) in 1990 and certified regional eradication of indigenous wild polioviruses in 1994 [112, 430], setting the standard for certification by individual regions and implicitly considering genetic evidence to distinguish indigenous wild polioviruses from imported virus. Because of the high proportion of inapparent wild poliovirus infections, regional certification requires a period of at least 3 years of sensitive surveillance since the last reported case associated with indigenous wild poliovirus. Small outbreaks from imported virus occurred on the eve of certification in the Western Pacific (in China in 1999 [483, 484]) and in Europe (in Bulgaria [485] and Georgia [11, 431] in 2001), but they were quickly controlled and followed by intensive surveillance. The certification of eradication of indigenous wild polioviruses by three WHO regions—the Americas in 1994 [112, 430], the Western Pacific in 2000 [486], and Europe in 2002 [431]—has stood the test of time. No indigenous wild poliovirus circulation has been detected in these regions post-certification. Cases and outbreaks associated with imported wild polioviruses and cVDPVs (in addition to cases of VAPP) have occurred subsequently (Sects. 10.6 and 10.8.1), but circulation has been promptly stopped by effective outbreak control measures [12, 82, 166, 178, 189, 190, 456]. The South-East Asia Region was certified by the RCC as polio-free in March 2014

(http://www.searo.who.int/entity/campaigns/polio-certification/en/). Key to certification was the observation that >3 years have passed since the last wild poliovirus case in India where surveillance has been maintained at high levels of sensitivity [12]. Similarly, documentation in all countries except Pakistan and Afghanistan has been accepted by the Eastern Mediterranean RCC. Several countries in the African Region have also prepared detailed documentation of polio-free status [22].

10.9.1 The Certification Process

Review of documentation to assess polio-free status is organized on three tiers [481]. National Certification Committees (NCCs) meet to critically assess national data and prepare detailed reports to Regional Certification Commissions (RCCs), who in turn report to the Global Certification Commission (GCC). The NCCs, RCCs, and GCC meet on a regular basis, and in the regions already certified as free of poliovirus circulation, the RCCs working with NCCs are primarily responsible to oversee and support activities to maintain the polio-free status. The NCC reports contain current information on the following: (1) national demographic data, including high-risk populations, (2) poliovirus vaccine coverage and any changes in vaccine policy, (3) surveillance data and indicators of surveillance sensitivity, (4) descriptions of any poliomyelitis cases, (5) information on the performance of laboratories serving each country, and (6) progress toward poliovirus containment. NCC, RCC, and GCC members are charged to serve as independent experts. Following certification of all WHO regions, the GCC will review all RCC reports and other relevant information to determine when the world can be declared free of all poliovirus circulation [481]. Special provisions are planned to recognize the global eradication of wild poliovirus type 2 (Sect. 11.2) [22]. An important prerequisite for certification is poliovirus containment.

10.9.2 Laboratory Containment of Polioviruses

Containment is integral to poliovirus eradication [487, 488]. Unlike smallpox, where very few facilities stored materials containing (virus stocks) or potentially containing (clinical specimens) smallpox virus (variola), many facilities worldwide store materials containing polioviruses. The purpose of containment is to minimize, as much as possible, the risk of reintroduction into the community of polioviruses stored in laboratories and vaccine production facilities. In 1998, the GCC approved the *WHO Global Action Plan for Laboratory Containment of Wild Polioviruses* [487] and subsequently established that satisfactory completion of containment activities be a requirement for regional certification. Containment will be implemented in three phases. During the Laboratory Inventory and Survey Phase (Phase 1) countries will (1) conduct national surveys of all biomedical laboratories to identify those storing materials containing (poliovirus stocks) or potentially containing (clinical specimens or environmental samples taken at locations during times of known poliovirus circulation) wild and vaccine-derived polioviruses, (2) encourage destruction of all unneeded materials, (3) develop inventories of laboratories retaining these materials and report to the RCC, (4) encourage implementation of biosafety level 2 (BSL-2) procedures in all enterovirus laboratories, and (5) plan for Phase 2. The Global Eradication Phase (Phase 2) will begin 1 year after detection of the last wild poliovirus or cVDPV at which time countries will (1) notify biomedical laboratories that wild poliovirus and cVDPV transmission has been stopped; (2) require laboratories on national inventories to select among the three options to (a) render materials noninfectious, (b) transfer all materials to high containment facilities, or (c) implement the appropriate laboratory procedures (BSL-2/polio or BSL-3/polio); and (3) document that all containment requirements have been met for global certification [487]. The Post-Global Certification Phase (Phase 3) was developed in response to the WHO goal of stopping all OPV use post-certification and proposes to minimize facility-associated poliovirus risk by destruction of both wild and vaccine-related polioviruses in all facilities, except for an absolute minimum needed for vaccine production, quality control, reference, and research [22].

Phase 1 containment was completed in the Americas several years after certification of polio-free status. In the United States, among the 105,356 laboratories surveyed, 180 laboratories in 122 institutions were found to be storing materials containing or potentially containing wild poliovirus; 87 held wild poliovirus stocks, 56 stored materials potentially containing wild polioviruses, and 37 stored both [489]. Europe completed Phase 1 containment in 2006 [96]. Among the 55,748 biomedical facilities surveyed, 265 laboratories in 164 institutions were found to be storing materials containing or potentially containing wild poliovirus; 116 held wild poliovirus stocks and 149 stored materials potentially containing wild polioviruses. In 20 European countries, 1 or more laboratories reported destroying all previously stored wild poliovirus materials during the survey. The Western Pacific Region completed Phase 1 containment in 2009 [490]. Of the 77,260 biomedical facilities surveyed, 45 laboratories (27 of which are members of the GPLN) retained materials containing or potentially containing wild polioviruses. Surveys have been completed in 155 of the 194 WHO member states, with the remaining surveys to be completed in countries in sub-Saharan Africa (these countries are thought unlikely to have many facilities with wild poliovirus materials). Worldwide ~550 facilities, including 6 IPV manufacturers, have been found to be storing wild poliovirus-infectious materials or potentially infectious materials [22]. VDPVs are stored in GPLN laboratories and a small number of collaborating laboratories.

11 Unresolved Problems

The immediate and crucial unresolved problem is to finish the task of eradicating wild polioviruses from the last remaining reservoir communities. The second unresolved problem is implementation of the "polio endgame" to ensure that the promise of polio eradication is forever secured. The third challenge is to build upon the legacy of polio eradication.

11.1 Eradication of Wild Polioviruses in Last Global Reservoirs

In May 2012, the WHA declared that polio eradication was a "programmatic emergency for global public health" and called for intensification of eradication activities in the remaining reservoir areas [22]. A Global Emergency Action Plan and National Emergency Action Plans (NEAPs) were developed and implemented in the remaining three reservoir countries [22]. All three countries face challenges of conflict and insecurity, as well as underperformance of immunization activities in high-risk areas. Afghanistan and Pakistan made clear improvements in 2012, but the pace of eradication has been slower in northern Nigeria.

11.1.1 Afghanistan

Polio has been controlled in most of Afghanistan except for the southern region, where intense armed conflict continues. The last case associated with wild poliovirus type 3 had onset in April 2010. Wild poliovirus type 1 had spread from the southern region provinces of Kandahar and Helmand in 2012 (Fig. 13.12), but the only 2013 cases were associated with wild poliovirus type 1 imported across the northeastern border from reservoirs in the insecure Tribal Areas of Pakistan. Only 2–5 % of children in southern Afghanistan were inaccessible in 2012 compared with 6–21 % in 2010 and 2011 [184]. In 2012, 65 % of case-patients were underimmunized and 35 % had received no OPV dose. The Afghanistan NEAP calls for reaching missed children through (1) improved detailed planning of mass campaigns; (2) better selection, training, monitoring, and support of vaccination teams; (3) enhanced community engagement; (4) robust response to poliomyelitis outbreaks; (5) expanded field staff in high-risk areas; and (6) use of permanent polio teams of trusted local people in insecure areas who visit homes and immunize children on a regular basis [22, 184].

11.1.2 Pakistan

Pakistan made dramatic progress in 2012 with implementation of the NEAP. Wild poliovirus type 3 was highly localized to the tribal areas in 2012 and was last detected in April 2012 from an AFP case, with no subsequent detections in the environment (Fig. 13.12) [184]. Several wild poliovirus type 1 reservoirs have been cleared and genetic diversity continues to decline. In recent years, >70 % of cases have been in the Pashtun minority, many of whom migrate widely within Pakistan and into Afghanistan. The NEAP focuses on (1) the implementation of an aggressive polio campaign schedule in the remaining reservoirs, (2) immunizing children of migrant and mobile Pashtun communities, (3) closer integration of immunization campaigns with community engagement, (4) closer civil–military cooperation in insecure areas, and (5) increased (>1,350) human resources for deployment in high-risk areas [22, 184]. Campaigns in some highest-risk areas (with ~165,000 children) have been suspended because of repeated fatal attacks on young women vaccinators from the community [184]. However, the attacks have been met by the young vaccinators with courage and resolve, and campaigns have continued elsewhere, with large numbers of children receiving OPV in the key reservoir areas.

Polio cases in Pakistan increased from 58 in 2012 to 93 in 2013; all cases in 2013 were associated with wild poliovirus type 1. Virus spread from Pakistan to Syria (33 cases in 2013) (http://www.polioeradication.org/), and to Egypt and Israel where wild poliovirus type 1 was detected in sewage [491].

11.1.3 Nigeria

All three poliovirus serotypes circulated in northern Nigeria in 2012: wild type 1, type 2 cVDPV, and wild type 3. In 2011–2012, 25 % of poliomyelitis case-patients had never received a dose of OPV [185]. Progress has been gradual in the northern states, and although polio campaign quality has improved, serious gaps remain in rural and hard-to-reach communities. In addition to insecurity in the northeast, 18 % of missed children are because their parents refuse them to be vaccinated because of anti-OPV rumors propagated by some clerics [22]. The Polio Emergency Action Plan calls for the following: (1) improved detailed planning of mass campaigns; (2) better selection, training, monitoring, and support of vaccination teams; (3) enhanced community engagement; (4) increased (~2,500) human resources for deployment in high-risk areas; (5) real-time data monitoring; (6) focused interventions in hard-to-reach rural and nomadic communities; (7) GIS mapping of settlements and GPS tracking of vaccination teams; and (8) strengthened surveillance [22, 185]. Full implementation of this plan should break all remaining chains of poliovirus transmission, as had been achieved a decade earlier in the more densely populated and tropical southern states. As in Pakistan, fatal attacks on young women vaccinators have been an impediment to complete implementation of the plan across the northern Nigerian states.

Polio cases in northern Nigeria decreased from 122 in 2012 to 53 in 2013; all cases in 2013 were associated with wild poliovirus type 1. Wild poliovirus type 1 spread from Nigeria to Somalia (194 cases in 2013), and from Somalia to Kenya (14 cases) and Ethiopia (9 cases). Wild poliovirus type 1 of Nigerian origin spread from Chad to Cameroon in 2013 (http://www.polioeradication.org/).

11.2 Implementation of the Polio Eradication Endgame

Compared with the straightforward smallpox eradication endgame, the polio eradication endgame is much more complex and includes the following elements, some operating on parallel tracks: (1) cessation of wild poliovirus transmission, (2) outbreak response (especially cVDPVs), (3) strengthened routine immunization, (4) IPV introduction and shift from tOPV to bOPV, (5) sequential IPV/bOPV in routine immunization, (6) completion of poliovirus containment (ultimately including vaccine-related isolates), (7) global certification, (8) cessation of bOPV use, and (9) mainstreaming of polio activities into national and global disease alert and response systems. Several of these activities are discussed above. A key new element is the worldwide withdrawal of use of the type 2 component of OPV.

11.2.1 Withdrawal tOPV

Since 1999, all poliomyelitis cases associated with poliovirus type 2 (apart from a few cases in India associated OPV contaminated with MEF-1 [335, 336]) have been associated with the continued use of tOPV. The rising incidence of type 2 cVDPV outbreaks (Sect. 10.8.1; Fig. 13.15), representing nearly 90 % of all reported cVDPV cases, prompted the WHO GPEI to plan for the logistically challenging step of worldwide withdrawal of tOPV and replacement with bOPV [22]. The tOPV–bOPV switch, targeted for 2016, would be predicated on the complete cessation of type 2 cVDPV transmission and will require continued sensitive AFP and poliovirus surveillance. Under the new strategic plan, by the end of 2014, polio-funded field staff will devote >50 % of their time assisting countries to strengthen routine immunization. Large stockpiles of mOPV2 (500 million doses; in addition to 300 million doses each of mOPV1 and mOPV3) will be maintained, and a robust surveillance and response capacity established. In addition, steps will be taken to secure affordable IPV and introduce at least one dose of IPV into the routine immunization programs of all countries by the end of 2015. Before tOPV withdrawal, the GCC must "validate" (certification will be for all poliovirus serotypes) the eradication of type 2 wild polioviruses and the elimination of type 2 cVDPV transmission. Also, Phase 2 containment of type 2 wild polioviruses and cVDPVs must be completed, along with Phase 1 containment of type 2 vaccine-related isolates. When all prerequisites are met, coordinated global cessation of tOPV use in routine immunization and mass campaigns will occur over a short time period, replaced with bOPV, the remaining tOPV stocks will be withdrawn worldwide, and the process carefully documented [22]. After the switch, the WHO will stockpile "stand-alone" IPV (IPV is usually formulated as a component of multivalent injectable vaccines) for emergency deployment to areas peripheral to outbreak communities. The tOPV–bOPV switch will precede the global bOPV cessation and withdrawal projected for 2019.

11.2.2 Transition to IPV

Many previously OPV-using countries, including the United States, have transitioned to exclusive use of IPV. Several countries have maintained a sequential IPV/OPV schedule (Fig. 13.17), similar to what the United States employed in 1997–1999 (Sect. 9.1.5). The WHO has obtained extensive experience in the introduction of new vaccines into low- and middle-income countries. However, worldwide use of IPV will be greatly facilitated by reducing the cost of IPV, which is substantially higher than OPV. Steps to reduce IPV costs could include (1) the use of intradermal fractional (1/5th) IPV doses [492], (2) development of new adjuvanted intramuscular IPV products, and (3) replacement of conventional IPV (using neurovirulent wild strains as seeds) with IPV based on the Sabin OPV strains [493–495], more suitable for production in developing countries [22]. New-generation biotechnology tools are being explored to develop genetically stable IPV seeds that would substantially enhance biological containment in IPV production facilities [496–499]. However, the many options for immunization products and schedules present increasingly complex policy decisions for national public health authorities [500].

11.3 The Legacy of Polio Eradication

The GPEI is the largest public health initiative in history, engaging communities, governments, health professionals, and private donors throughout the world. During the past quarter century, the GPEI has trained millions of volunteers, social mobilizers, and health workers to reach and immunize children in the most marginalized and vulnerable communities in the world [22]. In all but a few places, poliomyelitis, increasingly a disease of the poorest of the poor, has gone the way of smallpox. Moreover, other health interventions have directly benefited from polio immunization campaigns. For example, vitamin A supplements delivered during OPV campaigns are estimated to have prevented more than one million childhood deaths [22], and the administration of

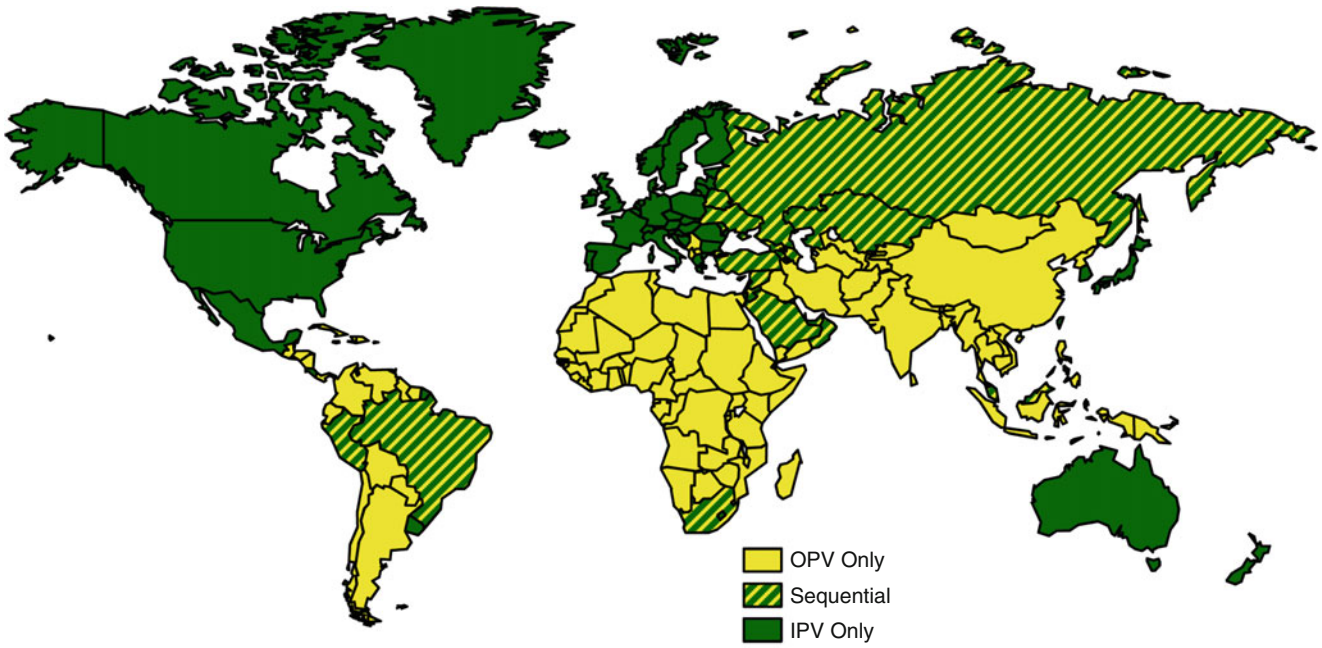

Fig. 13.17 Countries using exclusively oral poliovirus vaccine (*yellow* OPV), exclusively inactivated poliovirus vaccine (*green* IPV), or a combination of IPV and OPV (hatched pattern) (Modified from reference Sutter [7])

anti-helminthics and the distribution of bed nets have spared many more of disease and early death.

As the century-long struggle against poliomyelitis draws to a close, a new generation of highly experienced public health professionals—epidemiologists, virologists, and program managers—from around the world have built on the solid foundations of the GPEI to help guide the control of other vaccine-preventable diseases, including measles, rubella, rotaviral gastroenteritis, tetanus, invasive bacterial diseases, yellow fever, Japanese encephalitis, and hepatitis B [22, 422, 423, 501–503]. The model of close integration of field and laboratory surveillance with programmatic action has been replicated in other vaccine-preventable disease programs. The GPLN, the first laboratory network with global reach, established the blueprint for other vaccine-preventable disease laboratory networks [130, 131], some of which have grown to be more extensive than the GPLN [129]. These new networks are guided by laboratory network coordinators who are experienced in ensuring high technical performance and working in close cooperation with epidemiologists. Another important legacy of the GPEI, building on the models of smallpox eradication and the EPI, is a permanent worldwide change in public perception and expectation. Outbreaks of vaccine-preventable diseases, and the huge costs they inflict on individuals and communities, are no longer acceptable, and public demand for their control has steadily grown. As poliomyelitis fades into history, the legacy of its eradication will help shape global efforts to control infectious diseases for many years to come.

Filoviruses: Marburg and Ebola

14

Thomas G. Ksiazek

1 Historical Overview

Because of the inordinate media attention given to the filoviruses, particularly Ebola virus, a brief historical overview is in order.

1.1 Marburg Virus

In 1967 the first known appearance of the filoviruses occurred in Germany (Marburg and Frankfurt) and Yugoslavia (Belgrade) [1, 2]. The disease was associated with the import of green monkeys (*Cercopithecus aethiops*, now *Chlorocebus aethiops*) from Uganda as a source of monkey kidney cells for the manufacture of polio virus vaccine. There were 29 cases who had direct contact with the monkeys or tissues from the monkeys and an additional 6 cases among individuals who had contact with the initial patients. Seven fatalities occurred, all among the individuals with exposure to the primates or their tissues. The disease was initially called green monkey disease and the virus named after the town, Marburg, in which the initial cases were noted.

Over the ensuing months the virus was isolated by serial passage in guinea pigs and also produced disease in two species of monkey (*Chlorocebus aethiops* and *Macaca mulatta*) [3]. Interestingly, early reports suggested that there were no cytopathic effects in a variety of cell cultures, while there was suggestion of replication in the cultures by inoculation of guinea pigs with supernatant fluids of the cultures. Later reports do indicate the presence of cytopathic effect in a number of cell lines.

The virus had a distinct, long pleomorphic appearance in electron micrographs; this trait would eventually give the name to the family to which the virus belongs, the *Filoviridae*, because of the filamentous appearance of the virus.

Marburg virus appeared again in 1975 when a young Australian man, touring with his female companion in Southern Africa, became ill in South Africa after visiting Rhodesia (now Zimbabwe). He was hospitalized in Johannesburg 4 days after onset of illness and died there with rash and significant bleeding after 4 days of hospitalization. His companion, who remained at the side of the initial case constantly throughout his early illness and hospitalization, became ill 2 days after the death of the index case as did a nurse caring for him, 8 days after the death of the initial case. The companion and the nurse survived their infections [4]. The exact origin of the infection of the index patient was not clearly elucidated in the subsequent investigations [5].

2 The Dawn of Ebola Virus

In 1976 two outbreaks of a disease with similar signs and symptoms occurred more or less simultaneously in north central Zaire (now the Democratic Republic of the Congo or DRC) and in southern Sudan [6–8]. The outbreaks were larger than the initial Marburg incidents and were clearly comprised of chains of person-to-person transmission following the introduction of the infection into medical care facilities. The reuse of needles and syringes without proper sterilization was eventually thought to play a role in much of the transmission from patient to patient, at least within medical care facilities, in these outbreaks.

Material from patients was sent to a number of international laboratories, and it was soon discovered to be related to Marburg virus by its similar appearance in electron micrographs. In spite of the similarity of the appearance between Marburg virus and this new virus, there was no serological cross-reaction when reference sera from Marburg virus were reacted with this newer one or laboratory animals were cross-challenged [9].

R.A. Kaslow et al. (eds.), *Viral Infections of Humans*,
DOI 10.1007/978-1-4899-7448-8_14,

Field investigations of the Zaire and Sudan outbreaks did not yield evidence of a direct link between the outbreaks at the two locations. The virus was given the name Ebola virus after a river that is near the site of the original outbreak in Zaire. There was a single case in Zaire in 1977 [10] and another small outbreak in southern Sudan in 1979 [11, 12]. The viruses causing the outbreaks in Zaire and the outbreaks in Sudan are in fact quite distinct; however, they were not determined to be separate viruses until the early 1980s when a radioimmunoassay suggested that antibodies to the two viruses could distinguish between them [13] and then molecular biology had reached some ability to distinguish the two viruses from each other [14]. Following the 1979 outbreak in southern Sudan, there were no reported African outbreaks until 1995 when the outbreak in Kikwit, Zaire, occurred.

In 1989 Ebola virus came to the USA in, similar to the circumstances for Marburg virus in 1967 in Europe, in monkeys (cynomolgus macaques, *Macaca fascicularis*) in quarantine in Reston, Virginia, that were being imported for biomedical research into the USA from the Philippines. The monkeys were found to be dying of Ebola virus, although a second virus, Simian hemorrhagic fever virus, was also present [15]. By 1989, the ability of molecular biology to sequence and determine the relationships of viruses more easily indicated that this was a novel Ebola virus, given the name Ebola Reston, related but distinct from the two strains which had been the etiology of the Zaire and Sudan outbreaks in the 1970s, Ebola Zaire and Ebola Sudan. The outbreak was traced back to a facility in the Philippines where the imported monkeys had originated [16, 17]. There were to be further instances of monkeys from this same facility being infected with Ebola Reston, including 1992 into Italy [18, 19] and 1996 into the USA once more [20].

In 1994, a fourth Ebola virus, Ebola Ivory Coast, emerged when a female scientist studying mortality among chimpanzees in the Tai Forest National Park in Ivory Coast became ill following a postmortem exam that she had performed upon a chimp that had died. Her illness was a dengue-like syndrome, and the virus was isolated from her blood [21]. Serological testing at the Institute Pasteur in Paris and sequencing soon demonstrated that this was another novel Ebola virus.

Starting in the mid-1990s the number of Ebola virus outbreaks was more frequent and precludes individual discussion. Some of these outbreaks will be discussed in the context of their contribution to our knowledge of the diseases and viruses, but a complete listing of the occurrence of known outbreaks can be found in Table 14.1 (Marburg) and Table 14.2 (Ebola viruses). The relative size of each of these outbreaks and its location can also be seen in maps provided in Fig. 14.1 (Marburg) and Fig. 14.2 (Ebola).

Briefly, a fifth Ebola virus was discovered in late 2007 when an outbreak in western Uganda turned out to be caused by another novel and distinct virus, now known as Ebola Bundibugyo, after the Ugandan town in which the outbreak it caused was centered. Although next-generation sequencing sped up the characterization of this new virus, its novelty was indicated when targeted PCRs for the epidemic-prone viruses Ebola Zaire and Ebola Sudan failed to react, but an antigen detection assay reacted with initial patient bloods submitted to the Special Pathogens Branch at CDC in Atlanta [61]. As is common in Ebola outbreaks, much of the transmission occurred within medical facilities, where some of the initial patients sought care, and many of those subsequently infected included health-care workers [62]. In addition, the mortality associated with infection with this virus appears to be less than the Zaire and Sudan Ebola viruses [48].

Another filovirus has been associated with deaths in insectivorous bats in Spain, but the virus has not been isolated [63]. Its genetic signature appears to be between the existing Ebola viruses and Marburg virus, but its taxonomic status remains unsettled, and the host range and pathogenicity of the virus remain unknown and will probably remain so until a virus is either isolated or reconstructed from the sequence derived from the tissues of the dead bats.

3 The Virus

The filoviruses are negative-sense single-stranded RNA viruses. They are members of the family, *Filoviridae*, so named after the long filamentous appearance of the virions in electron micrographs. They belong to the order *Mononegavirales*. Marburg virus comprises one genus of the family (*Marburgvirus*), while the Ebola viruses comprise the other genus (*Ebolavirus*). The genomes are the largest of the viruses in this order having a genome of just over 19 kilobases. The order of the seven genes is similar to other members of the *Mononegavirales*, the rhabdoviruses and the paramyxoviruses. The nucleoprotein is located at the 3' end of the genome and is followed by VP35, VP40, glycoprotein, VP30, VP24, and the L (polymerase) open reading frames [64]. Several of these proteins have the ability to interfere with the immune response of the host and are believed to play a role in the high pathogenicity of the filoviruses [65–67].

4 The Disease

Infection with Marburg and Ebola viruses leads to similar diseases which are marked by inappropriate innate immune responses which both downregulate the useful antiviral effects expected in the early postinfection period and induce vigorous responses of certain cytokines and chemokines, inducing a sepsis-like syndrome with high mortality. The mortality ranges between a high of approximately 90 % seen with Ebola Zaire virus infection, followed by approximately 55 % seen with Ebola Sudan, and approximately

Table 14.1 Marburg outbreaks through 2012

Year(s)	Country	Apparent or suspected origin	Reported number of human cases	Reported number (%) of deaths among cases	Situation
1967	Germany and Yugoslavia	Uganda	31	7 (23 %)	Simultaneous outbreaks occurred in laboratory workers handling African green monkeys imported from Uganda [22]. In addition to the 31 reported cases, an additional primary case was retrospectively serologically diagnosed [23]
1975	Johannesburg, South Africa	Zimbabwe	3	1 (33 %)	A man with a recent travel history to Zimbabwe was admitted to a hospital in South Africa. Infection spread from the man to his traveling companion and a nurse at the hospital. The man died, but both women were given vigorous supportive treatment and eventually recovered [24]
1980	Kenya	Kenya	2	1 (50 %)	Recent travel history included a visit to Kitum Cave in Kenya's Mount Elgon National Park. Despite specialized care in Nairobi, the male patient died. A doctor who attempted resuscitation developed symptoms 9 days later but recovered [25]
1987	Kenya	Kenya	1	1 (100 %)	A 15-year-old Danish boy was hospitalized with a 3-day history of headache, malaise, fever, and vomiting. Nine days prior to symptom onset, he had visited Kitum Cave in Mount Elgon National Park. Despite aggressive supportive therapy, the patient died on the 11th day of illness. No further cases were detected [26]
1998–2000	Democratic Republic of Congo (DRC)	Durba, DRC	154	128 (83 %)	Most cases occurred in young male workers at a gold mine in Durba, in the northeastern part of the country, which proved to be the epicenter of the outbreak. Cases were subsequently detected in the neighboring village of Watsa. This is actually a series of small epidemics originating with miners who were working in a galleried gold mine [27]
2004–2005	Angola	Uige Province, Angola	252 [28]	227	Outbreak believed to have begun in Uige Province in October 2004. Most cases detected in other provinces have been linked directly to the outbreak in Uige [29]
2007	Uganda	Lead and gold mine in Kamwenge District, Uganda	2	2 (50 %)	Small outbreak, with 2 cases of young males working in a mine. To date, there were no reported cases among health workers [30]
2008	USA ex Uganda	Cave in Maramagambo forest in Uganda, at the southern edge of Queen Elizabeth National Park	1	0 (0)	A 44-year-old woman who resides in Colorado returned on January 1, 2008, from a Safari in Uganda. She became ill on January 4 and consulted her physician on January 6 and 8 and was hospitalized on January 8 with a diagnosis of acute hepatitis. She was discharged on January 19 with no serious sequelae. Testing of a sample drawn 10 days post-onset was initially negative by serology, virus isolation, and real-time RT-PCR. After the Dutch case, a convalescent serum was submitted which was found to be Marburg IgG positive by ELISA. A nested RT-PCR of the original sample was found to be positive for Marburg RNA [31]
2008	Netherlands ex Uganda	Cave in Maramagambo forest in Uganda, at the southern edge of Queen Elizabeth National Park	1	1 (100 %)	A 40-year-old Dutch woman with a recent history of travel to Uganda was admitted to a hospital in the Netherlands. Three days prior to hospitalization, the first symptoms (fever, chills) occurred, followed by rapid clinical deterioration. The woman died on the 10th day of the illness [32, 33]

(continued)

Table 14.1 (continued)

Year(s)	Country	Apparent or suspected origin	Reported number of human cases	Reported number (%) of deaths among cases	Situation
2012	Uganda	Kabale, Ibanda, Kampala, and Mbarara Districts	23	8 (35 %)	As of November 29, 2012, the Ugandan Ministry of Health reported 15 confirmed and 8 probable cases of Marburg virus infection, including 15 deaths, in the Kabale, Ibanda, Mbarara, and Kampala Districts of Uganda. Testing of samples by CDC's Viral Special Pathogens Branch is ongoing at the Uganda Virus Research Institute in Entebbe. Working with the Ministry's National Task Force, a CDC team is assisting in the diagnostic and epidemiologic aspects of the outbreak. Note that Kabale District, on the border with neighboring Rwanda, is distinct from Kibaale District, the site of the recently ended Ebola outbreak; both districts are in Uganda's Western Region [34]

Table 14.2 Outbreaks caused by Ebola viruses through 2012

Year(s)	Country	Ebola subtype	Reported no. of human cases	Reported no. (%) of deaths among cases	Situation
1976	Zaire [Democratic Republic of Congo(DRC)]	Ebola Zaire	318	280 (88 %)	Occurred in Yambuku and surrounding area. Disease was spread by close personal contact and by use of contaminated needles and syringes in hospitals/clinics. This outbreak was the first recognition of the disease [8]
1976	Sudan	Ebola Sudan	284	151 (53 %)	Occurred in Nzara, Maridi, and the surrounding area. Disease was spread mainly through close personal contact within hospitals. Many medical care personnel were infected [7]
1976	England	Ebola Sudan	1	0 (0 %)	Laboratory infection by accidental stick of contaminated needle [35]
1977	Zaire	Ebola Zaire	1	1 (100 %)	Noted retrospectively in the village of Tandala [10]
1979	Sudan	Ebola Sudan	34	22 (65 %)	Occurred in Nzara, Maridi. Recurrent outbreak at the same site as the 1976 Sudan epidemic [36]
1989	USA	Ebola Reston	0	0 (0 %)	Ebola Reston virus was introduced into quarantine facilities in Virginia, Texas, and Pennsylvania by monkeys imported from the Philippines [15]
1990	USA	Ebola Reston	0	0 (0 %)	Ebola Reston virus was introduced once again into quarantine facilities in Virginia and Texas by monkeys imported from the Philippines. Four humans developed antibodies but did not get sick [37]
1989–1990	Philippines	Ebola Reston	4 (asymptomatic)	0 (0 %)	High mortality among cynomolgus macaques in a primate facility responsible for exporting animals in the USA [17]. Three workers in the animal facility developed antibodies but did not get sick [16]
1992	Italy	Ebola Reston	3 (asymptomatic)	0 (0 %)	Ebola Reston virus was introduced into quarantine facilities in Sienna by monkeys imported from the same export facility in the Philippines that was involved in the episodes in the USA. No humans were infected [18]
1994	Gabon	Ebola Zaire	52	31 (60 %)	Occurred in Mékouka and other gold-mining camps deep in the rain forest. Initially thought to be yellow fever; identified as Ebola hemorrhagic fever in 1995 [38]
1994	Ivory Coast	Ebola Ivory Coast	1	0 (0 %)	Scientist became ill after conducting an autopsy on a wild chimpanzee in the Tai Forest. The patient was treated in Switzerland [21]

Table 14.2 (continued)

Year(s)	Country	Ebola subtype	Reported no. of human cases	Reported no. (%) of deaths among cases	Situation
1995	Democratic Republic of the Congo (formerly Zaire)	Ebola Zaire	315	250 (81 %)	Occurred in Kikwit and surrounding area. Traced to index case patient who worked in the forest adjoining the city. Epidemic spread through families and hospitals [38, 39]
1996 (Jan–April)	Gabon	Ebola Zaire	37	21 (57 %)	Occurred in Mayibout area. A chimpanzee found dead in the forest was eaten by people hunting for food. Nineteen people who were involved in the butchery of the animal became ill; other cases occurred in family members [38]
1996–1997 (July–Jan)	Gabon	Ebola Zaire	60	45 (74 %)	Occurred in Booué area with transport of patients to Libreville. Index case patient was a hunter who lived in a forest camp. Disease was spread through close contact with infected persons. A dead chimpanzee found in the forest at the time was determined to be infected [38]
1996	South Africa	Ebola Zaire	2	1 (50 %)	A medical professional traveled from Gabon to Johannesburg, South Africa, after having treated Ebola virus-infected patients and thus having been exposed to the virus. He was hospitalized, and a nurse who took care of him became infected and died [40]
1996	USA	Ebola Reston	0	0 (0 %)	Ebola Reston virus was introduced into a quarantine facility in Texas by monkeys imported from the Philippines. No human infections were identified [20]
1996	Philippines	Ebola Reston	0	0 (0 %)	Ebola Reston virus was identified in a monkey export facility in the Philippines. No human infections were identified; one animal handler has Ebola antibody [41]
2000–2001	Uganda	Ebola Sudan	425	224 (53 %)	Occurred in Gulu, Masindi, and Mbarara Districts of Uganda. The three most important risks associated with Ebola virus infection were attending funerals of Ebola hemorrhagic fever case patients, having contact with case patients in one's family, and providing medical care to Ebola case patients without using adequate personal protective measures [42]
2001–2002 (Oct 1–March 2)	Gabon	Ebola Zaire	65	53 (82 %)	Outbreak occurred over the border of Gabon and the Democratic Republic of the Congo [43]
2001–2002 (Oct 1–March 2)	Democratic Republic of Congo	Ebola Zaire	57	43 (75 %)	Outbreak occurred over the border of Gabon and the Democratic Republic of the Congo. This was the first time that Ebola hemorrhagic fever was reported in the Democratic Republic of the Congo [43]
2002–2003 (Dec 2–April 03)	Democratic Republic of Congo	Ebola Zaire	143	129 (89 %)	Outbreak occurred in the districts of Mbomo and Kéllé in Cuvette Ouest Département [44]
2003 (Nov–Dec)	Democratic Republic of Congo	Ebola Zaire	35	29 (83 %)	Outbreak occurred in Mbomo and Mbandza villages located in Mbomo District, Cuvette Ouest Département [45]
2004	Sudan	Ebola Sudan	17	7 (41 %)	Outbreak occurred in Yambio county of southern Sudan. This outbreak was concurrent with an outbreak of measles in the same area, and several suspected EHF cases were later reclassified as measles cases [46]
2007	Democratic Republic of Congo	Ebola Zaire	264	187 (71 %)	Outbreak occurred in Kasai Occidental Province. The outbreak was declared over November 20. Last confirmed case on October 4 and last death October 10 [47]
Dec 2007–Jan 2008	Uganda	Ebola Bundibugyo	131	42 (32 %)	Outbreak occurred in the Bundibugyo District in western Uganda. First reported occurrence of a new strain [48, 49]

(continued)

Table 14.2 (continued)

Year(s)	Country	Ebola subtype	Reported no. of human cases	Reported no. (%) of deaths among cases	Situation
Nov 2008	Philippines	Ebola Reston	6 (asymptomatic)	0 (0 %)	First known occurrence of Ebola Reston in pigs. Strain closely similar to earlier strains. Six workers from the pig farm and slaughterhouse developed antibodies but did not become sick [50, 51]
Dec2008–Feb 2009	Democratic Republic of the Congo	Ebola Zaire	32	15(47 %)	Outbreak occurred in the Mweka and Luebo health zones of the Province of Kasai Occidental [52]
May 2011	Uganda	Ebola Sudan	1	1(100 %)	Single case in Luwero District, Uganda [53]
July 2012	Uganda	Ebola Sudan	24	7(29 %)	On July 28, 2012, the Uganda Ministry of Health reported an outbreak of Ebola hemorrhagic fever in the Kibaale District of Uganda. A total of 24 human cases (probable and confirmed only), 17 of which were fatal, have been reported since the beginning of July. Laboratory tests of blood samples, conducted by the Uganda Virus Research Institute (UVRI) and the US Centers for Disease Control and Prevention (CDC), confirmed Ebola virus in 11 patients, four of whom have died [54]
2012	Democratic Republic of the Congo	Ebola Bundibugyo	77	36 (47 %)	The DRC Ministry of Health has declared an end to the most recent Ebola outbreak in DRC's Province Orientale. The November 26 press release reports a final total of 77 cases, including 36 laboratory-confirmed cases, 17 probable, and 24 suspect cases, with a total of 36 deaths. CDC assisted the Ministry of Health in the epidemiologic and diagnostic aspects of the investigation. Laboratory support was provided both through CDC's field laboratory in Isiro and through the CDC/UVRI lab in Uganda. The Public Health Agency of Canada (PHAC) also provides diagnostic support through its field lab in Isiro. The outbreak in DRC has no epidemiologic link to the near-contemporaneous Ebola outbreak in the Kibaale district of Uganda [55–57]
2012	Uganda	Ebola Sudan	7	4 (57 %)	As of December 2, 2012, the Ugandan Ministry of Health reported 7 cumulative cases (probable and confirmed) of Ebola virus infection, including 4 deaths, in the Luweero District of central Uganda. CDC is assisting the Ministry of Health in the epidemiologic and diagnostic aspects of the outbreak. Testing of samples by CDC's Viral Special Pathogens Branch is taking place at the Uganda Virus Research Institute in Entebbe [58]
2014	Guinea and Liberia	Ebola-Zaire	(See situation)	(See situation)	Guinea [59] As of 18:00 on 26 April 2014, the Ministry of Health (MOH) of Guinea has reported a cumulative total of 224 clinical cases of Ebola Virus Disease (EVD), including 143 deaths. To date, 202 patients have been tested for ebolavirus infection and 121 cases have been laboratory confirmed, including 74 deaths. In addition, 41 cases (34 deaths) meet the probable case definition for EVD and 62 cases (35 deaths) are classified as suspected cases. A revised number of 25 health care workers (HCW) have been affected (19 confirmed), with 16 deaths (12 confirmed); the number of HCW was previously reported as 26.
					Liberia [60] From 13 March, the date of onset of the first laboratory confirmed case in Liberia, to 24 April, the Ministry of Health and Social Welfare (MOHSW) of Liberia has reported a total of 35 clinically compatible cases of EVD; 6 confirmed cases, 2 probable cases and 27 suspected cases. The date of onset of the most recent confirmed case was 6 April. The MOHSW has started to reclassify suspected cases against their laboratory test results. Most of the suspected cases are expected to be discarded at the end of this process

Adapted from CDC. http://www.cdc.gov/ncidod/dvrd/spb/mnpages/dispages/ebola/ebolatable.htm

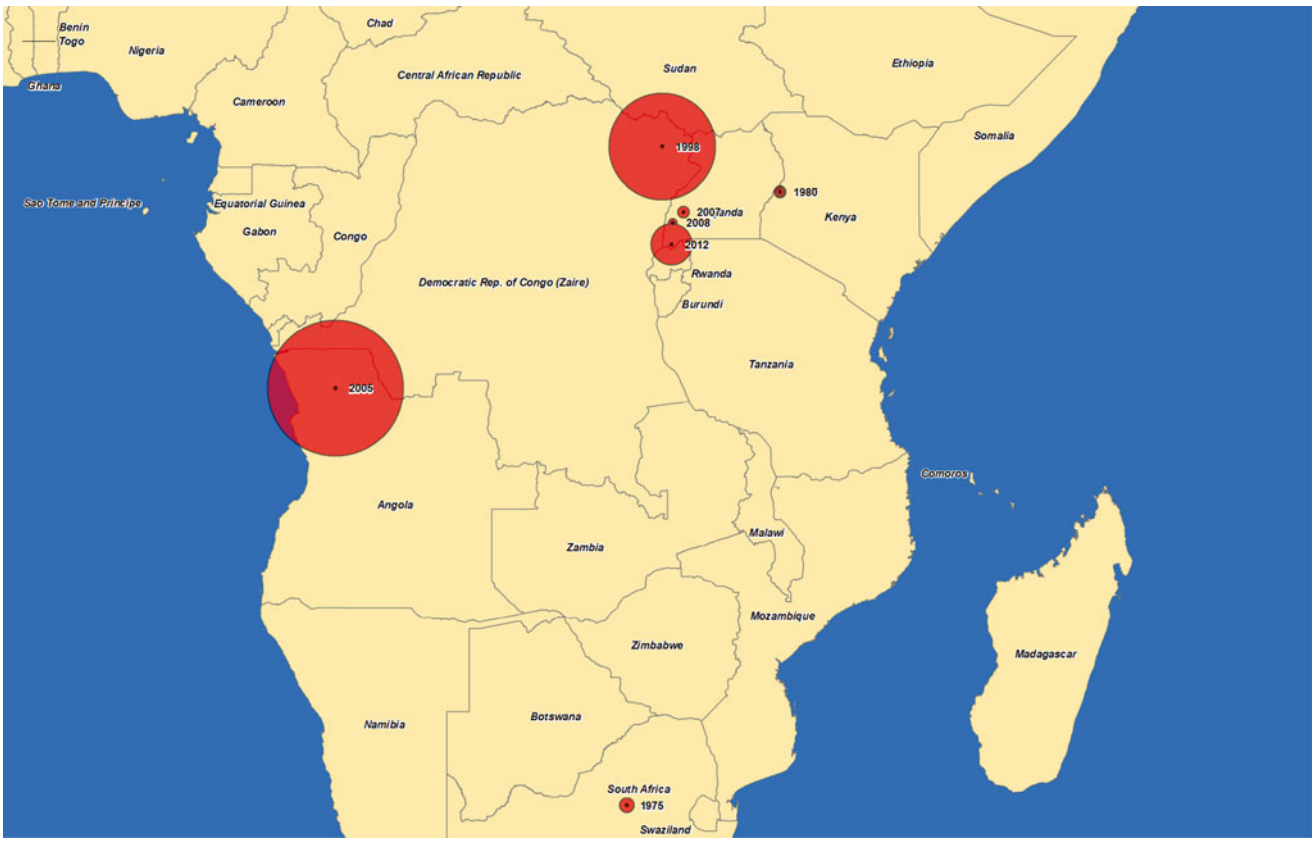

Fig. 14.1 Map of African Marburg virus outbreaks and year in which they occurred. The circles are proportional to the number of cases in the outbreak (see Table 14.1 for the number of cases). Note that the 1980 date obscures the date of the 1987 case, both of which originated at the same location, Kitum Cave on Mt. Elgon. The 1998 outbreak in DRC was actually a series of small outbreaks associated with a mine near the village of Durba which continued through 2000

35 % seen with Ebola Bundibugyo, the three viruses that seem to have epidemic potential. Ebola Ivory Coast has had too few infections, one or perhaps two, to allow a useful estimate of the mortality, while Ebola Reston has so far not caused mortality in the 10s of persons that have been infected. Marburg virus outbreaks have tended to be smaller, often with only one or two individuals infected, but there also may be strain differences in the mortality. Among the three outbreaks with significant numbers infected, the initial outbreak in Germany produced an overall mortality of approximately 23 % (7 of 30 or 31) [22, 23], while the small clusters constituting the 1998–2001 composite cases in the DRC outbreak had an overall mortality of 82 % (123/149) [27], and the 2005 outbreak in Uige, Angola, had a mortality of 90 % (227/252) [29].

In human cases, there is an incubation period of 5–7 days followed by onset of fever, weakness and often muscle pains, and abdominal discomfort. Rash is also a common feature, but in dark-skinned patients, it is not always apparent. Bleeding is not the common manifestation that many believe is the hallmark of the disease. In the Kikwit outbreak of Ebola Zaire in 1995, less than 50 % of the lab-confirmed cases had bleeding signs. The viruses are considered to be pantropic, infecting many tissues and also infecting many cell lines from a great many mammalian species [68]. Among those with bleeding signs, petechiae, ecchymoses, and gastrointestinal bleeding along with failure of venipuncture sites to clot are the most common forms of bleeding. Nevertheless the disease is severe and vascular permeability, loss of fluids from the GI tract from diarrhea and vomiting, and diminished fluid intake all combine with the effects of the inappropriate immune response to induce shock and eventual multiorgan failure.

Patients who do survive often have prolonged recoveries with hair loss and desquamation of areas initially affected by rash. Weakness, myalgias, and arthralgias were also common among survivors of the Kikwit outbreak in which convalescent survivors were compared to controls. In human cases, lesions are common throughout the tissues with endothelial cells and macrophages in many organs having demonstrable virus antigens as well as histological changes and virus antigens in the parenchyma [69–71].

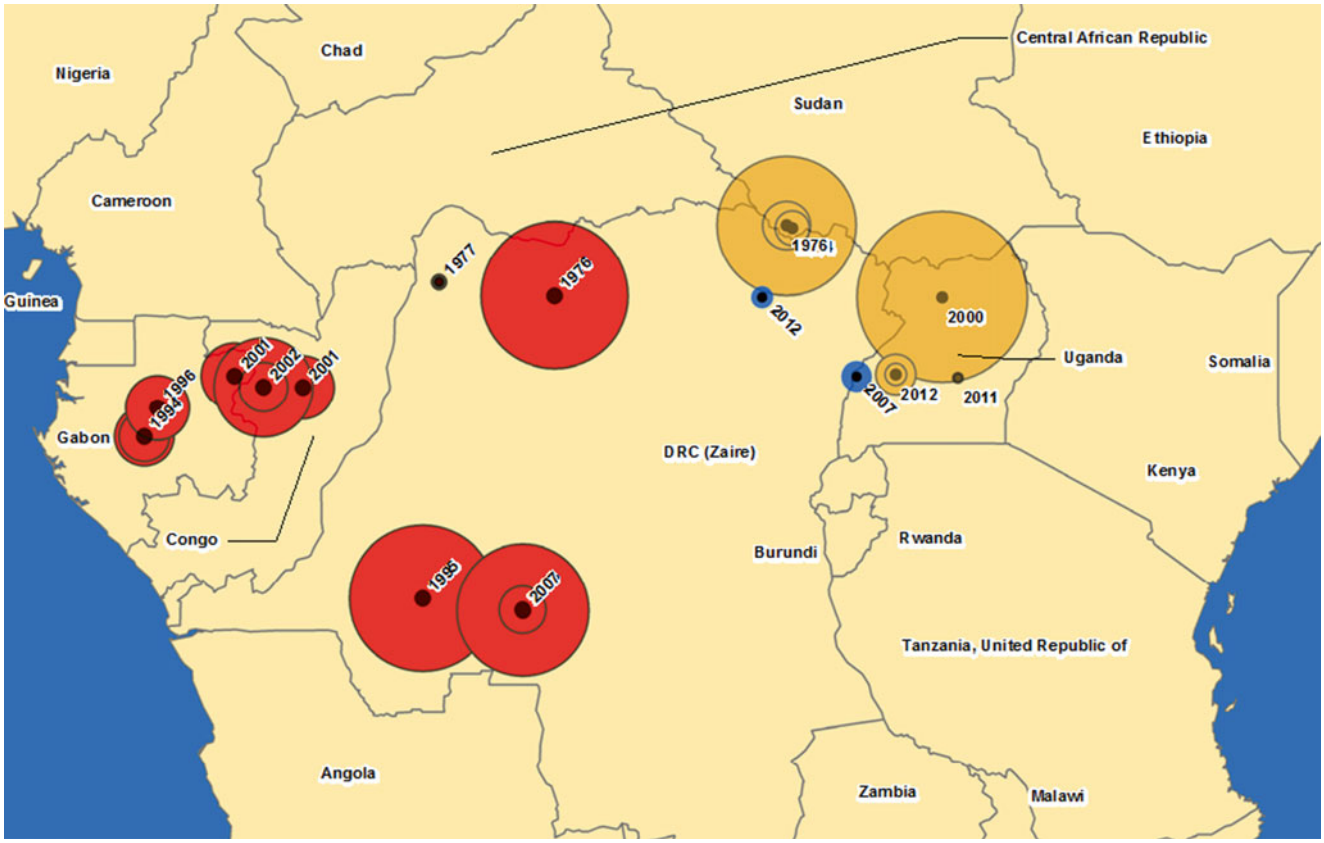

Fig. 14.2 Map of African Ebola virus outbreaks and the year in which each occurred. The circles are proportional to the number of cases in the outbreak (see Table 14.2 for the number of cases). The color of circles indicates which Ebola virus caused the outbreak: Ebola Zaire (*red*), Ebola Sudan (*burnt orange*), and Ebola Bundibugyo (*blue*). In order to show sufficient detail of the area in which the majority of outbreaks have occurred, the 1994 single case of Ebola Ivory Coast is not shown, and the 1996 South African imported case of Ebola Zaire is not shown. The 1976, 1979, and 2004 Ebola Sudan outbreaks overlap each other and the dates are obscured in the figure

5 Laboratory Diagnosis

As for all virus diseases, detection of the virus (or its antigens or nucleic acids) or detection of the resulting antibody response in patients is the primary means of confirming a specific diagnosis. Virus antigens are also found in the skin, a feature which has been exploited to allow for diagnosis using skin biopsies fixed in formalin, which may aid in surveillance for the filoviruses. Until the early 1990s, virus isolation and identification by electron microscopy or reference immune reagents remained the definitive means of definitive diagnosis. This was difficult as high-containment laboratories, of which there were very few in the world, were required to carry out this work safely. Detection of antibodies was also somewhat fraught with issues as the indirect fluorescent antibody test was prone to yield false positives in the sera of individuals who had no previous exposure to filoviruses and the antibody response requires some time to become apparent, and in many instances patients died without yet having detectable antibodies. Following the outbreak of a new Ebola virus in Reston in 1989, a number of newer technologies were applied to the diagnosis of Ebola virus infections. An antigen detection assay, utilized extensively in the Reston outbreak and its investigation, allowed for a rapid and specific identification of Ebola virus in the blood of acutely ill individuals even in remote areas [72]. Continued difficulties with the nonspecific detection of antibodies by the indirect fluorescent antibody test in primates during the Reston investigation led to the adaption of enzyme-linked immunosorbent assays to the detection of both IgM antibody in acute Ebola infections and IgG antibody in individuals surviving infection [73] and the application of these assays to human patients in the Kikwit outbreak [74]. These assays also had the advantage that they could be adapted for use in the field during outbreaks or outbreak investigations by utilizing appropriate personal protective equipment and inactivating the clinical specimens using heat and detergent. This allowed the diagnosis of patients quickly in either onsite or at a local laboratory, depending on the logistical support and demands of the particular outbreak. At about the same time that the antigen detection and serological assays were being developed, the

use of reverse transcriptase-polymerase chain reactions for the detection and diagnosis of RNA viruses advanced where it too began to play a role in Ebola diagnosis [75] which eventually led to it being deployed to the field setting along with the ELISA tests [29, 76]. Another means of diagnosis, particularly useful in remote areas, was described and shown to be of utility during the Kikwit outbreak and employs the use of formalin-fixed skin snips as a means of avoiding invasive postmortem exams and the safety and convenience of using formalin for transport of the biopsy to a suitable laboratory for diagnostic testing [72].

6 Epidemiology and Ecology

6.1 Epidemiology

The epidemiology of the filoviruses is largely comprised of the person-to-person transmission that occurs once the virus has been introduced into the human population. The distribution of the virus and, for the most part, the disease is dictated by the underlying ecology of these zoonotic viruses that reside in reservoir or maintenance hosts.

The high mortality associated with filovirus infection has created an aura of fear associated with the outbreaks. At a local level, particularly in the developing world where the virus appears to be resident, this is understandable. The history of outbreaks is marked by caregivers as early victims of the disease. However, intense investigations during more recent outbreaks have provided valuable information on how transmission occurs and the level of protection that is necessary to protect caregivers and aid in stopping the chain of transmission that continues to fuel the epidemics. This was afforded by an earlier response than had occurred in the initial Ebola outbreaks of the 1970s and was particularly taken advantage of during the Kikwit outbreak in 1995.

The principle lessons are that transmission of the filoviruses is by direct contact with infectious material and that moderate infection control practices, rigorously applied and controlled, can almost immediately stop transmission [77]. In most of the endemic areas, this is a matter of providing resources and training to health-care facilities where they may be available on only a limited basis and are not routinely used in the everyday practice of health care. In the developed world, standards of care and the employment of standard precautions for patient contact have addressed the majority of the risks associated with caring for patients with these infections as has been demonstrated in a number of instances of imported cases where no, or, at worst, very limited, transmission to care givers has occurred [31, 40].

Risks to individuals in the community who do not have direct contact with infected patients are practically nonexistent. Assessment of risks during the outbreak in Kikwit gave ample testament to the association of infection to exposure to seriously ill patients or the cadavers of individuals who had died of Ebola infection [78, 79]. Nevertheless, some care and education to avoid transmission via blood-borne routes by traditional medicine practices or reuse of needles in local pharmacies remain a concern.

Even though the filoviruses can be readily transmitted by the experimental creation of small particle aerosols, the role of aerosol transmission in outbreaks is, at most, minimal as attested by the lack of transmission in the community, other than by direct contact, and by studies of family members sharing small enclosed spaces with infected patients [78].

6.2 Ecology

The reservoirs of the filoviruses are just beginning to be understood, and only recently has the primary host for Marburg virus, rousette fruit bats (*Rousettus aegyptiacus*), been established with a degree of certainty [80–82]. The reservoir host(s) for the Ebola viruses is less certain, but indications are that, like Marburg virus, bats are the leading candidates [83, 84]. Anecdotal accounts of outbreaks going back to the Sudan outbreaks of the 1970s, in which the initial cases in both 1976 and 1979 worked in a cotton factory in which there were resident bats [85], have suggested to many in the field that bats were leading candidates, but hard scientific data was lacking until more recent circumstances provided stronger circumstantial and scientific support for this contention.

The big break for Marburg virus came when an outbreak in Durba in the Democratic Republic of Congo (formerly Zaire) which began in 1999 provided a combination of scientific and circumstantial evidence that led to further concentration on bats as the reservoir. The outbreak in this instance was not a typical filovirus outbreak with a single introduction of the virus and a serial passage of that virus through a chain of human cases; rather, in this instance, it was a series of small outbreaks. This could be discerned because the viruses that caused each of the mini-outbreaks could be genetically differentiated and the epidemiology of each small chain leads back to a single source of the virus. This source was a former commercial mine now being exploited by free-lance miners who were at the beginning of the transmission chain for each of the small mini-outbreaks [27]. Investigation of the mine found that bats were the principal fauna and genetic evidence of Marburg virus could be found in animals collected during the investigation [86]. These findings were further advanced by investigations of cases occurring or originating in Uganda that were associated with large concentrations of bats first at the Kamwenge mines [28, 30], where miners were infected, and then at a cave in Queen Elizabeth Park, where two tourists became infected [31, 32].

Subsequent investigations of the bat populations have allowed the repeated isolation of the virus from the rousette bats that are the principal fauna of these two locations and the demonstration of the persistence of the virus in the bat populations [80, 81].

7 Prevention

Prevention of filovirus outbreaks is possible. In the first instance, now that the reservoirs of the viruses are becoming apparent, education of local populations should enable them to avoid the source of the virus. However, this may be culturally difficult in hunter-gatherer populations that have strong traditional values that may be difficult to change, particularly in economically developing areas where hunting remains an important source of nutrition.

7.1 Infection Control

Outbreaks of disease are more often the product of exposure of individuals to the primary case who is infected by interaction with the reservoir. The lesson of the last 20 years is that infection control in health-care facilities, often the source of amplification of outbreaks, can stop the transmission of the viruses from patients in these settings. Unfortunately, this does require that these facilities have the basic supplies that are part of the daily routine of medical care in the developed world, what have come to be known as standard precautions. Without the ability to use these simple measures, including routine hand washing and single use of needles and syringes, outbreaks are likely to continue to be amplified by health-care facilities in the endemic areas.

7.2 Vaccines

Vaccines are being developed and have reached a stage where nonhuman primates can be protected from infection by Ebola and Marburg viruses [87–91]. Some of these vaccines have even demonstrated their potential use as therapeutics for treatment of individuals following exposure to a filovirus if the vaccine is administered relatively soon after infection [92]. While almost all funding for the development of filovirus vaccines is driven by biodefense concerns, the vaccines are of practical use in providing protection to individuals who have occupational exposure because they work with the agents in the laboratory and to individuals who respond to outbreaks that have similar risks of exposure from caring for patients in the field. There, in reality, is probably little use for filovirus vaccines as a means of protecting populations in endemic areas because the outbreaks are so sporadic and focal that the cost of immunization would not be economically viable; at best they might be used in the midst of an outbreak to provide protection to at-risk individuals, particularly if the protection is rapid, as the postexposure treatment use of certain of these vaccines is effective as pointed out above. One added note about the use of vaccines, there is at best limited cross-protection among the Ebola virus vaccines, and no cross-protection between Marburg virus and Ebola viruses; multivalent vaccines will have to be developed or the vaccines targeted at outbreaks with known filovirus etiology.

8 Treatment

Aside from vaccines used postexposure, there have been some advances in therapeutics for filoviruses.

8.1 Monoclonal Antibodies

Monoclonal antibodies have recently been shown to protect nonhuman primates against Ebola Zaire infection [92–95]. Efforts are underway to improve the utility of some of these preparations by making them more compatible for use as human therapeutics. As was the case for the vaccines, the monoclonal preparations are directed against specific filoviruses and would be most effective when used in situations where the specific virus causing disease was known. Monoclonal antibody cocktails would be needed to broaden protection against multiple viruses.

8.2 iRNAs

Specific iRNAs have recently been shown to be effective in the treatment of Ebola virus-infected animals [96, 97]. However, like vaccines, these are targeted and exhibit specificity of action which means that a cocktail of iRNAs would be required for situations in which the virus was not yet identified or if a new filovirus were to appear. Closely related to the use of iRNAs has been the use of antisense phosphorodiamidate morpholino oligomers (PMOs) which are also targeted at specific RNA sequences but increase the stability, affinity, and access into cells of the antisense nucleotides. In a recent study, they have been used and demonstrated to successfully treat up to 75 % of rhesus macaques from Ebola Zaire infection when used either pre- or post-virus challenge [98].

8.3 Small Molecule Inhibitors

Other small molecule inhibitors of the viruses have been described from in vitro screening exercises or testing of

compounds with antiviral activity with other non-filovirus viruses. However, there has only been limited screening of these compounds in in vivo screening in filovirus small animal models, which have not been great predictors of positive performance of vaccines and antiviral drugs in primates [99].

9 Unresolved Problems

Even though the reservoir of Marburg virus is now reasonably established as the cave-dwelling fruit bat, *Rousettus aegyptiacus*, the definitive reservoir of the Ebola viruses has remained elusive. As discussed in previous sections, although a number of species of fruit bats have been identified by RT-PCR as containing Ebola virus RNA, virus isolation and studies demonstrating persistence of the virus in reservoir populations remain lacking.

There remain a number of issues with the filoviruses. The foremost is probably the lack of approved vaccines or therapeutics for use in the rare individuals who are exposed in endemic areas during epidemics or individuals exposed during the course of lab work with the agents. Much progress has been made in finding candidate vaccines that have been effective in experimental use in primates, but the regulatory pathway for licensure of these products is dependent on the application of the so-called animal rule. This mechanism went into effect as a means of approving medical countermeasures that are unable to undergo traditional efficacy trials for ethical or practical reasons as 21 CFRParts 314 and 601 in July, 2002. However, the interpretation and implementation of the animal rule have remained a somewhat controversial pathway for product approval with much interpretation of various facets of the rule remaining illusive and resulting in only a few products being approved (and those being for medical countermeasures previously licensed for other purposes) [100, 101]. These issues will have to be resolved to provide a predictable pathway for approval of medical countermeasures for the filoviruses.

Field and laboratory research on the filoviruses have never been simple. High-containment laboratories capable of doing research have always been scarce. The post-9/11 environment has created other obstacles that are associated with these viruses being considered as "weapons of mass destruction" that have tangibly increased the practical burdens and expense of working with the agents. The public health importance of the filoviruses in endemic areas is emphasized by the number of outbreaks that have occurred recently (see Tables 14.1 and 14.2). The practical and administrative aspects of moving diagnostic specimens from suspected outbreaks, making virus isolates, curating virus strains, and clearing and training scientific personnel have all increased with the frequent advent of additional layers of security regulations that are levied on labs and personnel that work with these viruses.

Flaviviruses: Dengue

15

Stephen J. Thomas, Timothy P. Endy,
and Alan L. Rothman

1 Introduction

Dengue is the world's most important human arboviral disease with indigenous and endemic transmission in more than 100 tropical and subtropical countries. There are numerous other locales that experience non-sustained epidemic transmission with cases in returning travelers or military personnel [1, 2]. More than half the population of the world is at risk of being infected with a dengue virus (DENV). Despite its importance dengue is under-recognized and underreported with current literature estimating 400 million infections each year with 100 million being clinically apparent [3]. The human, community, country, and regional cost of dengue in terms of mortality, morbidity, and health care resource utilization is significant and growing in scope [4–9]. There are numerous factors that are believed to contribute to the increase in dengue burden, which include (1) rising number of susceptible hosts (population growth), (2) expanding *Aedes* mosquito vector populations (ineffective vector control, increasing breeding sites, changing ecology), (3) increasing DENV distribution (travel), and (4) the convergence of the these three: urbanization, poverty, and decaying infrastructure [10–12].

DENV infection produces a spectrum of clinical presentations from asymptomatic infection to a nonspecific febrile illness termed dengue fever (DF) to severe dengue known as dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS) [13]. The original World Health Organization (WHO) clinical classification scheme has recently been under review and an alternative classification has been proposed to account for instances where biochemical and clinical markers of severe disease are present in cases of otherwise uncomplicated dengue fever. Reconciling the value of the new scheme for both research and patient care purposes has been controversial [14–18]. Why some human-vector-virus interactions result in infection and others do not and why some infections result in no disease and others severe multisystem organ failure and death are incompletely understood. The pathophysiology of dengue is multifactorial with host (age, gender, clinical comorbidities, immunologic background), vector (salivary proteins), and virus (type and genotype virulence, escape mutants) factors and the interplay between them all playing a role [19–23]. There is no licensed anti-dengue antiviral or vaccine to treat or prevent dengue disease. Vector control, except in rare circumstances, has been insufficient to significantly curtail dengue expansion. Fortunately, there are numerous efforts underway to explore methods to strategically and effectively reduce vector populations or alter their ability to become infected and/or transmit dengue [24, 25]. Anti-dengue therapeutic development efforts have focused primarily on reducing viral burden (as measured in the peripheral circulation) or reducing the magnitude of the host pro-inflammatory response. New drug development and seeking new indications for existing drugs are both being actively explored [26–28]. The dengue vaccine pipeline is abundant with candidates at various stages of preclinical and clinical development [29–32].

2 Historical Background

Dengue's nonspecific clinical features make the interpretation of historical records for evidence of past epidemics difficult. David Bylon is sometimes credited with the first clinical description of dengue [33]. In 1779, he observed an epidemic of febrile disease in Batavia, a disease he termed "knokkel-koorts," knuckle or joint fever [34]. At the same time (1779), August Hirsch described a similar epidemic in Cairo [35]. Dr. Benjamin Rush provided one of the first in-depth clinical descriptions of dengue after observing numerous patients during a 1780 epidemic in Philadelphia, Pennsylvania [36]. Rush wrote, "…its more general name among all classes of people was, the Break-bone fever." The term "dengue" is derived from the Swahili phrase "Ka dinga pepo," where Ka means "a kind of"; dinga, "sudden cramp-like seizure"; and pepo, "plague." The phrase is believed to have crossed from Africa to the Caribbean in 1827 [37, 38]. Cubans identified this phrase with the Spanish word "dengue," which represented the painful and stiff gait of people afflicted with the disease. Spanish archives indicate the use of "quebranta huesos" (breakbone) by a physician in Puerto Rico describing a febrile illness in 1771 and the use of "dengue" by the Queen of Spain in 1801 to describe an acute febrile illness with bone and joint pains, hemorrhage, and jaundice [39].

Early research into the etiology of dengue implicated bacteriological, protozoan, and spirochetal causes [40, 41]. Ashburn and Craig provided evidence for the viral etiology of dengue making it the second human viral pathogen identified after the yellow fever virus [40, 42, 43]. Siler and colleagues built upon the work of Graham in exploring the dengue vector and transmission dynamics [41, 44]. Large outbreaks during World War II and human infection experiments resulted in the isolation of dengue virus types 1 and 2, identified the presence and possible protective role of anti-dengue virus neutralizing antibodies, and described the protective and disease attenuating capacity of homotypic and heterotypic immunity, respectively [43, 45, 46]. In 1956, a dengue epidemic occurred in Manila resulting in the identification and naming of dengue virus type 3 and 4 viruses [47].

Dengue has a consistent presence in Asia and a sporadic pattern in the Americas. In 1897, North Queensland reported a dengue outbreak clinical manifested as epistaxis, hematemesis, and gingival bleeding [48]. Severe dengue was implicated in major disease outbreaks in Greece in 1928 and in Formosa in 1931 [49–51]. After World War II, intensified and sequential transmission of multiple dengue virus types began in Southeast Asia, leading to hemorrhagic fever outbreaks. In the 1950s, the dengue viruses would be associated with Philippine hemorrhagic fever and Thai hemorrhagic fever, both later identified as dengue hemorrhagic fever (DHF) [52, 53]. Outbreaks in the Americas have been postulated since the 1600s, associated with dengue virus introduction into port cities by international commerce. Vector eradication efforts initiated in the 1940s were initially successful, but the program ultimately ended and reinfestation and the return of dengue occurred in the region by the early 1980s [54]. Dengue has been increasingly reported from the Middle East and Africa reaffirming the global spread of dengue [55, 56].

3 The Dengue Viruses

3.1 Evolution of the Dengue Viruses

The evolution of the flaviviruses has been covered in another chapter (Chap. 16). This section covers specifically the evolution of the dengue viruses (DENV) and why understanding its evolution is important in how these viruses have evolved into a global health problem and challenging dengue vaccine development. The dengue viruses evolved in fundamentally different ways from their flavivirus brothers though retaining the properties responsible for the characteristics of flaviviral infection in humans such as fever, myalgias, headache, hepatitis, encephalitis, and in particular hemorrhagic fever. The continent of origin of the dengue viruses is not known, though circumstantial evidence suggests an African origin based on the many flaviviruses that circulate there now, its principal mosquito vector *Aedes aegypti* is thought to have originated in Africa, and DENV circulates in an African sylvatic cycle with nonhuman primates [57]. An argument can be made that the DENVs originated in Asia or perhaps evolved into four separate serotypes in Asia based on the hyperendemicity of DENV in this geographic region and the phylogenetic relationship of the Asian sylvatic strains to current circulating DENV strains [58, 59]. It is estimated that DENV evolved into four antigenically distinct serotypes approximately 1,000 years ago, and each of these four serotypes emerged independently into a non-sylvatic endemic cycle of transmission between humans and *Aedes aegypti* approximately 125–320 years ago [59, 60]. The Asian relationship of the DENV is historically important as the first cases of the more severe form of DENV infection, dengue hemorrhagic fever (DHF), made its appearance in the 1950s first in the Philippines and then in Thailand [61]. The current Asian strains of each serotype are considered more severe than the American strains [62]. The evidence suggests that Asia plays a pivotal role historically and currently in creating viruses that produce severe illness and due to its population growth and urbanization, contributing to the increase in genetic diversity which has increased by a factor between 14 and 20 in the last 30 years [63]. In prospective cohort studies in Northern Thailand and hospitalized children in Bangkok, rates of genetic diversity have been high among all serotypes in any given year,

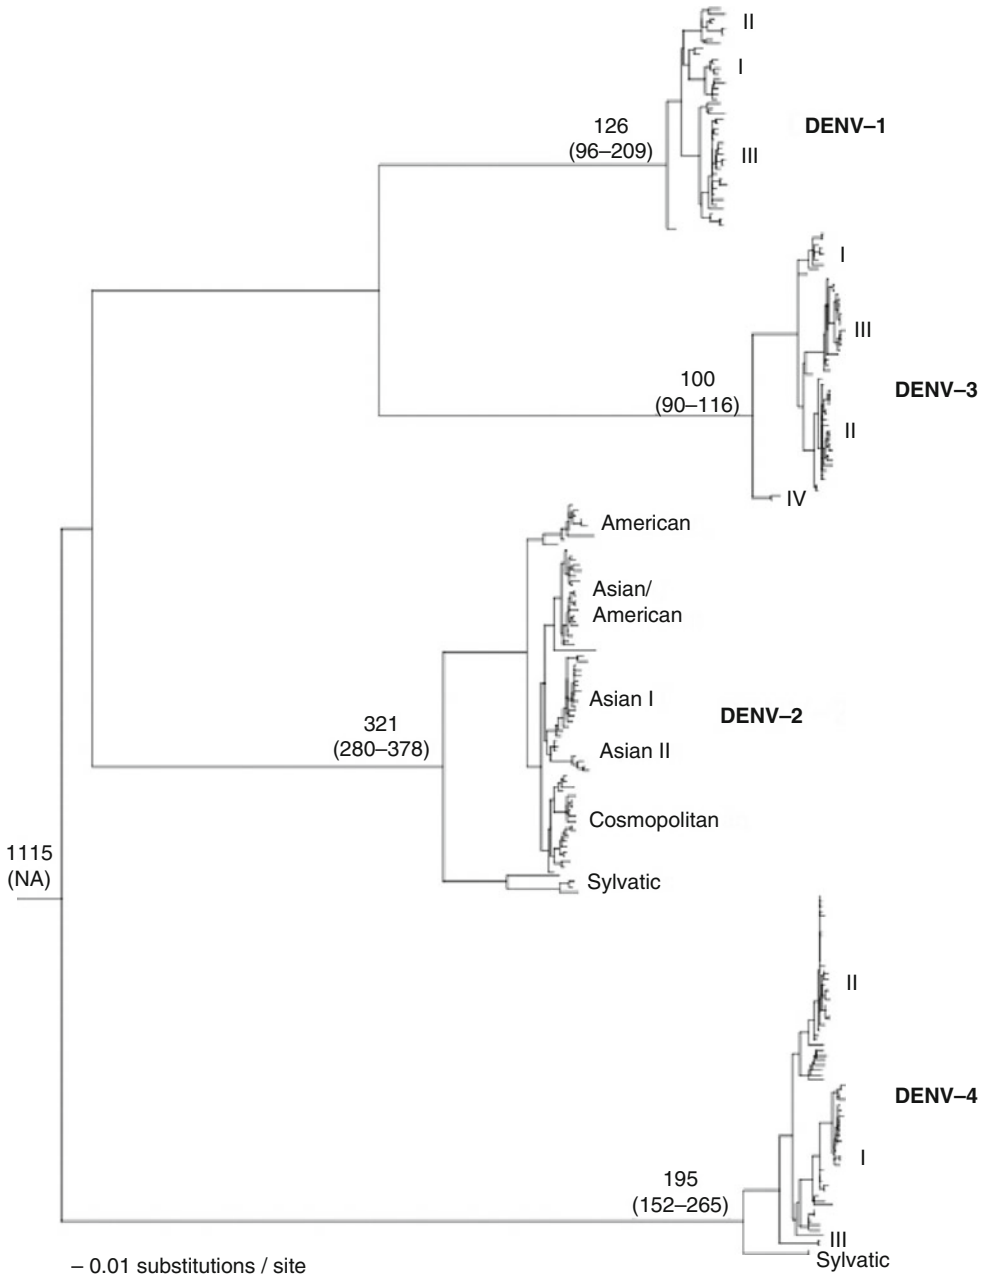

Fig. 15.1 The evolutionary history of the DENV as determined by phylogenetic analysis [68]

restricted flight of the vector has accounted for spatial genetic conservation, and major genetic clade replacements have occurred over time [64–67]. The change of DENV from a sylvatic cycle to a primarily human-vector cycle, especially in Asia, changed the viruses in a fundamental way. Each serotype adapted to infecting and replicating in a human population with high levels of flavivirus antibody from previous DENV infections or in Asia from DENV and Japanese encephalitis virus (JEV) infections. As a result, DENV have become adept at escaping heterologous neutralizing antibody and using it as a means to attain high viral load levels and more severe disease, i.e., antibody enhancement. Today the DENVs continue to evolve at a rapid rate, Asian strains are geographically distributed throughout the world, and DHF has become a global health problem.

3.1.1 DENV Phylogeny

The phylogeny of DENV demonstrates the genetic diversity of these viruses and its evolution as displayed in Fig. 15.1 [68]. The four serotypes diverge from each other by 30 % across their polyproteins, conferring their serotypic distinction. Variation among genes among the viruses range from highly variable for the C and E proteins to relatively conserved for NS3 and NS4B. Within a serotype there is a high degree of genetic variation with the formation of genotypes. There are three genotypes (I, II, and III) for DENV-1, four

genotypes (I, II, III, and IV) for DENV-3, six genotypes (American, Asian/American, Asian I, Asian II, Cosmopolitan, and Sylvatic) for DENV-2, and four genotypes (I, II, III, and sylvatic) for DENV-4. Understanding the genotypes is important in comprehending the epidemiology of the DENVs because genotypes arise in specific geographic regions and can be tracked as they spread to other areas of the world, as occurred with the Asian strains of DENV-2 introduced into the Americas. The other important reason for understanding the genotypes is that the occurrence of severe dengue illness is associated with specific genotypes, the Asian strain of DENV-2, for example. Finally there may be a valid concern for understanding the genotypes for vaccine development as certain circulating genotypes may not be covered by potential dengue vaccines that are being developed currently.

3.2 Flavivirus Genome and Structure

The DENV genome is typical of all the flaviviruses and consists of a single-stranded, positive sense RNA of 11 kilobases in length [69]. The DENV genome has an open reading frame (ORF) of over 10,000 bases that encodes polyproteins of 3,386–3,434 amino acids with the order of proteins 5′ –C-prM(M)-E-NS I -NS2A-NS2B-NS3-NS4A-NS4B-NS5-3′ [69]. The structural proteins consist of the proteins C (capsid) and M (membrane or its precursor prM) and the E (envelope) protein. The nonstructural proteins consist of the NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5 proteins. The reader is referred to an excellent review of the DENV genomic structure and the protein structures from each gene and their function by Perera and Kuhn [70]. Figure 15.2 displays the organizational structure of the DENV genome and the functions of each protein and its structure from this publication.

3.3 The E Protein

The E protein of DENV is the receptor that mediates virus-host cell binding and entry into cells by membrane fusion, and it is the target of serotype-specific neutralizing antibody during the human immune response following infection. The E protein is therefore the major target for vaccine developers in developing a protective tetravalent vaccine. As the DENVs evolved to infect the host in the presence of preexisting antibody, the E protein developed properties with which to evade the host response by utilizing non-neutralizing or sub-neutralizing concentrations of antibodies to mediate the phenomenon of antibody-dependent enhancement (ADE) of infection. This enhancement phenomenon is thought to result in severe hemorrhagic disease. The E protein is a glycoprotein that has dimers arranged in a herringbone pattern consisting of three domains termed the structurally central N-terminal domain I, domain II which contains the hydrophobic "fusion" peptide that allows virus-cell fusion, and the C-terminal domain III [71, 72]. Domain III is important in virus binding and as a neutralizing site for human antibody and important in protection following infection [73, 74]. Figure 15.3 demonstrates the crystal structure of the E protein and its conformation under varying conditions [70]. In panel (a) is the structure of the immature virion at a neutral pH where it exists as a heterodimer with 60 trimeric spikes that extend from the surface and the structure that exists as it develops in the endoplasmic reticulum (ER) of the host cell. Panel (b) displays the immature virion at a low pH as it encounters the trans-Golgi network (TGN). In this form the heterodimers form dimers giving a smooth surface to its structure. In panel (c) the prM protein is shown cleaved into the M protein by the host endoprotease, furin. In (d) the mature virion is seen secreted in the extracellular space. This figure is an elegant schematic of the processing of the E protein and the effects of pH on its conformational structure as it develops into a mature virion.

The E protein's structure was crystallized and its conformational structure revealed by cryoelectron microscopy by Kuhn and colleagues and demonstrated in Fig. 15.4 [75]. Domain I is red, domain II in yellow, and the neutralizing domain III in red. The fusion peptide is shown in green.

3.4 The Nonstructural Proteins

The nonstructural proteins of dengue virus play an important role in viral replication in the host cell and in immune evasion allowing viral replication. As shown in Fig. 15.2, there are five nonstructural dengue virus proteins, NS1 to NS5. NS1 is involved in RNA replication of the virus and thought to act with NS4A as an RNA replicase; it is secreted in the extracellular space by infected cells and can be measured in the serum of patients infected with DENV. NS2A binds to NS3 and NS5 and is involved in the recruitment of RNA templates to the membrane-bound replicase. NS2B is a membrane-associated protein and a cofactor for the serine protease function of NS3. NS3 is a cytoplasmic protein involved in the polyprotein processing of the virus and RNA replication. NS4A and NS4B are hydrophobic proteins that are membrane associated and function in RNA replication. NS5 is the largest of the nonstructural proteins and serves as the viral polymerase and methyltransferase. Host immune evasion is performed by the inhibition of interferon α and β production in human dendritic cells in which the nonstructural proteins play a major role [76, 77]. The nonstructural proteins (NS2A, NS4A, NS4B, and NS5) in particular inhibit the mammalian interferon signaling pathway [78].

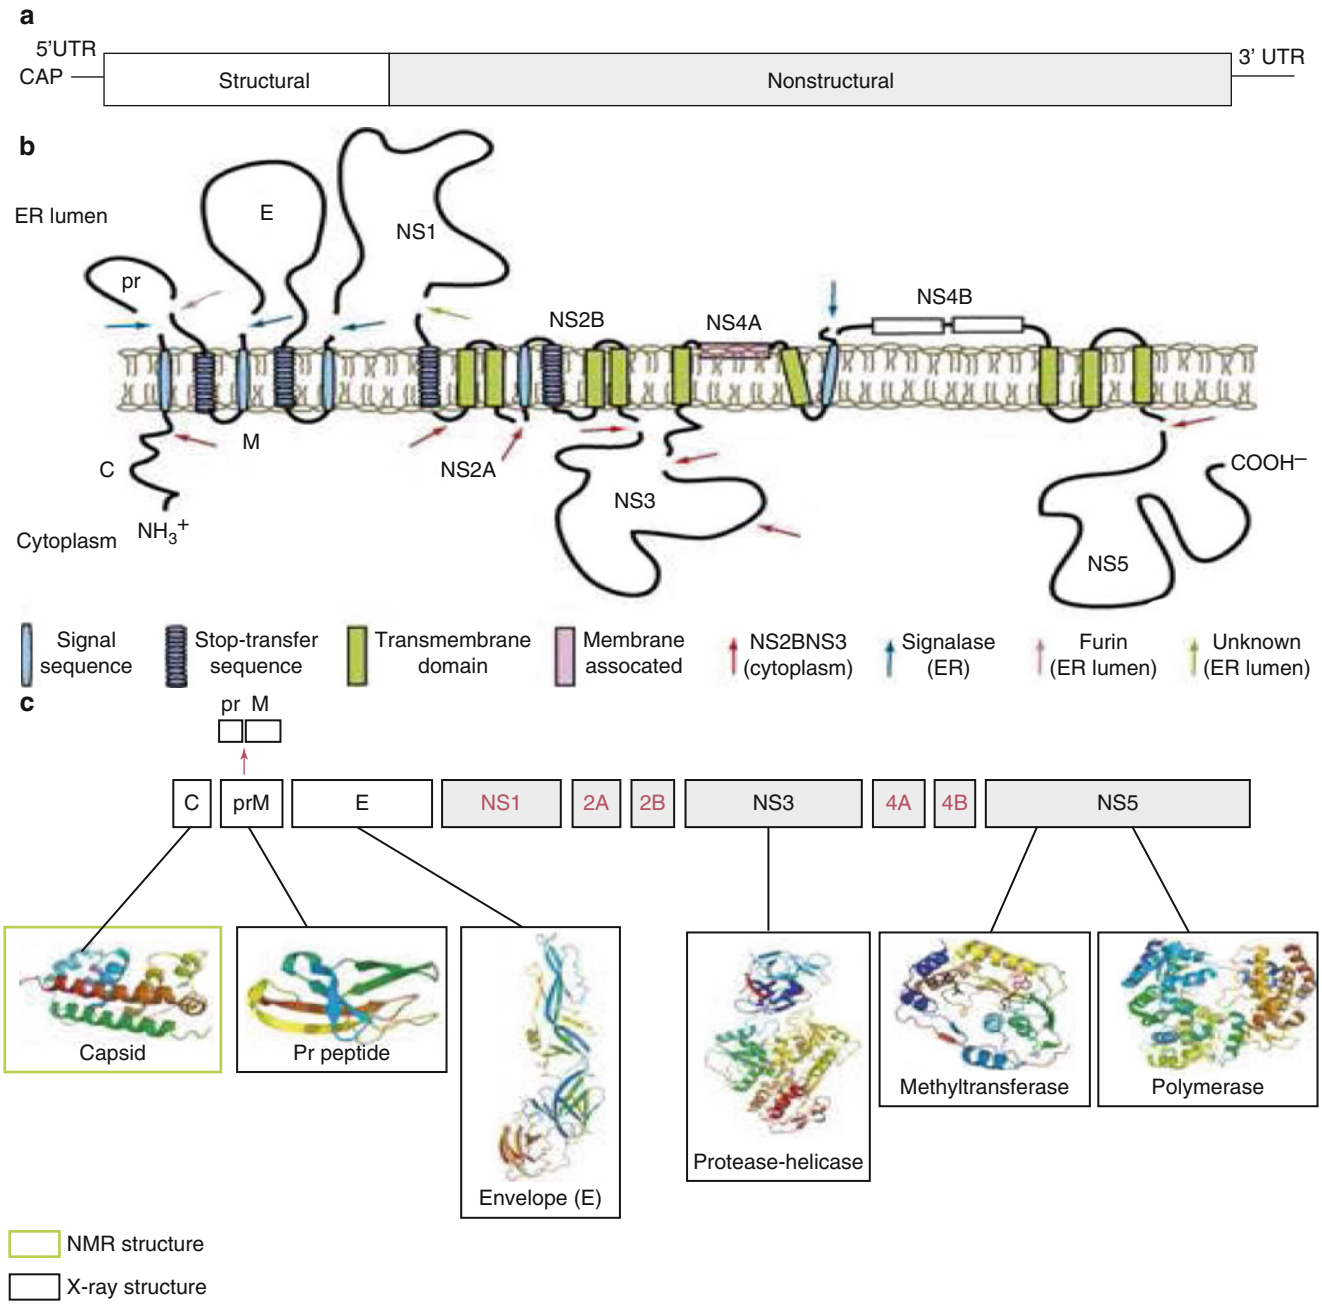

Fig. 15.2 Organizational structure of the DENV genome and its structural and nonstructural proteins [70]

NS5, for example, binds to STAT2 and reduces its expression essential for host cell interferon signaling [78]. The multiple ways DENV evades the host immune response is illustrated by findings that suggest DENV may use preexisting enhancing antibodies not only to promote its entry into Fc receptor-bearing cells but also to form DENV-antibody complexes inside human monocytic cells [79]. These complexes downregulate type 1 interferon production and upregulate cytokine IL-10, which in turn downregulates secondary antiviral responses, such as nitric oxide radical production [79].

3.5 Virus-Host Interactions

This section discusses the complex interplay of viral evolution and E protein assembly and its structural components that influence the host immune response and the role of the nonstructural proteins in virion replication and assembly and are equally important in evading the host innate immune response. The readers are referred to several excellent reviews referenced in this section and in addition an excellent summary of these complexities illustrated in Fig. 15.5 by Rothman [80]. This figure demonstrates the human antibody response

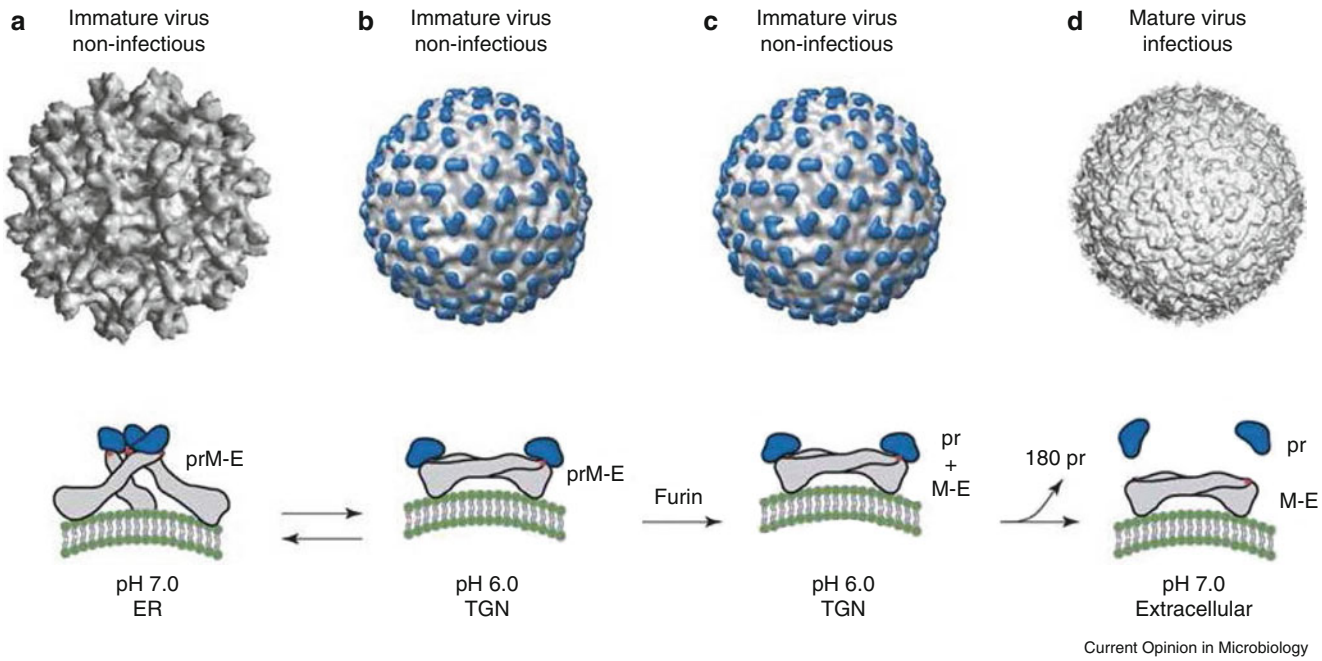

Fig. 15.3 Structures of the E protein and its conformations under varying conditions. (**a**) Structure of the E protein as an immature non-infectious virus in the endoplasmic reticulum (*ER*). (**b**) Structure of the E protein as an immature non-infectious virus in the trans golgi network (*TGN*). (**c**) Structure of the E protein as an immature non-infectious virus in the TGN after furin digestion. (**d**) E protein structure in a mature infectious virus (*Current Opinion in Microbiology*) [70])

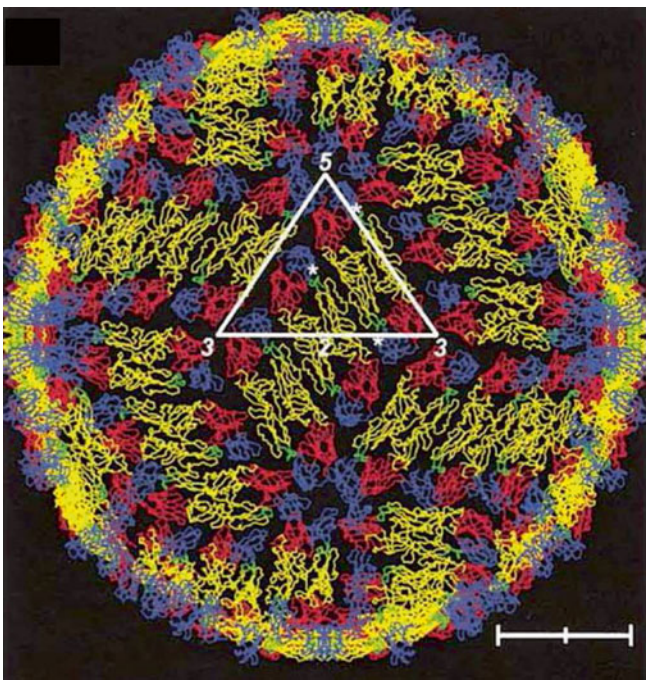

Fig. 15.4 Structure of the DENV E protein demonstrating domains I, II, and III and the fusion peptide [75]. Domains I, II, and III are in *red, yellow*, and *blue*, respectively. The fusion peptide is shown in *green*. The C-terminal residue 395 is shown as a *white asterisk* for monomers within the defined icosahedral asymmetric unit. Scale bar represents 100 Å

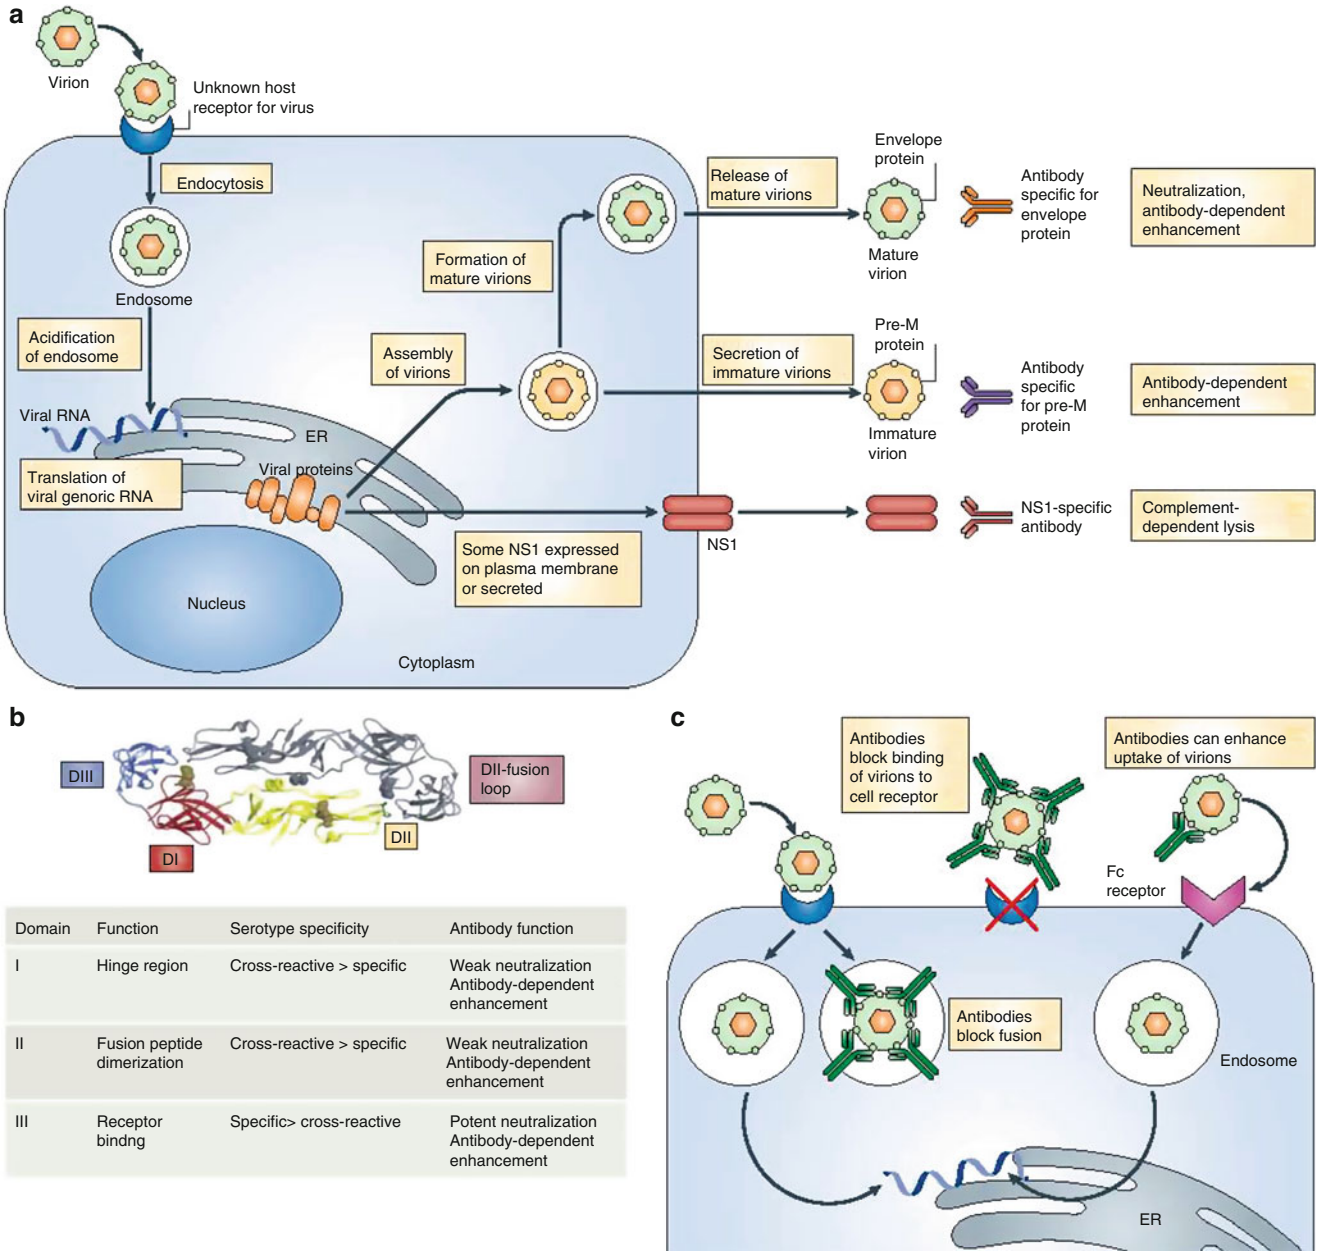
to dengue proteins as the virion enters the host cell and replicates. In (a), the mature virion binds to the cell surface receptor via the E protein in its conformational structure as shown in Fig. 15.3. The virion is internalized through endocytosis, and in the resultant lysosomes, acidification drops the pH, leading to a conformational change of the E protein as shown, and the virions are internalized through endocytosis. The acidification of the endocytic vesicle leads to the rearrangement of the surface E protein as shown in Fig. 15.2, fusion of the viral and vesicle membranes, uncoating of the virus, and release of viral RNA into the cytoplasm. Viral genomic RNA is then translated to produce viral proteins in the endoplasmic reticulum, and the viral proteins and newly synthesized viral RNA assemble into immature virions within the lumen. The cleavage of the viral precursor membrane occurs by the host cell enzyme furin, forming mature virions that are then secreted from the cell. In this figure also is shown how NS1 forms and secreted from the plasma membrane of the cell. As demonstrated, host antibody forms against both mature and immature virions that can neutralize virus or result in ADE. Anti-NS1 antibodies can cause complement-dependent lysis of virus-infected cells. In (b), the structure of the dengue virus E glycoprotein ectodomain and its three domains are shown with antibody specific to each. In (c), the mechanisms of neutralization and enhancement by dengue virus-specific antibodies are shown. Neutralization can occur when high levels of epitope-specific antibody block the binding of virions to the cellular receptor or can block fusion at the post-binding stage. At lower concentrations, antibodies can enhance the uptake of virions into cells by interacting with immunoglobulin (Fc) receptors and enhancing binding and cellular uptake of virus.



Domain	Function	Serotype specificity	Antibody function
I	Hinge region	Cross-reactive > specific	Weak neutralization Antibody-dependent enhancement
II	Fusion peptide dimerization	Cross-reactive > specific	Weak neutralization Antibody-dependent enhancement
III	Receptor bindng	Specific> cross-reactive	Potent neutralization Antibody-dependent enhancement

4 Methodology Involved in Epidemiologic Analysis of Dengue

4.1 Sources of Data

A variety of sources of data are used to estimate the occurrence of dengue in countries where it is endemic. These include hospital admissions, clinic visits, and prospective studies. The majority of countries rely on syndromic surveillance diagnosing patients by clinical symptoms consistent with dengue fever or dengue hemorrhagic fever using WHO criteria [81]. The reliance on syndromic surveillance is in large part due to the lack of affordable DENV diagnostics available and the lack of infrastructure in which to perform them. There are several problems with using syndromic surveillance, and these include an inability to detect other causes of fever in susceptible populations from other diseases with similar presentation such as leptospirosis and an underestimation of the true burden of dengue infection as the majority of cases are subclinical or of less severity, not requiring hospitalization or presentation to a health clinic. Incidence of dengue burden can be measured more reliably in prospective cohort studies, but these studies are expensive and require

technical expertise often lacking in endemic countries [82]. To compensate for this underestimation of dengue burden by syndromic surveillance, much has been written about using expansion factors (also called multiplication factors in some manuscripts) to estimate the true burden of infection. Expansion factors use a combination of incidence data from prospective studies to correct for the underestimation of disease burden by syndromic surveillance. For example, incidence data from cohort studies performed in children in Thailand and Cambodia were used as expansion factors to calculate the national burden of infection [83]. From these cohort studies the annual incidence of laboratory-confirmed dengue was 23/1,000–25/1,000 in Thailand and 41/1,000 in Cambodia. Age-specific rates of confirmed dengue were compared to the same national data and an expansion factor based on the degree of underestimation calculated and used to readjust the national rate. In Thailand, the median readjusted provincial number of dengue cases was 229,886 (range 210,612–331,236) annually during 2003–2007, and in Cambodia, the median was 111,178 (range 80,452–357,135). The degree of underestimation of the burden of dengue nationally was 8.7-fold in Thailand and 9.1-fold in Cambodia. Similar approaches have been used to estimate the true burden of infection in Southeast Asia and South America [84–87]. While using expansion factors to calculate national burden is well meaning, it is still inherently inaccurate due to the variable nature of DENV transmission spatially and temporally. Prospective studies have demonstrated a high degree of spatial and temporal variation on the incidence and burden of dengue among neighborhoods and districts and from year to year [88]. To capture the true burden of dengue infection in endemic countries requires an investment in training, infrastructure development, and accurate yet inexpensive dengue diagnostics combined with ongoing prospective studies to reflect national incidence.

4.2 Serologic Surveys

Serologic surveys to estimate serotype-specific DENV incidence have played an important role in understanding DENV transmission and burden of infection. The methods of serologic surveys and their importance have been discussed more extensively in Chaps. 3, 4, and 16, to which the reader is referred for more information. Serologic surveys involve sampling a defined population and measuring the amount of specific antibody to the targeted DENV protein which will indicate past or current infection. This is performed by a number of assays, but all currently employ a variation of the enzyme-linked immunosorbent assay (ELISA) or plaque reduction neutralization titer tests (PRNT). The results give a point prevalence of past or current DENV infection in different geographic areas or subpopulations or those at particular risk for infection. Several early prospective serologic surveys conducted in Thailand estimated risk factors for DHF and the incidence of dengue burden in defined populations. They established the important contribution of serologic surveys to the understanding of the pathogenesis of DENV infection [89, 90]. In one of the first prospective studies on DENV infection, Burke and colleagues prospectively studied 1, 757 children in a Bangkok school in June of 1980 [91]. At the start of the study, 50 % of children had DENV antibodies to at least 1 DENV serotype by the age of 7 years. Sequential serologic surveys of this population demonstrated that 87 % who became infected during the study period were asymptomatic; of those remaining who were symptomatic, 53 % were clinically recognized as cases of DHF requiring hospitalization. Incidence rates ranged from 5.5 % in children with preexisting DENV antibody to 6.3 % in those who were serologically naïve. None of the children with primary dengue infection required hospitalization as compared to 12 % of secondary infections. The authors concluded that preexistent dengue immunity was a significant risk factor for the development of DHF.

4.3 Dengue Diagnostics

4.3.1 Introduction

A variety of laboratory methods and diagnostic tests are available for diagnosing past or current DENV infection. They can be divided into two broad categories, those that detect the virus (viral isolation, RNA detection) and those that detect the host response via antibody production specific to DENV. Understanding the viral-host interaction and pathogenesis during a DENV infection is essential in understanding the predictive value of each assay by clinical illness day.

4.3.2 Virus Isolation and RNA Detection

Since the first isolation of a virus, tobacco mosaic virus in 1935 by Stanley, viral isolation has been the mainstay by which to detect viral infection [92]. DENV (DENV-1) was first isolated during an outbreak in the Nagasaki-Sasebo area of Japan brought in from returning seamen in 1942 by Kumura and Hotta and subsequently by Sabin and Schlesinger the following year [43, 45]. DENV isolation was performed by taking serum from ill patients within 48 h of their first fever and inoculating mice intracerebrally. Serial mouse brain passage isolated the virus, which was then identified through neutralization by convalescent sera of patients clinically ill with DENV infection. Though cell lines had been used to propagate viruses such as vaccinia virus and yellow fever virus since the early 1900s, the development of tissue culture lines for viral isolation by Weller and colleagues, first used for poliovirus culture, transformed the ability to isolate

and study viruses in the laboratory [93, 94]. Today a variety of cell lines are used to isolate and study DENV and include but are not limited to the mammalian monkey kidney cell lines, Vero cells and LLC-MK2 cells, as well as the mosquito cell lines from *Aedes albopictus* (C636) and *Aedes pseudoscutellaris* (AP61) [95, 96]. All have similar sensitivity and specificity for isolation, and their usefulness is limited to the viremic period of patients discussed below.

Amplification of the DENV ribonucleic acid (RNA) genome by polymerase chain reaction (PCR) provides a highly sensitive and specific assay in which to isolate the viral genetic material [97–99]. Specific primers and probes and nested PCR permits DENV serotyping with a reaction time of 4 h and represents a rapid means of detecting DENV both for diagnosis and for epidemiologic characterization of serotype-specific transmission. Today DENV PCR has become the mainstay technique to diagnose and serotype dengue-infected patients. Real-time quantitative PCR allows an estimation of the amount of virus (i.e., viral load) during clinical illness, thereby providing information on the pathogenesis of severe dengue illness [100].

4.3.3 Serologic Tests

Serologic testing for past or current DENV infection relies on the host response to produce specific antibody to the targeted DENV proteins that indicates host recognition of infection. Current serologic testing involves detection of either IgM or IgG antibody, the former indicating current active infection and the latter either current or past infection. Two important concepts are involved in understanding serologic testing for DENV infection. The first is that IgG antibody from current or past infection displays a high degree of cross-reactivity to other DENV serotypes or other flaviviruses. IgG antibody to a specific infecting DENV serotype is termed "homotypic" and antibody to another noninfecting serotype "heterotypic" or cross-reactive. This is particularly important as DENV occurs as four distinct serotypes. Infection from one serotype confers long-term immunity to that serotype but not to the others. Thus, the human host can be infected from multiple DENV serotypes during a lifetime. The second concept is that the host response to the first DENV infection differs from the response to subsequent DENV infections. The first infection is termed primary dengue and the second or additional DENV infection termed secondary dengue. The second or subsequent DENV infection is characterized by a blunted IgM response, a rapid and heightened IgG response, and cross-reactive T-cell responses inherently involved in the pathogenesis of DHF discussed in more detail below. This heightened host response during a secondary infection is termed "antigenic sin" and was first described by Francis and defined as the ability of the host immune system to utilize immunologic memory based on a previous similar infection [101]. This has been applied to DENV infection where antigenic sin forms the basis for severe dengue illness [102].

It is not within the scope of this section to discuss every available assay for detecting DENV infection. Most are experimental and performed in research laboratories and only a few assays have been licensed and are commercially available. The traditional DENV serologic diagnostics will be discussed in detail as most assays are variations of these and are essential in understanding the complexities of serology during and after infection.

Plaque Reduction Neutralization Test (PRNT)

The plaque reduction neutralization test utilizes the ability of a DENV to infect a single cell in a cell culture under agar, forming areas of cell death and clearing (plaques), and the ability of neutralizing IgG antibody to form complexes with the virus, preventing cell entry and thus plaque formation. The PRNT was first adapted to DENV by Russell and colleagues in 1967 [103]. The endpoint for the PRNT was calculated as the titer of neutralizing antibody that inhibits 50 % of the plaque formation known as the PRNT50. Originally used with LLC-MK2 cells, a variety of PRNT assays exist now utilizing the same principles but with differing cell lines such as Vero cells and assay formats including the use of microwell plates and a micro-focus assay [104]. The PRNT is an important assay for determining previous and current DENV infection. Two critical issues limit the interpretability of the results. The first is antibody cross-reactivity, making serotype-specific interpretation difficult, and the second is intra and inter-assay variability. The latter issue has been discussed extensively by Thomas and colleagues, demonstrating with one sera set a high degree of variability of the PRNT depending on the cell lines used, the type of prototype DENV, and the use of complement in the assay [105]. This is an important issue as the PRNT has been used by DENV vaccine developers in determining protective immunity from vaccines.

Hemagglutination Inhibition (HAI)

The hemagglutination inhibition assay (HAI) is a technique widely used to measure antibody to a variety of viruses including DENV and first described by Hirst in 1942 to measure influenza virus antibody [106]. As described in Chap. 3, the assay utilizes the ability of viruses to adhere to red blood cells (RBC) and form clusters thereby agglutinating them from solution. The HAI assay was adapted to DENV using goose RBCs and originally a powerful assay to measure DENV antibody though not much in use today except in specialized DENV research laboratory The HAI is distinct from the PRNT as it measures any DENV antibody that adheres to the serotype-specific DENV, not just neutralizing antibody. The advantages of the DENV HAI are that it is a high-throughput assay that can accommodate several hundred

samples in a short period of time, the reagents are relatively low cost, and intra- and inter-assay variabilities are well controlled. The disadvantage of the HAI test is similar to that of the PRNT in that cross-reactive antibody makes it difficult to determine serotype-specific infection. Unlike the PRNT, the HAI can be used to determine acute primary or secondary DENV infection by WHO criteria: a fourfold rise in HAI antibody titer between acute and convalescent sera is diagnostic for an acute DENV infection; the sera pair that is ≥7 days and the convalescent titer that is ≤ to 1:1,280 for an acute primary DENV infection; the convalescent titer that is ≥ than 1:2,560 for an acute secondary infection; and no fourfold rise in HAI titer between the acute and convalescent titer and the convalescent that titer is > 1:2,560 for a recent secondary flavivirus infection [81].

Enzyme-Linked Immunosorbent Assay (ELISA)

The enzyme-linked immunosorbent assay (ELISA) is an easily reproducible high-throughput assay in which to measure both IgM and IgG DENV antibody. In general, the indirect ELISA is the most widely performed assay for measuring DENV antibody. Like the HAI test, all DENV IgG antibodies are quantified and not just neutralizing antibody. Innis and colleagues were the first to develop an ELISA specifically to measure DENV IgG and also IgM, the latter known as an IgM antibody capture ELISA or MAC-ELISA [107]. This assay was unique as it capitalized on the observation that in secondary DENV infection the IgM to IgG ratio was lower than in primary DENV infection. In sera of children infected with DENV in Thailand, this assay demonstrated a sensitivity of 78 % in admission sera and 97 % in paired sera. Dengue infections were classified as either primary or a secondary DENV infection by determining the ratio of units of dengue IgM to IgG antibody where an IgM to IgG ratio of ≥1.78 was indicative of primary dengue and <1.78 secondary infection. The dengue IgM/IgG ELISA assay is commercially available and offers the advantage of being reproducible, technically within the scope of clinical laboratories; high throughput; and relatively inexpensive to perform. A characteristic feature of DENV infection is that the virus in infected cells secretes free NS1 protein into the extracellular space. NS1 can be measured in the serum of patients and correlates directly with viral replication and viral load. The NS1 ELISA assay is commercially available and uses an antibody capture of NS1 protein and a secondary enzyme-linked detection antibody to produce a colorimetric reaction that measures the amount of NS1 in the sample. The NS1 ELISA assay was 82 % sensitive in diagnosing patients with acute dengue [108]. The advantages of the ELISA assay for NS1 are its high-throughput capacity and ease of performance in most clinical laboratories. The disadvantage is that NS1 correlates to DENV viremia, and thus, detection is limited to the first 7–10 days of clinical illness.

Lateral Flow Immunochromatographic Assay

This assay use porous paper to allow the wicking and conjugation of the test sample; it is in essence an ELISA assay on paper. A number of DENV lateral flow assays have been developed, and some (e.g., the NS1 rapid lateral flow assay) are commercially available in endemic countries. Studies have demonstrated that this assay is less sensitive (72–73 %) than its ELISA format counterpart [108, 109]. The lateral flow assay has been developed to detect dengue IgM and IgG, potentially broadening the time window for clinical diagnosis of infection to several weeks while IgM is Detectable [110]. The lateral flow tests, also known as rapid diagnostic tests (RDTs), have a number of distinct advantages. The first is that they are potentially point-of-care diagnostic devices that can be done rapidly at the bedside or in villages where dengue infection is suspected. The second and third are that a cold chain is not needed to store material and interpreting the result requires nothing beyond the ability to determine the color lines that indicate a positive or negative test. The disadvantage is that in general they are less sensitive and specific than an ELISA format and PRNT-, or PCR-based assays. Table 15.1 summarizes the advantages and limitations of available DENV diagnostic tests [111].

4.3.4 Dengue Diagnostics During Clinical Illness

Figure 15.6a, b summarizes the importance of knowing the day of clinical illness, whether the suspected dengue infection is primary or secondary and the appropriateness of the diagnostic assay for the time of collection. In general, assays that detect the virus, whether by isolation or RNA detection, require viremia in the patient and are limited to the first week of infection. Assays that rely on host antibody detection, whether IgG or IgM, differ in primary and secondary detection with IgM higher and longer lasting in the first infection as compared to secondary infection. Figure 15.6 also illustrates the importance of obtaining an acute and a convalescent sample in both primary and secondary infections to determine a fourfold rise in IgG antibody as a criterion for diagnosis.

5 Descriptive Epidemiology

5.1 Incidence and Geographic Distribution

DENV is considered the most common arboviral infection in tropical and subtropical regions of the world. As mentioned in a previous section, the frequency of dengue infection is underestimated due to the emphasis on reporting of hospitalized cases by syndromic surveillance by most countries endemic for dengue. A recent analysis with mathematical modeling of the geographic distribution and global incidence of dengue in 2010 demonstrated that DENV is endemic

Table 15.1 Summary of DENV diagnostic assay[a]

Diagnostic tests	Advantages	Limitations
Viral isolation and identification	Confirms infection	Requires acute sample during the viremic period (first 7 days of illness)
	Is serotype specific	Needs specialized expertise and laboratory
	Allows additional scientific investigation into the virus	Requires several weeks to isolate virus and is not high throughput
		Does not differentiate between primary and secondary infection
		Can be expensive
RNA detection (PCR format)	Confirms infection	Has potential false-positives due to contamination
	Sensitive and specific	Requires acute sample during the viremic period (first 7 days of illness)
	Identifies serotype and genotype	Needs specialized expertise and laboratory
	Has rapid results in 24–48 h	Does not differentiate between primary and secondary infection
Antigen detection		
ELISA format for NS1 for example	Confirms infection and sensitive and specific	Is not as sensitive as virus isolation or RNA detection
	Is easy to perform and high throughput	Requires basic clinical laboratory and training
	Is less expensive than virus isolation or RNA detection	Requires acute sample during the viremic period (first 7 days of illness)
		Does not differentiate between primary and secondary infection
Lateral flow assay for NS1 for example	Confirms infection	Is not as sensitive as virus isolation, RNA detection, or ELISA format
	Is easy to perform and high throughput	Requires acute sample during the viremic period (first 7 days of illness)
	Is less expensive than virus isolation or RNA detection	Does not differentiate between primary and secondary infection
	Point of care and does not require specialized lab equipment or cold chain	
Serologic tests		
Plaque reduction neutralization test (PRNT)	Confirms infection	Is expensive and time-consuming to perform
	Is serotype specific in primary infection	Requires specialized training and laboratory
	Is considered the "gold standard"	Does not differentiate between primary and secondary infection
	Is considered a correlate for protection	Has high degree of antibody cross-reactivity
Hemagglutination inhibition (HAI)	Confirms infection	Requires specialized training and laboratory
	Confirms primary and secondary infection	Reagents such as goose red blood cells may be difficult to obtain
	Is relatively inexpensive	Confirmation may require two or more serum samples
	Is high throughput	
IgM/IgG ELISA	Is easy to perform	IgM levels can be low in secondary infections
	Confirms infection and sensitive and specific	Requires specialized training and laboratory
	Is high throughput	
	Confirms primary and secondary dengue	
Lateral flow assay for IgM/IgG	Confirms infection	Is not as sensitive as ELISA
	Is easy to perform and high throughput	Requires acute sample
	Is less expensive than ELISA	Does not differentiate between primary and secondary infection
	Point of care and does not require specialized lab equipment or cold chain	

[a]Adapted from Peeling et al. [111]

throughout the tropics with spatial variations and influenced by climate such as rainfall and temperature as well as urbanization [3]. The authors estimated that the number of DENV infections per year is 390 million (95 % confidence interval 284–528) of which 96 million (67–136) are symptomatic [3]. This estimate is greater than three times the dengue burden as determined by the WHO and further emphasizes importance of this infection for global health [18].

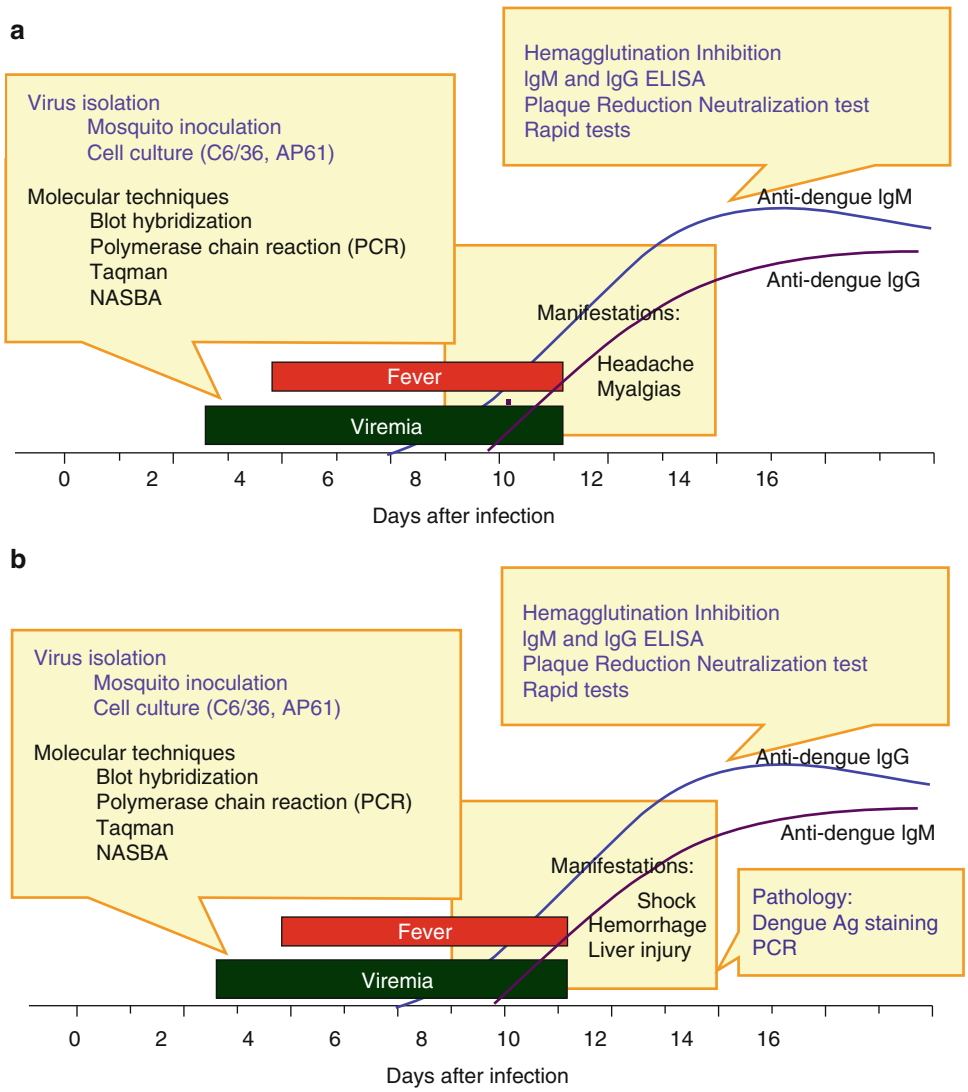

Fig. 15.6 (**a**) Types of dengue diagnostics appropriate by day of infection in primary dengue. (**b**) Types of dengue diagnostics appropriate by day of infection in secondary dengue

5.2 Epidemic Behavior and Contagiousness

5.2.1 Studies of DENV in Thailand

During the 1950s, collaboration between the United States and Southeast Asian countries through the Southeast Asian Treaty Organization (SEATO) created a number of host-country laboratories to respond to and study endemic diseases. In Thailand the SEATO General Medical Research Project originally was located at Mahidol University in Bangkok and later became a joint Thai and US military project named the Armed Forces Research Institute of Medical Sciences (AFRIMS) located on the Thai military medical complex. Bangkok and Thailand became the epicenter for severe dengue illness and allowed Thai and US investigators to study all aspects of DENV, an effort that has continued for more than half of a century and produced seminal advances in DENV epidemiology, vector transmission, and pathogenesis. Early studies of hospitalized children in Bangkok characterized the clinical severity of DHF resulting in thrombocytopenia, leukopenia, coagulopathy and plasma leakage [112]. Research on severe DENV resulted in the observation that both secondary DENV infection and primary infection of infants with declining maternal antibody were risk factors for DHF, and the theory of ADE as an important force in the pathogenesis of DHF was born [113]. Prospective studies of DENV in children living in Bangkok established the role of enhancing antibody in the peripheral blood mononuclear cells of children in producing severe dengue illness and DHF [114]. Additional prospective studies demonstrated the importance of viral load and T-cell responses in disease severity and the circulation of all DENV serotypes and their spatial and temporal diversity [88, 115–117].

5.3 Spatial and Temporal Distribution

DENV transmission, being vector-borne, is dependent on both the propagation of the *Aedes aegypti* vector mosquito

and the availability of viremic individuals from whom the mosquito can become infected. Thus, DENV transmission is seasonal and has both spatial and temporal distributions. The experience in Thailand in many ways illustrates how DENV can emerge in a population and through the combination of increasing urbanization, a high birth rate providing a continuous pool of susceptible individuals, and climate changes, evolved from a seasonal disease with periodic epidemics to a hyperendemic one involving transmission of all four serotypes. A classic paper by Nisalak and colleagues illustrates this concept nicely [118]. Dengue virus serotype was determined by viral isolation and PCR in hospitalized children with suspected dengue at the Queen Sirikit National Institute of Child Health in Bangkok, Thailand, from 1973 to 1999. During that period, acute dengue was diagnosed in 15,569 children with 4,846 viral isolations. All four DENV serotypes circulated with DENV-3 the most frequent serotype in primary dengue and DENV-2 in secondary infection and DHF. However, the change in predominant serotype from year to year was striking, with DENV-1 the major cause of the outbreak from 1990 to 1992, DENV-2 from 1973 to 1986 and 1988–1989, DENV-3 in 1987 and 1995–1999, and DENV-4 from 1993 to 1994. In Thailand there has been a progressive increase in the number of dengue cases from several thousand per year in the 1960s to 200–300,000 cases per year in the last decade. In the Americas the more recent pattern resembles the experience in Thailand during the 1970s and 1980s. DENV is introduced in a country producing localized epidemics and through the movement of infected individuals and transportation of the mosquito vector, the disease spreads and becomes endemic in a region. Continued urbanization and an increase in birth rate provide high vector burden and a pool of susceptible individuals for all four serotypes, and the country becomes hyperendemic for DENV. Like in Thailand, one serotype emerges as the predominant serotype causing an outbreak in any given year. As the population becomes infected and develops herd immunity to that serotype, another serotype becomes predominant and thus the cycle is repeated every year. Long-term prospective cohort studies of children in Northern Thailand from 1998 to the present illustrate the fine-scale spatial and temporal distribution of DENV transmission in a fixed geographic area. Using a school-absence surveillance system, absent students were evaluated for fever or a history of fever. If present, acute and convalescent blood samples were tested and DENV serotype determined by isolation and PCR [88, 119, 120]. DENV infection incidence and serotype circulation varied geographically and from year to year with one school having a DENV-3 outbreak and several miles away another school having a DENV-2 outbreak. The following year the same schools had outbreaks with different DENV serotypes. These studies demonstrate the complexity and remarkable diversity in DENV serotype transmission. A recent study of DENV transmission in Bangkok using the location of dengue patients' homes and the infecting serotype found evidence of localized transmission at distances of under 1 km [121]. In summary, there is a diverse spatial and temporal distribution of DENV transmission illustrating the complexities of transmission between the host and the mosquito vector. *Aedes aegypti,* as an urban mosquito, has a limited range of approximately 200–500 m from its breeding site as determined by capture-release studies [122]. Infected viremic individuals move from one *A. aegypti* area to another and introduce the virus to feeding vectors that then become infected. After an extrinsic incubation period of approximately 14 days, mosquitoes can then feed and infect the susceptible human host, typically within a 500 M radius, thereby propagating a restricted spatial outbreak. A useful metaphor is to imagine a large-scale DENV outbreak as throwing a series of small pebbles in a pond. Each pebble represents the location of one infected individual that infects an *A. aegypti* mosquito. The waves from the one pebble represent individuals who are infected from that mosquito producing a spatially confined outbreak. As more and more pebbles are thrown in the pond, the numerous resulting waves create more and more spatially confined outbreaks producing a large outbreak across a country or region. This wave concept was illustrated by a mathematical model of how DENV travels across Thailand during the epidemic season in each of several years [123]. The authors demonstrated the existence of a spatial-temporal traveling wave in the incidence of DHF with the wave emanating from Bangkok moving radially at a speed of 148 km per month.

5.4 Age and Sex Distribution

In countries with endemic DENV where the force of infection is high, dengue illness becomes primarily a pediatric disease. Maternal DENV antibody is transplacentally transferred to the infant conferring a degree of protection that lasts for approximately 12 months [124]. The first infection with DENV typically occurs before the age of five as a primary infection and goes largely unrecognized as just another febrile illness that infants experience. The second infection often occurs between the age of 5 and the teenage years and as a secondary infection produces severe DENV illness. The age for severe infection ranges between 5 and 15 years and both sexes are equally affected [115]. In a recent study of children in Bangkok with severe infection, ages ranged from 18 months to 15 years with a mean age of 8.6 years. The mean age of children diagnosed with DF was 8.5 years and 8.7 years for children with DHF [125]. Similar age and sex distributions are seen in the regions of the Americas where DENV infections are endemic [126].

5.4.1 Phenomenon of the Increasing Median Age in SE Asia

First in Thailand and then in other Southeast Asian countries, it was observed that the median age of severe dengue illness was increasing over time. To determine the reasons for this observation, an analysis was performed from 72 provinces of Thailand to examine the force of infection and demographic and climactic variables [127]. The force of infection was found to have declined by 2 % each year, with the strongest predictor for this change being the median age of the population. The increase in median age was explained by a reduced birth rate and a shift in the population age structure to include older individuals. Lower birth and death rates are thought to decrease the number of susceptible individuals in the population as a result of increased longevity of immune individuals. If true, other countries with shifts in the age of the population to older individuals may also see an increase in the age of severe dengue illness.

5.5 Occurrence in Different Settings

5.5.1 Prospective Studies in Families and Schools

A number of prospective studies conducted in families and schools have played an important role in increasing our understanding of DENV transmission and the pathogenesis of subclinical and severe infection. The readers are referred to a review that discusses these studies in more detail [82]. Table 15.2 summarizes these studies and their salient study findings. Burke and colleagues performed a 2-year (1980–1981) school-based study involving 1,757 children, ages 4–16 years, in Bangkok, Thailand [91]. DENV-antibody testing demonstrated a high antibody prevalence with 50 % of the children having evidence of preexisting dengue antibody, indicating infection prior to the age of 7 years. The majority (87 %) of the students became infected during the study period but remained asymptomatic. Of those who developed symptomatic illness, 53 % were classified as having DHF. Overall incidence was 6.3 % and a symptomatic-to-asymptomatic ratio of 1:8. The risk for DHF in secondary infection was ≥6.5. Table 15.2 summarizes the incidence of infection and the symptomatic-to-asymptomatic ratio in the various cohorts. An important result of these prospective studies has been a better understanding of the full burden of subclinical infection, particularly in those patients who contribute to the pool of potential hosts for mosquito infections but go unreported in most surveillance programs. Another value of the prospective studies is to determine the full economic burden of dengue disease. In the Thai studies, incidence and economic impact were used to calculate the disability-adjusted life years (DALYs) lost to DENV infections [117]. The mean DALYs per million population was 465 per year which accounted for 15 % of DALYs lost to all febrile illnesses. Nonhospitalized patients were an underappreciated economic burden that represented a substantial proportion of the overall disease burden; 44–73 % of the total DALYs were lost to dengue each year. During high incidence years, the number of DALYs lost to dengue was greater than that calculated for important tropical diseases such as meningitis and hepatitis B and was three times greater than reported by WHO [128].

5.5.2 Military

The US military considers developing a DENV vaccine a high priority and has sustained an effort to develop an effective vaccine for over 50 years [129]. The reason for this effort is the impact that DENV infection has had on US military operations since the Spanish-American War [2, 130]. Before WWII soldiers stationed in Panama and the Philippines experienced major outbreaks of DENV infection. During WWII several hundred soldiers stationed in Queensland, Australia, were hospitalized with dengue, and outbreaks occurred in soldiers throughout the South Pacific. Severe outbreaks occurred in US soldiers landing in Saipan in July 1944; the initial incidence of 300 cases per 1,000 rose to

Table 15.2 Prospective studies in families and schools[a]

Study site	Population size	Age range (years)	Study period	Incidence (average)			Symptomatic: asymptomatic ratio
				Dengue infection (%)	Symptomatic dengue (%)	Hospitalized dengue (%)	
Bangkok, Thailand [91]	1,757	4–16	1980–1981	11.8	0.7	0.4	1:8
Rayong, Thailand [90]	1,056	4–14	1980–1981	9.4		0.1	
Yangon, Myanmar [167]	12,489	1–9	1984–1988	5.1		0.3	
Yogyakarta, Indonesia [341]	1,837	4–9	1995–1996	29.2	0.6	0.4	
Kamphaeng Phet I, Thailand [115]	2,119	7–11	1998–2002	7.3	3.9	1.0	1:0.9
Managua, Nicaragua [342]	1,186	4–16	2001–2002	9.0	0.85		1:13–1:6
Kamphaeng Phet II, Thailand [119]	2,095	4–16	2004–2006	6.1	2.0	0.5	1:3.0
West Java, Indonesia [343]	2,536	18–66	2000–2002	7.4	1.8	0.1	1:3

Adapted from Endy et al. [82]

[a]Number in cohort tested for dengue antibody (incidence denominator)

3,500 per 1,000 [2]. After WWII dengue was a significant cause of illness and noncombat injuries in soldiers stationed in Vietnam and most recently during operations in both Haiti and Somalia. Soldiers deployed to Haiti in particular suffered from acute dengue illness, which was responsible for 30 % of all febrile illness [131]. DENV infections continue to be documented in deploying military personnel.

5.5.3 Risk to Travelers

Dengue poses a significant risk to travelers vacationing or working in dengue-endemic countries and is now considered the most common cause of febrile illness in returning travelers [132]. Information from the US Centers for Disease Control and Prevention's laboratory-based Passive Dengue Surveillance System (PDSS) described trends in travel-associated dengue from January 1, 1996 to December 31, 2005. Of 1,196 suspected dengue infections in returning travelers, 334 (28 %) were confirmed laboratory positive. Regions where travelers were at particularly high risk for infection were the Caribbean, Mexico, Central America, and Asia [132]. Dengue in returning travelers was examined by the GeoSentinel Surveillance Network [133]. Dengue cases demonstrated regional and seasonal peaks—June to September for Southeast Asia, October for South Central Asia, March for South America, and August to October for the Caribbean. In Southeast Asia, for example, the annual incidence of dengue in travelers increased from 50 cases per 1,000 in non-epidemic years to 159 cases per 1,000 during epidemic years [133].

5.5.4 Adult Symptomatic Dengue Infection

As noted, DENV infection in endemic countries due to the high force of infection is primarily a pediatric disease. However, DENV infection occurs at all ages. In countries that experience sporadic DENV outbreaks because of recent introductions, such as islands, all ages are infected and severe illness will occur in adults. Current knowledge of the pathogenesis of adult DHF is limited to a few studies. A prospective study performed in Thai patients in Phetchabun Provincial Hospital demonstrated significant clinical differences in adults as compared to children [134]. More common in adults than in children were manifestations such as petechiae, melena, headache, retro-orbital pain, joint pain, myalgia, nausea, and emesis. A retrospective study of Taiwanese adults and children during a DENV-2 outbreak in 2002 demonstrated that adult patients presented more frequently with arthralgias, myalgias, headache, and abdominal pain as compared to children [135]. Adults had more severe thrombocytopenia, elevated alanine aminotransferase (ALT) levels, and greater incidence of upper gastrointestinal bleeding and DHF. Clearly different in adults than in children are the higher rates of comorbidities such as diabetes mellitus, hypertension, chronic obstructive pulmonary disease, and previous stroke that contributed to the severity of dengue illness. In a recent study of 309 adults with DHF, causes of fatality were massive gastrointestinal (GI) bleeding, dengue shock syndrome (DSS), subarachnoid hemorrhage, and bacteremia from *Klebsiella pneumoniae* [136]. The influence of comorbidities and the pathogenesis of severe dengue illness in adults should be a high priority for future research.

6 Pathogenesis and Immunity

Most human infections with DENV originate from a transmission cycle between infected humans and mosquitoes of the genus *Aedes*, of which *A. aegypti* constitutes the most important vector for epidemic dengue worldwide [137]. Sylvatic transmission of DENV between nonhuman primates and other *Aedes* species has been documented in forest areas of Africa and Asia [138, 139]. Some evidence suggests that this cycle served as the original source of the viruses now circulating in the human population, but the latter viruses have since evolved as separate lineages with little evidence of ongoing interaction between these transmission cycles. Mosquitoes acquire DENV through feeding on the blood of viremic hosts. Viral infection of the mosquito midgut epithelium leads to dissemination and later infection of salivary gland tissue [140]. At that point, the mosquito is capable of transmitting the virus to a vertebrate host during subsequent blood feedings and remains infectious for the remainder of its lifetime. The time required for the mosquito to become infectious, or extrinsic incubation period, is modulated by ambient temperature, with higher temperatures resulting in a shorter extrinsic incubation period and therefore a greater potential for transmission [141].

DENV injected into the dermis during mosquito feeding most likely initially infects cells locally. Many different cell types can be infected with DENV in vitro, including human fibroblasts, but Langerhans cells or tissue macrophages are considered more likely initial targets of infection [142]. Additional components of the mosquito saliva may enhance infectivity, based on experiments in animal models, through mechanisms that are poorly defined [143]. The intrinsic (in humans) incubation period typically ranges from 4 to 9 days but can extend up to 14 days [141]. In experimental models, DENV is detected in local and regional lymph nodes and likely undergoes some replication there [144, 145]. Following the local/regional replication of DENV, systemic dissemination occurs. Viremia is detectable in nearly all symptomatic infections, often reaching very high titers within the first few days of symptoms [146, 147]. Dendritic cells, monocytes, and macrophages are considered the principal cellular targets; there is also substantial evidence of infection of B lymphocytes and hepatocytes [148–150]. Virus is detected principally in the liver and tissues of the reticuloendothelial

system including the bone marrow [151]. There is limited evidence for infection of other cells types in vivo, including mast cells, vascular endothelial cells, neurons, myocytes, and platelets; however, the frequency and significance of these phenomena remain controversial.

Innate immune responses, especially the production of type I interferons (IFN), are induced in both infected cells and in natural IFN-producing cells such as plasmacytoid dendritic cells [152, 153], and these responses likely account for many of the systemic symptoms and signs of infection. Plasma levels of IFN follow kinetics similar to plasma viral titers and are often at or near peak levels at the onset of fever and systemic symptoms [154]. Although DENV has evolved several immune evasion mechanisms, inhibiting both IFN production and response [155], studies in laboratory mice suggest that these innate responses are critical to the control of DENV infection [156].

Activation of adaptive immune responses can be detected within the first few days, with an increase in the circulating levels of activated T lymphocytes, plasmablasts, NK cells, DENV-specific T lymphocytes and antibodies, soluble markers of immune activation, and a wide array of both pro-inflammatory and anti-inflammatory cytokines [157–160]. This immune activation coincides with a rapid clearance of virus from both plasma and peripheral blood monocytes and lymphocytes, as well as the most serious symptoms and signs of dengue, including maximal thrombocytopenia, bleeding, elevation of hepatic transaminases, and plasma leakage.

Leukopenia, affecting both neutrophils and lymphocytes, is present throughout much of the symptomatic phase, and its severity does not correlate with other measures of disease severity [161]. Other common laboratory abnormalities include thombocytopenia and elevations in serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT); these abnormalities reach their extremes late in illness, coincident with plasma leakage, and correlate with the overall severity of illness. In fatal cases, the principal findings are serous effusions in pleural and peritoneal cavities, widely distributed microhemorrhages, and hepatocellular injury that can range from mild to severe [162]. The paucity of histologic findings in the vasculature has suggested that the enhanced vascular permeability represents physiologic disturbance to a greater extent than structural damage to blood vessel walls. Edema of the lung parenchyma is uncommon, even in patients with severe plasma leakage, and may reflect overly aggressive fluid administration rather than a consequence of DENV infection per se. Inflammation of the brain, heart, and other tissues has been described in isolated cases or small case series but is atypical.

DENV infection of bone marrow cells may in part explain the cytopenias [163], but platelet consumption is also increased, particularly in severe cases [164, 165]. Bleeding does not correlate well with the severity of thrombocytopenia, however. Other contributing factors may include coagulopathy due to clotting factor consumption and inhibitory antibodies recognizing cross-reactive determinants on clotting or hemostatic proteins [166]. The pathophysiologic basis of dengue-associated plasma leakage has been and remains a source of controversy. The competing hypotheses of a viral mechanism versus an immunologic mechanism for this syndrome have largely been decided in favor of a principally immunologic mechanism on the basis of strong epidemiologic data showing an association with prior DENV exposure [91, 167]. Nevertheless, viral factors are obviously also involved, as some DENV genotypes appear to be incapable of triggering plasma leakage [168]. Elevated production of factors promoting vascular permeability—TNF-α and vascular endothelial growth factor (VEGF) among others—is clearly correlated with the extent of plasma leakage [158]. The sources of these factors and reasons for their increased production remain unclear, however. High level viremia appears to be necessary to initiate this cascade of events, but is not sufficient to cause plasma leakage. Furthermore, plasma leakage occurs several days after the peak of viremia and instead closer in time to the period of rapid clearance of viremia; these observations support the immune-mediated model of pathogenesis [147]. Both DENV-infected cells, such as monocytes, macrophages, dendritic cells, and mast cells, and responding effector cells, such as NK and T cells, produce factors that are capable of contributing to vascular permeability under experimental conditions [152, 169–171]. Given this variety of potential mechanisms, it is possible that no one single pathway explains plasma leakage in all cases.

Patients who have recovered from acute dengue illness demonstrate antibodies and T lymphocytes that recognize both serotype-specific and serotype-cross-reactive determinants. The principal targets of DENV-specific antibodies are the E, pre-M, and NS1 proteins [172–174]. Antibodies to the E protein mediate neutralization in vitro and in vivo to various degrees determined by both the antibody affinity and the epitope targeted; antibodies directed at domain III of the protein tend to display greater serotype specificity and neutralization activity [172]. Antibodies with lower affinity and those with high affinity when present at concentrations below the threshold for neutralization form immune complexes with virions and facilitate uptake into and productive infection of immunoglobulin receptor-bearing cells in vitro and in vivo, i.e., ADE [175]. In addition to increasing the mass of infected cells, infection via ADE may also modify infection by (a) increasing the number of progeny virions produced by each infected cell and (b) inducing IL-10 and other cytokines via signaling from the immunoglobulin receptor(s) [176]. Antibodies to pre-M bind only to immature or partially

mature virions. Although a pre-M-specific monoclonal antibody was reported to protect mice from a lethal DENV challenge [177], other studies have found these antibodies to have poor neutralizing activity but to be capable of enhancing the infectivity of immature virions [178]. Antibodies to NS1, in contrast, are incapable of binding to virions; these antibodies bind both to soluble NS1, which is released from infected cells and is found in the circulation, and to NS1 on the surface of infected cells [179, 180]. Binding of anti-NS1 antibodies to cells can trigger complement-mediated and/or cell-mediated cytotoxicity [181, 182]. Under some conditions, soluble NS1 can attach to the surface of uninfected cells, thereby causing uninfected cells to be targeted by the same processes [183]. Some antibodies to NS1 also bind in a cross-reactive fashion to determinants on components of the coagulation pathway or platelet/endothelial cell surface proteins [166].

Epitopes recognized by CD4 and CD8 T lymphocytes have been identified in all of the DENV proteins [184–186]. Several studies have found a concentration of epitopes in the NS3 protein, however, raising the possibility that this protein has features associated with higher levels of MHC class I and II presentation or has sequence constraints that limit its ability to mutate toward reduced immunogenicity. Upon contact with DENV-infected cells, DENV-specific T cells secrete predominantly type 1 cytokines (IFN-γ, TNF-α, and IL-2) and lyse antigen-presenting cells [187, 188]. An intriguing feature of the serotype-cross-reactive T-cell response is that the sequence differences between serotypes (usually 1–3 residues of the 9 amino acids in the epitope) result in both quantitative and qualitative changes in the effector functions expressed by T cells, sometime referred to as heterologous immunity [170, 171, 189, 190]. In particular, the production of the antiviral cytokine IFN-γ is reportedly diminished, while the production of pro-inflammatory cytokines such as TNF-α and MIP-1β is unchanged.

The immune response differs substantially between the first (primary) DENV infection and subsequent (secondary, tertiary, and quarternary) DENV infections. The differences are attributed to two factors. First, at the time of the secondary and subsequent infections, memory T and B lymphocytes are already present, having been induced by the earlier primary infection. Second, because reinfection with the same serotype is not known to occur, secondary and subsequent infections involve antigenic differences from the earlier infection. Anti-DENV IgG antibodies rise earlier and reach dramatically higher peak titers, while IgM antibody responses are blunted, and the antibodies produced are predominantly serotype cross-reactive. Most of the serotype-cross-reactive antibodies display lower affinity for epitopes on the newly infecting DENV than for the previously encountered DENV, however [174, 191, 192]. The frequencies of circulating DENV-specific T lymphocytes and their expression of activation markers are similarly high in primary and subsequent infections [190]. However, a greater proportion of DENV-specific T lymphocytes target more conserved regions of the DENV proteome and show serotype cross-reactivity in their responses.

The immune responses induced by DENV infection described above can have either protective or pathological effects during the second or subsequent DENV infection. Protective immunity is mainly serotype specific. Protective immunity can be ascribed to high-avidity E protein-specific neutralizing antibodies based on experimental challenge studies in animal models [193]. However, in vitro assays of neutralizing antibody are a poor measure of protective immunity, especially in individuals who have had several prior DENV infections, in whom antibody responses are highly serotype cross-reactive [116]. Antibodies to the pre-M and NS1 proteins have also shown protective efficacy in animal models, but the applicability of these findings to human infection is unclear. Studies of protection mediated by DENV-specific T lymphocytes are more limited. However, one prospective cohort study conducted in Thailand found an association between higher baseline DENV-specific T-cell IFN-γ responses and subsequent subclinical DENV infection [194], and a survey of healthy adults from Sri Lanka found higher DENV-specific T-cell IFN-γ responses in subjects with HLA alleles that were associated with a lower risk of DHF [186].

Except for a short (several months) period of resistance to challenge with other serotypes, individuals who have had one (primary) DENV infection are not only at risk for infection with any of the other three serotypes, but they are actually at increased risk for development of dengue-related plasma leakage compared to individuals who have never had prior exposure to DENV [20, 82, 91]. This finding is the principal basis for proposing the existence of pathologic immune responses to DENV. Both DENV-specific antibodies and T cells have pathologic potential, through mechanisms discussed above. The observation by Halstead of enhanced DENV infection due to ADE (see above) provided a model for antibody-mediated immunopathology [195] and has also been invoked to explain dengue-associated plasma leakage among infants in endemic countries, who acquire DENV-specific antibodies transplacentally from their DENV-immune mothers [114]. At odds with this model are the observations that (a) plasma leakage occurs several days after the peak viremia, (b) anti-DENV antibodies are neither necessary nor sufficient for the occurrence of plasma leakage, and (c) preinfection serum ADE activity has not been correlated with disease severity [196, 197]. Immune activation and cytokine production thus appear to be a critical link in the pathogenetic cascade. One study has suggested an association with T-cell production of TNF-α [198], but the in vivo evidence for a specific T-cell mechanism remains extremely limited.

7 Patterns of Host Response

7.1 Common Clinical Features

Many DENV infections resolve without a recognized illness, particularly in children [115]. Among patients with laboratory-confirmed dengue illness, constitutional symptoms are most often reported, including fever, headache, eye pain, body pain, and joint pain (60–90 % of patients) [199]. Rash, typically macular or maculopapular, is reported in approximately half of the subjects. Gastrointestinal symptoms—nausea, vomiting, or diarrhea—occur in 30–50 % of patients, and respiratory symptoms, including cough, sore throat, and nasal congestion, are somewhat less common (~1/3 of patients). The frequency of symptoms is influenced by the patient's age, sex, and previous history of DENV exposure (primary vs. secondary DENV infections) [199]. All symptoms are less frequent in children. Joint pain, body pain, and rashes are more commonly reported in females. Rashes have been more frequently reported in primary DENV infections, whereas constitutional and gastrointestinal symptoms have been more common in patients experiencing a secondary DENV infection.

Fever accompanied by prominent headache, retro-orbital pain, and muscle and joint pains forms the syndrome of classical dengue fever (DF), which had historically evoked more descriptive terminology such as "breakbone fever" [39]. However, these classic symptoms have been reported in a minority of cases in studies of travelers or military personnel [131, 200–202]. The duration of symptoms in DF typically ranges 5–7 days [202], with some patients showing a biphasic ("saddleback") fever curve. Periods of marked fatigue lasting days to weeks after the acute illness are occasionally reported, especially in adults.

Hemorrhagic manifestations occur often in patients with DF, with spontaneous bleeding in as many as two thirds of cases [158]. The skin (petechiae) and nose are the most common bleeding sites; gastrointestinal or genitourinary bleeding is less common [202]. In rare cases, bleeding is severe enough to be life threatening, but this clinical presentation needs to be differentiated from dengue hemorrhagic fever (DHF), described below.

The physical examination in patients with DF is generally nonspecific, with fever and rash being the most common findings. Typical laboratory findings include leukopenia, thrombocytopenia, and elevated hepatic transaminases [131, 161, 203]. Thrombocytopenia can be profound, with platelet counts <100,000 cells/mm^3 observed in one quarter to one half of patients. Serum aspartate transaminase (AST) levels are characteristically more elevated than alanine aminotransferase (ALT) levels; elevations are usually modest (2–5 × upper limit of normal), but marked elevations (5–15 times the upper limit of normal) are occasionally noted [202, 203].

7.2 Dengue Hemorrhagic Fever

Plasma leakage is the most worrisome manifestation of DENV infection, although other less common syndromes can be life threatening. For historical reasons, this syndrome is referred to as dengue hemorrhagic fever (DHF) and has been defined based on the presence of four cardinal features [3, 5, 18]: fever lasting 2–7 days; increased vascular permeability as evidenced by hemoconcentration (20 % or greater rise in hematocrit above baseline value), pleural effusion, or ascites [15]; marked thrombocytopenia (platelet count 100,000 cells/mm^3 or lower); and a hemorrhagic tendency as demonstrated by a positive tourniquet test or spontaneous bleeding. The term dengue shock syndrome (DSS) is used when shock is present along with these four criteria [18].

The increase in vascular permeability leading to plasma leakage in DHF develops rapidly, over a period of 24–48 h, and characteristically occurs between 3 and 7 days after the onset of illness [204]. This time point coincides with the disappearance of fever, the nadir of platelet count, and the peak of serum aminotransferase elevations [205]. Abdominal pain is reported shortly before the onset of plasma leakage in ~60 % of patients with DHF [206–208]. Intense abdominal pain, persistent vomiting, change from fever to hypothermia, and marked restlessness or lethargy, especially occurring during this window of time, have been proposed as "alarm signs" for clinicians of possible impending shock [209].

The hemorrhagic manifestations are variable in severity among patients with DHF. Spontaneous petechiae or ecchymoses have been reported in approximately one half of cases with DHF [206, 208]. The tourniquet test, performed by inflating a blood pressure cuff on the arm to a level halfway between systolic and diastolic pressure for 5 min, elicits petechiae in the remaining cases. Less common sites of spontaneous bleeding include the nose, the gastrointestinal tract (hematemesis more often than melena), and genitourinary tract (more often in women).

Leukopenia and thrombocytopenia are common laboratory findings in DHF, the latter being a component of the WHO case definition. Serum transaminase levels are significantly different between DF and DHF, and they have been proposed as useful markers of illness severity prior to clinically evident plasma leakage [203, 210].

There continues to be debate as to whether DF and DHF are different diseases, implying distinct pathogenesis mechanisms, or whether DHF represents an extreme along a continuous spectrum of disease severity encompassing both patient populations. Some investigators have highlighted cases that have been difficult to classify, usually where plasma leakage is apparent, but the other three criteria of DHF were not all met [211]. Although such cases occur, they clearly represent a minority of patients, as most patients with plasma leakage display the full picture of DHF [158].

7.3 Atypical Dengue Syndromes

In rare cases, liver failure or neurologic dysfunction is the predominant clinical feature in a patient with DENV infection [212–215]. Liver failure may have been a consequence of prolonged shock in some cases, rather than a direct viral effect. A wide range of neurological manifestations have been described in patients with laboratory-confirmed DENV infection, including encephalopathy, seizures, pure motor weakness, mononeuropathies, polyneuropathies, Guillain-Barré syndrome, and transverse myelitis [212, 213, 216, 217]; some patients have none of the characteristic features of DF or DHF. A causal association has been supported by the occasional detection of DENV in cerebrospinal fluid. Myocarditis, cholecystitis, and retinal vasculitis [218], have been reported in isolated patients with serologic evidence of acute dengue, but a causal association with DENV is not definitively established since subclinical DENV infections are common in endemic areas.

7.4 Differential Diagnosis

The clinical features of DF are largely nonspecific. The differential diagnosis for this syndrome includes influenza, enteroviral infection, measles, and rubella. In residents of or travelers to endemic areas, malaria, leptospirosis, and typhoid fever are also relevant for consideration [219]. Over 90 % of patients in dengue-endemic areas who meet all of the criteria in the case definition for DHF have serologic evidence of DENV infection [158]. Bacterial sepsis, leptospirosis, malaria, and other viral hemorrhagic fevers are worthy of consideration, however.

8 Control and Prevention

8.1 Treatment

There is no licensed therapeutic agent or vaccine to prevent dengue disease. The recommended treatment for patients with suspected acute DENV infection includes supportive care, acetaminophen for relief of fever and aches, and monitoring to detect plasma leakage and other severe manifestations at the earliest stage possible. Aspirin and nonsteroidal anti-inflammatory drugs are best avoided to minimize the risk for bleeding and Reye syndrome. There are no antiviral drugs available at the present time with demonstrated efficacy in dengue. Chloroquine, which shows some antiviral activity in vitro, was ineffective in a high-quality clinical trial [220].

There has been substantial interest in the potential value of immunomodulation as a strategy to reduce the severity of dengue illness, based on the model of immune-mediated pathogenesis described above. In controlled clinical trials, corticosteroids have not proven effective either in patients with established shock [221] or when given earlier in illness [222]. Other adjunctive therapies, for example, pentoxifylline or intravenous immunoglobulins, have only been tested in uncontrolled case series or small clinical trials.

8.2 Vector Control

Efforts to control endemic and epidemic dengue transmission and reduce disease burden have been limited largely to vector control and personal protective measures to reduce human-vector interaction [223]. The World Health Organization (WHO) promotes a concept of Integrated Vector Management (IVM) with the aim to improve efficacy, cost-effectiveness, ecological soundness, and sustainability of disease-vector control. Program pillars include environmental management (i.e., reduce potential breeding containers, modify human behavior), chemical control (i.e., larvicides/adulticides and residual and space spraying), and biologic control (i.e., fish, predatory copepods) [224]. There are historic examples of successful vector control campaigns. In the late 1940s, Dr. Fred Soper led an *A. aegypti* eradication effort in the Americas; between 1948 and 1962, the species was eliminated from 21 countries. Unfortunately, success was short lived due to reduced funding, lack of program leadership, lack of political will, and a deficit of highly trained people to design and execute the programs [223]. In 1973, Singapore completed the implementation of a vector control program to reduce the premise index (i.e., the percentage of houses infested with *A. aegypti* larvae and/or pupae), bringing the index to ~2 % with an associated 15-year period of low dengue disease incidence. However, in the 1990s, despite maintaining the premise index ~2 %, dengue surged [225]. Singapore's experience highlighted the complexity of managing vector control programs and the need for a more evidenced-based and data-driven approach to designing and implementing control programs. In addition, a more strategic application of tools capable of defining and modeling dengue disease and vector population dynamics in space and time was needed.

Interesting advances have been made in vector-based interventions to include biocontrol and genetic modification of vector populations [226]. One example is the proposed use of *Wolbachia*, an endosymbiotic bacterium estimated to be present in up to 66 % of insect species [227]. The bacterium infects the gonads, where it ensures transmission to the next host generation (from mother to egg) and manipulates reproductive capabilities [226]. The manipulations directly or indirectly benefit the infected females assisting with its spread through host populations [228]. Other changes

associated with *Wolbachia* infections include a shortened lifespan, altered locomotor activity, and poor blood feeding in mosquitoes [229–231]. *Wolbachia* use to control insect populations has been explored since 1967 [232]. Three *Wolbachia* strains have been successfully introduced into the *A. aegypti* populations, setting the stage for release studies [230, 233, 234]. Mosquito population reduction and suppression, decreased pathogen transmission, and/or decreased pathogen replication in mosquito species are desirable outcomes [226]. Recent, small-scale releases demonstrated the ability for genetically modified males to persist in nature and reduce wild-type populations [235, 236]. Regulatory issues, proof-of-concept trial design, and sustainability are a few of the issues requiring extensive thought prior to large-scale use [237].

Vector control through any means will require community buy-in and, in some cases, active participation. Political will and sustained financial resources will be required for any effort to be effective in reducing disease burden. Providing scientists and operational personnel state-of-the-art education and access to advanced epidemiologic tools (global positioning systems, modeling software, etc.) will increase the likelihood of program success.

8.3 Vaccines

The dengue vaccine pipeline in 2013 is robust; the following is a review of the approaches currently being tested in human trials. Initial development efforts began in 1929 with unsuccessful attempts to produce an inactivated virus vaccine using phenol, formalin, or bile [46]. During World War II, live attenuated virus (LAV) vaccines were explored by serially passaging DENV-1 and DENV-2 strains in suckling mouse brain [45, 238, 239]. Mouse brain-derived candidates were eventually abandoned for cell culture-based vaccines. Currently, six different vaccine approaches have been tested in human clinical trials, and a single candidate is in phase 3 clinical trials.

Flaviviral live attenuated virus (LAV) vaccines (yellow fever (YF), Japanese encephalitis) have proved to be safe and durably efficacious [240–243]. LAV vaccines replicate in the recipient, presenting all viral antigens in the vaccine construct, and eliciting both antibody and T-cell responses, resembling those seen after natural infection. A tetravalent vaccine approach (i.e., DENV-1 + DENV-2 + DENV-3 + DENV-4) is designed to induce primary-type immune responses to all four dengue viruses simultaneously. The first major effort at live attenuated dengue vaccine development was made at Mahidol University in Bangkok; investigators used the classical method of serial passage of virus in dog (PDK) and nonhuman primate (PGMK) cell lines [244–250]. The effort experienced early success, but tetravalent formulation and balancing immunogenicity (i.e., neutralizing antibody responses to each dengue virus type) with safety proved difficult [251–254].

The Walter Reed Army Institute of Research (WRAIR) also developed LAV candidates by serial PDK passage of each dengue virus type with final passages in fetal rhesus lung cells (FRhL). Early development efforts identified dengue virus strains and promising formulations combining variations of attenuation and dengue virus antigen concentrations [255–263]. A single formulation was tested in Thai schoolchildren and toddlers. Vaccination was well tolerated and, although variable neutralizing antibody responses were observed across cohorts, was sufficiently immunogenic to pursue continued development of the candidate [264, 265]. Newly derived vaccine lots were tested in adults in the United States and in Thailand and Puerto Rico across a broad age range (12 months to 50 years). There were no overt safety signals in over 300 vaccine recipients, and rates of seroconversion were moderate to high [264, 266]. Although the candidate demonstrated promise, the WRAIR and its corporate partner indefinitely suspended development in pursuit of a superior target product profile (i.e., shorter dosing schedule).

The US National Institutes of Health (NIH) constructed viable cDNA clones of DENV-4 and induced a 30-nucleotide deletion in the 3′ untranslated region (i.e., directed mutagenesis). The result was lower viremia levels than the parental strain and retained immunogenicity. Numerous monovalent vaccine candidates were tested in phase 1 clinical trials to identify optimal candidates for tetravalent formulation [267–275]. Tetravalent candidates (admixtures, TetraVax-DV) were prepared and are being tested in phase 1/2 clinical trials [276].

The insertion of dengue *preM* and *E* genes into the cDNA backbone of YF 17D as a vaccine development platform (i.e., chimera) was pioneered at the St. Louis University Health Sciences Center, further developed by Acambis, Inc., and licensed for manufacture to Sanofi Pasteur [277–281]. Phase 1 clinical trials of monovalent vaccine preparations in YF-naïve and YF-primed volunteers demonstrated acceptable safety and immunogenicity profiles (i.e., neutralizing antibody responses) [282, 283]. Expanded trials with tetravalent preparations in volunteers of various ages, genetic backgrounds, and flavivirus priming status (i.e., preexisting immunity to YF, dengue, Japanese encephalitis) demonstrated a consistently excellent safety profile and robust, balanced neutralizing antibody profiles [284–288]. Sanofi's ChimeriVax (a construct containing yellow fever and dengue components) was the first dengue vaccine candidate tested in a clinical endpoint efficacy study. The phase 2b trial was an observer-blinded, randomized, controlled, single-center trial in healthy Thai schoolchildren ($N = 4{,}002$) aged 4–11 years who were randomly assigned (2:1) to receive three injections

of dengue vaccine or control (rabies vaccine or placebo) at 0, 6, and 12 months. All subjects were followed for dengue illness. The primary objective was to assess protective efficacy against virologically confirmed, symptomatic dengue, irrespective of severity or serotype, occurring 1 month or longer after the third injection. Although the vaccine was safe and neutralizing antibody responses were moderate to high, overall efficacy was 30.2 % (95 % CI −13.4 to 56.6) and differed by serotype [289]. The results of this trial were disappointing and highlighted the numerous, still unanswered, questions which exist regarding immuno-protective profiles (see below). Phase 3 trials in Latin America and Asia are ongoing.

The US Centers for Disease Control and Prevention (CDC) developed a tetravalent chimeric dengue vaccine by introducing DENV-1, DENV-3, and DENV-4 *prM* and *E* genes into cDNA derived from an attenuated LAV DENV-2 component [290–294]. Dengue-dengue chimeras were formulated as a DENV-1/DENV-2, DENV-2, DENV-3/DENV-2, and DENV-4/DENV-2 tetravalent vaccine candidates (DENVax) and licensed to Inviragen, Inc. [295, 296]. Phase 1 clinical trials in dengue-endemic and dengue-non-endemic areas are underway [297]. Another approach to producing viral vaccines is the use of inactivated whole virus or viral subunits. Such vaccines have potential advantages to include the inability to revert to a more pathogenic phenotype, they are unlikely to produce immune interference when combined into a tetravalent formulation, and, theoretically, there could be fewer safety issues. Inactivated flaviviral vaccines have been licensed and are in wide use to prevent Japanese encephalitis and tick-borne encephalitis [298–300].

These vaccines have certain potential disadvantages. Killed or subunit vaccines raise antibodies to only a portion of the structural proteins and normal virion-based structural conformation. High concentrations of antigens and multiple doses may also be required to induce a potent and protective immune response. Another concern is the potential for an adverse response resembling the occurrence of atypical measles and respiratory syncytial virus (RSV) infection following vaccination and subsequent wild-type exposure [301, 302]. Merck & Co. is developing a dengue vaccine candidate produced in a Drosophila S2 cell expression system [303–305]. A single DENV-1 monovalent trial has been completed and a phase 1 tetravalent trial is under way [297].

The WRAIR developed a purified inactivated virus (PIV) dengue vaccine candidate by inactivating with formalin each of the dengue virus types [305–308]. A phase 1 trial of a monovalent DENV-1 PIV adjuvanted with alum was completed in a small number of US flavivirus-naïve volunteers. The candidate had an acceptable safety profile with low to moderate immunogenicity. GlaxoSmithKline Vaccines (GSK) and the WRAIR are currently testing a tetravalent PIV formulation adjuvanted with GSK's proprietary adjuvant systems. Phase 1 trials in the United States and Puerto Rico are underway.

DNA vaccines consist of one or more plasmids containing DENV genes reproduced to high copy number in bacteria such as *E. coli*. The plasmid contains a eukaryotic promoter and termination sequence to drive transcription and presentation to the immune system. DNA vaccine advantages include ease of production, stability and ability to be transported at room temperature, ability to accept new genes, ability to immunize against multiple pathogens with a single construct, and reduced reactogenicity [309]. A DENV-1 monovalent DNA vaccine trial enrolled 22 flavivirus-naïve US volunteers. None of the low-dosage recipients and only five of 11 high-dosage recipients developed neutralizing antibodies. The safety profile was acceptable and supported exploration of an adjuvanted DNA dengue vaccine [310].

In addition to the dengue vaccine candidates listed above in clinical development, there are also numerous in preclinical development (i.e., mice and nonhuman primate studies). Without an animal model of disease, a human challenge model, or a correlate of protection, it will be a slow and arduous process to advance candidates through efficacy trials. Despite this, the field is hopeful a dengue vaccine can be licensed in an endemic country within 5 years.

9 Unresolved Problems

Unraveling the virologic and immunologic complexities of the dengue viruses, virus-vector-host interactions, and dengue disease has been challenging. The existence and co-circulation of four antigenically distinct viruses, the absence of an animal model of disease, the absence of a dengue human infection model, and gaps in our comprehensive understanding of what constitutes immunopathologic versus immuno-protective profiles have contributed to difficulties in prognosticating, in a clinically relevant way, dengue disease severity and the development of anti-dengue virus therapeutics and protective vaccine candidates. The disconnect between vaccine immunogenicity, as measured using a standard plaque reduction neutralizing antibody test, and clinical outcome following wild-type virus exposure further complicates the field. The following are a few of the knowledge gaps and areas of current scientific interest and exploration.

There is no well-characterized and comprehensive animal model of dengue disease. However, significant resources have been allocated and development progress has been made [311, 312, 313, 314]. Two models currently being explored include the hu-HSC mouse model created by human hematopoietic stem cell (HSC) engraftment and the

BLT mouse model prepared by co-transplantation of the human fetal liver, thymus, and HSC [315]. Humanized mouse models with a transplanted human immune system have the ability to generate T cells, B cells, macrophages, dendritic cells, and natural killer (NK) cells. Theoretically, these mice possess the immunologic "building blocks" required to generate the pro-inflammatory cascade of immunologic events required to induce clinical outcomes such as plasma leakage and hemorrhage. Until further development and optimization is achieved, mouse models will be absent from the "critical path" components of advanced drug or vaccine development programs.

Following dengue virus exposure, nonhuman primates develop infection as evidenced by measurable replicating peripheral viremia and neutralizing antibody and cellular immune responses. Nonhuman primates do not consistently develop objective and measurable clinical or biochemical markers of disease (i.e., elevated temperature, failure to feed, lethargy, rash, depressed white blood cell and platelet count, evidence of plasma leakage, or hemorrhage) [316–318]. A single study reported a hemorrhagic phenotype following intravenous administration of a high-titer DENV-2 strain, but these findings have not been reproduced [319]. Despite this, the nonhuman primate dengue virus infection and viremia model has been a required and necessary component of dengue vaccine development programs and the transition between preclinical and clinical development phases. How informative the nonhuman primate model is as it relates to predicting human responses to dengue virus exposure or vaccination with candidate dengue vaccines remains unclear. The observation of low clinical efficacy against DENV-2 infection following vaccination despite protective efficacy in nonhuman primates underscores the need to rethink the utility of the model and the need to further optimize or explore other options [249, 279].

Identifying which cytokines, factors, and/or other circulating immune mediators contribute to clinical disease or protection from the same is one challenge, and how to best measure these is another. Neutralizing antibodies have been associated with protection from other flaviviral diseases such as yellow fever and Japanese encephalitis [320]. It is therefore reasonable to assume that neutralizing antibodies play a similarly protective role in dengue. Measurement of neutralizing antibodies has classically been accomplished using a plaque reduction neutralization test (PRNT) [321]. Although very informative, properly performing and interpreting PRNT results requires advanced skill and experience. Variability among laboratories and technicians has been observed. Furthermore, the assay lacks robustness with minimal modifications in assay reagents or testing conditions producing significant variability in results [105]. It is for these reasons direct comparison of immunogenicity readouts between vaccine candidates and developers has been difficult [322]. Newer methods of measuring neutralizing antibodies have been proposed to increase throughput, reduce human error, reduce assay-to-assay variation, and increase the biologic and physiologic relevancy of the measurement [323–325].

Variation also permeates the measurement of cell-mediated immune responses. It is generally accepted that components of the cellular immune system contribute to both the disease severity and the immune profile which protects against disease following homotypic reinfection [186, 326–333]. What is less clear is the sequence of immunologic events which leads to one outcome (antiviral activity, asymptomatic, or highly attenuated illness) versus another (pro-inflammatory state, disease). How components of the humoral and cellular immune systems interact qualitatively, quantitatively, and kinetically during in vivo infection is incompletely understood. Furthermore, the immunologic events that may determine the resulting clinical phenotype likely occur prior to the onset of symptoms. As a result, when and how to collect the appropriate biologic samples following infection remains unknown, and important immunologic events are not measured.

Key to the study of dengue immunopathogenesis is being able to link biologic samples (i.e., whole blood, peripheral blood mononuclear cells, etc.) collected before, during, and after dengue virus exposure and to associate these with various clinical phenotypes observed following infection (i.e., asymptomatic infection, dengue fever, severe dengue). Establishing a correlate and/or surrogate of protection is probably not possible without this approach. The complexity of this task is not trivial as it involves establishing prospective cohorts in dengue-endemic areas with sustained and relatively high annual clinical attack rates (1.5–2.0 %). To complete comprehensive immunologic evaluations also requires a sample with a significant volume of biologic material, a challenge in places where dengue disease is preferentially experienced by toddlers and children. Prospective studies are performed over multiple years and are very costly. Despite these challenges, numerous cohorts have been established in Asia and Latin America and are making important contributions to our understanding of dengue [82, 115, 197, 334–339].

Additional challenges to the dengue field include understanding (1) how viral diversity over time and space may or may not impact disease severity or what diversity means for developing a protective vaccine, (2) immune response maturation following infection over time and the impact of waning immunity on both durable protection from disease and vaccination policies once a vaccine is available, and (3) the role of protective and non-protective heterotypic immunity [29, 340]. It is possible that the world will have a safe, efficacious, and effective dengue vaccine available before many of the above questions have been answered.

Flaviviruses: Yellow Fever, Japanese B, West Nile, and Others

16

Stephen J. Thomas, Luis J. Martinez, and Timothy P. Endy

1 Introduction

Historically and currently the flaviviruses are important human pathogens both as endemic viruses restricted to specific geographic areas and as emerging pathogens. Yellow fever, West Nile virus, and the dengue viruses (not discussed in this chapter) represent previous, current, and future important emerging pathogens that have produced large epidemics and human deaths. Why are these viruses such a threat to human populations as emerging pathogens? Several important factors interplay to create these pathogens as agents of emerging diseases. As mostly arthropod-borne viruses (arboviruses), they have complex life cycles involving both arthropods and vertebrate hosts with a life cycle involving all life stages of the arthropods (mosquitoes, ticks, and midges) and their reservoirs of vertebrates (birds or rodents) and ultimately higher vertebrates (humans) through the bite of the infected arthropod vector. The flaviviruses all contain ribonucleic acid (RNA) as their genetic core and as such have a high rate of mutations and thus adapt quickly to changes in vector competence and the environment. Climate change, urbanization, and increasing ease of travel have created opportunities for the vector to spread and expand into human populations. The combination of these factors produces a family of viruses that can change and emerge quickly as important human pathogens.

Yellow fever virus (discussed in detail in this chapter) was the first arbovirus identified in the 1800s as responsible for large epidemics of hemorrhagic fever in Africa and North, Central, and South America. By 1960 scientists recognized serologically two distinct arboviruses: the group A arboviruses now known as the family *Togaviridae* and the group B arboviruses, renamed the family *Flaviviridae* [1]. Serologic comparisons among the flaviviruses revealed cross-reactivity within groups distinguishing the flaviviruses as mosquito borne, tick borne, or nonvectored [2]. According to the International Committee on Taxonomy of Viruses, a subgroup of the Division of Virology of the International Union of Microbiology Societies, the Family *Flaviviridae* is comprised of three genera: *Flavivirus*, *Hepacivirus*, and *Pestivirus* (http://ictvonline.org/index.asp). Information on their isolation, morphology, sensitivity to inactivation by chemicals, arthropod vectors, vertebrate hosts, laboratory propagation, serologic reactions, geographic distribution, clinical manifestations, and epidemiology is found in the *International Catalogue of Arthropod-Borne Viruses*, compiled by the American Committee on Arthropod-Borne Viruses (ACAV) [3]. This exhaustive reference source has been used freely in preparing the text that follows. *Hepacivirus* and *Pestivirus* are discussed elsewhere in this textbook, and the focus of this chapter will be on the pathogenic viruses within the genera *Flavivirus*. The dengue viruses are discussed in a separate chapter. Within the genus *Flavivirus* there are 53 species of viruses and displayed in Table 16.1.

Despite their species variation, the flaviviruses have a remarkable genetic conservation throughout its genus [4]. The genome is a single positive-stranded RNA, 11 kilobases in length, encoding the viral proteins from an open reading frame (ORF) of over 10,000 bases of approximately 3,434 amino acids [4]. The proteins encoded from the ORF is 5′–C-prM (M)-E-NS I-NS2A-NS2B-NS3-NS4A-NS4B-NS5-3′. The structural proteins C (capsid), M (membrane), and E (envelope) comprise the outer coat of the flaviviruses and the epitopes responsible for attachment to host cells and cell entry. The nonstructural proteins include the highly

conserved proteins NS1, NS3, and NS5 and the four small hydrophobic proteins NS2A, NS2B, NS4A, and NS4B [4].

Molecular and phylogenetic analysis of the genus *Flavivirus* reveals a family of viruses that has evolved rapidly from a progenitor virus arising possibly in Africa several thousands of years ago. With evolution the flaviviruses have shown substantial ecological diversification with different lineages adapting to different vectors and modes of transmission. They have also evolved unique strategies to evade the host's innate and adaptive immunity [5]. Figure 16.1 displays the phylogenetic tree of the genus *Flavivirus* showing the association of the groups of related viruses with their invertebrate vectors, vertebrate hosts, and geographic distribution. All human pathogenic flaviviruses are transmitted by insect vectors, and all but the dengue viruses have an animal host (i.e., they are zoonotic). The ecological speciations of these viruses are diverse. For example, the Japanese encephalitis virus (JEV) group (e.g., Japanese encephalitis virus, West Nile virus (WNV), St. Louis encephalitis (SLE)) is maintained in a cycle of transmission between birds and *Culex* mosquitoes. Mammalian hosts, humans, and horses are infected but are dead-end hosts as the viremia achieved is too low for subsequent transmission to an insect vector. The tick-borne encephalitis group is transmitted among rodents by a tick vector; as with the JEV group, humans are a dead-end host. Yellow fever virus (YFV) is primarily maintained in a sylvatic cycle involving nonhuman primates and *Aedes* mosquitoes; but it has shown the capacity to spread in urban areas using *Aedes aegypti* mosquitoes and humans as its primary reservoir, resulting in extensive urban epidemics.

Analysis of the genetic changes of the flaviviruses over time reveals a group of viruses that have evolved rapidly. Methods using coalescent theory and a maximum likelihood (ML) demographic model reveal that the flaviviruses are growing at an exponential rate, with specific viruses such as the dengue viruses increasing rapidly in the recent past and Japanese encephalitis virus changing from constant population size to exponential growth within the last century [6]. For St. Louis encephalitis virus (SLEV), a Bayesian coalescent approach was used on the envelope gene sequence substitution rates and dates of divergence in the Americas [7]. The mean substitution rate estimated for all SLEV was 4.1×10^{-4} substitutions/site/year. The direction of the gene flow was South to North between 158N and 308N latitude consistent with migratory bird patterns from their northern breeding grounds after having acquired infection while wintering in the region of the Gulf of Mexico. This is an elegant example of the role of the vector and the vertebrate host especially migratory birds in influencing the gene flow and evolution of the flaviviruses. The dengue viruses (DENVs) are also an example of an emerged flavivirus and global health problem that have changed dramatically over the past century. DENV has evolved to a molecular clock that is serotype and genotype specific [8]. Phylogenetic analysis and time analysis suggest that dengue viruses serotypes separated within the last 1,000 years, and the change of DENV from a sylvatic cycle to sustained human transmission may have occurred between 125 and 320 years ago [9].

In this chapter we will review the characteristics of the flaviviruses, their modes of transmission, and their role in causing severe human clinical infection and emerging diseases of potential epidemiologic significance.

2 Historical Background

Yellow fever and its emergence as a deadly epidemic disease is a model on how diseases emerge to become a large recurrent epidemic disease in urban populations. Originally an African virus unknown to the western world prior to the 1600s, was introduced to the Western Hemisphere by the transportation of slaves from Africa with the first reported outbreak of yellow fever in the Yucatan in 1648 [10]. The transportation of the mosquito vector and infected passengers by ship and introduction of the virus into naive susceptible populations resulted over the next 200 years in the transmission of the virus and illness to many large urban populations with outbreaks occurring in the tropical Americas, costal North America, and Europe. Yellow fever became known in the Hispanic world as *La Vomito* for the black vomit that accompanies the hemorrhagic phase and yellow jack among the Europeans for the international signal flag for quarantine and its characteristic yellow and black squares known by the same name. During the summer months, epidemics occurred in New York in 1668, Boston in 1691, and Charleston in 1699, as well as later in the cities of the Gulf of Mexico and the Mississippi River. In 1793 a major yellow fever epidemic occurred in Philadelphia. Philadelphia at that time was the United States' largest and most cosmopolitan city. French refugees from a slave rebellion in Haiti arrived on the banks of the Delaware River which bounds the east side of the city bringing yellow fever with them [11]. In July of that year, cases developed among the working class living along the Delaware River who suffered high fevers, yellowing of the skin and eyes, hemorrhage, and death. By August 19 the epidemic potential was recognized by Dr. Benjamin Rush, professor at the University of Pennsylvania, founder of the College of Physicians of Philadelphia, and signer of the Declaration of Independence. Dr. Rush later gave an accounting of his clinical experience during this epidemic in a publication entitled, "An Account of the Bilious Remitting Yellow Fever, as It Appeared in the City of Philadelphia, in the Year 1793." The epidemic peaked in October of that year with total deaths estimated to be 4,041–5,000 in a population of 45,000 (crude mortality of 9–11 %). Subsequently Philadelphia experienced outbreaks of yellow fever in 1797, 1798, 1799, 1802, 1803, and 1805.

[2] with permission of the publisher) Reprinted with permission from [296]

Yellow fever took its toll on deployed US soldiers in the tropical Americas, especially in Cuba. Army Surgeon-General George Miller Sternberg created the US Army Yellow Fever Commission in 1893 and directed Major Walter Reed to conduct studies to establish its etiology. Together with his colleagues and Carlos Finlay, a series of human clinical trials were performed in Havana, Cuba, during 1900–1901 to discover the cause of yellow fever. Walter Reed, Jas Carroll, and Aristides Agramonte published in the JAMA in 1901 *The Etiology of Yellow Fever: An Additional Note* where they discussed the methods of their studies, results, analysis, and concluded the following: (1) the mosquito serves as the intermediate host for the parasite of yellow fever; (2) yellow fever is transmitted to the nonimmune individual by means of the bite of the mosquito that has previously fed on the blood of those sick with this disease; (3) an interval of about 12 days or more after contamination appears to be necessary before the mosquito is capable of conveying the infection; (4) yellow fever is not conveyed by fomites, and hence disinfection of articles of clothing, bedding, or merchandise, supposedly contaminated by contact with the sick with this disease, is unnecessary; and (5) the spread of yellow fever can be most effectually controlled by measures directed to the destruction of mosquitoes and the protection of the sick against the bites of those Insects [12].

With this information, General William C. Gorgas engineered the elimination of the mosquito initially from Havana and then later from the environs of the Panama Canal construction site and subsequently yellow fever cases disappeared [13–16]. In 1932, Soper and colleagues showed that there was a jungle cycle of yellow fever in the absence of *A. aegypti*. This significant observation meant that yellow fever could not be stopped just by controlling the mosquitoes in the cities. Theiler and Smith succeeded in cultivating the Asibi strain of yellow fever virus, first in monkeys and then in embryonated eggs, and attenuated it by passage [17]. In 1937, they announced their discovery of an attenuated vaccine—the 17D strain [18]. This vaccine is used throughout the world today to prevent yellow fever.

The discovery of the role of *Aedes aegypti* in the transmission and spread of yellow fever introduced the concept of mosquito control as an effective measure to disrupt yellow fever transmission. The International Health Board and the Rockefeller Foundation instituted mosquito control strategies including the use of a larvicidal, Paris green, throughout the United States and Central and South America [19]. These techniques were applied to malaria control during the years from 1924 to 1925 [19]. World War II created the Rockefeller Foundation Health Commission in 1942 to support national defense and malaria control for US forces. The need for lousicides to combat typhus introduced a new insecticide developed by the Swiss firm, Geigy, called dichlorodiphenyltrichloroethane (DDT) [19]. Led by Fred Soper, the Rockefeller team demonstrated the effectiveness of DDT as a lousicides and in disrupting typhus epidemics. DDT was soon used in aerial and ground spraying for Allied Forces during a malaria outbreak in Italy and was found to be highly effective. DDT became a key component of the World Health Organization's global malaria eradication campaign in 1955 [19]. This campaign resulted in the elimination of both the malaria mosquito vector and *Aedes aegypti* throughout South America and the virtual elimination of malaria, yellow fever, and dengue throughout the Americas. The growing concerns of the environmental effects of DDT led to the end of the use of DDT as an effective mosquito control larvicide in 1969 [20]. The cessation of the DDT-based mosquito control programs in the Americas and the social disruption that resulted from World War II allowed the emergence of dengue in Asia and its reintroduction and resurgence in the Americas.

By the 1950s, scientists of the Rockefeller Foundation, the US Army and Navy, the US Public Health Service, several US universities, and many foreign governments recognized that arboviruses could be recovered in nature from apparently healthy arthropods and wild vertebrate animals. This search in the natural cycles of arboviruses resulted in the discovery of over 500 different arboviruses with about 100 of them causing human disease. Unfortunately, the control of arbovirus infections has not kept pace with the discovery and spread of disease. Antiviral drugs for arboviruses are not commercially available. Except for yellow fever, tick-borne encephalitis, and Japanese encephalitis, there are no widely used vaccines available for humans. Source reduction and control measures against the mosquito vector such as pesticides and biological larvicides have neither been sustainable nor effective in vector control.

3 Methodology Involved in Epidemiologic Analysis

3.1 Sources of Mortality and Morbidity Data

Mortality data are collected systematically but passively by national governments for many arboviruses. Data are published in the Morbidity and Mortality Weekly Report of the US Centers for Disease Control and Prevention, in the Weekly Epidemiological Report of the Pan American Health Organization, and in the Weekly Epidemiological Report of the World Health Organization. The mortality data are grossly underreported but may serve as a comparative data base, since underreporting may be uniform throughout much of the world. The reporting of yellow fever mortality in Africa, for instance, was found to be about 10 % of the true figure [14, 21].

The information flow to the World Health Organization is sometimes facilitated by informal networks of scientists and interested citizens. Nevertheless, the organization is constrained from action until official reports are received. This constraint often means a delay in control of a disease of regional or world importance.

The same sources supply morbidity data as supply mortality data. In the United States, of the arbovirus diseases, those

producing neuroinvasive and non-neuroinvasive illnesses are reported and include the California serogroup virus, Eastern and Western equine encephalitis virus, and the flaviviruses Powassan virus, St. Louis encephalitis virus, and West Nile virus [22]. In addition, yellow fever is still reportable in the United States. Monath documented the time elapsed between onset of an epidemic of St. Louis encephalitis and its recognition [23]. That time varied between 2 and 8 weeks. In the Corpus Christi, Texas, epidemic of 1966, nearly 707 of the cases had occurred before recognition.

3.2 Serologic Surveys

Serologic surveys entail the sampling of a defined population and measuring the amount of specific antibody to the targeted protein which will indicate past or current infection. Because of the large sample size that is tested, high-throughput assays such as enzyme-linked immunosorbent assay (ELISA), complement fixation (CF), or hemagglutination inhibition (HAI or HI) are performed with confirmation by more time-intensive assays such as the plaque reduction neutralization titers (PRNT). The results give a point prevalence of past or current infection in different geographic areas and subpopulations or those at particular risk for infection. Distribution of the antibody in a population can give clues to the ecological conditions necessary for maintenance of the virus as well as the human behavior that might place persons at risk for infection. Surveys of different age groups will show if the virus is more prevalent as the population ages, typical of an endemically transmitted agent. Another prevalence pattern in which antibody is present only in persons born before a certain year may indicate an epidemic in that year. Alternatively, a constant percentage of antibodies in each age group may indicate a recent introduction of the virus in a naïve population. Broadly based serologic surveys of large populations can provide extensive information about virus distribution in different geographic areas, rural versus urban populations, different age and sex groups, and different occupational types. Arbovirus serosurveys have limitations. Cross-reactions occur among viruses of the same serogroup. This is especially true of the HI test and ELISA with flaviviruses. The neutralization test is more specific and should be used where feasible. Surveys with HI or ELISA must be interpreted with caution unless one is certain that only one flavivirus circulates in the region, or unless the results have been confirmed by neutralization test with a portion of the negative and positive sera.

The serosurvey usually will not indicate when the infection responsible for the antibody occurred. If the antibody is suspected to be of recent origin, the IgM antibody-capture ELISA is useful for detection of infections originating within the prior 3–6 months. A serosurvey is not a reliable indicator of natural infection in populations vaccinated for tick-borne encephalitis, yellow fever, or Japanese encephalitis. On the other hand, the survey is an excellent tool for determination of vaccination coverage and protection.

One very important use of serosurveys is in the calculation of the basic reproductive ratio, R naught (R_0) [24], which is defined as the number of new individuals in a susceptible population who are infected by a single individual during his/her infectious period (see also Chaps. 1 and 5). The higher the number, e.g., R_0 >1, the more transmissible the infection. For vector-borne diseases, in particular, R_0 is important and complicated as it takes into account the susceptible and infected vectors as well as the susceptible and infected vertebrate hosts; R_0 is thereby influenced by both the intrinsic and extrinsic incubation periods. Serosurveys can calculate the R_0 as a measurement of the epidemic impact of a pathogen on a population but also as an estimate on the impact of interventions such as vector control on reducing disease in a population. Furthermore, a concept integrally related to R_0 is the "critical vaccination threshold," which is the number of persons in a population needed to vaccinate in order to drive R_0 to <1. Thus, determining R_0 by serosurveys is important not only in gauging the epidemic potential of a pathogen but also in determining the interventions necessary to control an epidemic. Age-stratified seroprevalence studies with cohorts including ages surrounding the age of peak incidence allows estimation of the force of infection over previous years based on different exposure rates across age groups and a calculation of R_0 [25].

3.3 Laboratory Methods

The laboratory is an all-important resource and key cornerstone in the study of the epidemiology of arbovirus diseases as well as understanding the pathogenesis of severe illness. Diagnosis can rarely be made with certainty by clinical examination and understanding the clinical course of symptoms, viremia, and antibody rise essential in utilizing the appropriate laboratory assays. Isolation of virus from arthropods, wild and domestic animals, and people is essential to determine the natural history of infection with these agents. Figure 16.2 demonstrates the typical flavivirus infection after inoculation from a vector assuming an incubation period of 6 days. Viremia occurs prior to the first clinical symptoms with early symptoms, commonly fever, headache, myalgias, and laboratory findings of leukopenia and thrombocytopenia. Antibody rises late in the clinical illness with first IgM followed by IgG. IgM can persist for several months and disappear, while IgG can persist for years after the infection. From a laboratory perspective the utility of the assay is dependent on the stage of infection. PCR-based assays and viral isolation are useful during the days of viremia in the early part of the clinical illness, whereas antibody-based assays are useful during the latter part of the illness and in convalescent sera.

Nonstructural protein 1 or NS1 is a highly conserved 48-kDa glycoprotein that is a requirement for flavivirus

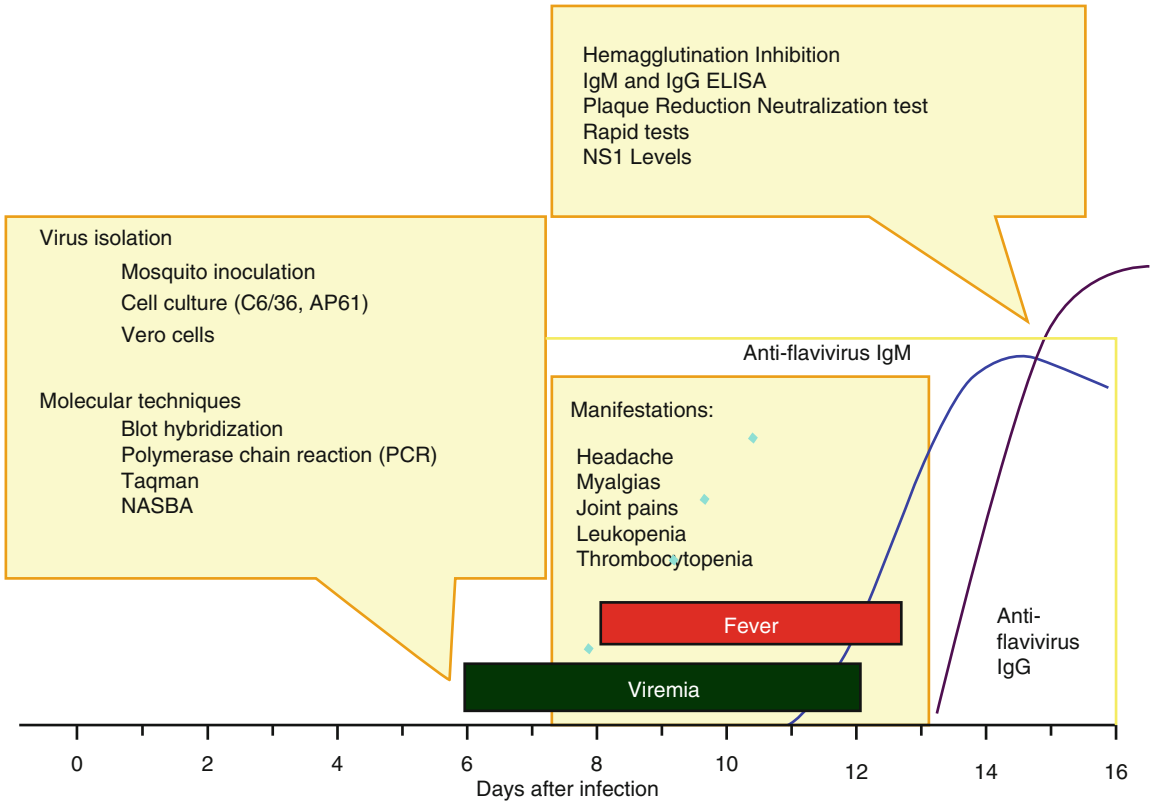

Fig. 16.2 Typical flavivirus infection and the human host response by clinical course and appropriate diagnostic assay

RNA replication [26]. Interestingly NS1 exists in the cell as a homodimer associated with organelle membranes and is actively transported to the mammalian cell surface where it is secreted as a soluble hexamer. Thus, NS1 can be detected in serum during flavivirus infections and has a half-life longer than detectable RNA in serum [27]. NS1 ELISA-based assays have become available for dengue virus infections and have the potential to be used for other flaviviruses [27]. The advantage of these assays is that they can be used throughout the early, middle, and late clinical course of infection with a sensitivity and specificity equivalent to PCR.

Virus isolation is key in understanding the virus and its effects on the vector and human population, but isolation is also the most challenging for laboratories. It requires serum from the early part of clinical illness, −80 °C or colder freezers, and special laboratory techniques. Viral isolation requires inoculation of a small amount of serum into laboratory animals, arthropods like mosquitoes, or cell culture. Cell culture systems (vertebrate or insect cell cultures) are used for both virus isolation and neutralization titers.

In the study of material derived from patients, it is ideal to have acute and convalescent sera available. As demonstrated in Fig. 16.2, antibody titer rises rapidly from the acute to the convalescent serum, and a fourfold rise between the two samples is indicative of an acute infection. Demonstration of IgM in ELISA permits a presumptive diagnosis with a single serum.

Details of the techniques of CF, HI, and virus neutralization relating specifically to arboviruses are available in current manuals. Fluorescent antibody (FA) techniques, antigen-based ELISA, often coupled with monoclonal antibody, and PCR are widely used for antibody, antigen, and RNA detection, respectively. Such advances are greatly extending the scope of field and laboratory investigations.

3.4 Genetic Sequencing

Molecular methods such as polymerase chain reaction (PCR) and the ability to detect and amplify small amounts of RNA or DNA to identify specific pathogens have revolutionized our diagnostic capabilities in identifying patients who are acutely ill from flavivirus infections [28]. Reverse transcriptase PCR (RT-PCR) methods are highly sensitive and specific in detecting the infecting arbovirus during viremia [29, 30]. Real-time assays that utilize exonuclease fluorogenic assays such as TaqMan® (Applied Biosystems, CA, USA) and SYBR® Green (Molecular Probes, Inc., OR, USA) have significantly shortened the time of detection of RNA and DNA in a specimen but also added the ability to quantify the amount of virus and correlate it to disease severity [31]. Interest and need for point of care devices that can be utilized at a clinic with little expertise has prompted the development of new molecular platforms such as "isother-

mal" methodologies including nucleic acid sequence-based amplification (NASBA), transcription-mediated amplification (TMA), and loop-mediated isothermal amplification (LAMP) technologies [32]. This allows an isothermal reaction and amplification to be performed at room temperature with potential reduction in time to detection to a matter of minutes.

Sequencing of the arboviruses has transformed our ability to understand the genetics and epidemiology of these viruses as well as the relatedness of each virus as demonstrated in Fig. 16.1. Genetic sequencing has rapidly evolved from a time-intensive process to technology for rapid full-length automated sequencing. Partial and full-length sequencing of the arboviruses has allowed phylogenetic analysis and revealed a series of clades defined by their epidemiology and disease associations [33]. Phylogenetic analysis has identified mosquito-borne, tick-borne, and no-known-vector (NKV) virus clades, which have been further divided into clades associated to their principal vertebrate host. Sequencing coupled with phylogenetic analysis is a powerful tool to understand the correlation between epidemiology, disease, and geography. It furthers our understanding of the complex evolutionary relationships between the virus, vector, and its vertebrate host. Metagenomics takes this concept further. It is the coordinated study of multiple genomes—the population of genetic material and, as applied to viruses, the entire community of viruses within the host environment [34]. This approach utilizes direct sequencing and bioinformatics to reconstruct the viral population and as such reveals the genetic diversity and evolution of the virus and its vector hosts. Especially powerful is the use of metagenomics when standard techniques fail to identify a viral infection, such as in emerging diseases. For example, metagenomics was used to identify specific viruses from samples collected from an enterovirus surveillance program in the Netherlands [34]. Samples were identified using conventional techniques including PCR that demonstrated cytopathic effects in cell culture without a virus. Metagenomics identified new viruses in all the samples.

3.5 Mathematical Modeling

Mathematical modeling is a powerful technique used to understand the interactions of the arbovirus, its vector, and host infection that produce endemic transmission or explosive epidemics in populations [35]. Mathematical models have the potential to predict epidemics and, equally importantly, to identify interventions by which to prevent or diminish the spread of the arbovirus through the use of vector reduction, personal protection methods, antivirals, or vaccines. Models have progressed from the basic susceptible, infected, and recovered SIR model to more advance modeling techniques using stochastic models in which the number of individuals in any class is an integer with events occurring randomly with a given probability based on the associated deterministic model. The value of stochastic models is the generation of different epidemics capturing the variability in the epidemic profile [35]. For example, a stochastic metapopulation model with spatiotemporal transmissibility scenarios was used to model the spread and transmission of yellow fever [36]. This model was useful to understand and assess the risk of yellow fever in producing urban outbreaks and to identify locations at risk for yellow fever introduction and subsequent transmission.

4 Biological Characteristics of the Virus That Affect the Epidemiologic Pattern

If you were to look at the world from the eyes of a flavivirus, you would find a bewildering array of environments you were forced to adapt and propagate in. The vector invertebrate environment is quite different from the vertebrate environment in requiring the virus to propagate at a lower body temperature and to utilize different cellular receptors for attachment and cellular entry. The virus upon infection of its vector host from a blood meal will replicate, escape from the midgut, evade vector host defenses, and replicate in high concentration in the salivary glands. Environmental factors including temperature and humidity affect vector longevity and viral replication and overwintering until the next transmission season. Upon infecting their vertebrate host after the bite of the infected vector, the flavivirus faces a new host environment with a different ambient temperature, new receptors for host cell entry and replication, and new host innate and adaptive immunity. Flaviviruses are remarkably adept and successful at adapting to an array of environments to replicate and produce infection and ultimately epidemics in human populations. Ultimately the biological characteristics of the flavivirus that affect human epidemiology rely on its ability to be successful in the host vector. The capacity of the virus to replicate in the vector is influenced by many factors including the environment, ecology, vector behavior, and viral molecular factors. The interaction of these factors is called the vectorial capacity. The extension of vectorial capacity to infect the host is known as vector competence—the intrinsic ability of a vector to become infected and to subsequently transmit a pathogen to a susceptible host [37].

The viral molecular factors involved in vectorial capacity and the ability of the virus to be highly specific for its vector host are determined by how arboviruses exist as a collection of variable genomes within a host known as a mutant spectrum, mutant swarm, or quasispecies [37]. During a replicative cycle, RNA viruses and its high mutation rate will develop as a distribution of genetic variants which is influenced by a balance between mutation and selection. Selection pressure will determine the most fit virus for the given environment with the least fit viruses going into

extinction. This Darwinian survival of the fittest is known as viral adaptability. Genetic bottlenecks, defined as survival of a minority of one generation to become the majority of the next generation, can occur in flaviviruses and have been well described for dengue virus [38]. During the course of an infection in a vector, host genetic bottlenecks can occur, for example, when the virus leaves the midgut or replicates in the salivary glands allowing the selection of one mutant to become the dominant genotype. Thus, bottlenecks diminish viral diversity by selecting a subpopulation of viruses particularly adapted to that environment; as a result, frequent bottlenecks enhance the evolution of phenotypic robustness of the virus [37].

Viral fitness is inherently tied to vector fitness. A particular virus strain that is selected for rapid killing of its vector host will have little success at survival to its next host, and an attenuated virus that does not replicate well in its vector may not propagate to the vertebrate host. Viral replication may disrupt the physiology of the vector host through disruption of digestion, salivation, or changes in the vector midgut [39, 40]. Other consequences to vector fitness from viral infection include energy costs associated with immune activation, behavioral changes resulting in decreased feeding, and alterations in mating and propagation. A meta-analysis of studies across a range of mosquito–virus systems showed that arboviruses do reduce the survival of their mosquito vectors, but the overall impact on vector fitness varies by the virus taxonomic group and mode of transmission [41]. Alphaviruses, for example, were associated with the highest virulence levels in mosquitoes and the least for the bunyaviruses. The conclusion was that virus and vector fitness are interwoven and dependent on multiple selection factors that are evolving. The complexities of this relationship between virus and vector fitness coupled with the viral fitness required to propagate in a vertebrate host highlight the exquisite balance needed to maintain the life cycle and the disease process. This "trade-off" hypothesis suggests that the replication in arthropod then vertebrate hosts shapes virus evolution. It is when this trade-off results in an increase in both vectorial capacity and vertebrate infection that human epidemics, global expansion, and emerging diseases may occur. An example of this is the emergence of chikungunya virus (CHIKV) infection in 2004 from the Indian Ocean to India, attributed to a single amino acid mutation that enhanced vector capacity in a secondary vector *Aedes albopictus* [42]. Another example is the emergence of a new lineage of West Nile virus (WNV) in North America that was adapted for more efficient transmission in *Culex* mosquitoes [43]. When vectorial capacity for an arbovirus is diminished or vector resistance to virus infection is induced, virus transmission may potentially be completely interrupted. The occurrence of this phenomenon may been realized recently with the observation that infection of *Aedes aegypti* by Wolbachia, an intracellular bacterium, confers resistance of the mosquito to DENV infection [44]. These findings are now being used to infect natural *A. aegypti* mosquitoes to diminish DENV transmission [45].

5 Epidemiology

The epidemiology of flavivirus infections in humans as noted in previous sections is a complex interplay between viral evolution, selection pressures, vectorial capacity, and risk of human infection from the vector and its spread in human populations. In practical terms, many factors account for the dramatic changes in the epidemiology of the flaviviruses: increasing travel and the speed of travel where an individual can go from rural areas of Africa or Asia to major metropolitan areas in less than 24 h, expanding trade and commerce, population growth, increasing urbanization and population detritus leading to increasing vector breeding areas, deforestation, and climate change [46]. Examples of this changing epidemiology are the spread of the dengue viruses throughout Asia, the Americas, and most recently Florida; resurgence of yellow fever in South America and Africa; spread of West Nile virus through North and Central America; and the spread of Japanese encephalitis in Southwest Asia [46].

5.1 Incidence and Prevalence

All infections with pathogenic flaviviruses discussed in this chapter are acute and can be diagnosed either through molecular means during the time of infection or by serology consistent with acute infection, i.e., detection of IgM antibody or a fourfold rise in antibody titer between acute and convalescent sera. Measurement of incidence requires documenting acute infection through the application of clinical criteria consistent with the flavivirus infection. All acute flavivirus infections progress from a classic presentation of fever, chills, myalgias, and headache to a more flavivirus-specific syndrome of an acute febrile illness, hemorrhagic fever, or encephalitis. These specific syndromes fall into a spectrum of overlapping clinical presentations, making it difficult to distinguish one flavivirus from another or from other pathogens based on clinical symptoms and signs alone.

All infections display a biological gradation ("iceberg") of clinical responses and disease severity both at a cellular and host response level (see Chap. 1). In the case of flaviviruses, although unobserved (below the "waterline" of the iceberg), subclinical infections are viremic and do contribute to the transmission and infection of the vector and thus represent a very important component of the epidemic. Further along the gradient of infection are mild ambulatory illness, moderate illness requiring medical care, more severe illness requiring hospitalization, and fulminant illness requiring intensive care with potentially fatal outcome. The shape of the gradient or "iceberg" varies among the flaviviruses and depends on the preexisting immunity in the population, vectorial capacity, and environmental factors. The subclinical infections are not well studied due to the requirement for long-term prospective studies of cohorts with the ability to diagnose asymptomatic infections. The best documentation of subclinical infection

has come from the prospective cohort studies conducted in Northern Thailand where at least 50 % of all DENV infections were subclinical [47, 48]. In general, a large majority of flavivirus infections occur below the waterline of detection and subclinical. The more severe forms of infection resulting in death occur in less than 5 % of all infections. Understanding the iceberg concept of infection is critical in thinking on the epidemiology and incidence of flavivirus infections. Surveillance confined to hospitalized cases will detect only 10–20 % of all cases. Extended to the ambulatory clinics, surveillance can detect an additional 30 % of all infections. It is apparent that even with detection of 50 % of acute cases, the incidence of infection is being grossly underestimated.

In contrast, seroprevalence studies (see Chap. 2) of flavivirus infection can define populations at risk, give a historical account of the transmission, and provide an estimate of the burden of infection in a population. A classic arbovirus seroprevalence study was the mapping of the worldwide distribution of yellow fever by Sawyer et al. in 1937 [49]. The virus neutralization test was performed using adult white mice as test animals. Yellow fever virus was found to be more widely distributed in South America and Africa than had been earlier suspected and was absent from Europe, Asia, and Australia. Neutralization tests measure durable antibody that persists for years. High rates of antibody prevalence could result from continued, widespread virus activity and/or from a large outbreak with a high attack rate. For example, yellow fever neutralization tests performed on sera collected from residents of Trinidad, West Indies, in 1953 revealed no immunes under the age of 15 years and therefore no apparent virus activity later than 1938. This situation changed dramatically with the reappearance of yellow fever on the island in epidemic form in 1954 [50].

Incidence and prevalence studies provide two views on flavivirus infection. The former can uncover newly occurring infections in the population and evidence of an outbreak; the latter offer a historical perspective on previous outbreaks and subpopulations that may be at risk. In most countries appropriate diagnostics are not available to diagnose a specific flavivirus infection, and clinical criteria are mostly used; as a result their population incidence is grossly underreported.

5.2 Epidemic Behavior and Geographic Distribution

Arbovirus infections are worldwide in distribution and may occur whenever the appropriate mosquito or other arthropod vectors abound in proximity to humans and a suitable amplifying host. Table 16.1 displays both the human pathogenic flavivirus and those where illness hasn't been documented, vector if known and human illness if known. The flaviviruses occur globally as both regional endemic diseases and epidemic diseases that can spread worldwide. The dengue viruses are now the most common mosquito-borne arboviral infection worldwide (http://www.who.int/csr/disease/dengue/en/). Other significant flaviviruses that have vast global distributions include West Nile virus, tick-borne encephalitis, and yellow fever. Regional flavivirus threats that produce epidemic diseases include Japanese encephalitis in Asia and West Nile virus and St. Louis encephalitis in North and South America. All are endemic diseases that produce transmission and disease every year with occasional epidemics.

5.3 Temporal Distribution

Temporal distribution is a consequence of overwintering and seasonal breeding and is region specific. If birds are the primary vertebrate host, temporal distribution is dependent on their migratory patterns, nesting, and hatching of young immunologically naïve chicks. In general, seasonal breeding of the vector occurs in spring, summer, and fall, although this is affected by the climate with warmer years having transmission during the winter months. Climate change and global warming will affect the temporal distribution of the flavivirus by changing the abundance of the vector. Global warming will increase the distribution of the vector as well as cause more rainfall and thus create more potential areas for breeding in the case of mosquitoes. The natural weather pattern that occurs approximately every 5 years, La Niña/El Niño-Southern Oscillation, or ENSO, can have dramatic effects on rainfall, flooding, and vector-borne diseases including the flaviviruses [51, 52]. This periodic climate change occurs across the tropical Pacific Ocean with variations in surface temperature (warming known as El Niño and cooling as La Niña). In a recent study, Murray Valley encephalitis virus (MVEV) in northern Australia and Papua New Guinea was monitored and correlated to the occurrence of rainfall [53]. Using multi-satellite precipitation analysis, the authors found that increases in monthly rainfall and monthly number of days above average rainfall increased the risk of MVEV activity at a time lag of 2–3 months. Clearly climate change and weather have an effect on the temporal distribution of vector-borne infections with a particular impact on the flaviviruses.

5.4 Age, Sex, and Other Demographic Factors

Infections with arboviruses can occur at any age. The age distribution depends on the degree of exposure to the particular transmitting arthropod relating to age, sex, occupation, and recreational habits of the individual or group of individuals. In highly endemic areas where transmission occurs every year, such as with Japanese encephalitis and dengue viruses, flavivirus infection is seen primarily in children, with adults

protected by the antibody from previous infections [54, 55]. In areas where transmission is sporadic and the entire population is at risk, extremes of age becomes a risk for severe infection such as seen in WNV infection in adults over the age of 50 years [56].

5.5 Other Factors

Genetic factors are known to influence disease severity from flavivirus infection and thus directly the epidemiology of arbovirus infections. Nutrition may have an effect on increasing disease severity in specific flavivirus infections such as in dengue hemorrhagic fever though it is unknown if there is an effect with other infections [57]. Certainly malnutrition can suppress the immune response and affect disease severity and thus the epidemiology. Genetic factors are very likely associated with disease severity. For example, in case–control gene association studies performed on cohorts of DENV-infected patients in Asia and the Caribbean, specific genes have shown associations with disease severity. These genes include the HLA molecules, the cell receptors for IgG (FcGII), vitamin D, and ICAM3 (DCSIGN or CD209) [58]. Also pathogen recognition molecules such as mannose-binding lectin (MBL) have associated with disease severity as well as the blood cell-related antigens including ABO and human platelet antigens (HPA1 and HPA2) [58]. African slaves were long known to be immune from the severity of yellow fever and were recruited to help stricken victims during the Philadelphia 1793 yellow fever epidemic [11]. Clearly genetics that determine both acquired and innate immune responses contribute to disease severity or protection from flavivirus infections and can affect the epidemiology of these infections.

6 Mechanism and Route of Transmission

By definition, the flaviviruses as arboviruses must be transmitted by arthropod vectors within which multiplication of the virus is a necessary requirement. Non-arthropod-related transmission to humans can occur such as through goat, sheep, or cow milk in the case of TBEV and respiratory and alimentary tract with Omsk HF [59, 60]. The primary vectors are mosquitoes and ticks. The duration of the necessary period of virus multiplication within the arthropod host before it becomes infectious varies from virus to virus and vector to vector and is also directly temperature dependent. For most viruses under average summer temperature conditions, the extrinsic incubation period falls in the 7- to 14-day range. Once infected, vectors may remain infected and able to transmit for many weeks or months. In the case of ticks, this infection may be years. Transmission of virus transovarially in arthropods, often referred to as "vertical transmission," has been demonstrated (specific examples, tick-borne encephalitis in ticks, DENV in mosquitoes). Venereal transmission of SLE viruses in vector mosquitoes has also been described. These mechanisms may be important for survival of some arboviruses in nature, permitting overwintering or survival over a protracted dry spell. Birds are important reservoir vertebrates for the viruses of JEV, WEE, and SLE.

There are a number of flaviviruses that cause human infections where the principal vector species is not known (Table 16.1). These include the viruses Apoi, Dakar bat, Koutango, Modoc, and Rio Bravo. More research is needed to establish the principal vector or, if not found, to gather details on their mode of transmission.

There are two nonvector modes of transmission to humans of the vector-borne flaviviruses that is essential to know—transfusion mediated and sexual. During the 2002 WNV epidemic in the United States, 23 patients were confirmed to have acquired WNV through transfused contaminated blood products [61]. Of these the majority were immunocompromised due to transplantation or cancer. Sixteen donors with evidence of WNV viremia at donation were linked to the 23 infected recipients. As a result of these findings, the US blood supply is now screened for WNV. Sexual transmission of another normally vector-borne flavivirus was recently documented. Zika virus (ZIKV) is a mosquito-transmitted flavivirus that has been isolated from sick persons in Africa and Southeast Asia. Two American scientists working in Senegal became acutely ill with ZIKV [62]. One of the scientists upon returning to the United States infected his wife who developed confirmed ZIKV symptomatic infection. Because she never traveled outside of the United States, direct person-to-person transmission was thought to be the mode of infection either through saliva or infected semen.

7 Pathogenesis and Immunity

Arbovirus infections are usually transmitted by the bite of the appropriate vector, and the skin is the normal portal of entry. Even before the virus enters the host through the skin, an important cofactor contributed by the vector assists in shaping virus entry. Saliva from arthropods (i.e., ticks and mosquitoes) has been shown to potentiate flavivirus infection and enhance in vertebrate hosts. Virus and arthropod saliva are delivered into the skin of the vertebrate host. Arthropod saliva contains a complex mixture of bioactive molecules that are capable of altering homeostasis, immune response, and dendritic cells and may contribute to the ability of flaviviruses to establish an infection [63]. The potentiation of flavivirus infection

by arthropod saliva has been demonstrated for a number of viruses including WNV and saliva from *Culex tarsalis* which resulted in enhancement of early WNV infection in vertebrate hosts [64].

The first cells that typically come in contact with flaviviruses are skin dendritic cells (DCs). These cells have been shown to be important initial targets of infection that shape the immune response for many of the pathogenic flaviviruses including DENV, YFV, and tick-borne encephalitis virus (TBEV) [50, 65–67]. TBEV targets DCs early in infection and are major inducers of interferon (IFN) and the innate immune response. TBEV modulates DCs and thus shapes the innate response via INF antagonism. DCs become infected and transport the virus to draining lymph nodes promoting virus dissemination. After viral replication in target cells, the virus becomes widely disseminated throughout the host. Viremia in the host is an important determinant for additional infection in noninfected biting arthropods. The degree of viremia determines if the vertebrate host becomes a "dead-end host" where viremia with agents such as JEV and WNV is minimal and no additional biting vectors are infected. In other flaviviruses, high and sustained viremia provides a source of additional vector infection, as is the case for DENV where humans are the primary reservoir for infection.

The site of multiplication of most arboviruses remains undetermined but is presumed to be in the vascular epithelium and the reticuloendothelial cells on the lymph nodes, liver, spleen, and elsewhere. Liberation of virus from these organs constitutes the "systemic phase of viremia," resulting after 4–7 days in fever, chills, and aching joints. A number of arbovirus infections have two phases—this early phase and then a second phase with or without a few days of freedom from symptoms. The second phase may be attended by encephalitis, joint involvement, rash, hemorrhage, and involvement of the liver and kidneys. In most arbovirus infections, only the first phase occurs, and the disease is mild and "nonspecific." In other instances, the early phase may be missed, and only the severe manifestations occur. The early phase is accompanied by leukopenia and the second phase often by leukocytosis. Tissue injury may be the direct effect of viral multiplication in susceptible cells, as is the case with liver involvement in yellow fever.

Humoral antibodies regularly appear early in the course of arbovirus infection and constitute the major basis of immunity. Such immunity may be lifelong. No infection with yellow fever virus has been recorded in an individual who either had antibodies from an earlier infection or had a history of yellow fever vaccination with development of postvaccination antibody. The presence of antibodies in the blood at the time of exposure to an infected arthropod vector provides a primary deterrent to reinfection with the homologous virus.

8 Patterns of Host Response

8.1 Clinical Features

Inapparent and subclinical human host responses predominate in most arbovirus infections. Clinical illness is frequently the exception rather than the rule. This varies from virus to virus. For example, infection with WNV, SLEV, and JEV viruses results principally in mild and inapparent infections, whereas in infection with YFV, the host response is likely to be clinically apparent and often severe (Table 16.2); the reasons for these differences are not known.

8.2 Diagnosis

Cases of arbovirus infections are not likely to be diagnosed unless there is a high degree of clinical suspicion. Outbreaks of encephalitis in horses and dying off of birds may be an early warning sign from some arboviruses. Recognition of the arbovirus infection acquired by the traveler outside the United States also depends on the alertness of the examining physician. Rapid jet transport now permits exposed overseas travelers to reach home and fall sick even within the short incubation period of such infections. The physician must maintain a high degree of suspicion when seeing central nervous system, influenza-like illnesses, or hemorrhage with fever occurring in travelers recently returned from areas endemic for arboviruses. Diagnosis will require specimens (serum, cerebrospinal fluid) to be sent to specific laboratories that have the capacity to perform the required assays such as the state laboratory or the Centers for Disease Control (CDC).

The laboratory diagnosis depends on the isolation of the virus from the blood and/or a fourfold antibody rise in titer or presence of specific IgM in sera taken during the acute and convalescent phases of illness. Often, the suspicion of an arbovirus infection in individual cases arises too late for

Table 16.2 Patterns of host response to arbovirus infections in man

Response	Examples[a]
Asymptomatic infection	WNV, DENV, JEV, SLEV
Mild febrile illness	SLEV, YFV, JEV, DENV
Influenza-like illness with aching and joint pains	DENV, ZIKV
Encephalitis, mild	WNV, TBEV, SLEV
Encephalitis, severe	WNV, TBEV, SLEV
Jaundice, proteinuria	YFV
Rash, sometimes with hemorrhagic manifestations	AHFV, DENV, KFDV
Shock syndrome	AHFV, DENV, KFDV

[a]Certain viruses have been selected for this list particularly to illustrate the range of symptoms that may be seen in populations infected with a single virus

virus isolation or for demonstration of a rise in antibody titer. Often only one acute serum specimen is sent without a convalescent specimen. Under these circumstances, the presence of a high antibody titer in a single serum may be significant if the infection is an uncommon one in that region and particularly if antibody surveys reveal a low antibody prevalence or if prior surveys have demonstrated the absence of antibody in that community. The appropriate procedure in suspected cases is to (1) notify the health department and seek background epidemiologic and clinical data and (2) send acute and convalescent serum samples to the nearest public health laboratory (usually a state laboratory), with a request for antibody tests for arboviruses and other encephalitis-producing viruses. Some state laboratories may not provide this testing, so a request for transshipment of sera to the CDC might be included.

9 Control and Prevention

Major control methods include (1) control of the arthropod vector, which may be by elimination of breeding sites, termed source reduction, or modification of them by application of insecticidal substances or by direct attack on the adult arthropods through residual insecticide treatment of adult resting places; (2) avoidance of exposure to vector bites by screening of houses, by use of protective clothing, and by application of insect repellent sprays or creams when outside in high-risk areas; and (3) immunization, a procedure widely used only for yellow fever, TBEV, and Japanese encephalitis in endemic areas.

Control of vectors through biological approaches ranges from introduction of competing species such as the use of parasites lethal to the vector including protozoa, helminths, bacteria, and viruses to introduction of genes deleterious to the vector population or influencing the vector behavior or capacity to be infected with a pathogen [68].

10 Characteristics of Selected Pathogenic Flaviviruses

Selected flaviviruses are discussed in this section and focused on those that produce human infections and represent emerged or emerging infection or have the potential to become global health problems. This section is organized by vector into tick-borne, mosquito-borne, or viruses with no known vector (see Table 16.1). Under the tick-borne flaviviruses are the mammalian tick-borne virus complex (tick-borne encephalitis, Gadgets Gully virus, Kadam virus, Kyasanur Forest disease, Alkhurma virus, Langat virus, Omsk hemorrhagic fever, Powassan virus, Royal Farm virus, and Louping ill virus). Under the mosquito-borne viruses are the Aroa virus, Japanese encephalitis virus, Kokobera virus, Ntaya virus, Spondweni virus, and the yellow fever virus complexes. Under the viruses with no known arthropod vector are the Entebbe bat virus complex, Modoc virus complex, and Rio Bravo virus complex. For each of the viruses, the epidemiology, vector, human disease, diagnosis, and epidemic potential will be briefly covered.

10.1 Tick-Borne Viruses

10.1.1 Mammalian Tick-Borne Virus Complex

The mammalian tick-borne virus complex, a genetic and antigenically related group of viruses, share similar features and have ticks as their vector and animal vertebrates as a reservoir [69]. These viruses are pathogenic to humans producing a range of diseases to include a mild febrile illness, severe hemorrhagic fever, and encephalitis and contain viruses that have emerged or emerging as global health problems. Some viruses, such as the agent of Kyasanur Forest disease, remain localized to specific geographic areas and have the potential to emerge as regional health threats. The mammalian tick-borne virus group includes Omsk hemorrhagic fever virus (OHFV), Langat virus (LGTV), Alkhurma hemorrhagic fever virus (AHFV), Kyasanur Forest disease virus (KFDV), Powassan virus (POWV), Royal Farm virus (RFV), Karshi virus (KSIV), Gadgets Gully virus (GGYV), and Louping ill virus (LIV) [2].

Gadgets Gully Virus (GGYV)

GGYV was first isolated from *Ixodes uriae* on the penguin rookeries of Macquarie Island, Australia, in 1976 [70]. Six other strains were isolated from the same location in 1976 and 1977. To date GGYV has not been known to be a cause of human disease.

Kyasanur Forest Disease Virus (KFDV)

KFVD, also known as monkey fever, is a disease of man that is transmitted primarily by *Haemaphysalis* ticks in the tropical deciduous forests of the Karnataka State in South India [71]. Its subsequent discovery in the Yunnan Province, China, in 1989, called Nanjianyin virus, is now known as a subtype of KFDV [72]. Results of a 1987–1990 seroepidemiologic investigation in the Yunnan Province demonstrated that residents of the Hengduan Mountain region had been infected with this virus [72]. This suggests that KFDV may have a wider geographic distribution, and migratory birds with attached infected ticks may be responsible. At-risk populations for KFDV include persons with recreational or occupational exposure to the forests in Karnataka, India. Human disease may be accompanied by outbreaks of hemorrhagic disease in forest monkeys maintained in a sylvatic cycle. After an incubation period of 3–8 days, the

symptoms of KFDV infection are fever, headache, severe muscle pain, cough, dehydration, and gastrointestinal symptoms. After 1–2 weeks of symptoms, some patients recover while most patients experience severe hemorrhagic fevers with a 2–10 % fatality [73]. Treatment is supportive care. A formalin-inactivated virus vaccine produced in chick embryo fibroblasts is licensed and available in India [74–77].

Alkhurma Hemorrhagic Fever Virus (AHFV)

AHFV has been isolated several times since 1995 from the blood of patients with severe hemorrhagic fever in Saudi Arabia. It is associated with the camel tick. Among 16 patients, 4 had lethal outcome [78]. Sequence analysis revealed the close genetic relationship of this virus to KFDV [79]. AHFV may be an emerging infection and a risk to travelers based on a report of tourists visiting southeastern Egypt near the border of Sudan who were infected by AHFV and developed hemorrhagic illness [80]. Like KFDV, AHFV may have its origin in Africa and in the case of AHFV transported from Africa and other countries to Saudi Arabia by the transport of camels and other livestock carrying infected ticks [80].

Karshi Virus (KSIV)

KSIV has been isolated from *Ornithodoros papillipes* ticks from Karshi, Uzbekistan. It has been reported in the Russian literature as a cause of encephalitis in humans though the exact numbers are not known (Dr. S. Khodjaev, personal communication). The vector competence of human isolates of KSIV was tested in a variety of mosquitoes and ticks. KSIV replicated in and was transmitted by all three species of Ornithodoros ticks tested (*O. parkeri*, *O. sonrai*, and *O. tartakovskyi*) [81]. Experiments demonstrated that when inoculated with Karshi virus, 90 % of *Ornithodoros* ticks transmitted this virus to suckling mice and transmission continued for at least 1 year [81]. Female *O. tartakovskyi* transmitted KSIV vertically to their progeny. This study suggests that *Ornithodoros* spp. are potential vectors and rodent species a possible reservoir, with the tick responsible for the long-term maintenance of KSIV in the environment.

Royal Farm Virus (RFV)

RFV was first isolated from *Argas hermanni* nymphs from Kabul, Afghanistan, by the US Naval Medical Research Unit in Cairo, Egypt [82]. Its group relation to Powassan and Langat viruses was demonstrated by complement fixation (CF) and neutralization tests (N). By CF test it is closely related to Powassan and by N test to Langat. RFV has never been found to be a cause of human disease.

Langat Virus (LGTV)

LGTV was first isolated in Malaysia and Thailand from pools of ticks of *Ixodes granulatus* and *Haemaphysalis* spp [83]. Although wild-type LGTV has never been found to cause human disease, patients with terminal malignancies were inoculated with LGTV in a clinical study hoping the virus might produce remission. The investigators also thought that data from this study might also support the use of LGTV as a live virus vaccine candidate against other tick-borne flaviviruses in healthy individuals. In this study, LGTV administered subcutaneously was able to produce viremia, fever, and leukopenia [84]. Further studies on this as a viable human vaccine are limited.

Louping Ill Virus (LIV)

Louping ill virus is a zoonotic disease of livestock on the British Isles transmitted by the tick *Ixodes ricinus*. It is also a very rare cause of disease in humans for people who work closely with sheep or the virus. There have been over 30 human cases of disease from LIV and several cases of laboratory-acquired infections [85, 86]. Four clinical syndromes can be seen in human disease to include influenza-like illness, a biphasic encephalitis, a poliomyelitis-like illness, and a hemorrhagic fever [86].

Omsk Hemorrhagic Fever Virus (OHFV)

OHFV is a significant cause of hemorrhagic fever and encephalitis in Western Siberia. While the disease may be transmitted by *Dermacentor* ticks, outbreaks related to direct human contact with the virus from muskrat trapping and skinning may occur [78]. The most marked clinical sign of this disease is hemorrhage, but clinical symptoms also include diffuse encephalitis which disappears during the recovery period [78].

Powassan Virus (POWV)

POWV is a tick-transmitted virus of the tick-borne encephalitis subgroup of flaviviruses. It is antigenically related to TBEV discussed below. POWV is a North American virus and originally isolated from the brain of a child who died in Ontario in 1959 [87]. Powassan virus has been found to be widely distributed in small mammals in Canada and the northern states of the United States including New York, Wisconsin, and Minnesota [88]. POWV was originally thought to be a minor cause of human encephalitis with 27 cases reported in Canada and the northeastern United States during 1958–1998 [89]. Over the past decade there has been an expansion of cases throughout Canada and the United States with four Maine and Vermont residents with encephalitis found to be infected with POWV in 1998–2001. During 1999–2005, there were nine cases of serologically confirmed POWV disease: four from Maine, two from New York, and one each from Michigan, Vermont, and Wisconsin [89, 90]. The Michigan and Wisconsin cases represent the first reported from the north-central United States and suggest that this infection may be underreported in the United States.

POWV encephalitis is characterized as a classic encephalitis with the acute onset of muscle weakness, confusion, and neurologic signs. All patients described in this series recovered but most had long-term neurologic sequelae. POWV is transmitted by hard ticks (*Ixodidae* spp.). Diagnosis can be accomplished by serology and PCR. There is no vaccine available for POWV or specific therapy for illness.

10.1.2 Tick-Borne Encephalitis

Tick-borne encephalitis virus (TBEV) produces a fatal encephalitis in Europe and Asia [91]. The disease has been known under several names, including Russian spring–summer encephalitis and Far Eastern encephalitis. Clinically, TBEV produces an acute febrile illness followed by encephalitis with a high mortality rate. The virus is maintained in an environmental cycle involving small mammals and birds in forested regions and transmitted by the ticks *Ixodes ricinus* and *I. persulcatus*. Humans become infected by the bite of infected ticks. Forest and construction workers, woodsmen, trappers, and farmers are at highest risk. TBEV is an emerging infection spreading geographically and increasing in mortality. From 1974 to 2003 there was a 400 % increase in morbidity in Europe and has spread to regions that were previously unaffected [92, 93]. TBEV is a notifiable disease in 16 European countries. There was an average of 8,755 reported cases of TBEV per year in Europe and Russia between the years 1990 and 2007 as compared to 2,755 cases per year between 1976 and 1989 [94]. The expansion of TBEV may be caused by changes in the number and geographic range of the tick vector due to climate changes and changes in land use. No specific therapy exists for TBEV. Prevention from infection is through control of tick populations, protection against tick bite (repellents, protective clothing), and avoidance of tick habitats. An inactivated vaccine is widely used in central Europe. Diagnosis is made by serology, virus isolation, and PCR.

10.1.3 Mosquito-Borne Viruses

The mosquito-borne viruses represent some of the most pathogenic viruses known to man. They have been historically a cause of large epidemics and have become emerging or emerged pathogens. They produce a range of illnesses from a severe febrile illness to fatal hemorrhagic disease and encephalitis. As mosquito-borne viruses the majority have an intermediate bird or rodent reservoir with humans infected by the bite of infected mosquitoes.

Aroa Virus Complex

Aroa Virus (AROAV)

AROAV was initially isolated from a hamster (*Cricetus auratus*) in the vicinity of the Aroa River, Venezuela, in the early 1970s. Complement fixation (CF) experiments concluded Aroa was a new group B virus most closely related to Bussuquara virus. Antigenic and biological properties categorize AROAV closely with Israel turkey meningoencephalitis, Koutango, and Negishi viruses. AROAV grows in C6/36 cells suggesting vector transmission potential [95]. There are no reports of human infection or disease [3].

Bussuquara Virus (BSQV)

BSQV was isolated in 1956 in Belem, Brazil, from a howler monkey (*Alouatta belzebul*). The virus has been isolated in the Amazon from sentinel and wild *Proechimys* spp. rodents and *Culex* mosquitoes [96]. The virus was known to circulate in Brazil, Colombia, and Panama [97]. In vitro experiments demonstrate infection across a range of murine, chick, and monkey cell lines [98]. Both *Aedes* and *Culex* mosquito species demonstrate a potential for infection. Liver lesions similar to those caused by YFV were noted in an infected howler monkey, *Alouatta belzebul*. There has been one human clinical case reported with fever, headache, profuse sweating, and arthralgia lasting 4 days [3, 99].

Iguape Virus (IGUV)

IGUV was isolated in 1979, from a sentinel mouse, in the rain forest of Iguape county, Sao Paulo state, Brazil [96, 100]. Serosurveys demonstrate wild birds may participate in the virus transmission cycle, as may rodents and marsupials. Defining virus reservoir–vector relationships requires further study [100]. There have been no known human infections.

Naranjal Virus (NJLV)

NJLV was first isolated from a hamster in 1976 in Guayaquil, Ecuador. It is closely related to BSQV, but CF and neutralizing antibody assays clearly demonstrate that it is distinct [101]. Experimental infection of mice produces death and viremia over 5.6–8 days [3]. There are no reports of human infection or disease.

Japanese Encephalitis Virus Complex

Cacipacore Virus (CPCV)

CPCV was first isolated from the *Formicarius analis* (black-faced ant bird) in Oriximina, Para, Brazil, in 1997 [102]. Serosurveys demonstrate evidence of infection in wild birds, rodents, bats, and humans. Injection into mice produces death [102]. A 33-year-old farmworker in the Brazilian state of Rondônia, Brazil, was admitted to intensive care with suspected leptospirosis and yellow fever; however, viral sequencing identified CPCV as the cause of infection [103].

Koutango Virus (KOUV)

KOUV was initially isolated in 1968 from a *Tatera kempi* (gerbil) in the Koutango Village, Saboya region, Dakar, Senegal. KOUV is known to circulate in Senegal, Central

African Republic, Somalia, and Gabon [104, 105]. Natural host range includes rodents, ticks, mosquitoes, and a single case of infection in man (laboratory accident). Mosquito (*Aedes aegypti*) transmission and reinfection experiments have been conducted as well as experimental transovarial transmission which suggest *A. aegypti* is a competent vector [3, 106].

Japanese Encephalitis Virus (JEV)

JEV is the leading cause of viral encephalitis in Asia [107]. JEV is a mosquito-borne zoonotic flavivirus transmitted predominantly between birds and mammals and to humans by mosquitoes. The principal vector of JEV in northern Asia is the rice paddy-breeding *Culex tritaeniorhynchus summarosus* and in southern Asia *C. tritaeniorhynchus* and related *C. vishnui* group. Many species of wild birds function as reservoirs, supporting JEV circulation and transmission. Domestic pigs may serve as amplifying hosts. Horses and humans are dead-end hosts because the virus circulates in blood at low levels and for a short duration, thereby not supporting transmission [108, 109].

Outbreaks of JEV occurred regularly in Japan, Korea, China, and Taiwan during the twentieth century. Seasonal outbreaks now involve portions of Vietnam, Thailand, Nepal, and India. The Philippines, Indonesia, and the northern tip of Queensland, Australia have witnessed smaller outbreaks [108, 109]. Large-scale vaccination programs made it possible for Japan, Korea, and Taiwan to nearly eliminate JEV. More recent vaccine adopters (Thailand, Sri Lanka, and Nepal) have also observed a reduced disease burden [108, 109]. Numerous JEV endemic regions remain at risk despite the availability of safe and efficacious JEV vaccines.

In JEV endemic areas, the incidence of disease is greater in the young; attack rates in the 3- to 15-year age group are five to ten times higher than in older persons; this is likely a herd-immunity phenomenon [108, 109]. Numerous studies and epidemiologic observations document a weak protective effect of prior dengue virus infection on subsequent JEV disease [110, 111]. The ratio of symptomatic JEV cases to infections varies between 1:25 and 1:300 with the lower rates (1:200–1:300) observed in Asians indigenous to areas with enzootic JEV transmission, while higher rates were measured in American military personnel [112–114]. The incidence of JEV for travelers from non-endemic countries to Asia is estimated at <1 case per million travelers. Expatriates and travelers who spend prolonged periods in JEV enzootic areas may share a similar or higher risk than the indigenous population [115–117]. Between 1973 and 2008, 55 cases of JEV were reported in travelers from non-endemic countries. Ten (18 %) of these were fatal and 44 % ($N=24$) recovered but experienced sequelae [115–124].

JEV is a small (50 nm), enveloped virus containing a 10.7-kb, single-stranded, positive-sense RNA genome. The viral envelope (E) protein serves as the cell receptor-binding protein and the fusion protein for virus attachment and entry into host target cells. Antibodies directed against E protein neutralize the virus and play an important role in protection [109, 125, 126]. The JEV was first isolated from the brain of an encephalitis patient in Tokyo (1935) and was virologically and serologically established as the prototype (Nakayama) strain [127]. Antigenic variation among JEV strains has been shown by serologic, virologic, and monoclonal antibody analysis [127–129]. The virus causes cytopathic effect (CPE) in varied cell lines that include chick embryo, human epithelial, mouse, Vero, LLC-MK2, and C6/36. A broad range of hosts experience encephalitis and death following intracranial or intraperitoneal administration of JEV to include mice, hamsters, dogs, foxes, cats, and goats. Asymptomatic viremia is observed in monkeys, guinea pigs, rabbits, chickens, pigs, and bats [3]. *Culex tritaeniorhynchus*, *C. fuscocephalues*, and *C. gelidus* were experimentally infected feeding on viremic pig and chicken and successfully transmitted infection to chicken [130–133]. Transovarial transmission was demonstrated in *Aedes albopictus* and *A. togoi* [134].

Following infection there is a 5- to 7-day incubation period and then a nonspecific viral prodrome. Early clinical symptoms include lethargy, fever, headache, abdominal pain, nausea, and vomiting [135]. Nuchal rigidity, photophobia, altered consciousness, hyperexcitability, masked facies, muscle rigidity, cranial nerve palsies, tremulous eye movements, tremors, involuntary movement of the extremities, paresis, incoordination, pathological reflexes, and meningeal (meningitis), parenchymal (encephalitis), or spinal cord (myelitis) signs may follow [136]. Sensory deficits are rare, and children (50–85 %) experience focal or general seizures more often than adults (10 %) and are associated with poor clinical outcome [136]. In a recently published study of 1,282 adult patients collected from 4 JEV epidemics in India (1978, 1980, 1988, and 1989), altered sensorium occurred in 96 %, convulsions in 86 %, and headache in 85 % [137]. Hyperkinetic movements were noted in 46 %, and most (83 %) were choreoathetoid in nature. Opsoclonus (20 %), gaze palsies (16 %), and pupillary changes (48 %) were observed, but cerebellar signs were not. Dystonia and decerebrate rigidity were observed in 43 and 6 %, respectively, of patients with 17 % having paralytic features and seizures in 30 %. Abnormal breathing patterns, pulmonary edema, and upper gastrointestinal hemorrhage were observations of prognostic importance.

Elevated peripheral white blood cell counts and low sodium may be observed. Cerebrospinal fluid (CSF) opening pressure, white blood cell content, and protein levels may be normal or mildly elevated [136]. Electroencephalogram may demonstrate diffuse delta wave activity and, rarely, seizure

patterns [136]. Imaging studies may demonstrate abnormal findings in the white matter, thalamus, basal ganglia, cerebellum, midbrain, pons, and/or spinal cord.

If the patient improves, it will typically begin about 1 week after symptom onset at the time of defervescence, but recovery of neurologic function may take weeks to years. Seizure disorders, motor and cranial nerve paresis, and movement disorders may persist in up to one third of patients. Persistent behavioral and/or psychological abnormalities occur in 45–75 % of survivors and are more severe in children [138]. JEV is managed with supportive care as there are no specific antivirals demonstrating clear benefit. Fatality rates vary between 5 and 40 % and are often reflective of medical care resources and capabilities.

Diagnosis by viral isolation is infrequent although feasible from brain tissue in fatal cases or CSF in about one third of cases during the acute infection period; this portends a bad prognosis [139]. Serologic diagnosis is possible, demonstrating a fourfold rise in antibody titer using hemagglutinin inhibition, complement fixation, or neutralizing antibody assays with appropriately timed acute and convalescent specimens. Serum IgM antibodies appear early in the course of infection, persist for 3–6 months, and are relatively specific. The IgM-capture ELISA is especially well suited for diagnosis by detection of locally synthesized JEV antibody in the CSF [140]. Earlier and more vigorous antibody responses correlate with improved survival. Serologic assays are plagued by cross-reactivity between JEV and other flaviviruses such as dengue and West Nile virus. Newer serologic, reverse transcriptase polymerase chain reaction and NS1 protein-based assays tout improved sensitivity and specificity.

Individuals can reduce exposure to vectors by use of mosquito repellant, wearing long-sleeved shirts and trousers, avoiding outdoor activities in the evening, and sleeping under permethrin-impregnated mosquito nets or in screened or air-conditioned rooms [141]. Active immunization, in addition to personal protective measures, is the optimal strategy for preventing JEV. JEV vaccines have been available since the 1950s [135]. Early vaccines were produced by inactivating virus grown in mouse brain or in primary hamster kidney (PHK) cells [135]. These vaccine constructs were used in the United States and Europe (BIKEN; distributed as JE-Vax by Sanofi Pasteur, Lyon, France) [142]. Seroconversion rates (i.e., quantitative neutralizing antibody titers following vaccination) and efficacy varied according to the population studied (indigenous vs. nonindigenous to JEV endemic area) and number of doses administered (one, two, or three doses) in the primary immunization series [135, 143]. Prolific vaccine use has contributed to significant decreases in JEV incidence in Thailand, India, Korea, Taiwan, Vietnam, and areas of Malaysia and Sri Lanka [135]. Since 1989, numerous cases of moderate to severe hypersensitivity-type reactions temporally associated with JEV vaccination have been reported, some resulting in hospitalization [144, 145]. The cause of the reactions is unclear, but the presence of murine neural proteins, gelatin, and/or thimerosal in vaccine preparations has been implicated, but not proven. More serious was the case in Japan of acute disseminated encephalomyelitis (ADEM) temporally related to vaccination. ADEM has been reported as a severe drug reaction following administration of inactivated mouse brain vaccine in 5×10^{-4} to 1×10^{-6} administered doses [143]. No definite increased risk of ADEM temporally associated with JEV vaccination has been proven.

To move away from mouse brain-derived vaccines, vero cells were adopted for the development of numerous JEV vaccine candidates [135]. Widespread distribution and use in Asia have demonstrated an excellent safety profile, immunogenicity, and efficacy [146]. Second-generation JEV vaccines with improved safety profiles and lower dosage requirements present new options for immunization [135]. The IC51 (IXIARO®, in Australia and New Zealand available as JESPECT; Intercell AG, Vienna, Austria) vaccine is a purified, formalin-inactivated, whole-virus JEV vaccine. The product is approved in the United States (persons aged ≥17 years), Europe, Canada, Switzerland, and Australia. IC51 is manufactured by Intercell Biomedical (Livingston, United Kingdom) and is distributed in the United States by Novartis vaccines (Cambridge, Massachusetts). The vaccine construct, developed at the Walter Reed Army Institute of Research (Silver Spring, MD), is based on a SA14-14-2 virus strain passaged in primary dog kidney (PDK) cells, cultivated in Vero cells, and formulated with aluminum hydroxide [147]. Numerous clinical trials have demonstrated IC51 safety and immunogenicity [148, 149]. A pooled, 6-month safety analysis of seven phase III trials included 3,558 subjects with at least one IC51 vaccination, 435 subjects with a JE-Vax® vaccination, and 657 with phosphate buffered saline solution with 0.1 % Al(OH)3 (PBS + Alum) control vaccination demonstrated a similar safety profile between the study arms with a superior local reactogenicity profile for IC51 compared to JE-Vax® [150]. Individuals previously given tick-borne encephalitis (TBE) vaccine and then vaccinated with IC51 demonstrated a 17 % higher incidence of at least one adverse event in volunteers with previous TBE vaccination and slightly higher seroconversion rates and higher GMT in the IC51 group who had received TBE vaccination (98 %, 470, compared to 92 %, 182) [151].

Sanofi Pasteur has developed a JEV vaccine based on a construct created at the St. Louis University Health Sciences Center, St. Louis, Missouri, and Acambis Inc., Cambridge, Massachusetts [152]. JEV-CV is produced by inserting prM and E genes from the SA14-14-2 JEV virus into the YFV 17D viral strain "backbone" containing the YF nonstructural genes [153]. The resulting chimeric RNA is electroporated into Vero cells and replicated by the highly stable YFV RNA-dependent replicase. The safety and immunogenicity of a

single dose of JEV-CV at two concentrations (1×5.0 $\log_{10}$PFU versus 1×4.0 $\log_{10}$PFU) was comparable to licensed YFV-VAX (1×5.0 $\log_{10}$PFU) in a phase 1 trial. Low-level viremias were observed in both JEV-CV groups, and the frequency of all adverse events was similar in each group. Overall, 96 % of subjects who received JEV-CV developed neutralizing antibodies to one or more of the wild-type JEV strains tested (Beijing, P3, Nakayama), and all developed antibodies to the homologous strain [154]. There is evidence that JEV-CV induced sterilizing immunity. Safety and immune responses were evaluated in $N = 10$ JEV-CV (1×4.0–5.0 $\log_{10}$PFU) vaccine recipients who, about 9 months later, were given a single dose of JE-Vax. No severe adverse events were noted and seroconversion rates rose from 50 % pre-JE-Vax to 90 % with a GMT greater than 1:150. Phase 3 studies assessed safety and immunogenicity comparing JEV-CV and a mouse brain-derived (MBD)-JEV vaccine. The safety profile of JEV-CV was superior to the MBD-JEV vaccine and similar to placebo. The percent of the cohort seroconverting following a single dose of JEV-CV by PRNT with the homologous strain was non-inferior to three doses of the MBD-JEV vaccine (99.1 % vs. 95.1 %) [155]. Additional studies assessing immunization of toddlers and children, co-administration and sequential administration with yellow fever (YF) vaccine (YF-17D strain; Stamaril((R)), Sanofi Pasteur), and administration of a booster doses demonstrated excellent safety profiles and immunogenicity [156].

Murray Valley Encephalitis Virus (MVEV)

MVEV has caused numerous encephalitis epidemics (Australian X disease) in Australia since the early 1900s. The virus was first isolated in 1951 from the brain of a 19-year-old male who succumbed to infection [3]. Encephalitis outbreaks in 1917, 1918, 1922, and 1925 were initially without an etiologic agent but are now believed to have been MVE [139]. Additional outbreaks occurred in 1956, 1971, 1974, 1978, 1981, and 1984, primarily in the Murray Valley of New South Wales and Victoria [157]. The 1974 outbreak was unique in its geographic expansiveness, infecting people in east central Queensland, Northern Territory, northern and southeastern South Australia, and the Ord River Basin of Western Australia [158]. Between 1978 and 1991 MVE was diagnosed in 26 patients, and 16 were in the Kimberley area of Western Australia [159]. During the 2007–2009 seasons, six human cases of MVEV were reported, at least two fatal, to the National Notifiable Diseases Surveillance System (NNDSS) [160]. Sixteen people are believed to have contracted MVE in 2011 [161]. MVEV is endemic to Papau New Guinea and Irian Jaya [162].

MVEV is a mosquito-borne flavivirus existing in an enzootic cycle involving primarily water birds [161]. *Culex annulirostris* is believed to be the principal vector, preferring to breed in shallow, warm, fresh water. Although MVE outbreaks occur most often during summer (January to May) and following high rain periods, the ecology remains largely unknown [161, 163]. Viral activity is monitored by trapping and testing mosquitoes or testing sentinel chicken flocks for serologic seroconversion (http://medent.usyd.edu.au/arbovirus/index.html, accessed 28 May 2012). Early indicators of MVEV circulation trigger increased public health vigilance and education regarding personal protective measures.

Complement fixation and neutralizing and cross-neutralizing antibody studies demonstrated MVEV was a group B arbovirus in a subgroup containing Japanese encephalitis, West Nile, St. Louis encephalitis, and Kunjin, Usutu, Kokobera, Stratford, and Alfuy viruses [3]. Nucleotide sequencing associates the MVEV most closely with the Japanese encephalitis virus. Phylogenetic studies suggest MVEV emerged in the Malay–Indonesian regions from an African progenitor virus, possibly Usutu. There appears to be persistent homogeneity of MVEV strains from widespread areas throughout Australia different from those circulating in New Guinea. The natural host range of MVEV is broad including humans, chickens, species of water and land birds, horses, dogs, foxes, and opossum. Experimental infection of mice, sheep, chick embryos, and hamsters resulted in death [3]. *Culex annulirostris* and *C. quinquefasciatus* and *Aedes occidentalis* and *A. vigilax* demonstrated competence to infect chicks following ingestion of an infected blood meal, and transovarial transmission following oral infection was achieved with *Aedes aegypti* [49, 164].

Approximately 1 of every 150–1,000 MVEV infections results in clinical disease. Complete recovery is seen in approximately 40 %, long-term neurologic sequelae in 30–50 %, and death in 15–30 % [165]. Following an incubation period of 1–4 weeks, patients will experience 2–5 days prodrome of high fever and headache with anorexia, myalgia, nausea, vomiting, diarrhea, rash, or cough [159, 166]. Neurologic features include lethargy, irritability, and confusion with or without seizures. The clinical spectrum of disease can be broad ranging from fever and headache without encephalitis to flaccid paralysis, cranial nerve and brainstem involvement, encephalitis with complete recovery, or death [161]. The disease appears to progress very rapidly in infants [139].

Magnetic resonance imaging (MRI) is the most sensitive and specific imaging study available to support a diagnosis. T2-weighted images demonstrate bilateral hyperintensity of the deep gray matter and may have findings mimicking herpes simplex virus (HSV) encephalitis involving the temporal lobes, red nucleus, and cervical spinal cord.

Laboratory confirmation of infection is achieved through viral isolation, detection of MVEV RNA, a fourfold rise in IgG between acute and convalescent serum samples, or finding IgM in the serum of cerebral spinal fluid (CSF) (http://www.health.gov.au/internet/main/publishing.nsf/Content/

health-arbovirus-mve-guidelines.htm, accessed 29 May 2012). Cross-reactivity among antibody-based tests complicates distinguishing MVEV from other flaviviruses following infection or vaccination. Neutralization assays or an epitope-blocking ELISA may add diagnostic specificity.

There are no licensed vaccines or therapeutics to protect against or treat MVE. Trials of steroids, ribavirin, interferon alpha-2a, and formulations of intravenous immunoglobulin have been evaluated in the context of Japanese encephalitis and West Nile virus infections but with little success [167, 168]. Treatment is supportive and has reduced mortality and morbidity. Passive immunization studies in animals using gamma globulin from MVE and Japanese encephalitis virus survivors demonstrated prophylactic efficacy. The ability of a live chimeric Japanese encephalitis virus vaccine (ChimeriVax-JE) to cross-protect against MVEV in two encephalitis mouse models suggested a single dose elicited a protective and durable immune response [169]. DNA-based and Semliki Forest virus-vectored vaccines using the MVEV prM and E proteins as immunogens were investigated in a murine model. Both candidates induced durable, MVE-specific neutralizing antibody responses [170].

St. Louis Encephalitis Virus (SLEV)

The first recognized outbreak of SLE occurred in Paris, Illinois, in 1932 followed the next year by epidemics in St. Louis and Kansas City, Missouri. The virus was first isolated from the brain of a fatal encephalitis case following inoculation in mice and rhesus monkeys [171]. Subsequent SLE outbreaks occurred in the Pacific coast states (1940s), Florida (1959, 1961), Texas, Ohio-Mississippi Valley (1970s), Colorado, California, Florida, Texas, and Arkansas [139, 171–175]. Disease has been reported throughout the majority of the United States, southern Canada, Mexico, and in limited areas of Central and South America [68, 173, 175–209]. There is a diffuse endemicity over vast rural areas, with low rates of seropositives in humans, but with occasional epidemics of hundreds to more than a thousand cases. The monitoring of sentinel flocks of birds for infection has proved useful as an early warning system [174].

The virus is transmitted by a number of culicine mosquitoes, including *Culex pipiens* and *C. quinquefasciatus* in the East and urban areas of the West, *C. tarsalis* in rural areas of the western states, and *C. nigripalpus* in Florida and southern areas [210–214]. In rural areas of the West and Southwest, it is closely tied to *C. tarsalis*. Depending on the climate of the region, maintenance of the virus can occur by year-round horizontal transmission from bird to mosquito, overwinter survival of infected mosquitoes, or venereal or transovarian infection [215–221].

SLE virus is in the JEV–MVE–West Nile virus complex or subgroup [139, 222, 223]. The virus produces cytopathic effect and plaques in numerous vertebrate cell lines that include primary chick embryo, hamster kidney, BHK-21, Vero, and LLC-MK2. Cell cultures from human, primate, rodent, swine, and avian cell cultures support replication [224]. Natural host range includes wild vertebrate species of birds as well as raccoons, opossums, and bats in North America and birds, rodents, nonhuman primates, and the three-toed sloth in tropical America. SLE varies in virulence for mice [139, 225, 226].
